The literature concerning EStim in the management of UI remains difficult to interpret, due to the lack of a well-substantiated biological rationale underpinning the use of EStim[217]. However, the theoretical basis of stimulation interventions is emerging with increasing understanding of the neuroanatomy and physiology of the central and peripheral nervous systems. The mechanisms of action may vary depending on the cause(s) of UI and the structure(s) being targeted e.g. PFM or detrusor, peripheral or central nervous system. In general, the aim of EStim for women with SUI appears to be to improve the function of the PFM, while for women with UUI the objective seems to be to inhibit detrusor overactivity (DO).

EStim is provided by clinic-based mains powered machines or portable battery powered stimulators (Figure 2) with a seemingly infinite combination of current types, waveforms, frequencies, intensities, electrode types and placements (Figure 3). Without a clear biological rationale it is difficult to make rationale choices about different ways of delivering EStim. Additional confusion is created by the relatively rapid developments in the area of EStim, and a wide variety of stimulation devices and protocols have been developed even for the same condition. For example, in the last 30 years or so women with SUI have been treated with a wide variety of EStim ranging from general anaesthetic for 20 minutes [168], to six months of low intensity stimulation at 10 Hz using a vaginal electrode [1,218].

Finally, the nomenclature used to describe EStim remains inconsistent. EStim has not only been described based on the type of current being used
1145
e.g. faradic, interferential), but also on the structures targeted (e.g. neuromuscular), the current intensity (e.g. low-intensity, or maximal stimulation), and the proposed mechanism of action (e.g. neuromodulation). In the absence of agreement of how best to classify EStim, no attempts were made to classify different types of EStim.

This section presents the evidence for the use of EStim in the prevention and treatment of UI in women. Questions addressed are:

- Is EStim effective in the prevention of UI?
- Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?
- Is one type of EStim better than another in the treatment of UI?
- Does the addition of EStim to other treatments add any benefit in the treatment of UI?
- Is EStim better than other treatments in the treatment of UI?
- What factors might affect the outcome of EStim in the treatment of UI?
- What is the effect of EStim on other LUTS?
- Is EStim effective in the prevention of UI?

Eligible interventions were non-invasive EStim with out implanted electrodes. (Magnetic stimulation is described in Section B.5.0.) Other criteria for inclusion were: (1) randomised or quasi-randomised (allocation) trial design; (2) women with UI or other LUTS; (3) no participants with incontinence due to neurological, or cognitive impairment and (4) no pregnant or postpartum women (within 12 months of delivery). Raw data were included as full-text papers were included. This section focuses on EStim compared with other conservative treatments or no active treatment. In previous sections (sections B.2 and B.3), EStim compared with PFMT and vaginal cones are covered. Study ID, population, Training Type, Training Program, Training Duration, Effectiveness, and Notes are included in Table 6.

Table 6: Characteristics of studies comparing PFMT + vaginal cones vs PFMT

</tbody>
</table>

Footnotes: PFMT = pelvic floor muscle training, VCs = vaginal cones, Estim = Electrical stimulation.
The primary outcomes were cure rates (the number of women cured), and improvement rates (the number of women improved, including cure). There was considerable variability in the way these outcomes were measured. Women’s self-report was given priority but for studies in which it was not reported, the rate based on diaries was used as a proxy; where diary data were also not reported, the rate based on pad tests or any other definitions chosen by the trialists was used [219]. Data on health-related quality of life and adverse effects were also extracted. Data at the end of the prescribed treatment phase, or at the first outcome measurement, if later, were used in the analysis. Any treatment effects shown are likely to reflect maximum effect of each intervention. Data from further follow-ups were also recorded.

Due to the small number of available studies per intervention, data were sub-grouped by dominant type or pattern of incontinence: (1) studies with all or at least 50% of participants having SUI alone or a predominant symptom of SUI (as defined by trialists), (2) studies with all or >50% of participants having UUI alone or a predominant symptom of UUI (as defined by trialists), (3) other studies of UI in which neither stress- or urge-Ul represented a predominant symptom in the study population, and (4) studies of OAB or DO in which it was unclear whether all participants had UI.

Single estimates with 95% confidence intervals (CI) were derived for each study comparison using odds ratios (OR) for dichotomous variables or mean difference (MD) for continuous variables. Summary estimates were calculated using random effects models if there was more than one study reporting the same outcome (meta-analysis).

‘Risk of bias’ in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group [220]. Risk of bias regarding blinding to the allocated intervention should be considered to be high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

Description of intervention in included studies of EStim

A total of 33 trials were eligible. The electrical stimulation parameters and protocols in this section are summarised in Table 7. Some approaches to treatment are now rare, such as the use of faradic current or external electrodes. There was considerable variation in the intervention protocol. Although the biological rationale and purpose of EStim might be different depending on diagnosis, there was no consistency in the EStim protocols used for women with SUI, UUI, MUI, or DO.

In addition, there were three trials that recruited both men and women. These include comparing: EStim (transcutaneous electrical nerve stimulation) with oxybutynin for 13 men and 30 women with idiopathic DO [221]; EStim with sham EStim for 29 men and 39 women with UI due to either idiopathic or neurogenic DO [222]; and EStim and MStim for 15 men and 17 women with UI due to either idiopathic or neurogenic DO [223]. These trials did not differentiate the effects of treatment by gender or by diagnosis and therefore did not contribute to the analysis.

1. PREVENTION

No published trials were found that investigated either the primary or secondary prevention of UI or LUTS.

2. TREATMENT

a) Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?

Seventeen studies compared EStim with no active treatment. Characteristics of studies comparing EStim with no active treatment are presented in Table 8. No active treatment consisted of sham EStim in the majority (11 of 17) of the studies. In others, the ‘no active treatment’ groups received no treatment [130,224], placebo drugs [225], non-active control intervention such as instruction in the use of an anti-incontinence device [134] or motivational phone calls [140].

One study [226] was a three-arm trial: two of the arms using EStim with either sacral or suprapubic electrodes were combined (N = 32) and compared with the sham ES arm (N = 16). The trial by Brubaker and colleagues [227] included women with SUI or DO with women with SUI comprising the majority of the study sample. Data from this trial therefore contributed to the analysis for SUI.

1. QUALITY OF DATA (RISK OF BIAS)

Three studies [134,225,228] reported adequate methods of allocation concealment, namely opaque (and sealed) envelopes with third party involvement in the allocation procedure. Allocation concealment was assessed as suboptimal in two [168,224] that used opaque or sealed envelopes but with no indication of third party involvement. The remainder did not describe methods used for allocation concealment. Trial results were reported for everyone who entered the trial in three studies [132,224,229] but this was not done in the others.

2. RESULTS

(a) SUI or predominant SUI. Pooled data suggest that cure rates were on average higher for EStim compared with no active treatment but the difference was not statistically significant [132,134,140,178,227,228,230]. Improvement rates were statistically significantly higher for EStim compared with no active treatment [134] [130,132,134,178,227,228,230] although there was some evidence of statistical heterogeneity for the improvement rate (I-squared = 59%).

Adverse effects appeared uncommon. One study reported tenderness and bleeding in 10 of 32 participants using the active EStim device, of which seven withdrew from treatment due to adverse effects [134]. Another study reported that 14 of 35 participants using the active EStim device and seven of 17 participants using the sham device experienced vaginal irritation, pain or infection [230].

Quality of life was reported using diverse measures in three studies. Two of these studies reported statistically significant differences favouring EStim compared with no active treatment: the first [134] used the Social Activity Index, and the second [140] used the I-QoL questionnaire. However, the third study [198] found no significant differences between the groups based on either the Urogenital Distress Inventory or the IIQ.

(b) UUI or predominant UUI. One small study in which all participants had MUI with UUI as a predominant pattern found no significant difference between the groups in cure rates [231] although the confidence interval was wide. Improvement rates were significantly higher for EStim compared with no active treatment based on another small study in which all participants had UUI alone [232]. However, these differences are not informative, because the confidence interval is very wide and the OR is clinically implausible. No information was available on adverse effects and quality of life.

(c) SUI, UUI or MUI. One study [168] that provided information on cure and improvement found no difference between the groups. No information was available on adverse effects and quality of life.

(d) DO (wet or dry). Cure and improvement rates were reported only in one study [225]. There was a statistically significant difference in the improvement rate in favour of the EStim group compared with no active treatment but no difference was found for the cure rate. Caution is required, as the OR is clinically implausible and may be a statistical artefact. Two studies with data on quality of life outcomes reported inconsistent results [224,225]. One study using the KHQ (total score) reported a statistically significant difference favouring EStim compared with no active treatment [225], whereas the other study using the IIQ found no significant difference between the groups [224]. No information was available on adverse effects.

3. SUMMARY

Included studies were generally assessed as having a high risk of bias. EStim might be more effective than no treatment in improving (not necessarily curing) symptoms in women with SUI, UUI or DO, although this may not result in cure (Level of Evidence: 2). Information on quality of life was sparsely reported and the limited data that were available were not consistent. Adverse effects appear uncommon but some women experienced discomfort with the treatment device. Few data were available on long-term performance.

4. RECOMMENDATIONS

EStim might be better than no treatment in improving symptoms (Grade of Recommendation: B). However, the recommendation should be viewed with caution until the findings are supported or refuted in
Table 8: Characteristics of studies comparing Electrical stimulation with no active treatment

Footnote: * abstract only; **Source of outcome: women’s self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy. † Publication in Danish with English abstract. English translation of the main text was not available at the time of writing. ‡ Part of 4-arm trial which randomised 83 women with OAB. The number in each arm was not reported; Estim = electrical stimulation, OAB= overactive bladder, DI = detrusor instability, SUI = stress urinary incontinence, UUI = urge urinary incontinence, MUI mixte urinary incontinence, NR = not reported
b) Is one type of EStim better than another in the treatment of UI?

Four studies compared one approach to EStim versus another; two in women with SUI [171,218] and two in women with DO and sensory urge [226,233]. The characteristics of studies comparing one type of Electrical stimulation with another are presented in Table 9. No study focusing on UUI or predominant UUI was identified.

1. QUALITY OF DATA (RISK OF BIAS)

Allocation concealment was inadequate in one study that used consecutive (alternative) assignment (quasi-randomisation) [171]. Allocation concealment was also suboptimal in another study in which sealed consecutively numbered envelopes were used but it was unclear if they were opaque and whether a third party was involved in the allocation procedure [218]. The other two studies did not mention allocation concealment [226,233]. In Lobel (1998) data were reported only for those who completed the trial (37 of 43 randomised). It was unclear in the other three studies if trial results were reported for everyone who entered the trial.

2. RESULTS

(a) SUI. Two studies assessed different variants of EStim performed as an adjunct to PFMT and biofeedback. The first compared faradism with interferential therapy: no difference was found between the groups in improvement rates, both after the supervised treatment phase and at six months after the end of the supervised phase [171]. The second study compared maximal EStim with low intensity EStim with higher improvement rates for maximum EStim either at the end of supervised phase or at 6 months after the supervised phase [218]. No information was available on cure rates, adverse effects or quality of life.

(b) DO (wet or dry). Data were available from one study comparing two groups receiving EStim either once or twice a week (for 10 weeks) [233]. The most common adverse effects reported were discomfort and leg tremor during treatment, and UTI, although it was unclear in which group these adverse effects occurred. No difference was found between the groups on a quality of life questionnaire (not specified). No information was available on cure and improvement rates.

3. SUMMARY

Included studies were generally assessed as having a high risk of bias. There were four small trials comparing different EStim protocols; the clinical heterogeneity between studies meant it was not appropriate to pool the data. Based on a single trial for women with SUI, maximal clinic-based stimulation may be more effective than low-intensity home-based stimulation in improving symptoms, although no data were available on cure rates, quality of life and adverse effects (Level of Evidence: 2). The other studies did not find clinically important differences between stimulation groups; the studies were small and may have been underpowered. Further comparisons of EStim protocols are needed.

4. RECOMMENDATIONS

For women with SUI maximal clinic-based EStim might be better than daily low-intensity home-based EStim in improving symptoms (Grade of Recommendation: B). There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.

c) Is EStim better than other treatments for UI?

EStim has been compared with PFMT, VC, magnetic stimulation (MStim), and drugs. The comparisons of EStim versus PFMT, and EStim versus VC, have been addressed in Sections B.2.3c and B.3.2b, respectively. For the comparison of EStim and MStim, one trial by Yamanishi and colleagues included both men and women with UI due to either idiopathic or urogenital DO [223]. Because data were not reported separately for women with idiopathic DO it is not clear from this trial whether there was any difference in the effect of MStim compared with EStim.

The remainder of this section focuses on studies that compared EStim with medications: vaginal oestrogen (Premarin) for women with SUI [130]; propantheline bromide 7.5 to 45 mg (various dose) two to three times per day for women with UI due to DO (assumed to be predominant UUI) [187]; oxybutynin 5 mg twice [188,201] or 2.5 mg three times per day [225] and tolterodine 2 mg twice per day [204]. Four studies recruited women with DO [201] or OAB [204,225], or both DO and OAB [188] where some but not all had UI. (See Table 10.)

1. QUALITY OF DATA (RISK OF BIAS)

Methods used for allocation concealment were adequate in one [225] but unclear in the other five. Trial results were reported for everyone who entered the trial in one study [187] but this was not done in four [130,188,201] and unclear in one [204].

2. RESULTS

(a) SUI. In one small study of 25 women, 32% in the EStim group and 13% in the oestrogen group reported improvement and the difference was statistically significant [130]. At 9 month follow-up, one of the eight women in the EStim group and all three in the oestrogen group who had reported improvement post-treatment had recurrent symptoms. There was no report of adverse effects. No information was available on cure rates or quality of life.

(b) Predominant UUI. Based on one older small study that recruited women with UUI due to DO (UUI was assumed to be the predominant symptom), there was no evidence of a difference between EStim and propantheline bromide in terms of cure and improvement [187]. No data were available for adverse effects or quality of life.

c) DO (wet or dry). In three studies with data on cure or improvement, there was no evidence of a difference in cure or improvement between EStim and oxybutynin [225], or between EStim and tolterodine [188]. In two of these studies cure and improvement were defined in terms of resolution or reduction of urgency symptoms rather than UUI [188,225] whereas the outcomes were not defined in the other [204]. Follow-up data based on one study found that treatment effects persisted over time (one year) in four of the 11 (36%) participants in the EStim group and 10 of the 17 (59%) participants in the oxybutynin group who had reported improvement in the initial treatment phase (three months) but the difference between the groups was not statistically significant [188].

More women with DO who received drugs, experienced adverse effects than those who did not. The most commonly reported adverse effect in both oxybutynin or tolterodine treatment group was a high percentage of dry mouth [188,204] which was “intolerable” [225] or “unacceptable” [201] in a smaller number. Other drug side effects were constipation, indigestion, nausea, headache, dizziness and blurred vision. There was no report of adverse effects or adverse effects resulting in treatment withdrawal in the EStim group. Quality of life outcomes were reported only in one study using the KHQ (total score) [225]. The study reported a statistically significant difference in favour of EStim over oxybutynin; no further data was provided).

3. Summary

Included studies were generally assessed as having a high risk of bias. With small numbers per comparison group available, there is insufficient evidence to determine if EStim is better than vaginal oestrogens in women with SUI, propantheline bromide in women with UUI, or oxybutynin and tolterodine for DO (Level of Evidence: 2).

4. Recommendation

Based on current evidence medical treatments appear to be no more effective than EStim (Grade of Recommendation: B). This hypothesis needs to be investigated further with high quality trials, if it is a clinical question of interest to women.

d) Does the addition of EStim to other treatments add any benefit in the treatment of UI?

A total of 12 studies assessed the effect of EStim as an adjunct to another treatment, compared with the other treatment alone (Table 11). Of these, 10 [121,132,135,173,177,234-238] combined EStim with PFMT (EStim + PFMT vs. PFMT), while the other two studies [171, 218] combined EStim with PFMT and biofeedback (EStim + PFMT + BF vs. PFMT + BF).

Two studies were three-arm trials that included both PFMT and PFMT plus sham EStim as two of the study arms [135,236]. These arms were classified as being equivalent to PFMT and combined in the analysis. In two other three-arm trials two of the study arms involving EStim were also combined [107,218]. In one, EStim arms included faradism and interferential therapy [218]; in another, maximal and low intensity EStim were included [171].

1. Quality of Data (Risk of Bias)

Allocation concealment was inadequate in two studies that used consecutive (alternative) assignment (quasi-randomisation) [171,236]. Allocation concealment was also suboptimal in another two in which sealed consecutively numbered envelopes were used but it was unclear whether they were opaque and whether a third party was involved in the allocation procedure [218,237]. The remainder (66%) did not mention allocation concealment. In six (50%) studies, results were reported for everyone who entered the trial [121,132,173,235,237,238], but this was not done in one [234] and unclear in three others [135,171,218].

2. Results

A. EStim + PFMT vs. PFMT

(a) SUI or predominant SUI. Pooled data found no evidence of a difference between the groups in terms of cure [121,132,173,234,235] or improvement [121,132,177]. Adverse effects were reported in one study [121]; the group randomised to EStim with PFMT recorded four occurrences (6%) of vaginal irritation due to application of EStim devices, compared with none in the PFMT only group. Quality of life was also reported only in one study [121]; the results based on the IIQ found no difference between the groups (no further data was provided).

(b) SUI, UUI and MUI. Data available from one study found no significant difference between the groups for either cure or improvement [237]. One small study using the KHQ reported that quality of life was on average better after EStim compared with no EStim during the treatment and at three-month follow-up [173]. The differences reached statistical significance at three-month follow-up. No adverse effects were reported.

B. EStim + PFMT with biofeedback vs. PFMT with biofeedback

SUI. Pooled data from two studies found no difference between the groups in terms of the improvement rate [171,218]. Improvement rates at six...

Foot note: **Source of outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy. Estim = electrical stimulation, SUI = stress urinary incontinence, MUI = mixed urinary incontinence, UUI urge urinary incontinence, NR = not reported
months after the end of the initial treatment phase did not differ between the groups in either study. No data were available on cure rates, adverse effects and quality of life.

3. Summary

For comparisons of EStim with PFMT versus PFMT alone, there was no evidence of a difference between the groups in women with SUI or MUI (in which SUI was the predominant symptom) (Level of Evidence: 2). There was also no evidence to suggest that the addition of EStim to a BF-assisted PFMT was more effective than BF-assisted PFMT in women with SUI (Level of Evidence: 2). A few women experienced side effects with EStim. There is no evidence to draw any conclusion about the effect of adding EStim to PFMT for women with UUI.

4. Recommendations

The addition of EStim to PFMT or BF-assisted PFMT programmes does not appear to add benefit (Grade of Recommendation:B); this hypothesis needs to be investigated further with high quality trials if it is a clinical/research question of interest to women.

3. OTHER LUTS

No trials were identified that analysed the effect of EStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

4. Factors Affecting Outcome

None of the included trials addressed the effect of age, or any other factor, on outcomes of EStim. Regarding age, there was no clear indication from the included trials that EStim could not be tolerated by elderly. On this basis there is no reason to exclude older women from studies of EStim, or not to offer EStim as part of a conservative management programme, except where recognised contraindications such as a cardiac pacemaker are present. However, it should be noted that this section considered the effect of EStim from studies recruiting independent, community dwelling women; the frail elderly are considered in the chapter on the elderly.

Of note, in a prospective cohort of 3,198 women treated with home-managed EStim in Norway during 1992-1994, there was no association between self-reported improvement and age [239]. In the same cohort, success rates defined by clinicians were higher in younger individuals but this effect was no longer significant after controlling for other factors.

Aside from age, other factors may have the potential to mediate treatment outcome. On the basis of trial reports to date, it appeared that there was considerable variation in EStim protocols with no consistent pattern emerging. EStim protocols are also often poorly reported, lacking detail of stimulation parameters, devices and methods of delivery. The wide range of protocols that have been tested may have impacted on the effect estimates reported in this section.

It is not clear whether one diagnostic group may benefit more than another from EStim. It has been hypothesised that, in women with SUI who cannot voluntarily contract the PFM to begin a PFMT programme, EStim might help initiate or substitute for a voluntary contraction. However, most studies focusing on the efficacy of EStim do use EStim to initiate or substitute for a voluntary PFM contraction [240]. To date, there has been no trial addressing this hypothesis.

EStim is reported to be unsuccessful in women with major descent of the vagina and prolapse of the uterus [228]. Additionally, denervated PFM muscles might not respond to EStim [241]. This means that in women with reduced or no integrity of the relevant nerve pathways EStim provides no or little chance of cure/improvement [217]. It has also been reported that treatment will fail if EStim does not increase urethral pressure profile, although age, oestrogenisation, and urethral mobility may also affect urethral pressure profile and may influence therapeutic outcome [242]. It is unfortunate that it is difficult to assess individuals easily in the clinical setting with regard to integrity of the sacral arc, and other factors, to determine the suitability of EStim as a treatment modality.

As with all conservative therapy modalities, one of the key factors to the success or failure of EStim is treatment adherence. Some authors commented on adherence or reported adherence data. However, adherence measures were highly variable, making comparison across studies difficult. Adherence to EStim was satisfactory and could be attributed to the physician motivating individuals to continue with EStim if they considered stopping prematurely [229]. ‘Excellent’ or ‘good’ adherence was observed in 45% of the study participants in one study and this did not differ between EStim and sham [234]. However, another [243] reported that the proportion of women achieving 80% adherence was lower in the active EStim group (61%) compared with the sham group (89%). Be [134] reported a 75% adherence rate, although it is not clear how this compares with the non-active control group (instruction in the use of an anti-incontinence device). Nevertheless, adherence to EStim was less than that for PFMT (93%) in the same trial, and the reasons for non-adherence to EStim were a lack of motivation and discomfort. Knight [218] reported adherence to home-based low intensity EStim (72.5%) was somewhat higher than that for clinic-based maximal intensity EStim (percentage not reported).

V. Magnetic Stimulation (MStim)

MStim has been developed for noninvasive stimulation of both central and peripheral nervous systems [244]. MStim for the treatment of UI was reported
for the first time in 1999 by Galloway [245]. In contrast to EStim, extracorporeal magnetic innervation (more commonly called magnetic stimulation) stimulates the PFM and sacral nerve roots without insertion of an anal or vaginal probe [246]. For treatment, the individual is positioned in a chair. Within the seat is a magnetic field generator (therapy head) that is powered and controlled by an external power unit (Figure 4). A concentrated steep gradient magnetic field is directed vertically through the seat of the chair. When seated, the individual's perineum is centred in the middle of the seat, which places the PFM and sphincters directly on the primary axis of the pulsing magnetic field (Figure 5). Because of this, all tissues of the perineum can be penetrated by the magnetic field. According to Galloway [1999] no electricity, but only magnetic flux enters the body from the device. Goldberg [2000] has suggested that, in contrast to electrical current, the conduction of magnetic energy is unaffected by tissue impedance, creating a theoretical advantage in its clinical application compared to EStim as structures such as sacral roots or pudendal nerves can be magnetically stimulated without discomfort or the inconvenience of a vaginal or rectal probe. Conventional magnetic stimulators deliver, at frequencies of 10 to 50 Hz, repetitive pulses of current lasting less than 100 μsec [246] and 275 Φs [245] in duration. Size and strength of the magnetic field is determined by adjustments of this amplitude by the therapist [245].

Possible advantages of MStim are that it is performed through full clothing, needs no probes, skin preparation, or physical or electrical contact with the skin surface. On the other hand, the need for repeated clinic based treatment sessions is a potential disadvantage. In contrast to EStim, MStim lacks portability, although in 2003 [247] reported the development of a portable small electromagnetic device (Pulsegen) for home use that fit into the underwear and was designed for continuous use for up to 8 weeks. Furthermore, because both the depth and width of magnetic field penetration is proportional to coil diameter, the present technology is still best suited for stimulation of a field, rather than a narrowly focused target as the sacral roots or the pudendal nerve [246].

MStim of the sacral nerve roots and pelvic floor is said to be effective for both UUI and SUI [246], although the mechanism of action is not fully understood [248]. Some authors have suggested that in SUI stimulation of the PFM causes external sphincter contraction [249], acts as a passive PFMT exercise [250], and increases maximal urethral closure pressure [247]. In UUI, MStim might suppress DO through activation of pudendal nerve afferents blocking parasympathetic detrusor motor fibres at the spinal reflex arc, activation of inhibitory hypogastric sympathetic neurons, or a combination of both mechanisms [251]. Stimulation of sympathetic fibres maintaining smooth muscle tone within the intrinsic urethral sphincter and modulation of pudendal nerve afferent branches stimulating an inhibitory spinal reflex at the S3 nerve root, are also suggested to play a role in this mechanism of action [251].

In this section the evidence is considered for the use of MStim for the prevention and treatment of UI in women. Questions addressed are:

- Is MStim effective in the prevention of UI?
- Is MStim better than no active treatment (placebo, sham, control or no treatment) for the treatment of UI?
• Is one type of MStim better than another in the treatment of UI?
• Is MStim better than other treatments in the treatment of UI?
• Does the addition of MStim to other treatments add any benefit in the treatment of UI?
• What is the effect of MStim on other LUTS?
• What factors might affect the outcome of MStim in the treatment of UI?

Description of intervention

Ten trials were identified. Characteristics of the MStim intervention in the included studies are summarised in Table 12. Two further trials that did not specify the gender of the participants were found: a cross-over trial comparing MStim plus PFMT with sham MStim plus PFMT for 56 individuals with UUI (due to DO) or SUI [252]; and a comparison of MStim with sham MStim for 87 participants with UUI (due to DO) or SUI [253]. These trials did not contribute to the analysis. Table 12 illustrates the intervention characteristics.

1. PREVENTION

No trials investigating the primary or secondary prevention effects of MStim for women with UI were found.

2. TREATMENT

(a) Is MStim better than no active treatment (placebo, control or no treatment)?

Nine RCTs comparing MStim with sham for women with UI were found. Characteristics of studies comparing magnetic stimulation with no active treatment are presented in Table 13. One report by Gilling [2002] [254] was an abstract. The trial, which has not yet been fully published, appears to be related to Gilling [2001] [255] of which a full report was published in 2009 [256] (comparing MStim plus PFMT with PFMT alone), but there was insufficient information to verify this. No data were available for any of the pre-specified outcomes. Of the nine included trials, three assessed the efficacy of a magnetic stimulator developed for home use, whereas in others treatment was provided in the clinic setting [247, 257, 258].

1. QUALITY OF DATA (RISK OF BIAS)

Allocation concealment was considered to be adequate in three (33%) trials that used numbered devices of identical appearance [247, 257, 259], or involved a randomisation list in a locked drawer only accessible to a member who had no other involvement in the trial. Allocation concealment was assessed as being sub-optimal in one study [258] that used sealed envelopes but did not mention whether envelopes were opaque nor any involvement of a third party in the allocation process. Another five (56%) did not describe methods used for allocation concealment [254, 260-263]. Two studies reported data for all participants randomised [260, 261]. In three, data were reported only for those participants who completed the study [247, 259, 263]. In particular, in the study by Morris [2007] only 29 of 44 (66%) women randomised completed the study, including 10 women deemed ineligible after randomisation. The number of women lost to follow-up was not clearly reported in the other four (45%) trials [247, 254].

2. RESULTS

(a) SUI. Data on cure and improvement rates were reported in one study [Fujishiro, 2000]: on average active treatment (single session) was better than sham treatment both in terms of cure and improvement but the difference was statistically significant only for improvement. One other study that provided stimulation for three days a week for two weeks (six sessions in all) that also measured cure and improvement did not provide any data but reported no statistically significant differences [262].

Information on quality of life was provided in two studies using different measures [261,262]. One study using the KHQ did not report a total score but scores on all questionnaire items were similar between the groups either at one week or one month after the intervention [262]. The second study did not describe how quality of life was ascertained but reported that mean scores did not differ significantly between the groups [261]. No adverse effects were observed in one of these studies [261].

(b) UUI. Suzuki and colleagues (2007)[263] conducted a cross-over trial including 16 men and 23 women with UUI refractory to PFMT [263]. Participants were randomised to either 10-week active treatment, four-week no treatment and 10-week sham treatment (A-S group) or 10-week sham treatment, four-week no treatment and 10-week active treatment (S-A group). Only quality of life outcomes were reported separately for women, based on the International Consultation on Incontinence-Questionnaire: Short Form (ICIQ-SF). In which lower scores indicate better quality of life. In women in the A-S group, ICIQ-SF scores (mean, SD) decreased from baseline by 4.6 (3.9) at 10 weeks and 3.5 (3.5) at 24 weeks. The corresponding scores in women in the S-A group were 1.3 (2.9) at 10 weeks and 4.5 (4.2) points at 24 weeks. These results were interpreted by the study authors to mean that active MStim was more effective than sham MStim. There was no report of adverse effects.

(c) MUI. In one small study, active treatment resulted in statistically significantly higher improvement rates compared with sham treatment [257]. There were no adverse effects in either group. Information on cure and quality of life was not available.

(d) SUI, UUI, or MUI. One small study reported statistically significant differences in favour of active treatment for cure or improvement [247].

Foot notes: NR = not reported; * abstract only; **Source of outcome: women’s self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.
this study, one of 31 women in the active treatment group had lumbar-ischial pain in the right leg and withdrew from treatment, whereas none of 24 women in the sham group experienced any adverse effects. Information on quality of life was not provided.

(e) DO (wet or dry). One small study reported that improvement rates did not differ significantly between active and sham treatments [258]. No information was available regarding cure rates. Quality of life outcomes were reported in three studies using different measures [258-260]. There was no difference between the groups in terms of the IIQ or the Urogenital Distress Inventory [259] or between KHQ or the Australian Quality of Life questionnaire [258]. There was one report of statistically significant better quality of life scores for treatment than sham, although it was unclear how this was ascertained [260]. No adverse effects were noted.

3. Summary

Since there was little duplication of MStim interventions, or sample populations, in the nine small trials, it was not thought appropriate to combine study findings. For women with SUI a single trial showed that one session of sacral root MStim might be more effective than sham in improving symptoms (Level of Evidence: 2), but another trial suggested that six sessions of a chair-based MStim might be no better than sham (Level of Evidence: 2). For women with UUI, evidence from a small trial suggests that active MStim might result in better quality of life than sham (Level of Evidence: 2), although there is some uncertainty surrounding this. Active MStim was associated with higher cure rates than sham in a small trial with women with MUI (Level of Evidence: 2), and also higher cure and improvement rates in another small trial with women with SUI, UUI or MUI (Level of Evidence: 2) but no such difference was observed for women with DO (wet or dry) (Level of Evidence: 2). In general, adverse effects appear uncommon.

4. Recommendations

Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI. No recommendation is possible based on current evidence (Level of recommendation: D).

b) Is one approach to MStim better than another?

One study from Korea [264] compared the effect of pelvic floor MStim with BIOCON compared with stimulation via NEOCONTROL for females with SUI (Table 14). This report was published in Korean. Data were extracted only from the abstract and main data tables that were reported in English.

1. Quality of data (risk of bias)

Risk of bias could not be assessed, because the trial was published in the Korean language and English translation was not available at the time of writing.

2. Results

Any UI. No statistical difference was found between the groups in terms of cure of UUI or cure of SUI. Quality of life scores based on the Bristol Female Urinary Tract Symptoms were also similar between the groups.

3. Summary

There is insufficient evidence to determine if one type of MStim is better than another (Level of Evidence: 2). No recommendation is possible (Level of Recommendation: D).

c) Is MStim better than other treatments?

There was a single trial by Yamanishi and colleagues that addressed this comparison [223]. In this trial, MStim was compared with intravaginal EStim in 17 women and 15 men with either idiopathic or neurogenic DO. As data were not reported separately by gender and by diagnosis, it is not clear whether there is any difference in effect of MStim compared to EStim for women with idiopathic DO.

d) Does the addition of MStim to other treatments add any benefit in the treatment of UI?

One trial [255] was identified for this comparison. This report was initially available only as an abstract published in 2001. Subsequently, a full-text publication became available in 2009 [256], although participants were followed up for six months post-intervention and no further follow-up was reported. It should be noted that the aim of the trial was to compare active and sham MStim treatments, rather than to examine the effect of MStim as an adjunct to PFMT. Because trial participants had varying degrees of pre-existing knowledge about their condition and available treatments such as PFMT, low-intensity PFMT supervised by a uro-physiotherapist was added to both groups in order to minimise a potential bias. Characteristics of studies comparing MStim combined with another treatment with the other treatment are presented in Table 15.

3. **Other LUTS**

No trials were identified that analysed the effect of MStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

4. **Factors affecting outcome**

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. In one early prospective multi-centre study, factors predicting success of MStim were included [243]. Treatment success was associated with no prior hysterectomy, no prior anti-incontinence operations, UI symptoms for less than 10 years, and no use of medications known to cause UI. Brodak has suggested that detrusor response to stimulation might be better in ‘thin’ individuals (presumably due to a shorter distance between the stimulating coil and the sacral nerve roots) and at low bladder volumes [265]. Overall, little is known about the factors affecting the outcome of MStim.

**VI. SCHEDULED VOIDING REGIMENS**

This section examines the evidence on use of scheduled voiding regimes in cognitively intact, non-institutionalised women with UUI, SUI, and MUI and provides recommendations for their use in clinical practice. A summary of the search strategy and inclusion/exclusion criteria for selecting studies for review is provided (See appendix). The chapters on the Frail Elderly and Neurogenic Incontinence provide detailed review of scheduled voiding regimes that are used in those with cognitive impairment, or UI secondary to central nervous system or spinal cord disease.

**Scheduled Voiding Regimens**

Bladder training is a broad term often used to describe any type of a scheduled toileting intervention. This has created conceptual confusion in interpreting research reports where few details are provided other than the statement that bladder training was used. The types of scheduled voiding regimes can be categorised as: bladder training, timed voiding, habit training, and prompted voiding [266]. Although these regimes share a common feature of a toileting schedule, they differ on the basis of adjustments to the voiding schedule, the active or passive involvement of the patient, the nature of patient education including the teaching of strategies to control urgency and prevent stress leakage, the use of reinforcement techniques, and the nature of the interactions between clinicians and patients. In practice, however, scheduled voiding regimes may share aspects of one or more of these features.

**Bladder training**

Bladder training (also referred to as bladder drill, bladder discipline, bladder re-education, and bladder re-training) involves a programme of patient education along with a scheduled voiding regimen with gradually progressive voiding intervals. Specific goals of bladder training are to correct faulty habit patterns of frequent urination (if present), improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore patient confidence in controlling bladder function. The underlying mechanism of how bladder training achieves its effect is poorly understood. Several hypotheses have been proposed including improved cortical inhibition over detrusor contractions; improved
cortical facilitation over urethral closure during bladder filling; improved central modulation of afferent sensory impulses; altered behaviour resulting from better individual awareness of the lower urinary tract function and circumstances that cause UI, and increasing the "reserve capacity" of the lower urinary tract system [189,267,268]. A Cochrane review of bladder training was last updated in 2010 [269].

**Timed voiding**

Timed voiding is a fixed voiding schedule that remains unchanged over the course of treatment [266]. The goal is to prevent UI by providing regular opportunities for bladder emptying prior to exceeding bladder capacity. Timed voiding has been recommended for patients who cannot participate in independent toileting [270]. It also has applicability for use in outpatient settings with incontinent women who have infrequent or irregular voiding patterns [271] and men who are independent in their voiding function [272]. A Cochrane review of timed voiding was last updated in 2009 (published 2010) [273].

**Habit training**

Habit training is a toileting schedule matched to the individual's voiding pattern based on their voiding diary. The toileting schedule is assigned to fit a time interval that is shorter than the person's normal voiding pattern and precedes the time period when incontinent episodes are expected. Thus, the voiding interval may be lengthened or shortened throughout the day depending on the patient's voiding pattern with the goal to pre-empt UI. Habit training is usually implemented by caregivers, in institutional settings with cognitively and/or physically impaired adults, but it has also been tested in homebound older adults [274]. It is potentially useful for adults without cognitive or physical impairment, who have a consistent pattern of UI [271].

A Cochrane review on habit training was updated in 2009 and published in 2010 [275] following first publication in 2004. Prior to this, the last literature review was published in 1986 [266]. The Cochrane review identified three trials that described the effects of habit training combined with other treatment components compared to usual care on the frequency and severity of UI [274, 276, 277]. A fourth trial compared habit training alone with habit training and an electronic monitoring device [278]. Participants from the first three trials were primarily care-dependent women with cognitive and/or mobility impairment, and the fourth trial comprised men and women with a mean age of 83 years and thus, did not meet the criteria for this chapter. No studies were located that investigated habit retraining in independent-living women.

**Prompted voiding**

Prompted voiding refers to a caregiver education programme in combination with a scheduled voiding regimen, typically every two hours. It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so [279]. It has been used primarily in institutionalized settings with cognitively and physically impaired older adults. In a 2009 Cochrane review of prompted voiding [279], nine trials were identified involving 674 elderly people, mainly women. These trials did not meet the criteria for this chapter as the samples were drawn from care home settings and comprised elderly individuals with impaired cognitive and/or functional ability.

This section will examine the evidence for the use of timed voiding and bladder training for the prevention and treatment of UI in non-institutionalised women of all ages without cognitive or mobility impairments. However, the majority of evidence available pertains to bladder training thus the effects of bladder training are the focus of this section.

Questions addressed are:

- Can scheduled voiding regimes prevent UI?
- What is the most appropriate bladder training protocol?
- Is bladder training better than no treatment, placebo or control treatments?
- Is bladder training better than other treatments?
- Can any other treatment be added to bladder training to add benefit?
- Does the addition of bladder training to other treatments add any benefit?
- What is the effect of bladder training on other LUTS?
- What factors might affect the outcome of bladder training?

This section is based on previously published systematic reviews, including Cochrane reviews, and additional searches of the literature. Studies that were excluded from prior systematic reviews, due to the inclusion criteria for the review or restriction to RCTs or quasi-RCTs, were also considered. Conference abstracts were considered where adequate information was available.

1. **PREVENTION**

   No trials were identified that examined scheduled voiding regimens as a sole intervention in the prevention of UI.

2. **TREATMENT**

   Three systematic reviews on bladder training were located that provided descriptive synthesis with evidence grading [269, 270, 280]. The third is a published Cochrane review that has been updated in 1999, 2004, 2007, and 2010 [269].
**a) What is the most appropriate bladder training (BT) protocol?**

No trials were identified that compared two or more methods of bladder training (BT). In the absence of trials comparing two or more approaches, a content analysis of the protocols used in trials investigating the effects of BT was performed. Seventeen trials on BT involving a total of 2462 women were identified. Six of the trials provided no or minimal details regarding the specific BT protocol used [128,269,281-285]. In trials that did provide some description, BT protocols were implemented in several ways.

All protocols involved some type of patient education, namely:

- Brief verbal [282,283] or written instructions [286, 287]
- Verbal, written, and audiovisual instruction [189, 268, 288]
- Introduction to an individual who successfully completed BT [284]

If specified, the education was provided by nurses [128,189,268,281,289,290], or general practitioners [291].

Scheduling of voids varied in the following ways:

- Assignment of the initial voiding interval varied from 30 minutes to two hours, with one hour being the most common interval based upon the participant’s voiding pattern or 30 minutes beyond the participant’s average voiding interval [287,292].
- Adjustments to the voiding interval varied from 15 to 30 minutes, with 30 minutes the most common interval. Increases were made daily for inpatient regimens [284], after 48 hours of dryness [293], every four to five days [292], or weekly if schedule was well-tolerated [189,268].
- Goals for optimal voiding interval varied from three to four hours.
- Voiding was ‘mandatory’ with restriction of voiding in between assigned toileting times even if UI occurred [284], a scheduled voiding regimen that allowed interruptions in the schedule if urgency became unbearable [189,268,289], or self-scheduling of voiding with a target goal to reach [286].
- Voids were not scheduled (allowed) during sleeping hours [284]; none of the other protocols identified how voids were handled during sleeping hours.

In some protocols the scheduled voiding regimen was supplemented by specific strategies to control urgency and/or stress leakage, including distraction and relaxation [189, 268, 286, 287, 289], and pelvic floor muscle contraction [189, 281, 287]. In other studies there was encouragement to suppress urge but it was not clear what strategies were used [48, 283, 291]. Feedback techniques included self-monitoring [189, 268, 282, 285, 289], goal setting with feedback of progress [290], and positive reinforcement [189, 268, 292].

Several protocols included use of adjunctive treatments:

- Fluid and caffeine adjustments [48,288,289]
- Fluids allowed up to a certain level (1,500 ml) [293]
- No fluid modifications [189,268,286,291]
- Advice on constipation prevention [289].

Both in and outpatient BT programmes have been used. Early inpatient BT programmes involved five to 13 days of hospitalisation to ensure strict protocol adherence [284]. Outpatient programmes are more commonly described and the amount of health professional contact had ranged from weekly visits for six weeks with fortnightly telephone calls for six additional weeks [189], to weekly visits [128,268], fortnightly visits [292], and monthly visits [293].

Overall, there is a lack of consistency in BT protocols. Based on the protocols described, a reasonable outpatient BT protocol is shown in **Figure 6.**

---

**Box: Typical Bladder Training Regimen**

- an initial voiding interval typically beginning at one hour during waking hours, which is increased by 15 to 30 minutes per week depending on tolerance of the schedule (such as fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the woman’s feeling of control over urgency and confidence to expand the voiding interval), until a two to three hour voiding interval is achieved. A shorter initial voiding interval, e.g. 30 minutes or less, may be necessary for women whose baseline micturition patterns reveal an average daytime voiding interval of less than one hour.

- education about normal bladder control and methods to control urgency such as distraction and relaxation techniques and PFM contraction.

- self-monitoring of voiding behaviour using diaries or logs in order to determine adherence to the schedule, enhance self-awareness, evaluate progress, and determine whether the voiding interval should be changed. **FIGURE 6** from 2009

- a supervising health care professional to monitor progress, suggest adjustments to the voiding interval, and provide positive reinforcement to women undergoing BT at least weekly during the training period.

If there is no improvement after three weeks of BT, re-evaluation is warranted and other treatment
options would be considered. Inpatient BT programmes may follow a more rigid scheduling regimen with progression of the voiding interval on a daily basis.

1. Summary

There is no trial evidence to suggest the most effective method or specific parameters of BT. For those undertaking BT it is likely that more health professional contact will be better than less, based on the developing evidence for PFMT, which like BT, requires behavioural change. The literature suggests several variables that could be investigated in future trials including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

2. Recommendations

It is not clear what the most effective BT parameters are. Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of BT parameters or approach (Grade of Recommendation: D). Clinicians should provide the most intensive BT supervision that is possible within service constraints (Grade of Recommendation: D). More research is needed to investigate which BT parameters, supervisory intensity, and adjunctive treatments are most effective. Future trials should include outcomes that matter to patients including the length and frequency of supervisory contact.

b) Is BT better than no treatment, placebo or control treatments?

BT as the sole therapy has been used in the treatment of DO, urodynamic SUI, MUI, UUI, UUI with a stable bladder, and OAB syndrome (also called urgency-frequency syndrome). Individual RCTs that met inclusion criteria and the Cochrane review [269] were used to address the question of whether BT is better than no treatment, placebo, or control treatments for UI.

Five RCTs reporting on 515 women were identified that compared the effect of BT to no treatment or control [128,268,285,289,291]. In one trial, it was not possible to identify the effect of BT alone, because results of participants in the treatment group who received BT (those with UUI or MUI) were combined with those who also received PFMT (SUI participants) [291]. However, in the Cochrane review, additional data were provided by the lead author to describe the women with DO who were randomised to BT versus control. In another trial with three consecutive treatments (self-monitoring, BT, and PFMT; with the decision for which treatments to implement based on participants’ goals), it was difficult to discern the effect of BT alone as compared to a control group, because some participants had already undergone lifestyle modifications (caffeine and fluid modifications and constipation advice) and diary keeping in a prior self-monitoring condition [289]. Thus, this trial is not discussed further in this section. A recent trial by Diokno et al 2010 [288] compares group session teaching of a behavioural modification program (BMP) includes both bladder training and pelvic floor muscle training, thus it was not possible to determine the effect of BT alone in this study and it is not included in subsequent discussion.
There were four older trials with analysable data: Jarvis (1980) investigated the effect of an in-patient BT programme in 60 women aged 27 to 79 years with a diagnosis of DO or coexisting SUI, whereas three [128,268,291] examined the effect of an outpatient programme. Fantl (1991) studied the effect of a six week outpatient programme in 123 women aged 55 to 90 years with urodynamic SUI, DO, or both who reported an effect of an eight week outpatient programme in 50 women aged 35 to 55 years with UI (type not identified) who had pad test weights at least 1g or more and 14 or more voids during a two day diary. Lagro-Jansen (1992) studied the effect of an outpatient programme in 18 women aged 20 to 65 years who reported UIUI twice or more per month and had urodynamically confirmed DO.

1. Quality of Data

In one trial random allocation concealment was inadequate [291]; in the remainder it was not clear if allocation was concealed. One used stratification based on urodynamic diagnosis of urodynamic SUI and/or DO [268]. Blinding of outcome assessors was described in only one trial [128].

Sample sizes in the four analysable trials were 18 [291], 50 [128], 60 [285], and 123 [268]. Fantl (1991) reported a power calculation although details were not described. Losses to follow up were none in one trial, although it was not clear if this was due to having no dropouts or due to lack of reporting [285]. In the other two analysable RCTs, loss to follow up was 6% [268] and 14% [128]. Dropout rates at the immediate follow-up time point seemed similar between the BT and the control groups, ranging from 8% vs. 5%, respectively [268], to 10% versus 14%, respectively [128]. No trials reported whether analyses were based on intent-to-treat principles. Follow-up periods ranged from six [268], eight [128] and 12 weeks [285,291], with an additional evaluation six months [285] and nine months [268], after initiation of treatment. Two trials noted whether there were adverse events with BT [268,285]. No trial reported on adherence.

All of these RCTs, with the exception of the one by Jarvis (1980), were considered in the Cochrane review [269]. The Cochrane reviewers based their conclusions on data available from 172 women in the other three trials.

2. Results

Three of the four RCTs reported statistically significant improvements in the BT group compared to the control group incontinent episodes [268,285,291]; the fourth did not report data on incontinent episodes [128].

Jarvis (1980) reported that 90% of the participants in the treatment group were continent and 83% were symptom free at six months (method for determination of continence and symptom status was not specified but probably self-report) compared to 23% of the control group who were both continent and symptom free. All women who were symptom free after treatment reverted to a normal cystometrogram.

Twelve percent of participants in the treatment group were continent and 75% had reduced their incontinent episodes by at least 50% or more at six weeks, measured by a seven day voiding diary, compared to 3% of controls with no incontinent episodes and 24% with at least 50% reduction in their incontinent episodes [268]. These results were maintained at six months. Women with DO and those with urodynamic SUI with and without DO had similar improvement rates. Participants in the treatment group also significantly decreased the grams of fluid lost on a retrograde pad filling test by 54% with results maintained six months later; this was more pronounced in those who had DO with or without urodynamic stress UI. While some women did revert back to normal bladder function following BT, no relationship was found between changes in urodynamic variables and the number of incontinent episodes [294].

Lagro-Jansen [1992] reported that eight or nine patients in BT perceived improvement of UI compared to none of nine in the control group. Yoon (2003) reported that there was no difference between the BT and control groups in the amount of leaked urine at an immediate follow-up; however, it was not clear if this referred to pad test weights solely or a UI severity score. Conclusions from this trial are uninterpretable because of insufficient power.

The Cochrane review [269] noted that the few data available tend to favour BT; however, the scarcity of data implies that they should be interpreted cautiously.

3. Summary

The few trials available were small and of variable quality, there is minimal Level 1 evidence that BT may be an effective treatment for women with UIUI, SUI, and MUI (Level of Evidence: 1).

4. Recommendations

BT is an appropriate first line conservative therapy for UI in women (Grade of Recommendation: A). Additional high quality studies are needed that examine the effect of BT versus no treatment in treatment of women with UIUI, SUI, and MUI.

c) Is BT better than other treatments?

To be included in this section, trials needed to compare BT alone versus another active therapy. For the comparison of BT versus PFMT see B.2.3d. The only other comparison for which trials were found was BT versus drug therapy. Individual trial reports that met inclusion criteria and the Cochrane review [269] were used as the basis of the review of BT versus drug therapy.
Three RCTs were located that compared BT to drug therapy in 322 women [281, 284, 292]. The study by Park and colleagues [281] compared a 12-week BT programme to 2mg tolterodine twice daily in women (ages unknown) with OAB (unclear if UI was present); because there were no findings reported on UI, this trial is discussed in the section on Other LUTS (B.6.3). The two trials included in this section used a combination of flavoxate hydrochloride and imipramine [284], or used immediate-release oxybutynin chloride [292].

1. QUALITY OF DATA

One trial reported adequate random allocation concealment [292]. Sample sizes were 50 [284] and 79 [292]. Neither trial reported a power calculation;

Follow up periods varied from four [284], six [292], and 12 weeks [284], and six months [292]. Both RCTs evaluated drug tolerability and adverse events. Dropouts were none in one trial; however, it is not clear whether this was a reporting issue [284]. In the other trial loss to follow up was 7% [292]. Neither trial identified whether intent-to-treat principles were followed. The conclusions of the Cochrane review [269] were based on the same trials.

2. RESULTS

One RCT published in 1981 suggested that BT may be superior to drug therapy in women with DO [284]. Inpatient BT was compared to outpatient treatment of 200mg of flavoxate hydrochloride (three times a day) and 25mg of imipramine (three times per day) in 50 women aged 17 to 78 years with DO, and concluded that BT was more effective. In the BT group, significantly more patients (84%) became continent and symptom free (76%) assessed by self-report, as compared to the drug group where 56% became continent and 48% were symptom free at four weeks. Patients who were symptom free at four weeks were able to maintain their outcomes at 12 weeks and more in the BT group perceived that they were cured at the end of the treatment phase and approximately two month after treatment ended. Adverse events included dry mouth, constipation, nausea and tachycardia in patients who received drug therapy, with none in those who received BT.

A similar clinical cure rate (i.e. self-reported total disappearance of UI, no protective pads or further treatment) was reported in outpatient BT women aged 24 to 65 years with DO [292]. ‘Clinical cure’ was observed in 93% and 62% of patients with DO, 67% and 75% of those with low compliance bladder, and 60% and 81% of those with urgency-frequency syndrome in those randomised to oxybutynin and BT respectively. The relapse rate at six months was higher for the drug group. In the analysis by the Cochrane Group (2010) participants’ perception of cure was not statistically significant at the end of the treatment phase but favoured BT six months after the treatment ended. Perceptions of improvement were also higher in the BT group at the end of the treatment phase but this difference was not statistically significant. Adverse events included dry mouth, constipation, nausea and tachycardia in patients who received drug therapy, with none in those who received BT.

3. SUMMARY

It is not clear whether BT is more effective than drug therapy for women with DO or UUI (Level of Evidence: 1). This is consistent with the findings of the Cochrane review [269], which concluded that there was not enough evidence to determine whether first line therapy should be BT or anticholinergic drugs.

4. RECOMMENDATIONS

In a choice between BT and anticholinergic drug for women with DO or UUI, either may be effective (Grade of Recommendation: B). BT may be preferred by some clinicians and women because it does not produce the side effects and adverse events associated with drug therapy (Grade of Recommendation: D).

d) Can any other treatment be added to BT to add benefit?

To be included, trials needed to investigate the effects of BT versus BT plus therapy A to address the additive benefit of therapy A. Trials addressing the additional benefit of three other treatments were found: caffeine reduction, PFMT, and drug therapy. The trial addressing the added benefit of caffeine reduction [48] is considered in the section on Lifestyle Interventions (A.1.2d), and the trial addressing the added benefit of PFMT [189] is considered in the section on PFMT (A.2.3e). The trials addressing the added benefit of drug therapy are considered below.

One RCT was found that compared BT alone versus BT with tolterodine (2mg, twice daily) in women with OAB [281]. However, incontinence status of the participants was unknown, and details regarding the study methodology were limited (abstract only). Therefore this trial was not considered further in this section.

A further three RCTs compared BT with placebo drug versus BT with drug therapy in patients with DO. One of these used terodoline (a drug that was withdrawn from the market) [283]. Therefore, this trial was not considered further in this section. In the other two trials the drugs used were imipramine [293] and immediate release oxybutynin [282].

Castleden [1986] studied 34 patients with DO (28 women aged 30 to 91 years and six men). Szonyi [1995] recruited 60 patients aged 70 years and over (56 women, four men). While it is possible that the placebo drug could augment BT, and both these trials included a small number of men in addition to women (and data for women were not reported
A new trial compared Solifenacin (5/10mg) alone with Solifenacin and bladder training [287]. One older study (Wyman 1998) compared BT, PFMT, and combination therapy in 204 community dwelling women aged 45 years and older with SUI and/or DO [189]. Two RCTs were identified that compared BT plus tolterodine (2mg twice daily) [281,286] to drug therapy alone. In one three arm trial [281], women with OAB were enrolled but it was unclear if UI was present. Therefore this trial was not considered further.

1. **Quality of data**

(a) **BT plus PFMT versus PFMT alone:** In an early, three arm RCT women were randomised to PFMT (n=69) or PFMT with BT (n=67) [189]. Outcomes were assessed after the 12 week intervention and three months later. It was not clear if random allocation was adequate or outcome assessors were blind. Study size was based on a power calculation. Losses to follow-up were six at 12 weeks, and 16 three months later.

(b) **BT plus drug therapy versus drug therapy alone:** Mattiasson [2003] evaluated “simplified” BT (consisting of a one page instruction sheet) in a single blind study of 501 participants (378 women and 123 men) aged 18 years and over with OAB with or without UI. Allocation concealment, blinding of assessors, and a prior power calculation were not described. Post-treatment follow-up was 12 weeks, and then 24 weeks. Seven participants were lost to follow-up: five in drug therapy and two in combination therapy. Analyses were based on intent-to-treat principles. However, because of reporting issues, it was not possible to discern the effect of treatment in women alone. In 2010, Mattiasson compared solifenacin alone with solifenacin and bladder training in a prospective, parallel group, open label study of 643 men and women with OAB, it was not possible to identify the treatment effect in women alone (85% of sample were women).

2. **Results**

(a) **BT plus PFMT versus PFMT alone:** Post-treatment the combination therapy group had significantly fewer incontinence episodes compared to PFMT alone. More women in the combination therapy group than PFMT group reported cure (31% versus 13% respectively), or 50% improvement or more (70% versus 50%). The combination therapy group also reported greater perception of improvement and more satisfaction with treatment than PFMT alone. However, three months later between group differences were not statistically significantly different for cure (27% versus 20%), improvement (59% versus 56%), perception of improvement, or satisfaction with treatment.

(b) **BT plus drug therapy versus drug therapy alone:** Mattiasson (2003) reported no difference between participants who received brief written BT instructions plus tolterodine versus tolterodine alone with

---

**1. Quality of data**

Adequate random allocation concealment, or blinding was not reported in either study [282,293]. Study size was based on a power calculation in one [282]. Post-treatment follow up periods were variable. One trial evaluated participants at six weeks [282]; 16 were lost to follow up. The other did not have a clear endpoint but followed participants for one to 11 months; one participant was lost to follow-up [293].

**2. Results**

It was not possible to discern the treatment effects in only women in these two trials, and the findings were inconsistent. More participants became dry on BT plus imipramine 25mg or more per day (14 of 19) compared to those in the BT plus placebo group (six of 14), but the authors reported that there was no statistically significant difference in outcome between the two groups [293]. One patient in the imipramine group became confused and another complained that the drug made him feel ill. Several patients taking imipramine reported dry mouth and constipation (data not reported), but none on placebo.

No difference was found in a comparison of BT plus 2.5mg of immediate release oxybutynin (twice daily) compared to BT and placebo for reducing incontinent episodes [282]. The authors concluded, however, that the combined therapy group was superior to the BT and placebo group, because it had greater subjective benefit (86% versus 55%), and adverse events were similar in the two groups at 50%.

**3. Summary**

In two small trials comparing BT plus placebo drug versus BT plus drug in DO, there was a suggestion that the effect of BT might be enhanced by active drug (Level of Evidence: 2). However both trials were small, placebo controlled, conducted in gender mixed sample populations, and the outcomes were not common to both trials. Thus, there is insufficient evidence to derive a conclusion related to the effectiveness of augmenting BT with drug therapy.

**4. Recommendations**

Direct comparisons of BT versus BT with drug are needed to address the question of whether the effect of BT can be augmented by drug therapy.

e) **Does the addition of BT to any other treatment add benefit?**

To be included, trials needed to investigate the effects of Therapy A versus Therapy A plus BT to assess the added benefit of BT over Therapy A alone. Trials were located that investigated the effects of PFMT alone versus PFMT plus BT, and drug therapy alone versus BT plus drug therapy.
respect to reducing incontinent episodes (median reduction 87% vs. 81%, respectively). Data were combined for men and women and most data were not presented separately for those who had UI versus those who did not. Mattiasson [2010] reported solifenacin was effective in improving OAB at 8 weeks reducing mean number of micturitions by 2.09, when BT was added there was a further significant improvement reducing episodes by 2.78. Again this study did not present data which enabled analysis of men and women separately.

A single trial found that combining BT with PFMT improves short-term outcomes compared to PFMT alone, but the added benefit did not persist three months later.

There is no evidence for an added benefit of combining brief written BT instructions with tolterodine alone for urge incontinence ([Level of Evidence: 2]), although this trial included men and women and it is not known if one gender did better than the other with respect to outcome. The use of BT with solifenacin (5/10mg) adds benefit to symptom reduction at 8 weeks compared to solifenacin alone, mainly to symptoms of frequency ([Level of Evidence 2 – NOTE: This evidence related to men and women]).

4. RECOMMENDATIONS

The current evidence is conflicting for the addition of written information on bladder training for women taking an antimuscarinic drug. One trial states no clinical benefit in adding brief written instruction in BT ([Grade of Recommendation: B]), whilst another suggests no significant improvements to urgency and urge incontinence but significant improvements in frequency ([Grade of recommendation: B]). More research is needed using an appropriately supervised BT programme (see B.6.2a) combined with anticholinergic or antimuscarinic drug therapies versus drug alone.

f) Timed Voiding

A 2010 Cochrane review on timed voiding for management of UI in adults was recently published [273]. Ostaszkiewicz (2010) considered randomised and quasi-randomised trials only and identified two trials that compared timed voiding combined with additional interventions (including medications) to usual care. Both trials were conducted in nursing facilities and most participants were elderly women with cognitive impairment, therefore neither study recruited participants that met the criteria of interest for this chapter.

Two non-randomised studies that were not included in the Cochrane review reported findings related to the effects of timed voiding in women with UUI, stable bladders with UUI, and MUI [194,295]. Klarskov [1986] reported a consecutive series of 20 women aged 27 to 75 years with a double-blind crossover to compare timed voiding plus anticholinergic drug therapy (terodoline) to timed voiding plus placebo. As terodoline has been withdrawn from the market, this study is not considered further.

1. QUALITY OF DATA

A 1984 case series report involved 20 women aged 24 to 94 years in women with a mild degree of UI, irregular voiding patterns, and normal urodynamic parameters (UI type not clearly reported) [295]. The voiding schedule consisted of a two hour voiding interval. Follow-up periods ranged from six weeks to eight months after treatment [295].

2. RESULTS

A 79% success rate (not objectively quantified) was reported in the case series. Fifteen patients became totally continent, one had less leakage, three (with neurogenic diseases) remained unchanged, and one patient was lost to follow-up.

3. SUMMARY

There are no RCTs, or high quality observational studies, providing evidence on the effects of timed voiding for UI in women. Based upon the data from one small uncontrolled study, it seems a two hour timed voiding schedule may be beneficial in treating women with mild UI, infrequent voiding patterns, and stable bladder function ([Level of Evidence: 3]).

4. RECOMMENDATIONS

Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns ([Grade of Recommendation: C]). It may also be helpful as an adjunct to other treatment.

3. OTHER LUTS

One trial recruited participants with OAB but the continence status was unclear [281]. BT was compared to tolterodine (2mg, twice daily) or combined BT and tolterodine in women with OAB [281]; this study was reported as a conference abstract. Tolterodine/ BT group had greater reductions in diurnal micturition (32.6%), nocturnal micturition (63.2%), urgency scores (63.2%), and bladder symptom improvement rates (69.3%) than those in BT alone or tolterodine alone. However, only the bladder symptom improvement scores were statistically significantly better in the combination therapy group. Thus, it is not clear if BT alone, tolterodine alone, or the combination, is better for LUTS other than UI in women with OAB symptoms.

The most common LUTS, aside from UI, are urgency, daytime (or diurnal) frequency and nocturia. Some trials that contributed to the sections above reported data specifically for these symptoms.
(a) Urgency: Jarvis [1981] compared BT and drug therapy (flavoxate and imipramine), and 16% versus 44% of participants reported they continued to experience urgency post-treatment. Mattiasson [2003] compared BT with tolterodine versus tolterodine alone and patient rating of urgency was somewhat less in the combination therapy group.

(b) Daytime (diurnal) frequency: Data on frequency are more commonly collected that data on urgency. Three trials reported diurnal frequency in comparisons of BT with no treatment. Jarvis [1980] reported a small controlled trial of inpatient bladder drill for DO [285]. After BT 17% in the treatment group and 77% in the control group continued to have symptoms of diurnal frequency. Fantl [1991], in subgroup analyses, found a significant reduction in diurnal frequency in participants with urodynamic SUI who had a baseline diurnal micturition frequency of at least 61 per week, and also in participants with DO with or without urodynamic SUI who had at least 57 diurnal micturitions per week [268]. Finally, Yoon (2003) reported that the BT group significantly reduced diurnal micturitions, whereas the control group deteriorated slightly [128].

Three trials compared BT with drug therapy. Jarvis [1981] reported that 24% of the BT group continued to experience frequency as compared to 48% of the drug group (flavoxate and imipramine) [284]. Columbo (1995) found that diurnal frequency was resolved in 18 (56%) of 32 patients taking oxybutynin versus 20 (69%) of 29 BT patients [292]. Kim SW et al [2008] found improvement in daytime frequency in 15 (65%) cases using bladder training alone and 21 (84%) using BT and propiverine combined.

Another trial compared BT plus placebo versus BT plus drug [282]. Szonyi [1995] found that there was a greater reduction in diurnal micturition frequencies in participants taking oxybutynin alongside BT compared to those on placebo and BT. Similarly, in a trial of BT plus drug versus drug alone Mattiasson (2003) found that “simplified” BT significantly augmented the effect of tolterodine compared to drug alone for voiding frequency (33% versus 25% improvement, respectively; p<0.001).

(c) Nocturia: Three trials reported data on nocturia in comparisons of BT with no treatment. Jarvis (1980) reported a small controlled trial of inpatient bladder drill for DO. After bladder training, there were 11% in the treatment group and 80% in the control group who continued to have symptoms of nocturnal frequency [285]. Fantl [1991] also found significant reductions in nocturnal frequency [268]. In subgroup analyses, nocturnal micturitions were only significantly decreased in women with urodynamic SUI alone, who experienced at least five episodes of nocturia per week, and not in those who had DO. Yoon [2003] reported that the BT group significantly reduced nocturnal micturitions, whereas the control group deteriorated slightly [128].

Two trials compared BT with drug therapy. Jarvis [1981] reported that the 19% of the BT group continued to experience nocturia compared to 68% of the drug group (flavoxate and imipramine) [284]. Columbo [1995] found that nocturia disappeared in three (27%) of 11 patients taking oxybutynin and 11 (61%) of 18 BT patients [292]. Another trial compared BT plus placebo versus BT plus drug [282]. Szonyi [1995] found no difference in nocturnal micturition frequencies.

1. Summary

Scheduled voiding regimens have been implemented in many forms and with a variety of intensities, ranging from strict in-patient regimens to simple instruction sheets. Most research has examined BT, and most of these trials have recruited women with symptoms of UUI or OAB. It is therefore disappointing that there is so little data about LUTS other than UI. The indications so far are that BT is effective for reducing UI, as well as frequency of micturition. The scant research comparing BT to drug therapy is inconsistent with some evidence for the superiority of each. It is not yet clear whether drug therapy can enhance BT, or whether BT can enhance UI outcomes from drug therapy, although it appears that reductions in frequency of micturition may be greater with the addition of BT.

4. FACTORS AFFECTING OUTCOME

a) Age

With the exception of two RCTs [128, 291] all trials included older women in their study populations. Three specifically recruited elderly women aged 65 to 70 years and over [282, 283, 293]; and two recruited women aged 55 years and over [268, 289]. In conducting analyses of factors predicting success, two trials reported that age was not a factor in treatment outcome [189, 289].

b) Other

Few trials on BT examined other predictors of treatment response. Several discussed the effect of diagnosis on treatment outcome; two reported that urodynamic diagnosis did not have an effect on treatment outcome as measured by incontinent episodes and the IIQ [189, 268]. These RCTs included women with urodynamic SUI, DO, or both diagnoses. BT also led to more clinical cures in one small drug trial. BT in women with sensory urgency (81%) and low compliance bladders (75%) produced better outcomes than in those on oxybutynin immediate release (60%, 67%, respectively); however, oxybutynin led to greater cure rates in patients with DO (93% versus 62%).

VII. COMPLEMENTARY AND ALTERNATIVE MEDICINES

There is minimal evidence that complementary and alternative medicines (CAMs) may influence physiologic function and/or health outcomes. CAMs include
those therapies that are not part of the traditional biomedical model, such as meditation, imagery, hypnosis, acupuncture and naturopathic and herbal remedies. While some consider biofeedback (BF) part of complementary therapy, we have included BF in this chapter as an adjunct to physical therapies.

A search of AMED (Allied and Complementary Medicine) using the key words randomised controlled trials, and urinary incontinence, retrieved 32 records in 2012. One reported a randomised controlled trial investigating the effect of hand acupuncture for female SUI on 52 women randomly assigned to either experimental hand acupuncture or control, assessment was made at 12 weeks and 37% less incontinence was reported in the experiential group. The reporting of this trial did not conform to traditional standards and should be treated with caution, however the undertaking of an RCT in the CAMs literature indicates a move towards the gathering of robust ‘main-stream’ evidence in this area.

There is a need for well conducted RCT’s in the area of CAMs before recommendations can be made.

VIII. SUMMARY AND RECOMMENDATIONS

1. SUMMARY

Whilst the effect of PFMT has received considerable research attention, the effect of lifestyle interventions or prevention trials have not. However even with the number of reasonable trials on conservative management of UI in women, the standards of trial conduct and reporting varied considerably and it is strongly recommended that future randomised trials account for sample size, heterogeneity, risk of bias, and followup.

2. RECOMMENDATIONS FOR PRACTICE

• While some recommendations are underpinned by good and consistent evidence of effect, there are also many recommendations that need further testing because there is insufficient Level 1 or 2 evidence. For this update, the recommendations from ICI 2009 remain. These are not based on robust research and require further study:

a) Lifestyle Intervention

• Weight loss in obese and morbidly should be considered a first line treatment to reduce UI prevalence (Grade of Recommendation: A).
• Caffeine reduction may help in improving incontinence symptoms (Grade of Recommendation: B)
• Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not less than 30 ml/kg a day (Grade of Recommendation: B) Moderate exercise may help in decreasing the incidence of UI; this effect may be mediated by weight control (Grade of Recommendation: C)

b) PFMT (principal recommendation)

• Supervised PFMT should be offered as first line conservative therapy to women with stress, urge, or mixed urinary incontinence (Grade of Recommendation: A)
• The most intensive PFMT programme possible should be provided (in terms of exercise dose, health professional teaching, and supervision) within service constraints; health professional taught and supervised programmes are better than self-directed programmes; more health professional contact is better than less (Grade of Recommendation: A).

• There does not appear to be a clear benefit of adding clinic (Grade of Recommendation: B) or home based BF (Grade of Recommendation: B) to a PFMT programme.

c) PFMT (other recommendation)

Pregnant women expecting their first baby:

• Intensive strengthening antepartum PFMT, with regular health professional contact to teach and supervise training, to prevent postpartum urinary incontinence (Grades of Recommendation: A) (for women continent at 18 weeks) and B (for population approaches, that is intervention offered whether women are continent or not at 20 weeks gestation)

Postnatal women, immediately after delivery:

• Individually taught PFMT programme that incorporates adherence strategies for women who had a vaginal delivery of a large baby (4000g or more) or a forceps delivery (Grade of Recommendation: C)

For postnatal women with persistent symptoms of UI three months after delivery:

• PFMT is offered as first line conservative therapy (Grade of Recommendation: A)
• The ‘best’ PFMT programmes are ‘intensive’ with regard to supervision and exercise content (Grade of Recommendation: B)

For women with SUI:

• PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised (Grade of Recommendation: B).
• PFMT is better than BT as first line conservative therapy (Grade of Recommendation: B).
• PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug (Grade of Recommendation: C).

• PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive (Grade of Recommendation: C).

For women with SUI or MUI:
• PFMT is better than VC as first line conservative therapy (Grade of Recommendation: B).

For women with UUI or MUI:
• PFMT and BT are effective first line conservative therapy (Grade of Recommendation: B).

For women with UUI:
• PFMT and BT are effective first line conservative therapy (Grade of Recommendation: B).

Vaginal cones:
• For women with SUI, VCs with supervised training sessions by a trained health professional can be a first-line therapy to women able and prepared to use them (Grade of Recommendation: B); some women cannot insert or retain the the cone or have side effects and discomfort. Trained health professional assessment is recommended (Grade of Recommendation: D).

Electrical stimulation (EStim)
While the usefulness of EStim in practice might be limited because some women cannot use it (due to contraindications), have difficulty using it, or dislike it:

• EStim might be better than no treatment in improving symptoms (Grade of Recommendation: B).

• EStim may be equal to other medical treatments (Grade of Recommendation: B).

• EStim plus PFMT or BF-assisted PFMT programmes does not appear to add benefit (Grade of Recommendation: B).

Magnetic stimulation (MStim)
• Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI. No recommendation is possible based on current evidence (Level of recommendation: D).

Bladder training (BT)
With regard to Grade A recommendations for BT:
• BT is an appropriate first line treatment for UI in women (Unchanged).

Grade B recommendations (all unchanged from ICI 2009):
• Either BT or antimuscarinic drug may be effective, although BT may be preferred by some because it does not produce side effects and adverse events associated with drug therapy.

• There may be no benefit in adding brief written instruction in BT to drug therapy for incontinence but it may improve episodes of frequency.

• A combination of PFMT/BT may be better than PFMT alone in the short-term for women with symptoms of SUI or MUI.

There are two Grade D recommendations (unchanged from C(2009):
• Clinicians and researchers should refer to the operant conditioning and educational literature to provide a rationale for their choice of training parameters or approach.

• Health Professionals should provide the most intensive BT supervision that is possible within service constraints.

Timed voiding (unchanged)
• Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns (Grade of Recommendation: C).

IX. FUTURE RESEARCH DIRECTIONS
Conservative management of incontinence is ripe for future research directions. Research that is urgently needed, in the opinion of the committee members, is highlighted with the use of italics. There are a few recommendations that apply to all further studies:

• All future trials must be designed, implemented and reported in ways that maximise their usefulness in practice; this includes being well powered, with longer term follow up, with evaluation of cost-effectiveness and planned secondary analysis of trial data to investigate factors affecting outcome. Readers are referred to the revised CONSORT statement for guidance (http://www.consort-statement.org/)

a) Lifestyle Intervention:
• Given the high prevalence of both UI and obesity in women, the dual issues of weight loss and prevention of weight gain (and exercise) should receive high research priority.
• Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.

• Further research is needed to define the role of straining in the pathogenesis of UI.

• Studies to establish whether heavy exertion is an etiologic factor in the pathogenesis of UI and whether changing exertions can alleviate established UI.

• Prospective studies on the effect of smoking cessation on the prevention or resolution of UI.

• Separate investigations of the impact of lifestyle interventions on nocturia, diurnal frequency, urgency and UUI to delineate whether certain interventions preferentially affect different areas of OAB.

b) Pelvic floor muscle training (PFMT)

In antenatal and postnatal women, trials are needed to investigate the effects of:

• Antepartum PFMT on preventing postpartum UI in multiparous women.

• Postpartum PFMT programme (suitable exercise dose and supervision) in the long term (five plus years).

• Periodic refresher sessions after an initial supervised postpartum PFMT programme, in the long term (five plus years).

In all women, trials are needed to investigate:

• The effect of different supervisory intensity in PFMT program. In addition to clinical effectiveness, this is an important question because of resource implications, both financial and human, for health-service delivery.

• Whether clinic BF may benefit certain women, such as those with a weak PFM or with difficulty contracting the PFM in isolation.

• Whether the addition of bladder training or medication adds benefit to PFMT.

c) Vaginal cones (VC)

• If the combination of VC with PFMT is an intervention of interest for women then this combination of therapies could be explored further. VC could be used as an overload progression to active PFM strengthening exercises. Thus, a VC programme could be offered to women with a demonstrated minimum PFM strength level and could be aimed at either additional strength training by pulling on the cone for three series of eight to 12 contractions daily, or endurance training, using a low-load over a sustained period of time.

d) Electrical stimulation (ESstim) and magnetic stimulation (MStim)

• Studies to elucidate the purpose and biological rationale for ESstim in different diagnostic groups, so these can then be tested and compared in clinical trials.

• Comparisons of ESstim with other treatments such as PFMT, vaginal cones, and bladder training are more important than comparison of ESstim with sham.

• ESstim as an adjunct to treatments that seem to be effective such as PFMT, vaginal cones, and bladder training.

• MStim protocols, both sacral root MStim and home-based MStim, are worthy of further investigation. Well powered RCT are needed to study the clinical effect of Mstim in different diagnostic group.

e) Scheduled voiding regimes, especially bladder training (BT)

• BT variables to be investigated include the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

• BT versus another active treatment such as PFMT or drug therapy.

• The potential benefits of combining BT and anticholinergic/antimuscarinic drug need further investigation, including comparisons of BT plus drug versus drug alone, and BT plus drug versus BT alone, or BT vs no treatment.

• Habit training in women with a consistent pattern of UI who are ambulatory and cognitively intact.

B. PELVIC ORGAN PROLAPSE (POP)

Pelvic organ prolapse is characterised by a variety of pelvic floor symptoms. Treatment depends on the severity of the prolapse and its symptoms, and the woman’s general health. Conservative treatment is generally considered for those with a mild degree of prolapse, those who wish to have more children, the frail or those unwilling to undergo surgery. Conservative treatment is defined here as lifestyle interventions, physical therapies and pessaries.

The aims of conservative treatment in the management of POP include:

• to prevent the prolapse becoming worse;

• to help decrease the frequency or severity of symptoms caused by prolapse (pelvic heaviness, vaginal symptoms, backache, urinary, bowel and sexual symptoms);

• to avert or delay the need for surgery.

In this section the evidence is applied for the use of conservative treatments in the management of
Lifestyle interventions include weight loss, reducing exacerbating activities (e.g. lifting, coughing) and treating constipation and are intended to avoid exacerbation of the prolapse by decreasing intra-abdominal pressure. The extent to which any of these lifestyle interventions are effective in managing prolapse is largely unknown [195].

1. PREVENTION

a) Quality of data

No new intervention studies were identified in this update, however further observational studies have been published and these are reported here and summarised in Table 16. In ICI 4th edition, no literature was found relating to the effects of lifestyle change interventions for the prevention of POP. Observational studies were identified that examined the association between factors such as occupation (including heavy lifting/strenuous physical activity), bodyweight and constipation, and POP.

(a) Association between POP and occupation:

Three new studies investigated the association between occupation and prolapse.

Miedel [298] undertook an assessment of non-obstetric risk factors, including heavy lifting at work, in a population-based, cross-sectional study derived from a sample of 5489 Stockholm women, 30 to 79 years old, who answered a validated questionnaire for the identification of symptomatic prolapse. 69% responded and of those, women who had symptomatic prolapse (n=454) and randomly selected controls (n=405) were given a detailed questionnaire regarding their risk factors, including current or previous occupations that involved heavy lifting (up to 10 kg daily, more than 10 kg) or exposure to vibrations, and participation in low- and high-impact exercise. Only women with intact uteri and no history of surgery for prolapse or incontinence were included (n=273 cases, n=285 controls). Odds ratios and confidence intervals were estimated from multiple logistic regression analysis.

Slieker-ten Hove undertook a cross-sectional study of all female residents between 45 and 85 years old in one Dutch city (n=2979), the results of which were reported in four articles [299-302]. Women received a validated questionnaires via which they were classified as symptomatic (if they reported feeling and/ or seeing a vaginal bulge) or non-symptomatic. A response rate of 63% was achieved. Finally 1224 women were included in the analysis (n=142 symptomatic; n=1082 asymptomatic). Multiple logistic regression was used to estimate the odds ratios and confidence intervals for the potential risk factors including current and past heavy physical work [299].

Braekken [303] carried out a one-to-one age and parity matched case-control study (n=49 women with prolapse >=stage II with or without symptoms, and n=49 controls with prolapse stage 0 or I) with recruitment via community gynaecologists and newspaper advertisements. Women had clinical examination, pelvic floor muscle (PFM) function assessment (strength, endurance and vaginal resting pressure in cmH2O) and completed questionnaires including risk factor assessment. The study primarily looked at the association between PFM function and POP, but also measured occupational heavy lifting and BMI as potential risk factors for POP. Heavy occupational work was defined by a positive response to three questions: self-report of physically heavy occupational work; >20 heavy lifts per week; >50% of working time in standing position. One or two positive responses was classified as moderate occupational work. Multivariate logistic regression was used to estimate odds ratios for risk factors.

(b) Association between POP and bodyweight:

Four new studies have addressed the relationship between obesity and prolapse [298, 303-305].

Whitcomb [2009] published a secondary analysis of the data from 1155 obese women from the Kaiser Permanente Continence-Associated Risk Epidemiology Study. Prolapse was identified from responses to a question regarding the sensation of a bulge or something falling out of the vagina. Women were asked to report bother on a visual analogue scale. Multivariable logistic regression was used to assess severity of obesity (obese, severely obese, morbidly obese) as a risk factor for various pelvic floor disorders including prolapse. Models were adjusted for age, parity and mode of delivery.

Washington [2010] reported on a cross-sectional study of all women with pelvic floor disorders (n=971) attending a tertiary urogynaecology centre over one year. Data on POP-Q, PFDI-20, and PFIQ-7 were gathered. Women with POP-Q >=stage II were classed as having prolapse; women with BMI>=30 were classed as obese.

In addition, two studies [298,306] (described above) assessed body mass index as one of several risk factors for prolapse.

(c) Association between POP and bowel function:

Four new studies, one relating to irritable bowel and prolapse [307] and three looking more generally at defecatory problems [298,301,308] were found.

Wang [2010] analysed data from the Reproductive Risks for Incontinence Study addressing the relationship between irritable bowel syndrome and pelvic

Foot notes: N/A non applicable; PFM= Pelvic floor muscle, PFMT = pelvic floor muscle training.
floor disorders, and the effects of such symptoms on quality of life. RRISK is a racially-diverse cohort of women aged between 40 and 69 years (n=2109). Data were collected by self-administered questionnaires and interviews. IBS status was determined by asking a single question regarding whether a woman had ever been told by a medical doctor that she had IBS. Prolapse was identified by asking about feeling or seeing a bulge or protrusion. Multivariate logistic regression was used to assess factors associated with having IBS including prolapse.

Saks [2010] in a cross-sectional study examined whether there was an association between obstructive defaecatory symptoms and prolapse. Women presenting with prolapse of grade 2 or greater (Baden-Walker system) of any compartment (anterior, posterior, apical) to one tertiary urogynaecology service completed a questionnaire (PFDI-20) that reported pelvic floor symptoms. A multivariate regression analysis was performed, adjusting for confounding variables, the dependent variable being presence of obstructive bowel symptoms (defined as at least moderate bother with one or more of: splinting, straining, incomplete emptying).

Both Miedel [2009] and Slieker-ten Hove [2009] assessed the presence of constipation (<3 bowel movements per week), hard stools and difficult evacuation as risk factors for symptomatic prolapse and changes in POP-Q stage.

(d) Association between POP and nutrition:

Previously one study of women in rural Gambia had been published on the association between prolapse severity and anaemia [309]. A new study by Badalian [310] addressed the association between Vitamin D deficiency and pelvic floor disorders. The authors hypothesised that there is a plausible link between vitamin D deficiency and poor muscle strength since vitamin D receptors are found in human muscle tissue. Over three thousand women aged 20 years or above from the US National Health and Nutrition Examination Study 2005-2006 were selected by probability sampling. Analysis was based on the 1881 non-pregnant women who participated, and who had data on both vitamin D levels and pelvic floor disorders. Prolapse was identified from a positive response to a question on the experience of a bulge or something falling out that is seen or felt in the vaginal area. Level of vitamin D was analysed both as a continuous variable and as a dichotomous variable (>= 30 ng/mL, <30 ng/mL). Analysis included both univariate and multivariate regression models. Models adjusted for age, BMI, parity, education and race.

b) Results

(a) Association between POP and occupation:

In the Miedel study [2009] a total of 655 (76.2%) women returned completed risk factor questionnaires with 558 women included in the analysis (n=273 symptomatic; n=285 controls). Heavy lifting at work was found to be positively linked to symptomatic prolapse in a simple age- and parity-adjusted model. Compared to women who did no heavy lifting at work, those lifting weights up to 10kg had an increased risk of symptomatic prolapse (OR 1.81, 95% CI 1.11–2.95). There was a similar increased risk for those women lifting 10kg or more at work: OR 1.67, 95% CI 1.07–2.61. This finding was confirmed in the multiple logistic regression analysis which indicated eight variables that were significantly associated with symptomatic prolapse. Age, parity, family history of prolapse, increased BMI, the presence of any condition suggestive of deficient connective tissue, fewer years smoking, heavy lifting at work, and abnormal bowel habit were all risk factors for symptomatic prolapse. From this model the results for heavy lifting compared to no heavy lifting were: <10kg OR 1.98, 95% CI 1.10–3.59; >=10kg OR 1.94, 95% CI 1.15–3.27. Thus no clear dose response was confirmed.

Slieker-ten Hove [299] found that current heavy physical work was an independently significant risk factor for symptomatic prolapse; 24.5% of cases versus 18.9% of controls were currently engaged in heavy work. The odds ratio was 1.48 (95% confidence interval 0.98-2.23) and the population attributable risk (PAR) was 8.5%. Other independent risk factors were having POP symptoms during pregnancy and mother having prolapse. Past heavy work was not a significant risk factor.

Braekken [2009] also reported that heavy occupational work, compared to moderate or light occupational work, was associated with greater risk of prolapse >= stage II. BMI and pelvic floor muscle function variables were also significantly associated with risk of prolapse as described in later sections.

Previously the majority of studies (5 out of 6) reported a positive association between occupations associated with lifting and the presence of prolapse. The additional three studies were supportive of an association between current heavy occupational lifting and prolapse, however the odds ratio in one study was only marginally significant.

(b) Association between POP and bodyweight:

Morbidly obese women had significantly increased odds of having prolapse (reported bulge) compared to obese women (Whitcomb, 2009). The odds for severely obese women compared to obese women were not significantly increased. The visual analogue scores for bother with prolapse did not differ significantly between obesity groups. There may be a trend towards increasing prevalence of prolapse with increasing severity of obesity. However this was not reflected in the bother reported.

In the Washington [2010] study of 971 women, 721 met the inclusion criteria and had sufficient data
to be included in the analysis. Mean age was 56.5 years (SD 16.2) and 65.2% were post-menopausal. 35.8% were obese and 62.2% non-obese. The mean BMI was 35.8 (SD 5.4). Stage II prolapse was present in 52% of women. No difference in presence of prolapse of stage II or greater was found between obese and non-obese women and similarly for stage 3 or greater prolapse: obese 16.2% vs non-obese 18.4%. Being obese was however associated with more pelvic floor symptom distress: the mean score on the PFDI-20 was significantly higher for obese women compared to non-obese women, due to higher mean scores on subscales for colorectal-anal distress and urinary distress. There was no significant difference between obese and non-obese women in the prolapse-specific subscale of the PFDI-20. The analysis performed was unadjusted, but it was reported that there were no significant differences in age, parity, race, prior pelvic surgery or co-morbidities between the obese and non-obese group.

Miedel [2009] found that although age, parity, and family history of prolapse were the dominating risk factors for symptomatic prolapse, increased BMI was also an independent significant risk factor in the final fully adjusted model (p=0.038). Compared to women of normal weight (BMI 19 to 25), overweight (BMI 26 to 30) and obese women (BMI >30) had increased odds of symptomatic prolapse (OR 1.88 95% CI 1.15 to 3.08 and OR 2.07 95% CI 0.95 to 4.50, respectively).

Braekken [2009] reported that having a BMI of >25 (compared to <=25) was significantly associated with having prolapse >= stage II (OR 5.0, 95% CI 1.1 to 23.0).

In ICI 4th edition the majority of studies (4 out of 6) indicated an association between being overweight and having prolapse. There are now four additional studies to draw on. Each study supported the previous finding.

(c) Association between POP and bowel function:

Symptomatic prolapse in the last 12 months was associated with having inflammatory bowel symptoms (IBS) after adjusting for age, race, medical history, urinary urgency and urinary incontinence: 5% in the no IBS group had symptomatic prolapse compared to 12% in the IBS group. Bother due to prolapse was also significantly associated with IBS. The authors suggest that women with IBS have cycles of constipation which makes them prone to having a weak pelvic floor and prolapse [Wang, 2010].

In the study by Saks [2010], 311 women met the inclusion criteria: mean age 60.5 years (SD 12.5), BMI 27.1 (SD 5.5), and parity 2.6 (SD 1.3). Most women were white (69%) and post-menopausal (79%). Apical prolapse was the most common type (86%), followed by anterior (77%) and posterior (23%). Most had prolapse involving more than one compartment. Nine bowel symptoms were examined and in all cases the prevalence of the symptom was not associated with grade of prolapse. Some obstructive symptoms (splinting, straining, anal incontinence, bulging of rectal tissue) were associated with the presence of a posterior prolapse, but none were associated with the grade of posterior prolapse. In a multivariate regression analysis adjusting for age, BMI and presence of apical or anterior prolapse it was confirmed that women with posterior wall prolapse were more likely to report obstructive bowel symptoms than who did not have posterior wall prolapse (OR 3.46, 95% CI 1.69 to 7.01). Grade of prolapse (either overall or specifically for the posterior wall) was not significantly associated with obstructive bowel symptoms. The authors concluded that obstructive bowel symptoms often co-exist with posterior vaginal wall prolapse but probably do not cause the symptoms.

Miedel [2009] found all bowel variables were significantly associated with risk of symptomatic prolapse in an age- and parity-adjusted model. In the final multivariable logistic model, one variable remained significant: lack of a normal bowel habit was associated with a two-fold risk of symptomatic prolapse (OR 2.13, 95% CI 1.37 to 3.31).

Slieker-ten Hove [2009] found, in an unadjusted analysis, no significant association between constipation and POP-Q stage, nor straining to defaecate and POP-Q stage.

Previously the evidence was inconclusive with regards to the relationship between constipation and prolapse. There tended to be positive associations with symptoms of prolapse but not anatomical prolapse measures (e.g. POP-Q). Four new studies add some information in this area. The conclusions from these are similar however: significant associations with prolapse symptoms, but no significant associations with prolapse stage.

(d) Association between POP and nutrition:

In the ICI 4th Edition, only one study was found that suggested anaemia was associated with increased odds of having prolapse. A new study by Badalian (2010), looking at the effects on prolapse of vitamin D, found in a univariate analysis that women reporting bulge had higher levels of vitamin D: in women over 50 years old 8.6% reported bulge in the >=30 ng/mL group compared to 3.3% in the <30 ng/mL group. However the model findings suggested that vitamin D level was not associated with vaginal bulge (prolapse): a vitamin D level of 30 ng/mL or more (normal) compared to lower levels had an odds ratio for prolapse of 1.66 (95% CI 0.61 to 4.49). The authors suggest that the small numbers of women reporting prolapse may have been an underestimate due to self-reporting. A significant association between low level of vitamin D and presence of urinary incontinence was reported.
c) Summary

Overall there are still no prospective studies of lifestyle interventions to prevent prolapse.

Some new observational studies were located adding to our knowledge of potentially helpful ways to modify lifestyle risk factors. There is now further evidence that occupations involving heavy lifting/hard physical labour or being overweight may play a role in the development of POP (Level of Evidence: 3).

Constipation is a modifiable risk factor which perhaps has potential to impact on development of prolapse symptoms. However, evidence regarding the association between constipation or straining at stool and prolapse remains conflicting. New studies were reasonably sized and adjusted for covariates.

No further studies on anaemia were found. A study of vitamin D found no association with self-reported bulge.

II. PHYSICAL THERAPIES

The primary physical therapy for POP is PFMT, with or without other adjuncts. PFMT may include PFM assessment and education, PFM exercise instruction, and PFM bracing against increased intra-abdominal pressure, for example when coughing and sneezing (termed “The Knack” [145]). Adjuncts (such as biofeedback) or other physical therapies (such as neuromuscular EStim) may be used. These therapies aim to improve PFM strength, endurance, coordination and function.

The promotion of PFMT for prolapse varies between treatment centres with some providing only a patient information leaflet and others giving individual instruction from a physiotherapist [311]. Research shows that verbal teaching of pelvic floor exercises alone is insufficient [312]. It is suggested that 15% of women are incorrectly ‘bearing down’ when trying to carry out these exercises. In women with prolapse, this could further add to the strain on the area and worsen the condition.

A Cochrane systematic review has indicated that PFMT should be offered as first-line conservative management for urinary stress, urge and mixed incontinence [126]. However, its role in managing prolapse is less well-established [313]. The importance of clarifying the place of PFMT in the prevention and management of prolapse has been highlighted [314,315].

1. PREVENTION

a) Quality of data

No studies have been identified to date that evaluate the role of PFMT in prevention of POP. This lack of evidence was noted by Harvey (2003) in a systematic review of PFMT during and after pregnancy [212].

However, one trial is now underway [http://clinicaltrials.gov/ct2/show/NCT01171846]. Four hundred women originally enrolled in a longitudinal follow-up of post-natal incontinence (including a subgroup involved in a trial of post-natal PFMT), who have not sought treatment for prolapse, have been randomised to receive either a programme of PFMT (individualised physiotherapy appointments, maintenance via Pilates-based classes and annual one-to-one check-ups) or a prolapse prevention advice leaflet. Women are being followed up at 2 years. This trial is due to report in late 2013.

In addition, three more cross-sectional studies have examined the relationship between pelvic floor muscle function and prolapse.

Braekken [2009] conducted a case-control study, in which they examined the association between PFM function and POP, but also measured occupational heavy lifting and BMI as risk factors for POP as reported above.

Moen [2009] [316] undertook an observational study in women presenting with pelvic floor disorders. Women were questioned about their performance of pelvic floor muscle exercises and then were examined to measure pelvic floor muscle contraction strength (Oxford grading scale). Prolapse stage was also recorded. Univariate analysis was performed to assess associations between prolapse stage and muscle strength.

Sliker-ten Hove, as described above, performed a cross-sectional study of women aged 45-85 (n=2979) in one town in the Netherlands [302]. Women completed a validated questionnaire and indicated if they would consent to a vaginal examination. A random sample of consenting women were examined to assess prolapse stage (POP-Q) and pelvic floor muscle function (voluntary muscle contraction and effective involuntary muscle contraction during coughing, relaxation and straining were scored by visual inspection and digital palpation). The chi squared test for trend or ANOVA was used in an unadjusted analysis to assess associations between prolapse stage and pelvic floor muscle variables.

b) Results

In one study [303] weaker pelvic floor muscles, poorer endurance and lower vaginal resting pressure were each significantly associated with greater risk of prolapse >=stage II. There was a significant interaction between muscle strength and vaginal
resting pressure: weak pelvic floor muscles and low vaginal resting pressure giving a higher odds ratio than other combinations. The authors concluded that women with poor PFM function were more likely to experience POP compared with women with good PFM function, and that this supports the hypothesis that PFM may be important in the prevention and treatment of POP.

In another study [316] of 325 women with a mean age of 57.8 years, 48.9% (159) had prolapse (stage II, III or IV) and 23.4% (76) were able to perform a contraction with strength rated 3, 4 or 5 on the Oxford scale. Pelvic floor muscle contraction strength was significantly lower in women with prolapse >=II compared to women with stage 0 or I prolapse (1.52 versus 1.87, p=0.007).

Slieker-ten Hove [2010] achieved a 62.7% response rate with 1140 women both completing the questionnaire and consenting to a vaginal examination. Of these 1140 women, 800 were randomly selected and 649 then underwent vaginal examination. Fifty four (8.3%) had prolapse. Higher stages of prolapse compared to lower stages were associated with less ability to attain levator closure. Higher stages of prolapse were also associated with lack of effective involuntary contraction during coughing, but better ability to perform proper straining technique. There was no association between stage of prolapse and voluntary muscle contraction strength or endurance. The authors suggest tentatively that strong pelvic floor muscles alone do not prevent the development of prolapse.

c) Summary

Previously one study had reported women with stage II prolapse were better able to elevate their pelvic floor than those with stage III or IV, and hypothesised that poor PFM may contribute to the development of prolapse. Now additionally three other studies have examined the association between pelvic floor muscle function and prolapse. Two studies had large sample sizes but unadjusted analyses; the third study was smaller but used an adjusted analysis. Two studies suggested the strength of voluntary pelvic floor muscle contractions was negatively associated with prolapse stage, whilst the third did not, but instead found an association between higher stages of prolapse and lack of an effective involuntary contraction.

Currently, there is no evidence from intervention studies regarding the role of PFMT or other physical therapies in the prevention of POP; better PFM function may be associated with less risk of prolapse (Level of Evidence: 3).

2. TREATMENT

a) Quality of data

An evidence-base is now emerging regarding the role of PFMT in the treatment of prolapse, both as a treatment in itself and as an adjunct to surgery. A Cochrane review specifically addressing this question was first published in 2004 and its second update was published in November 2011 [296].

(a) PFMT alone:

Six trials now exist in this area (Table 17), three of which were included in the 4th edition. The three new trials are reported in detail below.

Braeken [2010] undertook a single-centre trial where they randomised 109 women (59 PFMT, 50 control), the results of which were reported in two articles [306,317]. Women had stage I, II or III prolapse of any type (determined by POP-Q), and 63% were reporting symptoms of prolapse. Randomisation was stated as stratified by severity of prolapse. The intervention group women were instructed in PFMT for 6 months (weekly physiotherapy appointments for three months then fortnightly appointments) with home exercise (3 sets of 8-12 close to maximal contractions daily). Both groups were given lifestyle advice and taught “the Knack”. Prolapse stage, prolapse, bladder and bowel symptoms, pelvic floor muscle manometry and ultrasound measurements were taken at 6 months.

The risk of bias was judged to be low. A statistician generated and stored the allocation envelopes. The participant opened the opaque sealed envelope herself. Random permuted blocks were not used which resulted in unequal group sizes. There was a significant difference at baseline between the randomised groups in the prevalence of prolapse symptoms (43/59 PFMT group, 26/50 control group). Pelvic floor ultrasounds were taken and assessed blinded to women’s group in the trial, but pelvic floor assessments were not blinded. Dropouts were adequately reported and the rate was low (2%).

Stupp [2011] randomised women with untreated stage II anterior or posterior prolapse attending a urogynaecology service in Sao Paulo, Brazil [318]. POP symptoms were the women’s main clinical presentation. The PFMT group (n=21) received 6 appointments over 14 weeks with a specialist women’s health physiotherapist at weeks 0, 1, 2, 6, 10 and 14. The first 3 sessions aimed to achieve sensory awareness. A 12-week home exercise program was prescribed and women were encouraged to perform 3 sets of exercises daily. One set was 8-12 MVCs, held for 6-10 secs, double rest times between contractions, followed by 3-5 fast contractions in a row. Fortnightly the same physiotherapist phoned the woman. A standardised lifestyle advice sheet was given to both groups containing global stretching exercises and advice on weight loss, fluid intake, constipation, and avoidance of heavy lifting. No detail was provided of who delivered the intervention e.g. how many physiotherapists. Control group (n=16) received instructions on performing a PFM contraction without a protocol, and a lifestyle advice

</tr>
</tbody>
</table>

Foot notes: MVC = maximum voluntary contraction, PFMT = pelvic floor muscle training, PFME = pelvic floor muscle exercises,
The primary outcome measure was POP-Q performed by one gynaecologist who was blinded to group allocation. Secondary outcomes were: pelvic floor muscle function (strength – Oxford grading, endurance – PERFECT assessment); electrical activity (sEMG); symptom severity. It was stated that compliance in the PFM group was 100% and in the control group 76.2%. 91% in the PFM group adhered to the home exercise programme.

Risk of bias in this study was potentially high: no detail of the randomisation process was given, nor blinding of the outcomes measures, other than POP-Q.

A multicentre trial of PFMT for stage I, II or III prolapse which randomised 477 women has recently been completed [296]. This was a parallel group randomised controlled trial. Women in the intervention group were randomised to PFMT, delivered by a physiotherapist at 5 appointments over 16 weeks, and lifestyle advice. Women in the control group received a Lifestyle Advice Sheet by post only. Women had their prolapse assessed by a gynaecologist (POP-Q system) at baseline and (blinded) 6 months, and completed postal questionnaires at baseline (prior to randomisation) and 6 and 12 months. The primary outcome was prolapse symptom severity (Pelvic Organ Prolapse Symptom Score – POP-SS) at 12 months. Other key outcomes were prolapse severity (POP-Q), women’s perceived change in prolapse, uptake of further treatment and cost-effectiveness. Analysis was by intention-to-treat.

The risk of bias was judged to be low. Randomisation was by computer allocation using a remote randomisation service, and groups were comparable at baseline. Outcomes were measured mainly via questionnaire thus avoiding measurement bias. Gynaecologists were blinded to women’s trial group when undertaking the follow-up POP-Q assessments. Questionnaire response rates were high at 6 month follow-up (84% intervention; 86% control), but lower at 12 months (67% intervention; 65% control). Rates of attendance for 6-month prolapse assessment and POP-Q were good (81% intervention; 82% control). Compliance with the intervention was high: 80% of women attended 4 or 5 physiotherapy sessions.

(b) PFMT and surgery:

No new evidence to report.

(c) PFMT and pessary:

A feasibility study (the PEPPY study) looking at the possible effects of PFMT with a vaginal pessary in situ has been completed but full results have not yet been published.

(d) Ongoing trials:

There is currently one ongoing RCT (of PFMT as an adjunct to vault prolapse surgery – OPTIMAL) under the direction of the NIH-sponsored Pelvic Floor Disorders Network [319]. This trial compares two methods of suspending the vaginal vault in women undergoing vaginal surgery for POP and additionally will randomise half of the participants to adjunctive post-operative PFM exercises and behavioural therapy and half to routine care. The analysis will assess whether such adjunct therapy improves both anatomic and symptomatic outcomes two years after surgery. The study is expected to be complete by 2012 (the OPTIMAL trial, ClinicalTrials.gov Identifier: NCT00597935).

A further feasibility study of pre- and post-operative PFMT for women undergoing prolapse repair is underway (the SUPER study: ISRCTN 08203457). This study aims to recruit 30 participants over 3 sites. Participants are randomised to either the intervention group (n=15) or the control group (n=15). Prior to surgery all patients who have agreed to take part are seen by a physiotherapist to complete baseline outcome measures. Those in the intervention group are also seen once pre-operatively by another physiotherapist to be taught pelvic floor muscle exercises. After 6 weeks those in the intervention group are seen for a total of 5 visits over a 16 week period for further instruction in pelvic floor muscle exercises and advice. Both groups complete outcome measures at 6 and 12 months post-surgery.

b) Results

(a) PFMT alone:

In the Braekken trial [306,317], in women with prolapse symptoms at baseline (69/109), those in the PFMT group compared to the control group were significantly more likely to have reduced symptom frequency (74% vs 31%) and bother (67% vs 42%). Fewer women in the PFMT group than the control group had no improvement in POP-Q stage (81% versus 92%). In contrast, no significant difference was noted in the subgroup of women with prolapse beyond the hymen (80% versus 80%). The authors also used ultrasound to measure the position of the bladder and rectum within the pelvis, and the dimensions of the muscles and hiatal area, to indicate the severity of prolapse. They found the change in resting position in standing of the bladder and rectum, compared to baseline, were significantly greater (both were higher) in the intervention group than the control group; and changes in measures of the muscles and hiatal area were also significantly different in favour of the intervention group. Manometry (unblinded) was used to measure contraction strength and endurance and found improvement in strength and endurance were significantly greater in the intervention group compared to the control group. Braeken also reported better urinary outcomes for women in the intervention group in their trial.

Stupp [2011] showed that the intervention group had significantly greater anatomic improvements in anterior and posterior vaginal wall prolapse than did the
control group, and a decrease in symptoms [318]. In addition, the intervention group had greater improvements in muscle strength, endurance, and electromyography parameters compared to the control group.

Hagen [2011] found prolapse symptoms were reduced significantly more in the intervention group compared to the control group at 6 months and 12 months. Change in prolapse stage from baseline to 6-month follow-up showed a marginally significant difference between trial groups: 20% in the intervention group had an improved stage versus 12% in the control group. The majority of women in both groups had no change in their prolapse stage. By 12 months, a significantly greater proportion of control women (55%) reported they had received further treatment for prolapse compared to the intervention women (30%). Control women were significantly more likely than intervention women to report subsequent referral to physiotherapy. Rates for receiving other treatments were similar. When analysis of the primary outcome measure was adjusted for additional treatment received, the estimate of the effect of PFMT at 12 months was greater and comparable with that at 6 months.

ICI 4th edition reported on three trials of PFMT versus control for prolapse that found a positive effect, however two of the trials were small (<25 per arm) and the remaining trial had serious methodological limitations. Results from an additional three trials are now available [296,306,317,318] indicating a benefit on both anatomical and symptom measures of prolapse. Stupp (2011) was a pilot study; the remaining two trials were rigorously conducted trials with large sample sizes which provide level 1 evidence of the effectiveness of PFMT for women with stage I to III prolapse.

c) Summary

Based on previous studies and new evidence from two rigorously conducted trials and a smaller pilot trial, we conclude that PFMT can improve the symptoms of prolapse and the anatomical defects. (Level of Evidence: 1)

No further evidence is available regarding the role of PFMT as an adjunct to surgery and thus conclusions are unchanged: pre- and post-operative PFMT may help to improve quality of life and urinary symptoms in women undergoing surgery for POP, but the findings regarding its effects on PFM strength are contradictory. The evidence available however is based on two small trials, one of which included women undergoing surgery for UI and/or prolapse. (Level of Evidence: 2)

d) Recommendations

PFMT can improve prolapse symptoms and severity (Grade of Recommendation: A).

Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse (Grade of Recommendation: C). Larger trials are needed, and prolapse-specific measures should be primary outcomes in such trials.

Future studies of PFMT for POP should aim to reach a consensus on the optimal intervention programme prescribed and might also consider comparisons of individualised training with group training.

### III. PESSARIES

Pessaries offer a non-surgical option for the treatment of urinary incontinence and pelvic organ prolapse (POP). Pessary use dates back prior to the days of Hippocrates, and innumerable varieties such as half a pomegranate, a linen tampon soaked with astringent vinegar or a piece of beef have been used. It was only in the 16th century that a device was made specifically to be used as a pessary, as opposed to using naturally occurring objects. Since the 20th century, considerable refinements have occurred and modern pessaries are made from a variety of materials including rubber, clear plastic, soft plastic with metal reinforcements and silicone [320].

A range of vaginal pessaries (Figure 7) exist which can be broadly divided into two types: support and space-filling pessaries. Support pessaries lie along the vaginal axis, with the posterior component sitting in the posterior fornix and the anterior component coming to rest just under the symphysis pubis, thus providing a supportive shelf for the descending pelvic organs [321]. As there is no evidence to support the use of a specific type of pessary, choice is based on experience and trial and error. It is generally accepted that the ring pessary should be tried first because of ease of insertion and removal, and if this fails, other pessaries can be used [322]. Clemons [323,324] found that the ring pessary was successful in grades II and III prolapse, but for higher grades, a Gellhorn pessary was more effective. By contrast, a randomised crossover trial of the ring versus the Gellhorn pessary, did not demonstrate any difference in effectiveness between the two types of pessaries [325].

While it is not possible to establish a global perspective of the full extent of pessary use, a survey of the members of the American Urogynecologic Society showed that 75% of members used pessaries as first-line therapy for POP. Ninety two percent of physicians believed that pessaries relieve symptoms associated with POP, while 48% felt that pessaries also had therapeutic benefit in addition to relieving symptoms. No clear consensus emerged regarding the type of pessary or their indications for use [326]. Similarly there are no clear prevailing removal regimes [Cundiff, 2000]. In the United Kingdom, a recent postal survey demonstrated that 87% of consultants use vaginal pessaries for management of POP [327]. Many physicians receive little or no
training in the use of pessaries [328] and have limited experience with pessary selection and fitting.

Likely candidates for vaginal pessaries are those with co-morbid medical conditions, those who still wish to bear children, as interim relief prior to surgery and for those who prefer non-surgical treatment [314]. Kapoor (2009) demonstrated that when pessaries are offered to patients with symptomatic pelvic organ prolapse, nearly two thirds of women choose a pessary rather than surgery as initial management [329]. Furthermore, a case-control study comparing women who chose pessaries to those who underwent surgery one year after their respective treatment found no difference in prolapse symptoms, bladder, bowel or sexual dysfunction between groups [330]. Thus, although traditionally thought of as treatment only for women deemed unfit for surgery or infirm, pessaries should be considered a viable treatment option for the majority of women in the initial management of POP. Other indications include vaginal laxity, neonatal prolapse mainly seen in association with neural tube defects such as spina bifida and prolapse during pregnancy [322].

Factors that predict the type of treatment chosen for POP have been evaluated in various studies. Powers [2004] [331] noted that patients who refused a pessary were significantly younger and had a higher incidence of urodynamic stress urinary incontinence (SUI). More patients with stage III prolapse refused while more patients with stage IV accepted pessary trial. Heit [2003] [332] found that the probability of choosing a pessary over surgery increased as age increased and decreased as the prolapse severity increased. Clemens 2004 [324] evaluated characteristics that were predictive for pessary usage for up to one year. Age greater than 65 years at the time of pessary insertion and more severe prolapse (Stage III-IV) were more predictive for pessary discontinuation. Brincat [2004] [333] found that women who were sexually active and those with POP were more likely to continue wearing a pessary than women with urinary incontinence. In keeping with this, Ko [2011] [334] found that substantially older women or menopausal women opted for a pessary rather than surgery, and significantly more sexually active women preferred surgery.

Evidence of the effectiveness of pessary use for prolapse can be obtained from a large number of observational studies (prospective and retrospective) and two RCTs (Table 18 and Table 19).

1. QUALITY OF DATA

(a) Randomised controlled studies:

One new randomised intervention was found [335] in which the Colpexin Sphere was compared to PFMT in women with stage I and II pelvic organ prolapse on improving pelvic floor muscle strength and reducing symptoms. The device is a spherical
intravaginal device, similar to a pessary, which is placed above the levator musculature and requires active PFM contractions to keep it in place. Its purpose is to reduce the prolapse while facilitating PFM strengthening. Group 1 used Colpexin Sphere with PFMT and the other group did PFMT only for a 16 week period. Outcomes were evaluated at baseline and at 16 weeks for comparison of pelvic floor muscle strength. A total of 50 women were enrolled and 48 women completed the full 16 week assessment which consisted of Colpexin pull through test and a digital test. All assessments were performed by one investigator who was blinded to the group assigned. The small sample size and the short period of treatment are limitations. In addition, the authors did not report a power calculation. The participants were stratified into two groups by using computer-generated random numbers. Participants within each stratum were randomised by using opaque sealed envelopes to one of two study groups.

No other new randomised controlled trials were found on the use of a pessary compared to another device or treatment protocol. Cundiff [325] conducted the largest multi-centre crossover trial, comparing a ring with support and a gelhorn pessary for the treatment of symptomatic stage II or greater symptomatic prolapse. There were no significant differences between groups in baseline characteristics. Participants were fitted with one of the pessaries for three months, and with the second for a further three months. During each three-month period, data were collected at one, six and twelve weeks from women who had a successful fit. Outcomes were measured at enrolment and three and 12 months, and included objective assessment using POP-Q and subjective assessment using Pelvic Floor Distress Inventory (PFDI), Pelvic Floor Impact Questionnaire (PFIQ), and a sexual function questionnaire. Random allocation was by computer-generated random numbers using permuted blocks of variable size. Opaque, sealed envelopes were used to store the random allocation. Participants and clinicians were not blind to the allocation, but data were coded such that analysis was conducted blind.

(b) Prospective observational cohort studies

Wu [1997] [336] conducted a prospective study of 110 women with symptomatic POP to evaluate a protocol for pessary treatment. After initial fitting, they were seen at two weeks for re-examination and thereafter at 3-6 month intervals. Handa (2002) [337] described the course of POP amongst 56 women who used a supportive vaginal pessary for at least one year.

In 100 women with prolapse, Clemons [2004] [323], analysed the factors that contributed to successful pessary use. Two publications resulted: one on the symptoms and patient satisfaction at two months on 73 out of the original 100 study women who had a successful pessary fit and the other on the continuation with pessary at one year of the sub-group who were satisfied users [324].

Lukban [2006] [338] described a study of the effectiveness and safety of the Colpexin Sphere device in women (n=39) with prolapse beyond the hymenal ring; all women had grade three or greater prolapse of at least one vaginal compartment (69% cystocele, 44% rectocele, 31% enterocele, 8% vault prolapse, 21% uterine prolapse). Women were instructed to use the Colpexin Sphere only whilst in bed for the first week, and to use continuously thereafter, and were taught PFMT exercises to be performed twice daily (PFMT and knee squeezes). The intervention period was 16 weeks. Outcome measures included prolapse stage (modified Baden and Walker classification system), PFMT assessment (Brink Scale score), and a Pull Test to measure PFMT tone and strength (a tensiometer is used to measure the force required to remove a 35mm sphere from above the levator plate). The small sample size, lack of control group and short follow-up were limitations of the study.

Using the Sheffield Pelvic Organ Prolapse quality of life questionnaire, Fernando [2006] [339] addressed the effectiveness of pessaries in alleviating symptoms associated with POP in a prospective study of 203 consecutive women attending a specialist urogynaecology unit four months after pessary insertion. Abdool [2011] [330] evaluated and compared the effectiveness of pessaries and surgery in patients with pelvic organ prolapse in 554 women one year after treatment. Of these 359 were treated with a vaginal pessary and 195 had surgery. Lone [2011] [340] prospectively evaluated the use of pessaries in 246 women over a 5 year period and identified complication rates and reasons for discontinuing use over the 5 year period. There was an overlap of patients in these studies as they are from one institute. Kuhn [2009] [341] used the same Sheffield Pelvic Organ Prolapse quality of life questionnaire and Female Sexual Function Index questionnaire to evaluate quality of life and pelvic organ and sexual function before and during pessary use in 73 women of whom 31 were sexually active.

Komesu [2007] [342] compared pelvic floor symptom changes in 36 who continued pessary use to 28 who discontinued using the Pelvic Floor Distress Inventory-20 (PFDI-20) before and after pessary use. In the same group of women, they further explored whether patient determined goal achievement was associated with pessary continuation.

Barber [343] undertook a study to evaluate the responsiveness PFDI and PFIQ in women with pop undergoing surgical and non-surgical management. The pessary group consisted of 42 women with stage II or greater prolapse enrolled in an multicentre randomised trial comparing two different pessaries and 64 women with Stage III or greater prolapse who underwent vaginal reconstructive surgery. All subjects completed the questionnaires at baseline and again
either three months (pessary group) or six months (surgery group) after initiation of treatment.

Jones [344] evaluated 90 women who had a pessary inserted for POP at baseline and 3 months after pessary use. Pelvic Floor symptoms were assessed using PDFI scales. In addition they assessed the change in genital hiatus measurements. Logistic regression analysis was used to assess baseline characteristics predictive of continued pessary use.

Patel [345] sought to evaluate whether use of a vaginal pessary would change body image, bother symptoms, and quality of life in women with pelvic organ prolapse. Seventy five women presenting for pessary insertion completed the short forms of Pelvic Floor Distress Inventory-20, Pelvic Floor Impact Questionnaire, and Body Image Scale. After successful pessary insertion and use for at least 3 months, 54 subjects repeated the surveys.

(c) Retrospective studies:

There are several retrospective studies on pessary benefits and outcomes but these are limited by the retrospective study design [334,346-351]. Thus we have chosen not to evaluate them in this review as there are several prospective cohort studies that allow a better assessment of effect.

2. OUTCOME

a) Patient reported outcomes

As can be seen in Table 18, follow-up periods evaluating patient reported quality of life varied from three to 12 months. In most studies a recognised measure of prolapse was used i.e. POP-Q examination, to objectively assess and evaluate the prolapse. One study [342] included patients with prolapse and/or incontinence. Various types of pessaries were used. Validated questionnaires to assess patient related outcome were used in eight studies. Commonly used questionnaires were the Sheffield Pelvic POP symptom questionnaire, and the Pelvic Floor Distress Inventory (PFDI) and Pelvic Floor Impact Questionnaire (PFIQ). Other questionnaires used were Female Sexual Function Index, Body Image Scale and Kings Health Questionnaire.

A direct comparison between studies is difficult as different outcome measures have been used. When pessary insertion was successful, there appears to be a significant improvement in prolapse symptoms. Cundiff [2007] found significant and clinically significant improvements in majority of the PFDI scales and many PDIQ scales with both pessaries but no difference between the ring or gellhorn pessary. Two prospective studies [343,344] found a significant improvement in the urinary and prolapse scales of the PFDI but not in the colorectal scale 3 months after insertion of pessary compared to baseline. Others [342,345] demonstrated a significant improvement of the PFDI-20 scale 3 months after pessary use. However data on the questionnaire that measures impact i.e. PFIQ varies as Barber (2006) demonstrated no significant changes in the 3 scales while Patel (2010) showed significant decrease in PFIQ scores and prolapse/vaginal subscale of the PFIQ. Fernando (2006) and Abdool (2011) administered the Sheffield Pelvic Organ Prolapse Quality of Life questionnaire (SPS-Q) at before, 4 months and one year after pessary insertion. Two hundred and three patients from the previous study (Fernando) were included in the later paper (Abdool). A significant improvement was seen in prolapse symptoms, bladder and bowel function as seen in Table 18. Contrary to Fernando ‘s study, Abdool did not demonstrate improvement in bowel evacuation at one year probably as this was only marginally significant (p=0.045) at 4 months.

Women who were sexually active and wore a pessary showed significant improvement in satisfaction of sexual activity at 4 months [339] and at 12 months [330]. Kuhn [341] found a significant improvements in desire, orgasm, lubrication and satisfaction after pessary use. This suggests that a vaginal pessary does not negatively interfere with sexual activity but may even improve sexual function. However, sexual activity is only possible with a ring pessary insitu [330,339]. The other pessaries need to be removed prior to sexual intercourse.

Self-perception of body image is reduced in women with advanced POP [352]. A significant decrease in body image scale scores has been reported indicating an improvement in women’s perception of themselves in addition to improvement in PFDI-20 and PFIQ scores at 3 months [345]. However, majority of subjects in this study had stage 3 prolapse, so it is possible that improvements might not be the same for women with less advanced prolapse (i.e., stage 2) and those with urinary incontinence alone.

Two studies [330,343] compared patient related outcome after pessary and surgery use. Abdool demonstrated a significant improvement in prolapse, urinary, bowel and sexual function in both treatment arms but no difference between the two groups. However, Barber (2006) found that subjects in the surgery group had significantly greater improvement in each of the scales of the PFDI and the prolapse and urinary scales of the PFIQ than did the pessary group.

The placebo effect of treatment for prolapse needs further exploration. Komesu [2007] found an improvement in the PFDI-20 total, bladder and prolapse scores in women who discontinued and those who continued pessary use although this was more modest [342]. This could be because of placebo effect or because of conservative interventions such as dietary change and pelvic floor exercises. In the same group they further studied the association between patient determined goal achievement and pessary continuation. Goals commonly listed were...
bladder (36%), activity (20%), and general health (13%) and prolapse related (11%). Although goals were found to be variable, women who continued pessary use were more likely to meet one to two goals. Women who attained self-determined goals were more likely to continue pessary use.

1. Success Rates

There is no agreement in the literature on what is considered successful fitting of a pessary. Some consider success if a pessary was perceived comfortable by a patient when retained during valsalva and voiding at the initial visit, while others consider it success if a patient continued to use the pessary until the following visit to the doctor. Therefore, the rates of successful fitting vary between 89% to 8% with the follow-up time to define success ranging from initial fit to 7 years. (Table 19). Five studies [333,342,347,349,351] included patients with prolapse and/or incontinence.

Higher success rates for specific types of prolapse (83% for uterine prolapse and 82% for cystocele) are recorded [349]. Comparison of success rates by pessary type was difficult due to use of differing protocols for pessary selection within studies (Table 19). Wu [1997] [336] used ring pessaries in 96% of women who were successfully fitted. Similarly, ring pessaries were the primary choice of treatment in other studies [337,339,353]. The fitting protocol used by Mutone [348] specified the ring pessary with support diaphragm in the first instance. Of women who had a successful pessary fitting, ring pessaries were used more often in women with stage II (100%) and stage III (71%) prolapse whereas Gellhorn pessaries were used more often with stage IV (64%) prolapsed [353]. Hanson [2006] found significantly greater success with the ring, ring with support and Gellhorn pessaries than other type of pessaries (p<0.05), however only 54% of women in this study had prolapse (the remainder had UI).

Parameters reported as associated with a successful pessary fitting were often contradictory. Hanson [2006], Clemons [2004], and Mutone [2005] reported that patient age was not significantly related to the success of pessary fitting whereas Wu [1997] and Friedman [2010] reported that women who were fitted successfully tended to be older. Mutone [2005] found that women classed as obese were significantly less likely to have a successful fit, whereas Maito [2006] [347] indicated that weight was not a predictor of successful pessary fit.

Clemons 2004 [353] reported no effect on fitting success of previous surgical intervention while others found a significant relationship between unsuccessful fit and previous hysterectomy or prolapse repair [346-348]. Wu [1997] reported that a history of pelvic surgery reduced the probability of a successful pessary fitting from 79% to 67%, although this result was not significant (p=0.2). Hanson [2006] found a higher fitting success rate in women with previous abdominal genitourinary surgery (71%) compared to those with a history of genitourinary surgery via the vaginal route (60%). Fernando [2006] found 75% retained the pessary at two weeks, and that failure to retain was associated both with increasing parity and hysterectomy in a multivariate logistic regression analysis; site and type of prolapse did not affect success.

Current hormone use did not predict greater likelihood of fitting success [336,353] whereas use of local oestrogen (with or without systemic HRT) was felt to play an important role in successful pessary fitting [349]. Sexually active women were more likely to continue wearing a pessary for a longer period of time [333,343].

Women with SUI before pessary fitting are reported to have a significantly lower success rate in two trials [336,346] but not in one [324]. Maito [2006] found no significant difference in success rates between women with SUI (94%), POP (89%), or both (81%).

Increasing severity of prolapse did not affect the success of pessary fit [336, 348, 353]. Neither was large genital hiatus [324,348,350], severe vaginal atrophy nor a foreshortened vagina affected success nor was the location of the prolapsed an issue [348]. However, a shorter vaginal length and wider vaginal introitus were associated with an unsuccessful fitting [324,350]. On the other hand, Maito [2006] [347] found mild posterior prolapse to be a significant predictor of successful fit. Clearly, differing techniques, follow up, support and skills affect how well pessaries are tolerated and maintained.

Comparison of long term pessary usage rates was difficult due to differing follow-up periods used in the studies reported. Maito [2006] reported continued pessary use of on average six months (range one to 17 months); discontinuation of pessary use was significantly associated with severe posterior prolapse after adjustment for age. Wu [1997] found that 66% of those who used a pessary for more than one month were still users after 12 months and 53% were still users after 36 months. Lone [2011] prospectively evaluated 246 women who opted to use a vaginal pessary (ring, cube, gellhorn, donut) [340]. One hundred and eighty seven (76%) successfully retained the pessary four weeks after pessary insertion. Over a five year period, 19% of the 187 women were lost too follow-up. Of the 151 women included in the analysis, 13.9% discontinued use at some point after four weeks, whereas 86.1% used the pessary successfully over 5 years. The authors concluded that if the treatment for pessary is successful at four weeks, most women will continue to use the pessary over 5 years without a concomitant increase in complications.

Reasons for failure range from expulsion to complications such as vaginal discharge, erosion, de novo SUI, pain, voiding difficulty and constipation (Table 19).
2. COMPLICATIONS

Minor complications after pessary insertion range from vaginal discharge, erosion, de novo SUI, bleeding pain and constipation as can be seen in Table 19. Sarma [2009] [351] reported a complication rate of 56% after pessary use. Rarely major complications may occur. Neglected pessaries present with more serious complications namely fistula formation and peritonitis. Erosion into the bowel or bladder and dense adhesions to other pelvic structures has been reported. Unusual complications of cervical entrapment, small bowel incarceration, and hydronephrosis [354] have been reported.

3. PELVIC FLOOR MUSCLE STRENGTH

In a randomised study on the use of Colpexin Sphere [335] a statistically significant improvement in pelvic floor muscle strength was noted as compared with baseline values and at 16 weeks was shown in both groups, with mean difference pull test contraction values of $2.25 + 3.28 \text{ N}(P < 0.05)$ in the study group and $1.38 + 2.17 \text{ N}(P < 0.05)$ in the control group. There was no statistically significant difference in improving pelvic floor muscle strength between the study and the control groups. The authors concluded that even though Colpexin Sphere plus pelvic floor exercise improved pelvic floor muscle strength, the improvement was not statistically different from exercise alone.

4. FINANCIAL IMPLICATIONS:

Hullish [355], developed a Markov decision analysis model to assess and compare the relative cost effectiveness of treatment decision alternatives for post-hysterectomy pelvic organ prolapse e.g. expectant management, use of a pessary and surgery obtaining months of quality-adjusted life over one year. Sensitivity analysis was conducted to determine whether the results depended on specific estimates of patient utilities for pessary use, probabilities for complications and other events and estimated costs. Only two treatments i.e. initial pessary use and vaginal reconstructive surgery were found to be efficient choices. Pessary use (including patients that eventually transitioned to surgery) achieved 10.4 quality-adjusted months at a cost of $10,000 per patient, while vaginal reconstructive surgery obtained 11.4 quality adjusted months at a cost of $15,000 per patient. The authors concluded that research is needed to standardise POP outcomes and complication, so that healthcare providers best utilise cost information in balancing the risks and benefits of their treatment decisions.

IV. SUMMARY AND RECOMMENDATIONS

There is growing attention being paid to the effectiveness of conservative interventions for the condition. There are encouraging signs of more rigorous research in this area, with the publication of 4 RCTs [296,306,318,335] in this field since the 4th ICI and 3 more trials awaited.

C.4.1 Recommendations for practice

There is limited Level 1 and Level 2 evidence on which to base recommendations for practice, and most recommendations are, in effect, hypotheses that need further testing in RCTs.

Pelvic floor muscle training (PFMT)

• PFMT can help improve prolapse symptoms and severity (Grade of Recommendation: A) (New).

• Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse (Grade of Recommendation: C) (Unchanged).

Pessaries

• In a choice between the Gellhorn pessary and a ring with support, either may improve prolapse symptoms and reduce their impact (Grade of Recommendation: B).

2. FUTURE RESEARCH DIRECTIONS

a) Lifestyle interventions

• Studies are needed to fully investigate the association between occupation/heavy lifting, bodyweight, constipation and POP. These studies should ensure that:
  
  o Occupation, physical activity, bowel function and diet are assessed rigorously, using instruments with sound psychometric properties.
  
  o Potential confounding variables are considered.
  
  o Attempts are made to overcome some of the obstacles in research in this area such as recall bias inherent in assessing lifetime occupational history, or healthy worker bias which is a problem when attempting to compare POP in women currently employed in heavy labour type jobs versus others.
  
  • Only when the links between various lifestyle factors and POP have been more clearly established can good RCTs be set up to investigate the effects that changes in these lifestyle factors can have on preventing POP.
  
  • Anaemia is a treatable condition, either through diet or medication, and further research on its role in prevention of prolapse is warranted.

b) Pelvic floor muscle training (PFMT)

• Studies are needed to fully investigate the role of physical therapies in the prevention of POP. Such studies should:

Foot notes: N/A = not applicable; N/R = not reported,*Includes patients with incontinence and/or prolapse; ** women who discontinued pessary usage after two weeks and within the first two 2 months; ***Predictors identified at one year.
Consider the exact nature and timing of any physical therapies.

Ensure that the effects of lifestyle factors and other potential confounding variables are taken into account.

• Further trials are needed to add to the evidence regarding:
  - The effectiveness of PFMT for different stages and types of prolapse.
  - The role of PFMT as an adjunct to prolapse surgery.

• There are no trials that address the following comparisons of interest:
  - Low versus high intensity supervision of PFMT
  - Individual versus group PFMT.
  - PFMT versus surgery.
  - PFMT versus pessary.

c) Pessaries

• There remains a pressing need for well-designed RCTs to examine the effects of using the wide variety of different pessaries in the treatment of POP. Such studies need to:
  - Address optimal pessary effectiveness, including the symptomatic and therapeutic benefits of pessaries as well as the indications for use, pessary fit, replacement and care.
  - Adopt consistent protocols regarding choice of pessary.
  - Allow sufficient follow-up periods.

• Randomisation may not be appropriate but efforts should be made to match the characteristics of the treatment groups being compared. Comparisons of interest are:
  - Pessaries versus surgery.
  - Pessaries versus physical therapies.
  - Pessary in conjunction with PFMT.

The assessment and measurement of POP and the assessment of prolapse symptoms need to be made in a standardised fashion using a validated outcome measure (such as the POP-Q examination). The choice of a single validated symptom tool is problematic at the present time.

C. URINARY INCONTINENCE IN MEN

UI in men remains under-reported and under-studied in comparison to studies including women. The report from the 4th ICI indicated that the prevalence of UI and LUTS in men ranged from eight to 23% depending on the method of data collection, population accessed, and location [1,356]. As for previous consultations, despite the prevalence of UI and LUTS in older men, the only aspect which continues to receive systematic consideration with respect to conservative management are post-prostatectomy urinary symptoms. Thus, the major focus of this section is UI after prostatectomy for benign or malignant disease. All prostatectomy types and approaches were considered including radical prostatectomy (open radical retropubic or perineal, laparoscopic, and robotic) or endoscopic procedures (such as transurethral prostatic resection, high intensity microwave therapy).

The PMFT, EStim and MStim interventions in the current review were reorganized to reflect the evolving evidence and emerging directions of research on post-prostatectomy urinary incontinence. Studies of EStim and MStim in men post prostatectomy all included PFMT as an intervention as well, so these were combined under PFMT. EStim and MStim studies of non prostatectomy related incontinence or other LUTS were kept in separate sections. As preoperative studies may represent the only truly preventative studies, and studies that only included incontinent men the true treatment studies, the categories of prevention and treatment were changed in the PFMT section. Instead, studies in these sections have been grouped into three types: preoperative interventions, mixed pre and post operatives studies of all men undergoing prostatectomy and studies of post operative interventions for men with established incontinence. Studies in the pre and post operative study category are heterogenous in timing of recruitment and intervention, an ongoing concern in this research area.

Aetiology of UI after prostatectomy

For purposes of the current review, the reader is directed to the report from the 3rd and 4th ICI (1,356) in which the aetiology of UI after prostatectomy is covered in detail (see report from Committee 13: Surgery for urinary incontinence in men). In brief, risk factors which have been repeatedly identified for UI after radical prostatectomy and transurethral resection of prostate (TURP) are abnormalities of detrusor contractility [357] and age [358]. Other related factors include neurovascular injury during surgery, previous TURP [359], preoperative radiotherapy, trauma, spinal cord lesion, new obstruction such as prostatic regrowth, bladder neck contracture, urethral stricture, Parkinson’s disease [360,361], dementia, and medications [356].

Treatment

The primary conservative treatment for UI after prostatectomy remains physical therapies with or without some form of Biofeedback (BF). PFMT, along with
anal EStim, BF or transcutaneous electrical nerve stimulation (TENS), MStim, and even pharmaceuticals have all been utilised and reported as modestly successful in some trials and not in others.

A literature search of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed. No other types of study design were considered. The report of the 4th ICI (1) identified 14 relevant RCTs on conservative management of UI post radical prostatectomy (n = 12) or TURP (n = 2) [362-375]. For this review, nine new published trials [376-384], and seven abstracts [385-391] were found, 14 in men undergoing radical prostatectomy, two in men undergoing TURP. One was excluded as it was a study in progress [388], and one [386] was found to be the same study as one of the published trials [384]. Thus, 14 trials were added to the current evidence base for a total of 32 RCTs on some aspect of continence treatment after radical prostatectomy and four on treatment after TURP. Table 20 provides summary information on the trials.

I. LIFESTYLE INTERVENTIONS

Lifestyle recommendations such as smoking cessation, healthy eating, appropriate body weight, avoiding excessive caffeine or alcohol are all part of a primary care approach and are intended to be preventative in the onset of obesity, cardiovascular disease, diabetes. Whether these factors have a direct impact on continence is suggested but not known. To date, no trials have addressed the topic of lifestyle interventions alone for men with UI. Nevertheless, in practice, it seems reasonable to offer advice on healthy lifestyle choices that may reduce or delay the onset of continence problems.

II. PELVIC FLOOR MUSCLE TRAINING (PFMT)

The quality of trials included in this update of PFMT has improved from earlier ICI reports although heterogeneity and varying outcome measures continue affect the ability to compare trial findings.

1. PREOPERATIVE RP PFMT

Trials in this section compared preoperative interventions. Two new studies were identified as focusing on preoperative PFMT [385,389].

Delmastro [2010] report a trial in which men undergoing radical prostatectomy were randomised preoperatively to PFMT plus proprioceptive training (n=60) vs PFMT alone (n=57). The authors present a novel argument that proprioceptive training of the agonist and antagonist muscle activity preoperatively may affect acute adaptive responsiveness, enhancing the effectiveness of PFMT in men undergoing radical prostatectomy. Outcomes were measured at baseline (preop) and 4, 8, and 24 weeks post surgery; Although the authors report significant differences in outcomes favouring the intervention group (PFMT plus proprioceptive training) the report of the study was available in abstract form only, and details of the randomisation technique and data were not available. This study represents an innovative theoretical perspective, but further investigation and testing is needed to establish efficacy of the treatment approach.

Tobia [2008] (article translated from Spanish) randomised 38 men to to preoperative kinesical exercises (n=19) or no preoperative treatment (n=19). Using DRE and perinometer plus ‘low to medium frequency EStim’, participants undertook ‘kinesthetic exercises’, practiced daily at home 7-10 times. No further details of the intervention were provided such as the number of times the participants visited the therapist, how participants were randomised, assessors blinded. Nor was continence defined. The authors reported no difference between groups in continence at 14, 30 or 60 days post catheter removal.

2. PREOPERATIVE AND/OR POSTOPERATIVE RP PFMT, POST RP CONTINENCE STATUS NOT ESTABLISHED PRIOR TO INTERVENTION

Trials in this section addressed the effect of PFMT initiated preoperatively and/or postoperatively but before post op continence/incontinence was established. In these studies, men were recruited preoperatively or immediately postoperatively and the investigators compared a treatment group that received the intervention preoperatively and/or postoperatively RP to a group receiving an intervention only post operatively. Post operative interventions were often described as usual care. Nine trials from the previous review [210,362,369,370,372,375,392-394] and one new study [382] are included for a total of 10 trials in this category. One study in abstract form [388] was not included as it described a study in progress with no findings presented.

a) Preoperative PFMT instruction with postoperative home PFMT versus control

No new trials were added to this section. Three were all addressed in the ICI 2009 chapter [1,362,392,393]. Two utilised preoperative BF assisted instruction in PFMT followed by postoperative self-PFMT at home, compared to postoperative verbal instruction [362] or usual postoperative exercise advice [392]. The other study (abstract only), assigned participants to PFMT plus BF (method/type not described) or PFMT alone plus home exercises. Primary outcomes were pads or bladder diary.

1. QUALITY OF DATA

Of the three trials in this subsection, only one [392] reported adequate random allocation concealment. With regard to blinding of outcome assessment, Bales [2000] attempted to control for bias in outcome

</table>
assessments by having a nurse not directly involved in the study interview the subjects. It is not clear whether he/she was blinded to allocation group. Burgio [2006] had outcomes assessors blinded to group assignment and described dropouts.

2. Results

Burgio [2006] reported a statistically significant difference in favour of PFMT in time to regain continence and proportion of men with severe or continual leakage measured by voiding diary at six months, PFMT (59%) versus controls (78%); additional data provided by the authors on the 24 hour pad test did not indicate a difference between groups. Bales [2000] found no significant group difference on participant report of number of pads used or time to return to continence. Lilli [2006] did not find a difference between participants who received BF in addition to PFMT at any of the time points; at six months, 71% and 67% respectively dry and no use of pads. In the Lilli trial both groups received intervention and it is not clear how intensive the pre-operative PFMT instruction was.

D.2.2b Pre-operative PFMT instruction followed by supervised post-operative PFMT versus post-operative PFMT

One new trial was added to this subsection, making a total of four studies included [369,370,372,382]. Centemero [2010] randomised 118 men more than four weeks preoperatively, with the treatment group receiving twice weekly BF (anal probe) intensive PFMT with a physical therapist plus home exercise and repeated the twice weekly sessions for four weeks post operatively with home exercise until dry. The control group received only post operative PFMT. Outcomes were self report of leakage on bladder diary and provocative (stress) pad test. As reported in ICI 2009 [1], one trial compared active pre- and post-operative PFMT programme to no PFMT instruction [372] and two others pre- and post-operative instruction versus post-operative instruction [369,370]. Participants in one trial [372] had two pre-operative and four post-operative sessions of anal probe BF plus post-operative home PFMT using an exercise ball, or no intervention (similar to Burgio [2006] above). Contention was assessed by pads report and continence questionnaires at six, 12, 16, 20, 28 and 52 weeks post surgery. Sueppel (2001) randomised 16 men (no dropouts) to two pre-operative and five post-operative sessions of anal probe BF or five post-operative sessions plus home PFMT. Contention and quality of life were assessed by AUA symptom score and quality of life questionnaire, pad count, 45 minute standardised pad test, and a leakage questionnaire at six weeks and one year post surgery. In another [369] all participants had one session of pre-operative instruction using BF and verbal coaching and were then randomised to intervention or control groups. The intervention group (n=26) practised PFMT daily with a home BF unit (anal probe) from week 3 to 12 after surgery, whereas the control group (n=24) only followed written instructions. Both groups completed questionnaires, pad counts, and 24 hour pad tests at two, five and 12 weeks post-operatively.

Quality of data

Centemero [2010] had surgeons blinded to group allocation and reported no dropouts. Sueppel [2001] indicated incomplete data but did not describe dropouts. Two did not provide any information [372].

Results

Treatment group was more likely to be continent at one and three months post operatively measured by leakage recorded on a bladder diary (44%, 59% vs 20%, 37%) and on pad test (25%, 17% vs 34%, 32% > 150 gm) [382]. More men were continent in the pre and post treatment group at 12 weeks but there was no statistically significant difference at any other time point to 12 months [372]. Sueppel [2001] reported that at one year the pre and post treatment group had less leakage on a standardised 45 minute pad test compared to the postoperative group (mean 2.8g (range 0.0-13.0g) versus 33.3g (range 0 to 194g) and Mathewson-Chapman [1997] found no statistically significant differences between groups at any of the time points.

c) Post-operative PFMT immediately after catheter removal (no pre-operative instruction)

No new trials were found comparing post operative PFMT immediately post catheter removal. Three previously reported trials in ICI 2009 commenced post-operative PFMT immediately after catheter removal [210, 375, 394]. A total of 524 men were randomised to PFMT programme or no formal instruction [210]. Another had data analysed by a professional statistician [375]. Dropout reasons were not described. ITT analysis was described by two [394].

1. Quality of data

In one study, surgeons were blinded to group allocation [210]. Another had data analysed by a professional statistician [375]. Dropout reasons were described by two [210] and number of dropouts was provided by one [375] but reasons were not described. ITT analysis was described by two [394].

2. Results

One trial [394] favoured treatment at three and 6 months for self-reported ‘completely dry’. Differences between treatment and control were 96% versus 65%
at six months and at one year 99% and 88% (not significant). There were no significant differences between groups on 24 hour pad test (Filocamo, personal communication). Overgård (2008) reported no difference between groups for proportion dry (no pads) or 24 hour pad test at three months; however, at 12 months, the proportion of continent men was statistically significantly greater in the treatment group (33/36; 94%) versus the control (28/39; 72%). PFMT strength and 24 hour pad test results did not differ between groups at any of the time points. Of note is that 20 participants in the treatment group did not receive face to face instruction due to distance from facility but rather followed detailed instructions provided on a DVD. Wille (2003) found more men in the PFMT/ESstim group reported recovery compared to PFMT alone, but the difference was not statistically significantly different (OR 0.48, 95% CI 0.21 to 1.09).

3. Summary
A total of 10 trials were found applying a variety of pre- or post-operative PFMT based interventions (or a combination of both). Any differences between experimental and control groups were modest and short term; differences did not appear to be sustained up to 12 months post surgery. A particular challenge in evaluating the trials was that participant reported outcomes in three of the studies [210, 392, 394] all indicate some level of improvement in the treatment groups; however, there were no clear differences in pad test results in any of the trials. Because all the studies reviewed were generally small, varied in design, and had different outcome measures, it is difficult to interpret them as a whole. Whilst the evidence that therapist delivered PFMT with or without BF before or after surgery improves continence recovery after radical prostatectomy remains inconsistent, there is some suggestion that men who undergo some sort of conservative management including PFMT will achieve continence in a shorter time frame than non-treated men but that this difference is not significant at 12 months post surgery (Level of Evidence: 2).

Further discussion is needed on the outcomes of most importance. It is possible that the emphasis on quantitative outcomes is not meaningful to participants; men appear to find therapy personally helpful and value the direction provided by a therapist.

4. Recommendations
Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful (Grade of Recommendation: B); whether this is in the form of ‘hands on’ therapy of verbal instruction and support remains unclear. Studies comparing the effectiveness of pre- versus post-operative PFMT; and the number of sessions required, are needed so that practitioners may advise men about pre-operative preparation and budget conscious health boards can make informed decisions on programme funding. In designing such studies, the natural history of UI after radical prostatectomy must be taken into account because the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.

3. POSTOPERATIVE RP PFMT FOR INCONTINENT MEN

a) PFMT with digital rectal feedback (DRE) after radical prostatectomy

Two additional trials were identified for this update [376,379] resulting in a total of five trials as Dubbelman [2004] is considered a duplicate [367, 368, 376, 379, 395, 396] in which PFMT was taught using digital rectal feedback (DRE) in at least one arm.

In the largest RCT to date, 411 men who had undergone open or laproscopic RP and who reported incontinence 6 weeks after surgery were randomised to lifestyle information leaflet or leaflet plus 4 sessions of PFMT with a continence physiotherapist or nurse and home exercises (2,376). PFMT regimen was three maximum strength contractions with 10 second break between each lying, sitting and standing twice daily plus submaximal contractions when walking. DRE was used to assess strength of contraction during training sessions. Dubbelman [2010] randomised 79 men who were incontinent one week after catheter removal to physiotherapist guided PFMT using DRE to to written material only. Treatment group received nine 30 minute sessions plus daily home exercises and written material provided one day prior to surgery; the control group received only the written material. This trial appears to be the same as the 2004 report by the authors which was a poster at the ICS [395].

Joseph [2000] randomised a mixed group of 10 men (four radical retropubic prostatectomy and six radical perineal prostatectomy) to weekly verbal teaching plus DRE or BF assisted PFMT over a four week period. Manassero [2007] randomised 107 (94 completed) men to urologist taught PFMT using DRE (unclear how often) plus daily home exercises for up to a year; the control group did not receive any instruction. Participants were assessed at one, three, six and 12 months with a home pad test, VAS and DRE. In Moore [1999] 63 men (58 completed) were randomised to one of three groups: control (written materials only and no therapist contact), PFMT using DRE, or PFMT augmented with ESstim via anal probe. Both treatment groups met with the therapist twice a week for up to 12 weeks.

1. Quality of data

Three trials [368, 376, 379] reported adequate random allocation concealment. Data were collected by blinded assessors in two [379,396]. In another, data were collected and outcomes as-
sessed by the primary investigator who had a direct involvement in the trial, although treatment was provided by a therapist blinded to the control group outcomes [368]. Three trials described reasons for dropout [368, 376, 396] but only Glazener [2011] indicated how withdrawals/dropouts were dealt with in the analysis and provided intention to treat analysis. Dubbelman [2010] conducted a power analysis for sample size, but fell short of recruiting the target number.

There was considerable variation in the type and intensity of interventions, follow-up ranged from six and a half months to 12 months, and primary outcomes varied from pad test, pad count or subject report.

2. Results

Between them, the five trials, considering Dubbelman [2004] as a duplicate, had over 600 participants with complete data. Four of the five studies did not find statistically significant differences between the groups. Outcomes included one and 24 hour pad tests, voiding diary or quality of life (IIQ-7). No differences were reported between groups at 1, 4, 8, 12 and 26 weeks on one and 24 hour pad test as well as no difference in time to continence [379]; between treatment and control groups in participant reports of any incontinence or severe incontinence at 12 months [376]; or in pad test between PFMT and PFMT with EStim groups [368]. In a small study of 10 participants no differences between treatment and control groups were found [367].

One research group reported a difference between groups [396]. There was a statistically significant difference in proportion of continent subjects (<2g on 24 hour pad test) in the PFMT group at three, six and 12 months (54%, 33%, 17% compared to 78%, 60%, and 53% for the controls), with 9/54 versus 21/40 incontinent at 12 months.

3. Summary

The most recent and largest trials [376, 379, 396], which compared PFMT taught by DRE or no instruction used different approaches to defining and measuring continence and showed conflicting results. Whereas Mannasero [2007] reported a statistically significant difference in the proportion of continent men (based on 24 hour pad test) in the treatment group at three, six and 12 months the other two found no differences in continence status between groups based on participant report using standardized questionnaires or 24 hour pad test respectively [376, 379]. In the three other smaller and earlier trials, in which the control groups had written or verbal instruction on PFMT, there were no statistically significant differences between groups on pad test. (Level of Evidence: 2). Clinical heterogeneity meant that it was difficult to consider the findings from the studies as a whole.

4. Recommendations

Some instruction in PFMT may be helpful; it remains unclear on the objective benefit of the PFMT. Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction (Grade of Recommendation: B) is not clear. Further well designed studies using standardized outcome measures and participant input are needed to test this hypothesis.

b) PFMT with BF after radical prostatectomy

No new trials were found under this category although reference Riberio [2008] [397] was a conference abstract and is replaced by Ribeiro [2010] [398]. Thus to date, there are six trials evaluating PFMT with BF compared to a non active or alternate treatment commencing after radical prostatectomy [365, 366, 371, 374, 397-399].

Three compared PFMT with BF versus no treatment, placebo treatment, or usual care [366,374,398] and three compared PFMT with BF versus verbal instruction and home PFMT [365,371,399]. Continence was measured variously by 1 hour, 24, and 48 hour pad test.

1. Quality of Data

Two trials appeared to have adequate random allocation and concealment [374,398], although in the latter treatment was provided by the primary investigator who was aware of group assignment. In another [399], therapists were blinded to the results of the control group; pads were weighed by a person unaware of group assignment; data was entered by a data manager. Van Kampen (2000) had pad weights done directly by the individual at home. Dropouts were accounted for and described fully in two [374,399], partially in one [371]. There was a high dropout rate in Franke (2000) and these data were not accounted for in the analysis. There were no reported dropouts two others [365,398]. ITT analysis was described by three [365,374,399].

Continence evaluation was different for each study as well as timing of recruitment and intervention, content of intervention and control treatments. Outcomes varied widely; percentage of participants pad free [366]; one hour pad test [365]; 24 hour pad test (<2g=continent) [374,398]; <8g=continent [399]; and pad test not described [371]. Follow up ranged from 12 weeks to one year.

2. Results

Three trials compared PFMT and BF to a control condition [366,374,398]. At 12 weeks, Ribeiro [2010] reported statistically significant difference in 24 hour pad tests (51g, SD 119 versus 197g, SD 269, p=0.026), but there was no statistically significant difference at six months post surgery. In another study [374] at 8 weeks, there was a statistically significant difference in mean urine loss (30g treatment; 82g control). By 12 weeks this difference
was no longer statistically significant but the proportion of treatment group participants reporting continence compared to control (88% versus 56%) was statistically significant; no differences were found beyond three months. One other trial reported no difference between groups on 24 hour pad test or pad-free rates but sample was small and dropout rate nearly 50% [366].

None of the three trials that utilised PFMT and BF versus verbal or written instruction on home PFMT showed statistically significant differences between the groups. Outcomes were measured using one hour pad test or number of pads [365], 24 hour pad test, International Prostate Symptom Score (IPSS), or subjective report of continence at eight, 12, 16, 18, or 52 weeks [399], and pad test at 12 weeks [371].

3. Summary

Health professional instruction in PFMT with BF when compared with control conditions seemed to reduce the amount of leakage in the early weeks of recovery (up to three months). However, comparisons of PFMT with clinic BF versus PFMT at home did not find similar differences. Based on the current evidence the addition of EStim or BF does not appear to improve continence outcomes over and above PFMT. (Level of Evidence: 2). However, BF may be less difficult for the therapist than DRE.

It seems men who participate in PFMT compared to no active treatment might have less leakage in the first three months postoperatively. To the individual, this early improvement may be important in activity, well-being, and socialising. Such concepts require further investigation.

4. Recommendations

The use of BF in clinic, over and above home PFMT, is currently a therapist/individual decision based on economics and preference. (Grade of Recommendation: B).

c) PFMT plus or minus BF with EStim or MStim after radical prostatectomy

The most notable addition to the evidence base in this section is five new trials which combined EStim with PFMT for men incontinent post radical prostatectomy [378, 380, 383, 384, 387] with four of these including BF as part of the intervention. These five trials were added to two RCTs previously included in the EStim section [400]. Opsomer [1994] compared intensive PFMT plus EStim (once a week) plus BF versus simple PFMT in 43 men. As it was not possible to differentiate the effects of additive EStim (method not described) from adjunctive BF this study was not further considered for this section.

Two studies [400] previously reported and one new [378] reported comparisons of PFMT to PFMT plus EStim and recruited men with severe post prostatectomy UI one week after catheter removal (more than 200 gm of urine lost daily on pad test). In the Yamanishi trial, men were randomised into active EStim group (n=26) or sham EStim (n=30) by computerized random assessment through a connection to the stimulation device. All men had PFMT by nurses (verbal and written information) and were coached to continue this though the study period. Active EStim was 50 Hz with a 300 μsecond pulse duration, 5 seconds on/5 seconds off duty cycle and maximum output of 70 mA. Men receiving sham EStim received limited stimulation at 3 mA with a 2 seconds on/13 seconds off duty cycle. Treatment continued until the incontinence was cured or the 12 month study period ended.

Moore [1999] compared standard treatment (verbal and written instructions about PFMT) versus intensive PFMT, versus intensive PFMT plus rectal EStim in 63 men with UI median of 8 weeks (range 4-241) post radical prostatectomy. EStim was provided by a surface anal electrode, with intensity to induce visual lifting of the levator ani. Stimulation parameters were 50Hz, biphasic pulse shape with one second burst, a one second pulse width and one second pulse trains. All therapy was performed by one experienced physiotherapist. Hofmann [2004] compared percutaneous EStim plus PFMT versus anal EStim plus PFMT versus PFMT alone in men with post-prostatectomy incontinence; this trial allocated 60 men per group, the intervention was for four weeks, and each individual was followed up for three months. PFMT consisted of a “specialized program” of “continence training”, lifestyle changes, osteopathy and “Feldenkrais Lehre” three times/week in the clinic and three times/day at home, with a daily maintenance home programme after finishing the therapy. In comparing PFMT with BF plus EStim, three trials [383,384,387] included men one to four weeks after catheter removal and one [380] enrolled men at least one year after surgery. Mariotti [2009] compared PFMT with BF plus EStim to a control group which received only verbal and written information from a urologist. Randomisation occurred one week after catheter removal, and severity of incontinence among participants at enrolment varied from 20-1500 gm of urine lost on 24 hour pad test. Men in the intervention group received 12 treatment sessions (twice weekly for 6 weeks) of PFMT with BF and EStim from a single clinician. EStim was delivered by anal surface electrode at 30 Hz for 10 minutes and 50 Hz for the following 10 minutes, 300 μsecond pulse duration and a maximum output of 24 mA. BF was via perineal and abdominal surface electrodes. The frequency details of home PFMT were not provided. Marchiori [2010] randomised 332 men one month after catheter removal to intensive PFMT with BF plus EStim or a control group that received only verbal and written instruction and home exercises. This study was available only as an abstract, and the intervention was not fully described.
Zellner [2011] [383] used a three group design in which men on Day 22 post surgery were randomised to PFMT, PFMT plus EStim and Biofeedback (Myo-420 unitR via rectal probe) or whole body vibration daily at 20 Hz on a vibration plate (Fitvibe MedicalR) plus exercises (not described). Each group was in contact with the therapist over a 3-4 week period and had home exercises prescribed (protocols not described). Outcomes were testosterone, blood sugar, IPSS, pad count, and pad test. This trial was translated from German for this review.

Goode [2011] recruited 208 men with post radical prostatectomy incontinence persisting at least one year after surgery (range 1-17 years) and conducted a three group comparison of behaviour therapy BT that included PFMT, bladder control techniques and fluid management, BT/PFMT plus EStim and control (delayed treatment) [380]. Four visits two weeks apart to teach PFMT were provided for instruction from physician investigators or nurse practitioners. Anal palpation was used during instruction. The second group (BT plus) received BT with added in office dual channel biofeedback with either perianal surface or anal probe and 15 minutes of daily home EStim via anal probe with setting at 20 Hz, pulse width 1 milisecond, duty cycle of 5 seconds on and 15 seconds off and current up to 100 mA (adjusted by participant). The control group received office visits only for 8 weeks to monitor bladder diaries, and were provided with a choice of treatment after 8 weeks.

In a three arm trial [401] electrical stimulation (EStim), magnetic stimulation (MStim) and verbal/written instruction in PFMT were compared in 36 men with post RP incontinence. Home EStim comprised 15 minutes of twice daily stimulation for one month, at maximum tolerable level of intensity. For MStim, treatment sessions were 20 minutes, twice a week for two months, with stimulating intensity gradually increased up to the tolerable level. PFMT consisted of PFM exercises in supine position with instructions how to contract the anal muscles selectively. Verbal and written instructions for home practice were given to the men. Participants were followed up for six months.

1. Quality of data

Blinding, dropouts and continence evaluation

Three studies had adequate concealment of randomisation [368,378,380]; one included a power calculation, and adherence to protocol was monitored using patient-recorded diaries. Five participants dropped out, three in PFMT/EStim and two in the PFMT group. In one participant dropout was related to the use of EStim (rectal pain) [368]. Goode (2011) included a power calculation and stratified participants by site, incontinence type and severity. Randomization was conducted via a computer generated random assignment schedule. Sealed envelopes with group assignments were opened sequen-
tially at the time of randomization. There were 23/70 dropouts in the BT group, 30/70 dropout in the BT plus EStim plus BF group and 4/68 in the group that received no intervention. Dropouts were explained and analysis was by intention to treat. Interventions were not concealed as physician investigators were involved in delivery of interventions. Yamamishi [2010] used a computer generated random assignment that connected to the EStim devices, thereby blinding participants, physicians and staff to assignment. Dropouts included 4/26 in the active EStim group and 5/30 in the sham EStim group.

Randomisation details were not provided in two trials [384,401]. In the Mariotti trial, intervention was directed by the lead author, therefore there was no blinding of the researcher to the intervention group. A power analysis was performed to determine sample size. All participants completed the study. Another [400] did not make clear if allocation was concealed or if observers were blinded. Dropouts were 22/60 in the anal EStim/PFMT group, 4/60 in the percutaneous EStim/PFMT group and 0/60 in the PFMT group. Marchioni [2010] data was available only in abstract form and details of randomization and blinding are not described. In the Yokoyama trial, the number of treatments, duration and intensity seemed to be different between groups.

2. Results

In comparisons of PFMT +/- EStim, 9/60 men in the anal EStim/PFMT group reported recovery, versus 11/60 in the percutaneous EStim/PFMT group; data were not reported for the PFMT only group [400]. For comparisons of PFMT to PFMT plus EStim and BF, Goode [2011] found that both treatment groups (BT/PFMT and BT/PFMT plus EStim and BF) reported a statistically significant reduction in incontinence episodes at 8 weeks compared to the control group as recorded on bladder diaries. Both treatment groups maintained improvement at six and twelve months, although there were no statistically significant differences between treatment groups. No comparison to the control group was made after 8 weeks.

Pad test results were not consistent. Using a 24 hour pad test [368] one reported a decrease of urine loss favouring PFMT over EStim/PFMT; another found that at three months 77% in EStim/PFMT group were continent versus 65% in the PFMT group, with 82% and 77% continent respectively after 12 months [375]. None of these differences at any of the time points were statistically significant. Yamamishi [2010] reported more men in the active EStim group were continent (less than 8 gm urine lost on 24 hour pad test) at 1, 3 and 6 months than those in the sham EStim group (4%, 16%, 44% versus 36%, 63%, 81% respectively), although there was no difference at 12 months (86% continent in both groups).

For comparisons of PFMT plus EStim and BF, men in the treatment group who received PFMT plus EStim
and BF had a shorter mean time to continence (urine loss less than 2 gm on 24 hour pad test) than those in the control group (8 weeks versus 13.88 weeks) [384]. At six months, 3.3% of the intervention group and 33.3% of the control group were still incontinent, at 12 months there was no difference between the groups. A shorter time to continence favouring intervention group receiving PFMT with EStim and BF (44 days intervention group vs 76 days control group), was reported with all participants continent (2 mini pads or less per day) at 12 months [384].

EStim was associated with adverse events. Discomfort [378,400], urethral stricture [378], or bladder neck contractures [368]. Whether the EStim caused the strictures or contractures is debatable. Yokoyama (2004) reported that at one month, urine loss on 24 hour pad test was 72g, 83g and 175g (FES, ExMI, and control groups respectively (EStim versus PFMT, p<0.05), and was 54g, 18g and 92g respectively at two months (MStim versus PFMT, p<0.05). At six months mean loss was less than 10g in all groups. No complications were noted in any of the groups. The authors concluded that both MStim and EStim offered earlier continence compared with PFMT after radical prostatectomy.

Zellner [2011] (translated from German) reported no difference between control and the PFMT/BF/EStim groups based on IPSS, pad test, and pad count but the whole body vibration group (FitVibe medicalTM) had a statistically significant decrease in pad test results from 41 g pre therapy to 11g post relative to the other two groups. Whole body vibration was not described in detail.

3. Summary

Seven RCTs investigated the addition of EStim to PFMT plus or minus BF for men with post-prostatectomy incontinence. Data suggested no further benefit of EStim when added to PFMT over PFMT alone, although EStim may help achieve continence earlier in men with severe incontinence post prostatectomy; the numbers in each trial were relatively small. (Level of Evidence: 2)

4. Recommendations

For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme (Grade of Recommendation: B).

d) PFMT compared to other interventions after radical prostatectomy

Two new trials were identified that combined PFMT postoperatively with other novel interventions in men with post prostatectomy incontinence [390,391]. Park [2011] compared PFMT to an overall 12 week exercise program plus PFMT in 49 men over 65 years after RP, reporting that the exercise (treatment) group had an earlier return to continence on pad test and self report. Zhang [2008] randomised 29 men to PFMT + BF plus six biweekly meetings of a support group (n=14) or to a control group which had only the PFMT +BF. The treatment group reported less UI on VAS rating scale (3.2 vs 4.7), less pad use (50% vs 84.6%), and had better adherence to the PFMT regime. Both trials were available only in abstract form, and details on baseline incontinence, randomisation, blinding and data were not provided.

4. PREOPERATIVE TURP PFMT

Little study has been dedicated to UI after TURP. In fact, the issue has been largely ignored, perhaps because the incidence of UI after TURP is reported to be very low.

5. PREOPERATIVE AND/OR POSTOPERATIVE TURP PFMT

In previous consultations, two trials were potentially eligible for inclusion [367], but the latter trial was grouped with studies of PFMT after radical prostatectomy because the 11 participants comprised one following TURP and 10 following radical prostatectomy.

One new trial on TURP pre and post operatively was added [381].

Men undergoing TURP were randomised preoperatively to a treatment group (n=26) which involved preoperative PFMT of 1 hour individual and a 3 hour group session along with home exercises compared to control group (n=23) which received verbal information only post operatively. Outcome was symptoms as measured by the Danish Prostate Score. Three day bladder diaries and a pad test were also identified as measurements in the study but data from these were not included in the published report, therefore the effect on incontinence is not clear. An earlier trial included men booked for TURP [373]. At the baseline preoperative visit, PFM strength, tone and grading were established with a DRE. There were weekly follow up sessions for four weeks post TURP. It was unclear what information, if any, the control group received.

Quality of data

It was unclear if random allocation was concealed or outcome assessment blinded, and the proportion of dropouts was not stated.

Results

While there were statistically significant differences in UI and post micturition dribble as measured by voiding diary and IPSS, there was no statistically significant difference at four weeks.

Summary

In the absence of sufficient data from rigorous and well-reported trials it is not known if PFMT reduces
UI following TURP. More systematic investigation of the natural history of UI after TURP is probably needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

6. POSTOPERATIVE TURP PFMT FOR INCONTINENT MEN

Only one study was identified which included men incontinent after TURP. Glazener [376] randomised 442 men post TURP who reported incontinence 6 weeks after surgery. All men received a lifestyle information leaflet; those assigned to the intervention group had four 1:1 sessions with specialist continence physiotherapist or nurse. PFMT regime was three maximum strength contractions with 10 second break between each practiced lying, sitting, and standing twice daily plus submaximal contractions when walking plus home exercises. DRE was used to assess strength of contraction during training sessions.

The 4rd ICI identified two RCTs on conservative management of PMD [364,402] and no further trials were found for the past two updates. No trials were found on prevention of PMD and it is unlikely that such studies would be undertaken because of the longitudinal nature of such an exploration.

a) PFMT for post micturition dribble (PMD)

Two RCTs totalling 85 participants who had not undergone prostatectomy have been reported in which PFMT and/or urethral milking were compared to verbal instruction and lifestyle changes [364,402]. In one men were assigned: daily PFMT, urethral milking, or lifestyle changes using four hour pad test at five, nine, and 13 weeks. In another study on erectile dysfunction [403], over 65% of participants also complained of PMD and were randomised to PFMT using BF (5 weekly treatments plus home exercises) or lifestyle advice. Outcome was patient report using a standardised questionnaire administered by an interviewer unaware of group assignment.

1. Quality of data

It was not clear if allocation was adequately concealed in either study. In both studies data collection was done by the researchers but data analysis was done by a separate party.

2. Results

Paterson [1997] found both PFMT and urethral milking were equally effective and better than lifestyle changes. Dorey [2004] found that the PFMT group not only reported a significant improvement in erectile function measured by International Index of Erectile Function (p=0.001) but also a significant improvement in PMD measured by standardised questionnaire (67% improved in treatment group compared to 7% of controls; p<0.002).

3. Summary

Based on two small studies, it seems that PFMT and urethral milking might both be effective in the control of the annoying symptom of PMD (Level of Evidence: 2).

4. Recommendations

Men can be offered instruction to do a strong PFM contraction immediately after voiding, or urethral massage to empty the urethra, to improve symptoms of PMD (Grade of Recommendation: C).

8. FACTORS AFFECTING OUTCOME

Based on the current evidence, it appears that time from surgery to implementation of exercises does affect outcome and that by three months after surgery less improvement is noted. Future trials could consider analysis to evaluate the effect of length of time from prostatectomy surgery, co-morbid conditions, prior pelvic surgery, and medications (including smoking and alcohol use) on treatment outcome.

III. ELECTRICAL STIMULATION (ESTIM)

ESTim (ESTim) is reported to be effective in the treatment of UUI but no better than PFMT alone for men with SUI [242,404,405].

Symptoms of DO and UUI can be associated with neurogenic disorders and to bladder outlet obstruction such as benign prostatic hyperplasia; in some men the cause is unknown. It is believed that ESTim for UUI acts through reflex inhibition of pelvic efferents or activation of hypogastric efferents through stimulation of the afferent input in the sacral route [223,405].

SUI is rare unless iatrogenic with radical prostatectomy, pelvic surgery or radiation, or TURP [368,406-408]. DO, poor compliance and decreased contractility may also be factors related to post-prostatectomy incontinence [368, 409]. For male SUI, ESTim could be used to enhance sensory response to contraction of the PFMs in the same way as female SUI [410,411]. As a stand alone therapy it is unclear whether ESTim enhances continence recovery [375,412]. It has been postulated that continence is regained more rapidly [413] and the duration of the application of ESTim is reduced when PFMT is augmented with ESTim [413,414]. ESTim is also believed to be more effective in participants who are initially unable to identify and contract the correct PFMs [415]. Interestingly, it is generally agreed amongst those using
EStim that it should be avoided for those with carcinoma of the bladder for fear that EStim may increase abnormal cell activity [403]. Although there are no data to confirm or refute this, many physiotherapists are unwilling to use EStim for individuals with cancer and, therefore, post radical prostatectomy. Further research is needed to clarify this risk.

This section will examine evidence for the use of EStim for the prevention and treatment of UI in men. Questions addressed are:

- What is the most appropriate EStim protocol?
- Can EStim prevent UI?
- Is EStim better than no treatment, placebo or control treatments for UI?
- Is EStim better than other treatments?
- Does the addition of EStim to other treatments add any benefit?
- What is the effect of EStim on LUTS other than UI?
- What factors might affect the outcome of EStim?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see Appendix 2). No other types of study design were considered. Since the 3rd ICI only one new RCT [400] was identified and included in this chapter. A previous relevant Cochrane systematic [412] was updated and contributed to this section [416].

1. PREVENTION OF UI

There have been no studies on the effect of EStim for prevention of non postprostatectomy UUI or SUI in men.

2. TREATMENT OF UI

In the 4th ICI, one systematic review was identified [412], along with nine RCTs [221-223,368,371,375,400,401,404]. An abstract of a trial [417] reported data for men, but the separate effects of EStim could not be assessed and the study was excluded.

a) Is EStim better than no treatment, placebo or control treatments?

No new studies were identified that compared EStim with no treatment or a control. Two earlier placebo controlled trials both included men and women. One included 29 men and 39 women with UUI [222,404] and the other 30 women and five men with SUI [404]. In the latter trial, four men had post-prostatectomy incontinence and one had sphincter deficiency due to sacral cord tumour.

1. QUALITY OF DATA

Both trials blinded participants and doctors to treatment allocation [222,404]. For EStim in UUI, three participants (8%) in the active group and one (3%) in the sham group dropped out, and two in each group discontinued the treatment due to adverse events (5.4% and 6.5% respectively). For EStim in SUI, two of 35 participants (6%) dropped out and none had adverse events.

2. RESULTS

(a) Men with UUI: The authors reported statistically significant differences in cure (22% active and 4% sham) and improvement rates (81% active and 35% sham) between the groups; data were not differentiated for men and women [222].

(b) Men with SUI: None of the participants in the sham group were cured or improved. One man in the active EStim group was cured and a second was improved; five men participated in the study but it was not clear how many were allocated to sham and how many to active EStim.

3. SUMMARY

In the absence of sufficient data from rigorous and well-reported trials it is not known if EStim, as a stand alone treatment for male UUI or SUI, is better than no treatment, placebo or control treatments.

b) Is one approach to EStim better than another?

EStim protocols for men are similar to those for women and like protocols in women vary widely. Intermittent, short-term stimulation (or maximal EStim) using a portable stimulation device at home or in clinic is most common [368,375,401]. Rectal or surface electrodes are most common; surface electrodes are positioned over the perineal region.

For the treatment of SUI (and post-prostatectomy incontinence) EStim amy be combined with PFMT or monotherapy. Usually a rectal electrode is used, and the stimulation artificially stimulates the pudendal nerve and its branches to cause direct reflex responses of the urethral and periurethral striated muscles [368,400,401].

Frequencies of 14Hz have been used for UUI [400], while 20Hz [401], 27Hz [375] and 50Hz [368] have been used for SUI. Pulse form is mostly biphasic; pulse width varies and includes 300 microseconds [401], 250 milliseconds [400][401], one [368] and five seconds [375]. Duration of the stimulation varies as well, from 15 minutes [375] to 30 minutes [368], and from twice daily [375] to twice weekly [368]. Duration of treatment has ranged from one month [401], to three months [375].

1. SUMMARY

So far, no studies comparing EStim protocols have been identified. The most appropriate EStim protocol for different types of symptoms is unknown. EStim protocols for men have been developed from studies in women. The variability in the findings of
the trials included in the remainder of this section may in part be due to differences in the effectiveness of the wide range of protocols that have been tested. There are many differences in clinical application that have not yet been investigated. Some populations or subgroups of men may benefit from EStim more than others, but this observation has not yet been investigated.

c) Is EStim better than other treatments?
No new trials were found comparing EStim with other treatments making a total of two comparing EStim with MStim [223] or medication [221] in men and women with UUI. One evaluated EStim with MStim for inhibition of DO in a urodynamic study of 32 participants (15 males, 17 females) [223]. The other compared EStim (TENS) with medication (oxybutynin) for UUI in 43 participants (13 men, 30 women) with DO [221]. Results were not reported by gender. Oxybutynin was started at a dose of 2.5mg orally twice daily and titrated to 5mg orally three times daily by day seven. Dual channel TENS with two self-adhesive pads connected to the stimulator and applied bilaterally over the perianal region (S2 to S3 dermatome) was used. Stimulation parameters were set at a frequency of 20Hz and a pulse width of 0.2msecs on a continuous mode. TENS duration was up to six hours daily.

1. QUALITY OF DATA
Random allocation concealment was adequate; results were not reported by gender [222]; another did not provide information about randomisation procedure, random allocation concealment, blinding of observers, or drop-outs [221].

2. RESULTS
In the urodynamic study of EStim versus MStim in men with DO, bladder capacity at first desire to void and maximum cystometric capacity increased significantly in both groups compared to baseline; the increase in maximum cystometric capacity was statistically significantly greater in the MStim (106%, SD 130) than the EStim group (16%, SD 34).

EStim and medication improved subjective parameters but only oxybutynin showed statistically significant improvements in objective urodynamic parameters such as bladder volume at first desire to void and at first overactive detrusor contraction [221].

3. SUMMARY
There were few men in either of the two trials comparing EStim and MStim, the single trial comparing EStim with verbal/verbal instruction in PFMT, or single crossover trial comparing EStim with oxybutynin. In the absence of sufficient data it is not known if EStim is better than MStim or written/verbal instruction in PFMT or oxybutynin for UI in men.

d) Does the addition of EStim to other treatments add benefit?
Four RCTs have been identified investigating the addition of EStim to other treatments for men with post-prostatectomy incontinence [368,371,375,400] and are discussed under the PFMT section on post-prostatectomy incontinence. No studies of EStim being added to other treatments for UUI and SUI were identified.

3. OTHER LUTS
No studies were identified which addressed this comparison in men.

4. FACTORS AFFECTING OUTCOME
a) Age
There are no comparisons of the effects of EStim for UI between younger and older men. While many EStim studies include participants over 50 years most studies don’t include those over about 80 years [418]. In the studies of EStim for post-prostatectomy incontinence in this chapter the mean age of men is about 66 years. Although post-prostatectomy studies have included older men it may be unwise to extrapolate the effects of EStim in older men with SUI to older men with UUI, because in the former UI is usually as a result of sphincter incompetence whereas in the latter the symptoms are those of an OAB.

b) Other
Many other factors, such as types of electrodes, intensity, frequency and duration of stimulation, electrode positioning, the number of treatment sessions, diagnosis and underlying cause, participant selection, and treatment adherence are plausible factors affecting outcome. Little is known about the effect of any of these and there are no trials investigating these factors in males.

IV. MAGNETIC STIMULATION (MSTIM)
Background information about extra corporeal magnetic innervation, more commonly called magnetic stimulation (MStim), has been given in the section on MStim for women (see B5). MStim has also been used in men; it is unclear whether the mode of action and effects of MStim are similar in men and women. In men, MStim is used to treat UI after radical prostatectomy [401,419] and for the inhibition of DO [223].

The questions to be addressed are the same as those for women (see B5). Since the 4th ICI no further RCTs were found. Suzuki [2007] compared the effect of MStim versus sham MStim for UUI in 39 individuals (23 females and 16 males). The study was not included in the review below because both groups also received PFMT, and data were not reported separately for men and women [263].

1209
1. PREVENTION OF UI

No trials investigating the primary or secondary prevention effects of MStim for men with UI were found.

2. TREATMENT OF UI

Three treatment RCTs were identified; two published articles [223,401] and one abstract of an ongoing study without data [419]. The first trial [223] included both men and women with UI; because the effects of MStim might be different between sexes (due to differences in the underlying aetiology of symptoms) this study has only contributed to the analysis where the researchers’ differentiated the effects of treatment in men and women.

a) Is MStim better than no treatment, placebo or control treatment?

No studies were found addressing this question.

b) Is one approach to MStim better than another?

No studies were found addressing this question.

c) Is MStim better than other treatments?

Two studies were identified [223]. Both compared MStim with EStim; the latter also compared MStim and PFMT. Readers are referred to section D.3.2c for a description of these studies, findings, and summary.

3. OTHER LUTS

No studies were found.

4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. The relationship between age (or any other factor, such as treatment parameters, treatment adherence, or diagnosis) and the outcome of MStim has yet to be determined.

V. SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens include bladder training, timed voiding, habit training and prompted voiding. They are frequently combined to achieve maximum benefits. Although there is evidence to indicate that scheduled voiding regimens, especially bladder training and timed voiding, are commonly used in the treatment of men with UI and other LUTS, there has been substantially less research that addresses their use in men compared to the literature on their use in women.

1. PREVENTION OF UI

No trials investigating the preventive effects of scheduled voiding regimens for men with UI were found.

2. TREATMENT OF UI

Since the 4th ICI in 2009, there have been no new reports of bladder training that have included men. Of the five that have included men, most had only a small number of men in the sample [48,282,283,286,293]. Two observational studies, but no RCTs, were found regarding timed voiding. No studies were located that addressed habit training or prompted voiding in men.

a) Bladder training

A total of five RCTs involving 142 men met the criteria for inclusion in this review. All trials (previously described in section B6) had predominantly female participants; one RCT compared bladder training (BT) to BT plus caffeine reduction (seven men, 86 women) [48]; and three RCTs compared BT plus placebo drug versus anticholinergic drug therapy (six men, 28 women [293]; four men, 30 women [283]; two men, 58 women [282]. The largest RCT compared drug therapy alone (toltolodine) to drug therapy plus BT (123 men, 378 women) [286]. A sixth study was located that compared BT supplemented with drug therapy after three months, but it was excluded from review because the full length report was in Japanese and an English translation was not available [420].

As none of the trials reported outcome data separately for men, and with the proportion of male participants being so small (3%, [282]; 8%, [48]; 12%, [283]; 8%, [293]; 25%, [286]), there is insufficient evidence available to comment on the effectiveness of BT in men.

b) Timed voiding

No new trials were found on timed voiding. There are two clinical series that investigated timed voiding in men only [272,421]. In the first, timed voiding was initiated in incontinent men in a geriatric hospital [421] and in the other men with persistent post-prostatectomy incontinence [272]. Outcomes were measured by a two week voiding diary kept at baseline and during two weeks of timed voiding by patients diagnosed with SUI, UUI, and/or continual leakage.

1. Quality of data

Both studies used a clinical series design and patients in both subsequently received other treatment if they were not adequately improved. In the Sogbein study, nurses checked the patients’ clothing for wetness at each two-hour voiding interval and recorded the results. Data in the Burgio study were based on bladder diaries completed by the patients. Reasons for drop-out [421] and non-adherence [272] were provided.

2. Results

In one study an 85% improvement rate in UI was reported [421]. In the second, the two hour timed voiding schedule was used with only 12 out of 20 men, because they were either already on a voiding schedule, unwilling to go on a voiding schedule, or were noncompliant [272]. In five men with SUI,
there was a 29% decrease of incontinent episodes; in three men with UUI, two improved and one dramatically regressed producing a 33% increase in incontinent episodes. In four patients with continual leakage, there was no reduction in percentage of wet intervals.

3. SUMMARY

With limited Level 3 evidence (and no higher order evidence), there is insufficient evidence available to comment on the effectiveness of TV in men.

3. OTHER LUTS

No studies were identified in men.

4. FACTORS AFFECTING OUTCOME

a) Age

No new trials were found addressing outcome. The five RCTs involving bladder training included older men, as well as women. Three specifically recruited adults aged over 65 years [282, 283, 293]. The largest trial recruited men with a median age of 62 years. There was no subgroup analysis related to age and gender effects, so it is not possible to draw conclusions regarding the effect of BT in older men [286]. Voiding regimens are of particular interest for the elderly, but some are effective in younger patients with UI [266].

b) Other

No studies were identified on other factors affecting outcome of BT or prompted voiding in men.

Individuals who appear to benefit most from scheduled voiding regimens are highly motivated without cognitive deficits. Men and women with SUI and UUI have benefited, whereas patients with severe sphincter damage (e.g. after radical prostatectomy) generally do not [Hadley, 1986].

VI. COMPLEMENTARY AND ALTERNATIVE MEDICINES

Therapies include acupuncture, relaxation, meditation, imagery, hypnosis, naturopathic and herbal remedies, but only trials of acupuncture therapy have been found in men with UI. Therefore, only acupuncture will be considered in the remainder of this section.

Acupuncture is a traditional Chinese modality and has been used for the treatment of urinary disturbances. Acupuncture has been reported to relieve OAB symptoms including UI due to spinal cord injury [422], and idiopathic DO or MUI [423,424].

1. PREVENTION OF UI

No studies were identified on the preventative role of complementary therapies in men.

2. TREATMENT UI

Acupuncture may improve urodynamic parameters such as sphincter function [425,426] or bladder capacity in men with UUI (Honjo, 2000; Kitakoji, 1995). It is a form of somatic sensory stimulation [Bergstrom, 2000]. The mechanism by which acupuncture inhibits DO remains unclear, but suppression of the spinal and supraspinal reflexes that lead to detrusor contractions is considered one of the most important mechanisms [427,428] or release of endorphins [Bergstrom, 2000]. There has been no report on the effects of acupuncture for male SUI or post-prostatectomy incontinence.

a) What is the most effective acupuncture protocol?

Acupuncture has been carried out with disposable stainless steel needles (0.3mm in diameter, 60mm in length) inserted into the bilateral BL-33 points on the skin of the third posterior sacral foramina [422,423,429] or several other points (BL-31,32, 21, 23, SP-6, KI-3, LI-11,CV-1,2,4,5 ) [430], and usually performed once or twice weekly [422-424,429,431]. Acupuncture protocols vary and there is no apparent consensus between investigators. It is not known if any acupuncture protocol is more effective than another.

b) Acupuncture versus no treatment, sham acupuncture or any other treatment

No new studies were identified. Only one RCT has been identified including both men and women [432], but there is no study exclusively for men. In a randomised, placebo-controlled, single-blind study among 20 elderly patients (three males, 17 females) Ellis (1990) showed that the frequency of voiding at night was reduced after acupuncture. Uncontrolled studies suggest improved symptoms post acupuncture [422,423].

The evidence of the effectiveness of acupuncture for men with UI is limited by the lacked of controlled studies. To date, the studies are small, objective measures of UI are not included and long-term follow-up is lacking. Uncontrolled studies suggest that RCTs of acupuncture in the treatment of UI in men are warranted.

3. OTHER LUTS

No new trials were found in this category. In the one trial in men with sensory urgency after TURP [431] a significant improvement was reported by acupuncture reflexotherapy (ESTim of somatic and auricular points) in terms of IPSS, QOL scores, decrease of daytime frequency and nocturia, but no improvements with the use of placebo or oxybutynin.

4. FACTORS AFFECTING OUTCOME

Aside from Ellis [1990], reported above, who specifically recruited elderly participants there is a lack of
evidence about the effect of any prognostic factor for the outcome of complementary therapies in men.

### VII. SUMMARY

Despite the prevalence of UI and LUTS in older men, the only group that has received much attention in research is men following radical prostatectomy. Overall, the effect of conservative treatment (lifestyle interventions, physical therapies, schedule voiding regimes, complementary therapies) for men has received much less research attention compared to women.

### 1. RECOMMENDATIONS FOR PRACTICE

There is generally insufficient Level 1 or 2 evidence on which to base recommendations for practice, and most recommendations are, in effect hypotheses, that need further testing in research.

**Lifestyle interventions**

- It seems reasonable for health professionals to offer men advice on healthy lifestyle choices that may reduce or delay the onset co-morbid conditions that are risk factors for incontinence *(Grade of Recommendation: D)* (Unchanged).

**Pelvic floor muscle training (PFMT)**

- Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful *(Grade of Recommendation: B)* (Unchanged).
- It is not clear whether PFMT taught by digital rectal examination (DRE) offers any benefit over and above verbal or written instruction in PFMT *(Grade of Recommendation: B)* (Unchanged).
- The use of BF to assist PFMT is currently a therapist/patient decision based on economics and preference *(Grade of Recommendation: B)* (Unchanged).
- Use of a strong pelvic floor muscle contraction immediately after voiding, or urethral massage to empty the urethra, can improve symptoms of post micturition dribble *(Grade of Recommendation: C)* (Unchanged).

**ESIm (ESIm)**

- For men with post-prostatectomy incontinence there does not appear to be any benefit of adding ESIm to a PFMT programme *(Grade of Recommendation: B)* (Unchanged).

### 2. FUTURE RESEARCH DIRECTIONS

There is much scope for research on the effects of conservative therapies for UI and LUTS in men. Research that is urgently needed, in the opinion of committee members, is highlighted with the use of italics. There are a few recommendations that apply to all future studies in men, namely:

- All future intervention studies must be designed to allow standardised and comprehensive reporting of results based on the ICS and CONSORT recommendations.
- The natural history of UI after radical prostatectomy must be taken into account in study design as the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.
- More research is needed to find out what are the most important outcomes for men with UI, so such measures can be incorporated as the primary outcome measures in further trials.
- Data are needed to establish to the cost, and cost effectiveness, of conservative therapies in men with UI.
- Surgical approaches with laparoscopy or robotics offer promising improvements in visualisation for nerve-sparing procedures; further research should address continence and erectile function after these newer surgical procedures.

#### a) Lifestyle interventions

- To date, no trials have addressed the topic of lifestyle interventions for men with UI.
- The effects of interventions such as weight and caffeine reduction, both of which show some evidence of benefit in women, are priorities for future research.

#### b) Pelvic floor muscle training (PFMT)

- Further studies to test the hypothesis that preoperative proprioceptive training plus PFMT is more effective than PFMT alone to prevent UI in men undergoing radical prostatectomy.
- A comparison of preoperative versus postoperative PFMT verbal and written feedback to reduce prevalence and severity of UI following radical prostatectomy is needed.
- Methods of PFMT instruction and supervision require further investigation. Two areas of research interest are:
  - Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction.
  - The effect of group exercise. Because of the peer support that men may receive from participating in a group [433] this might be useful after radical prostatectomy; three reported that support in the post operative period may be important to healthy recovery [368,371,391].
• More systematic investigation of the the natural history of UI after TURP is needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

• The relationship between age, or any other factor, and the outcome of PFMT for UI in men has yet to be determined.

c) Electrical stimulation (EStim) and magnetic stimulation (MStim)

• It is not known if pre or postoperative EStim or MStim has a role in reducing UI after radical prostatectomy.

• RCTs in larger samples, with long-term follow up, are needed to investigate all aspects of the effectiveness of EStim and MStim as a treatment for UI in men, including:
  - Either type of stimulation versus no treatment, sham stimulation or other control conditions.
  - Comparisons of both EStim and MStim protocols.
  - EStim versus MStim.
  - Either type of stimulation versus medication.
  - Whether the addition of either type of stimulation to other treatments adds benefit, in particular the addition of stimulation to PFMT.

• The effect of age, and other factors, on outcome of stimulation. Elderly men may have more comorbid conditions than young men and a more pragmatic approach to inclusion in EStim studies is needed.

d) Scheduled voiding regimens

In the absence of trials exclusively in men, or trials that report data separately for men and women, there is a pressing need for high quality RCTs with an appropriate sample size and long-term follow up to address the effects of BT, Timed voiding, habit training and prompted voiding in men suffering from UI.
APPENDIX 1

TERMINOLOGY

Pelvic Floor Muscle Therapy (PFMT): any programme of repetitious, voluntary PFM contractions taught by a healthcare professional. It is the PFMs, not pelvic muscles in general, which are the target of the intervention. This broad definition accommodates variations in the PFMT end-goal, type of supervision (e.g. individual or group sessions) and the exercise programme (e.g. variations in frequency, intensity, number of contractions and duration of training). It may include the use of PFM contractions for urge suppression and to prevent stress leakage, under the term “the knack”.

PFMT is used in preference to other previously-used terms such as Kegel’s Exercises, pelvic floor exercises and PFM exercises. The term ‘Kegel’s Exercises’ is no longer appropriate because it refers to Kegel’s original exercise programme of 500 contractions per day (58). Current PFM programmes are very different from the one originally prescribed by Kegel (1948).

“Training” is also viewed as a more appropriate word than “exercise”. The term “exercise” is commonly interpreted as one training episode or a single muscle action, whereas, “training” encompasses repeated exercises over a sustained period of time.

APPENDIX 2

REVIEW OF THE LITERATURE/SEARCH TERMS

A systematic search of studies up to the end of August 2011 was conducted. Only papers published in English or in a language for which a translator could be found were included. Relevant systematic reviews and reports of RCTs and quasi-RCTs were included. Therefore, only Level 1 evidence is considered in this section and recommendations are based on the findings of existing up-to-date systematic reviews and more recent RCTs.

Several Cochrane reviews were critical to the rigour of the present chapter: UI prevention (96,170); management of urinary continence in women (97,126,213); management of urinary incontinence in men (412,416); management of pelvic organ prolapse (296,297); habit training and timed voiding (273,275); and bladder training (269). Pre-specified outcomes of interest were urinary continence (for prevention studies), urinary continence, patient symptoms, quality-of-life measures and pad tests (for treatment studies).

Data for SUI were taken from a recent UK Health Technology Assessment (HTA) on non-surgical interventions for stress urinary incontinence in women (219). This was supplemented with additional studies for SUI completed after publication of this HTA, and studies for UUI and other LUTS, located through additional literature searching conducted in the Cochrane Incontinence Group Specialised Register as part of an ongoing Cochrane review. The same methods used in the HTA for data collection and analysis for SUI were applied to the studies on UUI and LUTS.

Criteria for inclusion were (1) randomised or quasi-randomised (alternate allocation) trial study design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and (4) no pregnant or postpartum women. Retrospective data was not included.

‘Risk of bias’ in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group (220). Risk of bias due to blinding to the allocated intervention should be considered to be high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

The Consort Statement Checklist was used to determine the quality each study (434). Empirical evidence indicates that two elements of trial quality, allocation concealment and double blinding, are important for estimating treatment effect with precision. Trials with inadequate or unclear concealment of allocation appear to overestimate treatment effect by about 30% and trials that are not double-blinded overestimate effect by about 15% (435). Therefore, trials that reported adequate allocation concealment have been noted. Although it is often difficult or impossible to blind patients to PFMT, trials that reported blinding of the outcome assessment have also been noted. Readers may wish to consider these factors in their interpretation of the data.

The search terms may be seen at http://hdl.handle.net/10402/era.26262. (Click on the “download” link, top right.)

I. INTRODUCTION

Surgery for male incontinence is an important aspect of treatment with the changing demographics of society and the continuing large numbers of men undergoing surgery and other treatments for prostate cancer.

Basic evaluation of the patient is similar to other areas of incontinence and includes primarily a clinical approach with history, pad testing, frequency-volume chart or bladder diary, and physical examination. Since most of the surgeries apply to patients with incontinence after other operations or trauma, other investigations such as radiographic imaging of the lower urinary tract, cystoscopy, and urodynamıc studies may provide important information for the treating clinician.

Although prostatectomy for benign disease has become less frequent in many countries, the complication of incontinence is a rare but unfortunate occurrence that merits treatment. After a period of conservative therapy has been tried, surgical treatment is indicated following similar strategies applied in post-prostate cancer treatment incontinence i.e. slings and artificial urinary sphincter (AUS).

Radical prostatectomy for prostate cancer is performed far more frequently now than 15 to 20 years ago, with nearly two-thirds of surgical cases being performed via the robotic-assisted laparoscopic approach in the United States [1]. Approximately 5-25% of patients will experience incontinence that fails to improve with conservative management, and a substantial minority will ultimately undergo surgical treatment [2]. The AUS has provided a satisfactory result in most cases, regardless of the degree of urinary incontinence, with a positive impact on quality of life. Sling procedures have emerged as an efficacious treatment in the majority of men with mild to moderate stress urinary incontinence, however, they have not proven predictably successful in men with higher degrees of incontinence. Injectable agents have not shown durable long-term results. Volume adjustable balloons have been limited in their utility due to a high complication rate. Newer techniques involving adjustable urethral slings have demonstrated efficacy similar to that of non-adjustable slings, with the potential advantage of postoperative alterations in sling tensioning (tightening) but a higher complication rate.

Stratification of treatment based on the degree of stress incontinence is now feasible. Men with milder degrees of incontinence and normal bladder function are candidates for either artificial urinary sphincter placement or sling surgery, each with similar success rates. Sling surgery appears to have a lower risk of surgical complications in this population. Patient preference may be for a sling versus a mechanical device [3]. On the other hand, with more severe incontinence, AUS surgery has a more predictable success profile than does sling surgery.

Incontinence following radiation therapy, cryosurgery, high-intensity focused ultrasound, other pelvic operations and trauma is a particularly challenging problem because of tissue damage inside and outside the lower urinary tract. In such instances, periurethral bulking, sling procedures, and inflatable periurethral balloons have generally proven inefficacious and worsening of incontinence may happen after such surgery. The AUS is the most successful surgical procedure in this setting, but is associated with a higher rate of complications compared to implantation following surgery in the absence of adjuvant cancer therapy. With tissue damage beyond the urinary sphincter, other surgical approaches may be necessary. Patients with unresolved problems from pediatric age and with associated incontinence from detrusor overactivity may benefit from a variety of complex reconstructive surgical procedures. Other complicated problems encountered include urethrocutaneous fistulae, and fistulae between the prostate, bladder neck, or urethra and rectum. Surgical reconstruction, in experienced hands, often in a staged manner, is usually successful.

With decades of worldwide use of the AUS in the surgical management of male incontinence, its complications and their management are well known. Durability of the device is an important aspect that impacts on outcome and cost of treatment. A growing body of literature regarding male sling surgery, its indications, factors affecting outcome, and complications and their management,
has changed the landscape of incontinence surgery over the past 5 years.

Although the literature is replete with well-done cohort studies, there is a continuing need for prospective randomized clinical trials, especially needed for adequate comparisons among surgical techniques.

MATERIALS AND METHODS

The committee was charged with the responsibility of assessing and reviewing the outcomes of surgical therapy that have been published since the Third Consultation [4] for non-neurogenic male incontinence. Articles from peer-reviewed journals, abstracts from scientific meetings, and literature searches by hand and electronically formed the basis of this review. The outcomes were analyzed, discussed among the members of the committee and included in the chapter.

The incontinence problems were classified according to their etiology, i.e. either primarily sphincter or bladder related, and are listed in Table 1. Treatment of fistulae is covered separately.

Specific recommendations are made on the basis of published results and determined by the levels of evidence. Consensus of the committee determined the recommendations, which are found at the end of the chapter. Recommendations for future research are also included.

II. EVALUATION PRIOR TO SURGICAL THERAPY

Recommendations for evaluation prior surgery have not changed substantially from the last edition in 2009 [5]. A basic history and physical is the cornerstone of this evaluation. The history should focus on the precipitating events (surgery, trauma, etc) that led to the incontinence, the evolution over time of the leakage symptoms (has there been improvement, etc), what precipitates the leakage (straining, cough, exercise, etc – suggestive of stress urinary incontinence (SUI) or the sudden onset of urgency, the sense of needing to void immediately, particularly in the absence of any physical activity – suggestive of urgency incontinence) as well as other potential comorbidities. A general sense of the degree of bother of these symptoms, sexual function and pad use is important as well. The physical examination should note any gross urine leakage per meatus with patient straining or coughing as well as general characteristics of the lower abdomen, perineal area and penis and scrotum. Assessment of hand function is important to assess manual dexterity for manipulation of an implanted device. A brief neuro-urological examination (perineal sensation, anal tone, voluntary contraction and relaxation of the anal sphincter, bulbocavernosus reflex [6]) should be performed. A urinalysis to rule out infection or signs of inflammation or hematuria should be obtained.

A frequency-volume chart [7], or bladder diary (indicating daytime and nighttime frequency of micturition, incontinence episodes, voided volumes, 24-hour urinary output, etc.) is also helpful. According to Wyman et al. [8] the 7-day diary can be considered as the gold standard for voiding diaries. Schick et al. [9] demonstrated that a 4 day frequency-volume chart gives a reliable snapshot of the patient’s situation. A pad test quantifies the severity of incontinence and may be the most objective measure of the incontinence. The 24-hour home test is the most accurate pad test for quantification and diagnosis of urinary incontinence because it is the most reproducible. [10] The 1-hour pad test may be used because it is easily done and standardized, however there is no strict

parallel with the 24-hour pad test and it may underestimate the weakness of the sphincter in the later part of the day. A pad test may be helpful in quantifying leak in AUS failures.

The ICIQ-SF (short form) questionnaire (www.iciq.net) can be recommended for the assessment of the man’s incontinence, and has been used in RCTs of treatment for post prostatectomy incontinence.

Postvoid residual urine measurement is a good estimation of voiding efficiency [11,12]. These basic investigations are recommended in incontinent males prior to surgical therapy.

Blood testing (BUN, creatinine, glucose) is recommended only if compromised renal function is suspected or if polyuria (in the absence of diuretics) is documented by the frequency-volume chart [13].

Further evaluation should be adapted to the particular patient. Cysto-urethroscopy will verify the integrity of the urethral wall (anterior aspect of the distal sphincteric mechanism in post-TURP incontinence [14], erosion by the cuff of the artificial sphincter), and the status of the bladder (trabeculation, stone, diverticula, etc.). It will allow observation of the urethral sphincter and voluntary contraction on the part of the patient, if done under local anaesthesia. The presence or absence of urethral, prostatic, or bladder neck stenosis is also necessary to ascertain prior to incontinence surgery, especially in patients who have undergone treatment for prostate cancer.

Imaging techniques include plain film of the abdomen (KUB or Kidneys, Ureters, Bladder), in cases of incontinence following artificial sphincter implantation when during the original procedure the hydraulic system was filled with contrast medium. A KUB immediately following sphincter implantation serves as a reference point for subsequent comparisons [15].

Figure 1 illustrates the case of a young spina bifida patient in whom an artificial sphincter has been implanted with the cuff around the bladder neck. After more than 10 years, he became suddenly incontinent. Second KUB compared to previous one clearly demonstrated fluid loss from the system. Contrast studies include cystography which may demonstrate an open bladder neck when bladder denervation is suspected [16], e.g.: following abdominoperineal resection of the rectum. Cystourethrography may be used to demonstrate a fistula, stricture or urethral diverticulum e.g., following healing of the urethral wall erosion caused by the cuff of the artificial urinary sphincter (Figure 2). Ultrasound is widely used not only to evaluate the upper urinary tract, but also to evaluate postvoid residual urine. The sensitivity of 66.7% and specificity of 96.5% when post-void residual is 100 ml or more is adequate for routine clinical use [17]. It has been shown to be cost-effective when compared to catheterization [18]. Other modalities, for example transurethral ultrasound [19] and magnetic resonance imaging of the external sphincter are still under development.

URODYNAMIC TESTING

Urodynamic studies (UDS) have traditionally been performed in men under consideration for invasive treatment in order to assess Valsalva Leak Point Pressure (VLPP), detrusor overactivity and bladder compliance. However, there are now several studies, which call into question the use of routine UDS in men with pure SUI. These studies will be commented on at the end of this section.

When performing UDS there are specific issues that must be considered. In patients with incontinence secondary to radical prostatectomy who developed bladder neck stenosis, the urethral catheter can create obstruction giving false values for Valsalva leak.

Figure 1. Young spina bifida patient who had a bladder neck artificial sphincter implanted. After more than 10 years, he became incontinent. Early abdominal plain film, A, shows a full reservoir. After leakage started abdominal plain film, B, demonstrates loss of fluid from the reservoir.
point pressure (VLPP). Sphincter weakness can be documented by the Valsalva [20] or cough or abdominal leak point pressure [21]. Catheter size seems to have a significant influence even with a small size 7-F urethral catheter [22], and the correlation is extremely high between the test-retest leak point pressure when the same size of catheter is used [23,24]. In male patients, abdominal leak point pressure may be evaluated via a rectal catheter because a urethral catheter is much more likely to invalidate VLPP measurements than it does in female [25]. It has become evident that bladder volume influences VLPP, i.e. it decreases with bladder filling [26-28]. However, this observation is not consistent [29]. Unfortunately, there is no agreed standardization of the technique at the present time which somewhat limits its usefulness [30]. Measurement of leak point volume may also provide information on the functional capacity of the bladder [31].

Retrograde leak point pressure has been used to study incontinence following placement of an artificial sphincter [32,33]. It correlates with the lowest abdominal leak point pressure [34]. The intraoperative use of this technique has been proposed and this allows early recognition of intraoperative urethral injury and mechanical malfunction [35]. Intraoperative retrograde perfusion sphincterometry may be helpful to determine the appropriate tension on male slings [36]. Similarly, others have utilized repeated intraoperative abdominal leak point pressure (ALPP) measurements to adjust the tension for male slings [37]. Electrophysiologic studies, mainly sphincter electromyography, may be useful to document denervation of the pelvic floor when nerve injury or neuropathology is suspected [38].

Detrusor function is best evaluated by multichannel urodynamics. Its main purpose is to detect detrusor overactivity and/or decreased compliance during bladder filling. It can be coupled with fluoroscopic imaging, video-urodynamics. It has also been proposed by some that fluoroscopy be replaced by transrectal ultrasound [39,40]. Ultrasound measurement of bladder wall thickness was proposed as a better predictor of bladder outlet obstruction than uroflowmetry [41] but at present its use is controversial [42].

Non-invasive pressure-flow urodynamic evaluation based on Doppler ultrasound seems to have potential for diagnosing bladder outlet obstruction [43]. However invasive pressure-flow studies are still the gold standard in the incontinent male to rule out bladder outlet obstruction accompanied by detrusor overactivity [44] which in turn can cause incontinence. In most recently published studies, urodynamic testing has been done prior to surgery [45-49]. Cystoscopy is frequently done as well [48,50-54]. However, as noted above, there are some reports that question the value of urodynamics studies in predicting outcomes after surgery. Thiel et al. [55] found no evidence that patients with detrusor overactivity, early first sensation of filling, decreased compliance or low bladder capacity had worse outcomes after artificial sphincter placement in 86 men. Trigo Rocha et al. [56] also found that preoperative urodynamic findings such as detrusor overactivity, impaired detrusor contraction, low Valsalva leak pressure, bladder outlet obstruction, and mildly reduced compliance did not lead to a poor outcome after artificial sphincter implantation. Ballert et al. [57] studied the association between preoperative detrusor overactivity and postoperative outcome after male sling surgery and found no difference in the number of pads used postoperatively. Preoperative detrusor overactivity was not associated with worse postoperative outcomes. Finally, Lai et al. [58] reviewed 129 patients with post-prostatectomy incontinence, all of whom had multichannel videourodyamics, and noted that the presence of adverse preoperative urodynamic features (such as detrusor overactivity, early sensation of desire to void, reduced cystometric capacity of <200cc, low abdominal LPP <30 cm H2O, low maximum flow <10cm H2O and poor bladder contractility) did not negatively affect the continence results after AUS implantation.

The proposed evaluation of the incontinent male is summarized in Table 2.

III. INCONTINENCE AFTER RADICAL PROSTATECTOMY FOR PROSTATE CANCER

1. INCIDENCE AND PREVALENCE

Urinary incontinence occurring after radical prostatectomy (RP) is a substantial problem. Despite improvements in continence preservation [59] during the 1990’s and 2000’s primarily due to a better
understanding of the pathophysiology and improvements in surgical technique, continence rates have generally plateaued over the past decade. As RP has continued to increase in popularity as a treatment for prostate cancer, especially with the advent of robotic-assisted surgery, the prevalence of post prostatectomy incontinence (PPI) has increased in developed countries, which has led to an overall increase in the number of patients affected.

Data from large multicenter studies and prostate cancer databases suggest that following RP, 1% to 40% of patients complain of persistent urinary incontinence. The incidence of post prostatectomy incontinence (PPI) depends on the definition of urinary incontinence and the length of follow-up. [60-62] In addition to numerous definitions of incontinence, the tools used to evaluate incontinence vary from self-administered validated and non-validated questionnaires, to interviews from a data manager, to response to the surgeon's inquiry, to insurance data base inquiries regarding secondary surgical procedures. It should be noted that SUI also affects men who have not had surgery for prostate cancer, occurring at a baseline prevalence of 1.3%-4.8% [63,64]. In addition, men with prostate cancer who choose radiation therapy, androgen ablation, or even watchful waiting also develop urinary incontinence, recently reported at rates of up to 12%, 11%, and 3%, respectively [65,66]. In addition to urinary incontinence, bothersome lower urinary tract symptoms may affect patients following any treatment (or even watchful waiting) for prostate cancer.

Typically, reports of large cohorts use definitions that include “total control/perfect continence/dry”, “occasional leakage but no pad”, and “less than one pad”. Because 1/3 to 1/2 of men who do not wear pads will have occasional leakage of urine [60,67] it is important to distinguish among those men who leak enough to require pad use versus those who do not, as it has been demonstrated that health related quality of life (QOL) is strongly correlated with the level of incontinence. Wearing one pad, even if this pad is considered “a security pad”, more significantly affects the quality of life than wearing no pad at all [68,69]. In addition, not all men who leak will elect to have further treatment. Most large cohort studies indicate that between 6% and 9% of patients undergo subsequent surgical treatment for PPI following prostate cancer surgery. [70-73] Several large cohort studies are listed in Table 3 [62,67,69,74-92].

Another bothersome type of incontinence occurring during orgasm in men post-prostatectomy has been termed 'climacturia' and may significantly affect the quality of men with post-prostatectomy potency [93].

### Table 2: Evaluation prior to surgical therapy

- History
- Physical examination
- Urinalysis
- Urine culture
- Post-void residual (by ultrasound)
- Voiding diary (2-7 days)
  o polyuria without diuretics: BUN, Creatinine, Glucose
- Pad-test
- Cystourethroscopy
- Urodynamics:
  - Multichannel urodynamics:
    - to characterize the incontinence and to detect detrusor overactivity, decreased compliance, and/or outflow obstruction

2. RISK FACTORS

Reported risk factors for incontinence following radical prostatectomy include patient age at surgery, socio-economic status, preoperative continence status, obesity, pre-surgical bladder dysfunction, stage of disease, surgical technique (including nerve sparing, bladder neck preservation, and posterior reconstruction of Denonvilliers' musculofascial plate, anterior periurethral suspension sutures [94,95], prior radiation therapy, preoperative length and intraoperative preservation of the membranous urethra, prior transurethral resection of the prostate (TURP), postoperative radiation or cryotherapy, and vascular comorbidities. However, various studies have come to conflicting conclusions regarding the importance of specific risk factors. Predisposing factors contributing to incontinence after TURP have been less clearly defined, probably because the incidence is so low, (and the plethora of minimally invasive therapies is reducing the popularity of TURP surgery), making the accumulation of large prospective series of this type of incontinence difficult. However, previous external beam radiation and prior brachytherapy does predispose to post-TURP incontinence (Section VII in this chapter).

Pre-operative urinary incontinence has been reported as a risk factor for post-operative SUI. While preoperative lower urinary tract symptoms, including
Table 3: Continence rates after radical prostatectomy according definition of continence,
Definition 1: total control without any pad or leakage,
Definition 2: no pad use but loses a few drops of urine,
Definition 3: use no or one pad per day.

RRP: radical retropubic prostatectomy; RPP: radical perineal prostatectomy; LRP: Laparoscopic radical prostatectomy; Rx: radiotherapy; RALP: robotic assisted laparoscopic prostatectomy
urgency incontinence and "overflow incontinence" may improve with de-obstruction secondary to ex- tirpative surgery [96], pre-operative SUI does not improve following RP. Several recent cohort studies have demonstrated that pre-operative sphincteric insufficiency (demonstrated either the pre-existing clinical sign of SUI or the urodynamic finding of lower maximal urethral closure pressure) predicts post-operative SUI. [97,98] Pre-operative bladder dysfunction can also contribute to post-operative incontinence. Pre-existing abnormalities of detrusor function may predispose to leakage following surgery, especially in the setting of neurogenic detrusor overactivity due to Parkinson’s disease, dementia or spinal cord injury. [99]

Advancing age as a risk factor is supported by several studies [73,96,100-106]. Steiner, et al found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older [107]. Others have found advancing age and the number of co-morbidities to have a negative impact on the recovering time for continence during the first year after radical prostatectomy [108] although the rate at one and two years did not seem to be significantly affected [109]. Mohamad and colleagues reviewed 16,524 patients who underwent RRP in public hospitals, covering 95% of all procedures in Austria between 1992 and 2003. They found that increasing age was associated with an increased risk of future AUS implantation. In those aged 45-49, 0.5% were bothered enough by PPI to merit AUS placement, while those age 70-74 were five times as likely to undergo AUS placement for PPI.[110] Similarly, Rogers et al. demonstrated that age affected post-operative continence status following laparoscopic RRP. In those < 50 years old, 100% achieved 0-1 pad per day continence at 1 year, which decreased to 91% and 81% for those age 50-59 and > 60 yrs, respectivly (p<0.01). [111] Nilsson et al. [112] reported that age at surgery predicted in an exponenţial manner the long-term risk for urinary incontinence, with an estimated relative increase of 6% per year.

In addition to age, overall well-being has also been related to the risk of PPI. For example, a recent study out of Italy demonstrated that both age and Charlson comorbidity index were independent predictors of return to urinary continence [105]. It is especially interesting to note that in this particular cohort study, there were no variables related to the prostate cancer itself that were significantly corre-lated with urinary continence. A large study from Sweden recently demonstrated that in addition to age as a risk factor (relative risk of 2.4 between the oldest and youngest quartiles), educational level also impacted incontinence, with low educational level, as compared with high education level, being associated with a 2.5 time risk of incontinence [112].

Obesity, especially when coupled with physical inactivity, appears to be a risk factor for PPI in men undergoing RRP. Obesity with a BMI >30 was reported as a risk factor with an incontinence rate of 25.8% versus 8.7% in BMI <30 in a series of 252 men after RRP [113].

Wolin, et al. demonstrated that greater than one year after surgery, obese men were markedly more likely to have urinary incontinence (defined as any pad use) than were non obese men, while this risk was exacerbated by sedentary lifestyle, and amelio-rated by at least 1 hour of physical activity per day (preoperatively). Nonobese active men were 26% less likely to have urinary incontinence than obese inactive men. In obese men who were physically active, the relative risk of urinary incontinence was 15% less than in the inactive obese men [114].

Most large series have found no correlation be-tween the stage of disease and incontinence rates [101,102,115-117] Loeb and colleagues specifically demonstrated excellent continence rates even in high risk (high local stage) patients. [118] However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing) and inconti-nence rates may be higher, but this appears to be a reflection on surgical technique and not disease stage [103]. Yang et al reported that neoadjuvant hormonal ablation was associated with a lower risk of urinary incontinence, and while patients with higher stage disease may have been more likely to receive hormonal ablation pre-operatively, it is not clear that stage of disease was an important risk factor [106].

Regarding surgical technique, the many parameters involved in continence may explain difficulties in understanding the benefit of certain technical points. Bladder neck preservation has been reported to improve continence at 1 month [119] and at 3 months [116] but no difference was found at 6 and 12 months [120,121]. Nerve sparing has no significant impact according to Steiner et al. [107] and Lepor and Kaci [76]. Recently Pick et al. reported that nerve sparing, whether unilateral or bilateral, did not affect continence rates following RALP [122]. Others did find benefit [97]. In particular, Nandipati and colleagues reported that in a cohort of 152 patients followed prospectively, bilateral nerve sparing surgery was associated with a shorter time to regain continence as well as improved long-term continence rates com-pared to non-nerve sparing surgery. They additionally found that increased age was a risk factor for post-prostatectomy incontinence [123]. Burkhard, et al. similarly demonstrated a positive effect of nerve-sparing surgery on post-operative continence. In a prospective cohort study of 536 patients, PPI developed in 1/75 (1.3%), 11/322 (3.4%), and 19/139 (13.7%) with attempted bilateral, attempted unilateral and without attempted nerve sparing, respectively. Attempted nerve sparing was in fact the only statisti-cally significant factor influencing urinary continence after RRP in this cohort [124]. Two recent reports have linked pre-operative sexual function with post-operative continence. While those who are sexually active pre-operatively may be more likely to have
their cavernosal nerves spared during surgery, it appears that the pre-operative status has a significant effect on post-operative continence rather than the nerve sparing technique [119,122,125].

Within the last decade, laparoscopic and robotic-assisted laparoscopic radical prostatectomy have become standard treatments for men with prostate cancer. Over the past 4 years, the body of available data on post-operative continence has generally demonstrated no obvious differences in continence rates between open and laparoscopic/robotic approaches. Several studies have compared the techniques either prospectively in non-randomized fashion, [85,86,88-91,126,127] or via limited meta-analysis [84,128] and similar continence rates were found. Further prospective comparative studies with open surgery are needed. Currently, a multicenter prospective comparative study of robot assisted laparoscopic and retropubic open radical prostatectomy is underway, with an accrual goal of 2100 patient, with the primary objective of comparing rates of urinary incontinence at 1 year post-operatively [126].

Perineal prostatectomy is done by only a limited number of urologists but is still advocated for markedly obese patients and the continence rate was reported as similar to the retropubic route [79,90,129,130].

3. PATHOPHYSIOLOGY

Post-prostatectomy incontinence, like any urinary incontinence, may be caused by bladder dysfunction, sphincter dysfunction or a combination of both. Urodynamic investigations are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be associated [129,131]. Urodynamics demonstrated that the sphincter incompetence occurs as the sole cause in more than two thirds of patients, while isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% [132-135].

Sphincter and bladder dysfunction can coexist in at least one third of continent patients. Bladder dysfunction may occur de novo after prostatectomy perhaps induced by bladder denervation; may be caused by outlet obstruction, or may be related to pre-existing factors such as age. Impaired detrusor contractility, which occurs in 29% - 61% of patients (de novo in approximately 47%), and poor compliance, which occurs in 8%-39% of patients (de novo in approximately half), have traditionally been thought to resolve in the majority of patients within 8 months [135,136]. However, two recent prospective urodynamic studies have demonstrated that decreased bladder compliance can occur in up to one-third of patients following RP, and persist in 28% at 36 months, while detrusor underactivity can occur in half of the patients, and persist in 25% at 36 months [136,137]. Decreased sphincter resistance may be due to tissue scarring in some cases and reflected by a low urethral compliance, however this parameter is difficult to measure [132]. Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography, and is clinically suspected when both incontinence and decreased force of stream coexist.

The pre-operative length of the membranous urethra determined on MRI has been shown to be significantly related to time to post-operative continence. When urethral length was greater than 12 mm, 89% of the patients were continent at one year, versus 77% with or less than this length [138]. Urodynamic studies revealed that a reduced functional urethral length was a predictive parameter of incontinence [97,139,140]. A recent elegant study of intraoperative stretched urethral length (from the urogenital diaphragm to the prostatic apex with cephalad retraction) and cut urethral length (length of preserved urethral stump) during RALP revealed that although in this cohort, MRI urethral length did not correlate well with continence, the intraoperative measurements correlated significantly with time to continence [141]. Different components of the urethra may also be involved. The urethral intrinsic component responsible for passive continence as well as the extrinsic component responsible for active continence may be involved as has been demonstrated in a urodynamic alpha blockade test [142]. This may explain passive incontinence despite a high voluntary urethral pressure or that measured during an active squeeze by the patient. Post-operative disruption of the innervation of the posterior urethra may also be involved and can affect both motor and sensory functions [143,144]. In clinical practice, urodynamic evaluation of a urethral weakness may be assessed by resistance to antegrade leakage (ALPP or VLPP), retrograde leakage, or profilometric measurement (MUCP) [145]. However no such parameters have been correlated to outcomes of treatments for the correction of post-prostatectomy incontinence.

The state of a patient's pelvic floor may also influence continence or return to continence after RP. Physiotherapy and pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the post-operative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal [146,147]. Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. Another study showed that providing patients with instructions for pelvic floor muscle exercise alone was equivalent to biofeedback or electrical stimulation [148]. A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months [149]. On the other hand, a recent trial from Brazil did demonstrate significant difference in 12-month continence rates, quality of life, and lower urinary tract symptoms in general when randomizing patients to biofeedback-
pelvic floor muscle training versus verbal instructions alone [150]. Studies in which physiotherapy was used as a treatment modality for established incontinence have shown more variable results [151-154]. A recent randomized trial of formal one-to-one pelvic-floor muscle training versus advice alone for incontinent men 6 weeks after RP failed to demonstrate any difference in continence rates at 12 months. Nor did the physiotherapy improve SUI after TURP [155].

No medical treatment is available to cure post-prostatectomy incontinence. Duloxetine at 60 mg per day could improve mild or moderate incontinence but half of the patients had some side effects and 25% stopped the treatment because of adverse effects in two short non-randomized series. This treatment is not approved in many countries and could be only a treatment option to improve symptoms in selected patients informed of side effects [156].

4. SURGICAL AND MINIMALLY INVASIVE TREATMENTS

a) Urethral Bulking Agents

Urethral bulking is a minimally invasive treatment proposed for post prostatectomy incontinence, and theoretically works by adding bulk and increasing coaptation at the level of the bladder neck and distal sphincter. It can be done in an office or outpatient setting in a retrograde or antegrade fashion. Several different agents have been used for urethral bulking in men including bovine collagen (Contigen®), silicone macroparticles (Macroplastique®), ethylene vinyl alcohol copolymer (Tegress®), Dextranomer hyaluronic acid (Deflux®), and carbon-coated zirconium beads (Durasphere®). All agents share the similar problems including the need for multiple injections, deterioration of effect over time, and very low cure rates.

For collagen, “success rates” for post-prostatectomy incontinence ranged from 36-69%, with 4-20% of patients reporting being dry [157-164]. Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections were required to achieve modest rates of subjective improvement. There was no advantage of delivery technique (retrograde vs. antegrade). Several authors identified factors which negatively affect results include extensive scarring or stricture formation, previous radiation, and high grade stress incontinence and low ALPP [158,160,161,164]. One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to radical prostatectomy (35.2% ‘social continence’ versus 62.5%) [161]. It appears that collagen injection did not adversely affect outcomes of artificial sphincter implantation and did not increase the complication rate [165]. Nor did collagen injection adversely affect the outcome of the bone-anchored male sling (BAMS). [166,167] The cost efficacy of injections remains to be determined. Collagen is no longer available as an injectable agent.

Other bulking agents such as polydimethylsiloxane (Macrophlastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months respectively [168]. They also noted that a urethral closure pressure of at least 30 cmH2O was essential for success. Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving short-term continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively. Follow-up, however, was limited to 3 months.[169] In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the majority had SUI following BPH surgery, with more than 1/3 of the cohort suffering from SUI following RRP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. [52]

With regard to the newer (not FDA approved for male SUI) injectable bulking agents, dextranomer hyaluronic acid has been reported in men with PPI and in men with neurogenic ISD. Four of four patients with PPI failed to improve, and 1 of 2 neurogenic patients (both with detrusor areflexia, wet between catheterizations) failed [170]. With ethylene vinyl alcohol copolymer (Tegress®) in a report by Hurtado et al., not only was the failure rate high, but also the complication rate was unacceptable. In 17 men, who averaged 1.4 injection sessions followed at a mean of 4 months, 10 had complications, with erosion of injected material in 41.1%, and with only a minority of patients achieving a 50% decrease in leakage [171]. Tegress® has been withdrawn. Carbon-coated zirconium beads have been similarly reported to be inefficacious, with a recent report of 8 men with mild to moderate incontinence receiving a relatively large average injected volume (23.8 ml), none of whom achieved subjective or objective cure [172].

There has been interest in the use of autologous muscle cells, stem cells, and fibroblasts as an injectable sphincter-restorative agent for PPI. Transurethral injection of living muscle stem cells to reconstitute the deficient urethral sphincter has been reported. Mitterberger and colleagues demonstrated a 67% continence rate at an average of 1 year follow-up in a cohort of men suffering from PPI who were treated with transurethral ultrasound.
guided injections of autologous fibroblasts and myoblasts obtained from skeletal muscle biopsies. 173 An earlier report from the same group demonstrated that men with PPI achieved a 52% dry rate with injection of adult autologous stem cells, which was superior to a similar cohort of men treated with collagen injection.174 However, it must be pointed out that there was a retraction issued by the editors of The Lancet175 for a previous article on the treatment of female SUI with autologous cells published by the same group176. The project was investigated by the AGES PharmMed, a department of the Austrian Government’s Agency for Health and Food Safety. The editors stated that in their view “the conclusions of the official investigation pinpoint so many irregularities in the conduct of their work that, taken together, the paper should be retracted from the published record.” Current research has focused on the relatively abundant adipose derived stem cells, which are believed to be easier to harvest (higher yield) than are autologous bone-marrow derived stem cells [177].

Conclusion: Bulking agents remain the most minimally invasive treatment for post RP incontinence after conservative measures. All agents for which there is peer-reviewed data available, show only modest success rates with very low cure rates. Effects tend to deteriorate over time. It remains to be seen if improvements in outcomes can be achieved with alternative agents, or if the concept of urethral bulking has achieved its maximal benefit with the agents available now. (Level of evidence 3; Grade of recommendation C)

b) Male Sling

The male sling procedure is based upon the concept of urethral support and external urethral compression, and has established itself as an accepted and efficacious treatment for PPI. The male sling is actually based on the concept similar to that described by Kaufman and associates in the early 1970’s [178-180]. At that time a high rate of failure, septic complications and pelvic pain as well as the advent of the mechanical artificial urinary sphincter (AUS) led to the abandonment of the Kaufman prosthesis. Now with the higher prevalence of PPI and patient desire for less invasive surgery and a non-mechanical device the concept has been revisited. Procedures have been developed based on principles used to treat female stress urinary incontinence. These procedures rely on compression from the ventral side of the urethra rather than the circular compression caused by a natural or artificial sphincter. Therefore, most successful sling surgeries rely on a device that is placed under tension, occluding the urethra at rest, and during stress manoeuvres.[181-183]

Schaeffer and Stamey described the bulbourethral sling which uses Dacron bolsters placed under the urethra, which are suspended to the anterior rectus fascia by sutures [184]. Data on this procedure are limited to retrospective analyses from the two authors who described the procedure: it did not gain widespread popularity. In the initial report from 2 centers, 64 patients were included and 56% were “dry” and 8% “improved” at a mean follow up of 22.4 months [184]. Almost one-third needed secondary retightening procedures and patients with radiation fared poorly. Subsequently, Clemens, et al reported a questionnaire-based study of 66 men from a single institution and 41% were cured and 51% improved but mean follow up was only 9.6 months [185]. They also reported that the bulbourethral sling did not cause significant outlet obstruction [186].

The long-term efficacy of the bulbourethral sling was evaluated in 2005, where 95 patients were followed retrospectively at an average of 4 years post-operatively. With follow-up questionnaires returned by 71 patients, the authors found that patients who had undergone radiation, had worse outcomes with only 14% dry and 43% requiring 1 or 2 or fewer pads daily. Moderate to severe pain was reported by 12% of patients after 4 years. Patients who had not had radiation treatment had a cure rate of 42% and 72% used only 0-2 pads per day for mild leakage.[187] Others have described a bulbourethral sling using a polypropylene mesh graft with or without a porcine dermis backing (presumably to reduce the risk of erosion) [53]. In two small studies of 9188 and 1653 patients cure rates range from 56-69% and failure rates from 22-25% at a mean follow up of 14 months. John described the bulbourethral composite suspension where porcine dermis is secured to the bulbospongious muscle and a 1 cm wide polypropylene sling is placed over this and passed through the retropubic space to emerge from two suprapubic incisions (similar to the tension free vaginal tape procedure in women) [53]. He reported a 69% cure and additional 6% improvement in 19 patients, with a mean follow up of 14 months. Eight intraoperative bladder perforations healed without complication.

Xu and colleagues described a bulbourethral composite suspension utilizing a suburethral polyester patch plus a narrow polypropylene tape passed from a perineal incision to a suprapubic incision. At an average of 28 months, 22 (85%) of 26 patients were successfully treated. [189]

A common method of sling fixation involved use of bone anchors. The bone anchored male sling (BAMS) obviated the need for any suprapubic incision for suture passage and fixation. In 2001, Madjar, et al reported on 14 patients with post RP incontinence that underwent the procedure with a synthetic or cadaveric fascial sling 190. At a mean follow up of 12.2 months, 86% were “cured” wearing none or 1 pad. Comiter reported a 76% cure and 14% “substantially improved” rate in 21
men with post prostatectomy incontinence using polypropylene mesh with a mean follow up of 12 months 166. In a 2005 update, the same author reported that with a median of 48 months follow-up, 65% of patients remained pad free and 15% required 1 pad per day. 191 Urodynamic follow up in 22 men, revealed that the sling had no substantial effects on voiding function and no one was obstructed postoperatively [192]. Onur and colleagues reported on 46 men with a mean follow-up of 17 months (6-26) [193]. They used different materials for the sling (allograft dermis, allograft fascia lata, porcine small intestine submucosal (SIS) graft, synthetic mesh, and a composite of synthetic and dermis). Overall they reported 41% of patients dry and 35% improved (50% reduction in the number of pads). All patients in whom allograft or xenograft alone was used failed. A 24-month update revealed a patient satisfaction rate of 70% and a 74% improvement in leakage at a median of 24 months.194 Giberti et al195 reported that in 36 men followed for an average of 41 months, 62% were cured and 70% were satisfactorily improved. In the subset who had a synthetic sling implanted, a higher success rate was experienced, with 77% achieving cure. Complications included sling infection in 4.8%, and de novo detrusor overactivity in 7.1%. Carmel et al196 reported that at an average follow up of 36 months, in a cohort of 45 men with moderate to severe PPI, 78% were improved by pad use, 76% had dry ICS 1-hour pad tests, and 72% were satisfied or very satisfied. Infection occurred in 1 patient, and pain resolved in all patients by 12 weeks postoperatively.

However, the morbidity (infection, pubic bone osteitis, perineal pain) related to bone screws coupled with the emergence of effective alternatives has decreased the popularity of the InVance sling.

The transobturator (TO) male sling technique was introduced in 2004 [197] and has since become the most common type implanted for PPI, since the early reports of 2007, [49,197,198]. This approach relies more on rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than on direct compression of the urethral lumen.[199] Over the past few years, there have been several large case series reporting favorable outcomes. Cornu et al [200] followed 136 men with mild to moderate (< 5 pads per day) PPI for an average of 21 months following implantation of the TO sling. A 78% success rate (based on pad test) was achieved. Rehder et al201 reported their cohort of 118 men with mild to moderate SUI, with a 1-year success rate of 91% at 12 months. Bauer et al202 achieved a success rate of 76%, at a median of 27 months follow-up in 137 men with PPI. In contrast, Gill et al203 reported a subjective success rate of only 51% (PGI-I scale) and objective success rate of 60% (pad use) at a mean follow up of 9 months, and Cornel et al204 reported only 9% of men achieving total dryness at 1 year post-operatively, with a 46% improvement rate.

Membranous rather than bulbular placement of the sling was introduced with the Advance sling with the aim of relocating the urethra in a more proximal direction. However, the concept is controversial as patient anatomy and pathophysiologic modifications are complex. This type of sling surgery close to the membranous urethra requires a deeper dissection compared to bulbar or perineal compression slings.

The I-Stop TOMS sling with four arms and a large surface over the bulbous urethra involves tensioning each corner of the sling. A prospective multicenter study [205] was recently published with 122 patients after minimum follow-up of 12 months for 84% of them, and showed a cure rate of 60% and improvement with only one pad per day in 20%. There were no erosions or acute urinary retention. Wound infection was reported in 2% and all resolved. An “inside-out” TO sling also positioned over the bulbous urethra206 was implanted in 173 men, of whom 49% were cured and an additional 35% improved at a median follow-up of 24 months [207].

In case of failure after sling surgery, no clear guidelines exist. Surgical options include repeat sling and balloon or artificial sphincter implant. More studies are needed to document results and predictive factors. With respect to “repeat” TO sling following previous sling failure, Soljanik et al208 reported a cohort of 35 men undergoing a second TO sling. Success rate at 6 months was 79% (46% dry, 33% improved), and was maintained at 76% at an average of 16.6 months, demonstrating that the TO sling may be an effective treatment for managing SUI after a prior failed sling surgery.

Two adjustable retropubic slings have been introduced, with the objective of overcoming potential problems of overcorrection or under correction of continence - the “Argus” [209] and the REMEEX210 slings. In a multicenter trial of the Argus sling in 48 patients211, a 73% continence rate and additional 10% improvement rate was reported after an average of 7.5 months. Erosion and infection necessitated sling removal in 10% of patients. Adjustments were indicated for persistent incontinence as well as for urinary retention [211]. In an update reported of 47 patients after a mean follow up of 45 months, 66% were dry and 79% used < 1 pad per day [212]. Hubner’s group [213] reported similarly favorable results, with 79% of 101 men achieving dryness at an average of 2.2 years post-operatively. Thirty-nine per cent required adjustment (10% loosening, 29% tightening) at a mean of 104 days after surgery. Erosion or infection necessitated explantation in 16% at a mean of 1 year. A report from the Netherlands [214] revealed a 72% success rate for the Argus at a median follow up of 27 months. Outcome was
dependent on the degree of pre-operative incontinence, with surgical success in 92% of men with mild leakage (1-2 pads per day), 67% in men with moderate leakage (3-5 pads per day) and 67% in those with severe (> 5 pads per day) incontinence. Explantation was required in 11%, due to infection, erosion, sling rupture or pain. Bladder perforation occurred in 16%, and de novo urethral stricture requiring treatment in 12%. Dalpiaz et al. [215] reported less favorable results, with 79% of 29 patients achieving dryness and 76% satisfaction in the short term, but the dry rate and satisfaction rates deteriorated to 17% and 28% respectively at 35 months. Complications occurred in >80% of cases, with a 35% explanation rate, 14% de novo urgency rate, and a single instance each of urethral stricture and ureteral injury. In a retrospective cohort study of 16 men treated with a MEEX adjustable sling, 51 patients were followed for an average of 32 months (range: 16-50). With 90% of patients requiring at least 2 adjustments, a continence rate of 64.7% was achieved, with an additional 19.6% reporting improvement over baseline [158]. More recent, but smaller studies have also shown promising results. Navalon Verdejo et al. [217] reported that 3 of 5 men were dry at an average of 1.4 months, with the other 2 patients experiencing marked improvement. Four of 5 patients experienced recurrent SUI, which was resolved after surgical re-adjustment via the varitensor. A study with lower success rates was reported from Spain with a cohort of 14 men at an average of 18.6 months postoperatively, 42% are dry and 33% are improved [218]. However, bladder perforation occurred intraoperatively in 29%, sling explantation was required in 21%, urinary retention occurred in 36%, and readjustment was necessary in 83%.

The newest iteration of the male sling is the VIR-TUE® Male Sling (Coloplast, Humlebaek, Denmark) an implantable, sub-urethral, permanent, non-absorbable support sling. The sling is a synthetic suburethral mesh of knitted, monofilament polypropylene that measures 5.5 cm x 7 cm, with superior and inferior extension arms. Quadratic fixation is achieved with both transobturator and suprapubic components [198]. This hybrid sling is based upon the mechanisms of action of the TO sling and the BAMS, providing a broad area of urethral compression and achieving proximal relocation of the membranous urethra. The sling has been shown to increase the retrograde leak pressure in 22 patients from 33.4 to 68.8 cm water after tensioning intraoperatively [36].

Sling results are shown in Table 4 [45,46,53,184,187-195,209-211,219-222].

1. Sling Complications

Due to the small size of most reported cohort series of BAMS patients, the precise complication rate is 221 not known. However, reports from the largest cohorts of patients reveal an infection rate ranging from 0-6%, and a urethral erosion rate of 0-2%. [46,191,221] Both bothersome scrotal pain or numbness affects 16%-72% of patients post-operatively, but has been reported to resolve in nearly all patients by 3 months [191,195]. Postoperative urinary retention was reported in 2-12% of patients. In most cases, it was self-limited and resolved in within 2 weeks [50,194,196,222,223] or rarely required loosening after one month [46].

Infection of the perineal incision/mesh occurred in 3-12%. These infections usually required removal of the implanted sling. Some superficial infections were successfully treated with antibiotics. In men postoperative mesh infections, 76% [19/25] required surgical explantation of sling [50,191,195,221,222,223,224]. The majority of infections occurred early, however late infections at 3 months and 1 year have been reported [50,196].

Urethral erosion is a well-defined complication in the female SUI population. It has not been frequently reported with BAMS, although theoretically it may be associated with infection necessitating sling removal in some patients [46].

Abnormal postoperative pain or paresthesia is thought to be from compression or intraoperative disruption of the perineal nerves, or from healing around the newly placed bone screws. This complication is difficult to characterize because there is no standard level of pain that is considered abnormal. While some series acknowledged that the majority of patients experience mild pain for 1-3 months after surgery [221], others reported only those with severe pain that required explantation of the sling [222]. The pain generally resolves within 3 months [191,193,196,221,223] although persistent pain beyond 3 months has been reported [46,50]. Sling removal has been reported in two patients for persistent pain [46,50].

De novo detrusor overactivity or urinary urgency has been reported at 1-14% of patients, and can be treated with oral anticholinergics when necessary. One patient required sling explantation due to this complication [50].

There is a report of early loosening of one of the bone screws [223]. This caused recurrent incontinence and required a second operation to replace the bone screw. Bone screw dislodgement can happen as a late complication and has been reported in 3 patients [191,225].

</table>
The most common complications reported with the TO sling are perineal pain and urinary retention and studies are needed to establish the best rate between success and side effects among different slings.

Pain beyond the normal perioperative period has been reported to affect 0-20% of patients, and urinary retention has been reported in 3-21% of cases. While incision or explantation for retention is rare, the need for catheterization can persist for up to 12 weeks [200, 201, 226], with rare instances of retention lasting longer than 3 months203. Less commonly experienced is wound infection, with only rare sling infection or erosion requiring explantation [204, 226, 227]. Unlike the BAMS, however, there are occasional instances of worsening incontinence following TO sling placement, which likely occur if the sling is not adequately fixed in position, and allowed to migrate proximally and posterior to the urethra, thereby exerting a pulling tension that opens the dysfunctional urethral sphincter [204, 228].

Reported rates of recurrent incontinence following sling surgery are generally low [46, 191, 194, 208], and it is unclear which patients are amenable to revision surgery. In theory, the adjustable slings are designed to allow increased sling tensioning via a simple adjustment of the tensioning mechanism silicone washer adjustment for the Argus [212], and varitensor adjustment for the REMEEX [229]. But the small sizes of the cohorts, and the limited follow-up of less than 5 years prevent meaningful comparisons of male slings and to the AUS at this time.

Permanent urinary retention is uncommon with male sling surgery, and may be avoided by excluding those patients with detrusor underactivity on preoperative urodynamics. [195, 230, 231]. However, a recent report from Han et al. [232] found no difference in postoperative residual or urinary retention when comparing 2 groups of men after sling surgery, one with preoperative normal contractility and one with impaired contractility.

2. Predictors of Success

Several cohort studies have demonstrated that prior radiation therapy is associated with diminished efficacy of the male sling, probably due to urethral fibrosis and inadequate urethral coaptation. [49, 187, 193, 195, 207, 233-235] Bauer et al [236] recently published their results of a cohort of men undergoing TO sling placement, all of whom had adjuvant radiotherapy following RP. They reported that success was only achieved in 50% of the cohort (cure in 25%), and that only 46% of men reported they were satisfied with the surgical outcome. With respect to the BAMS, Giberti et al. [195] recently reported a markedly lower rate of success in men who had had previous pelvic radiation, with only 15% cure in those patients. The adjustable REMEEX sling also appears to have inferior success in radiated men (60%) compared to patients without radiotherapy (90.2%) [229]. Worsening of incontinence may also occur and patients must be informed of this, especially those with mild incontinence.

The use of organic (resorbable) material is less efficacious than synthetic (permanent) sling material. [193, 195, 221, 237]. The treatment of male SUI with a suburethral sling requires tension that can only be maintained with the use of synthetic material. Pre-treatment severity of incontinence measured by the degree of leakage also appears to influence sling results. Several reports indicate that those with more severe leakage do not achieve similar continence rates when compared to those with milder leakage. [193, 195, 221, 224]. Fischer and colleagues were able to quantify, in prospective fashion, that leakage greater than 423gm on pre-operative pad weight predicted an inferior outcome, compared to those men with less leakage on pre-operative pad weight test. [46] In their report, 62 patients with SUI were followed prospectively. All patients were rigorously evaluated with 24-hour pad test, urodynamics and validated incontinence questionnaires. Success was determined by the Patient Global Impression of Improvement. Overall, 36/62 (58%) of surgeries were successful at a mean follow-up of 15 months. The only preoperative predictive factor was 24-hour pad weight. If pad weight was less than 423 gm, there was a 6-fold greater success rate compared to those with a pre-operative pad weight of greater than 423 gm.

Finally, previous AUS placement and explantation predicts sling failure. [192, 216, 221]. However, it is not clear if this is directly due to the urethral fibrosis and poor urethral coaptability, and/or if those patients simply suffer from more severe incontinence, which interferes with successful sling surgery.

3. Conclusion

In the intermediate term, the male sling appears to perform well. Slings have surpassed the artificial sphincter as the most common surgical treatment for PPI. The European Association of Urology Guidelines has concluded that there is limited short-term evidence that fixed slings cure PPI, that men with severe incontinence, previous radiotherapy or urethral stricture surgery have poor outcomes and no sling is superior to other slings. Adjustable slings have limited evidence of efficacy. [238] However, in the UK, the National Clinical Guidelines Centre in The Management of Lower Urinary Tract Symptoms in Men has stated that implanted compression devices and slings can be
offered to men with SUI only within the context of a randomized clinical trial [239].

The best candidates appear to be those with lower and moderate degrees of incontinence, who have neither had previous radiation nor AUS placement. With non-circumferential urethral compression, the male sling appears to have a lower risk of urethral erosion and atrophy than does the AUS in the intermediate term. In men with mild to moderate degrees of SUI, or for patients demanding less invasive procedure or non-mechanical device, the male sling has established itself as a viable alternative to artificial sphincter. Kumar et al [3] reported that in men with moderate PPI (pad weight 100 to 400 gm/24 hours) who were recommended to receive an AUS or a male sling, 92% opted for the sling. Interestingly, even when the surgeon recommended an AUS for severe leakage (> 400 gm/24 hours), 25% still opted for the sling. While intermediate and long-term data support the BAMS as a durable treatment for PPI, longer term outcomes of the TO sling, pubourethral sling, and quadratic sling are unknown. (Level of evidence 3; Grade of recommendation C)

c) Adjustable Balloons

The adjustable balloon procedure is based upon the concept of passive compression of the urethra utilizing two balloons located on either side of the urethra. Balloons may be progressively inflated until there is optimal coaptation, thereby achieving continence. The biomaterial name ACT™ (Adjustable Continence Therapy) was originally conceived and developed for female stress urinary incontinence, and subsequently was applied to male incontinence. The proACT™ device was developed and reported in 2000 [240].

The device consists of a silicone elastomer balloon attached to an injectable titanium port via a silicone tube. A balloon is implanted on either side of the urethra, either under the bladder neck for post-radical prostatectomy incontinence, or under the veru montanum for post TURP-incontinence. The ports are located subcutaneously in the scrotum, allowing simple access for percutaneous adjustment of the balloon volume. The implantation is performed under general or spinal anesthesia through a short perineal incision. A trocar covered with a U-shaped sheath is inserted up to the site of implantation, and then the balloon is pushed along inside the sheath. Fluoroscopic and urethroscopic guidance are used for the procedure. Transrectal ultrasound guided implantation [241] is a possible option. An isotonic medium with sterile water and contrast medium is prepared to fill the balloons with 2 ml during the initial procedure. Then, after a period of time, approximately one month, the balloons are topped up with 1 ml of this solution at each period (maximum filling is 8 ml) until continence is achieved. The adjustment of the filling are volume limited and are carried out step by step in order to obtain a pseudo-capsule surrounding the balloons and therefore to minimize the risk of urethral erosion or migration. Results from 8 prospective studies [48, 51, 242 - 247] reported are shown in Table 5. Of 170 patients reported by Hubner [242] and Lebret [51], one-third became pad free. In other studies

2. Conclusion

The proACT™ balloon technique appears to be a feasible procedure to improve the continence in short and median term, with better results occurring with more operator experience. Similar to the male sling procedure, appropriate candidates include those with mild to moderate leakage due to intrinsic sphincter deficiency, and no previous radiation. The benefit of an adjustable system should be weighed against the need for multiple sessions of refilling the balloon, and with reported rate of peri-operative and post-operative complications. Longer follow-up is needed before definitive comparison to male sling or artificial sphincter can be made. No recommendation is possible due to variable data on complication rates (12-58%). (Level of evidence 3, Grade of recommendation D).

d) Artificial Urinary Sphincter

The artificial urinary sphincter remains the most effective long-term surgical treatment for post RP incontinence due to sphincteric insufficiency. However, due to the cost, the perceived cumbersome-ness of the device with resultant patient reluctance to have or inability to use a mechanical implant, and the fear of complications, it is not suitable for all patients. In addition, the development of less invasive techniques (as described above) potentially gives patients new options for treatment. Ultimately the choice of AUS will be based upon patient dexterity, economics, degree of incontinence, previous incontinence surgery, and expectations from surgery. Patient preference was tested in a study by Kumar et al.[3]. Based on the magnitude of their incontinence patients either had an AUS (high grade incontinence) or sling (low grade incontinence) or a choice between the two (moderated grade incontinence) recommended. Outcomes, length of experience and complications were reviewed with the patients. Of interest, all recommended to have a sling chose a sling, 75% recommended to have an AUS had an AUS while of those given a choice 92% chose a sling. This sheds some light on patient preferences in this area.

The AUS has the longest track record of success in the treatment of PPI. Two older studies have reported that about half of the patients with severe incontinence will undergo AUS implantation [249,250]. However, these studies were conducted before male slings and bulking agents became popular, and sling surgery has since surpassed the AUS in number of procedures performed annually. To this end, it is likely that the advent of the male slings has increased the rate of surgery in men with milder incontinence who may not otherwise have opted for an artificially sphincter. The success rates for AUS as defined by a continence status of zero to one pad per day range from 59% to 90% [251, 252], as shown in Table 6 [56, 251, 253 - 262]. Just as with
reported rates of incontinence following prostate cancer surgery depend on the definition of incontinence, continence rates with the AUS can vary with the definition of continence, the method of evaluation, and the length of follow-up. The lowest rates are from patient administered questionnaires when pad free rates range from 10-72% [254, 263 - 267]. Nevertheless, high satisfaction rates of 87% to 90% are consistently reported, even without total continence [255, 259, 263].

One potential downside of the AUS is the need for periodic revisions in a number of patients. Revision and explantation rates due to mechanical failure, urethral atrophy, infection and erosion vary considerably among studies with respectively reports of 8-45% and 7-17% [267]. In a large cohort reported by Lai and colleagues [262], non-mechanical failure has decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff and mean time to reoperation was 26.2 months (mean 2-68 months). With a Kaplan-Meier analysis, the overall 5-year expected product survival was 75%. Only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years. Actuarial freedom from revision at 5 years was estimated at 50%-75%. Interestingly, there do not appear to be any urodynamic factors that predict AUS failure in men with ISD. Whereas the male sling has been shown to have inferior success rates in patients with severe leakage, the AUS has been reported to have predictable success regardless of the degree of incontinence and regardless of detrusor underactivity, detrusor overactivity, low abdominal leak point pressure, or diminished compliance [58]. And while the success of the AUS in treating incontinence is not adversely affected by preoperative detrusor overactivity, the rate of persistent overactive bladder symptoms may be high (71%), and patients must be counselled accordingly [268].

The long term efficacy of the AUS was demonstrated by Fulford et al who reported that at 10-15 year followup, 269 75% of patients with an implanted AUS either still had or died with a functioning device. Revisions include replacement of the malfunctioning part, cuff replacement, repositioning or downsizing due to urethral atrophy, a second or tandem cuff [270,271] or transcorporal cuff placement [272]. Transcorporal cuff placement, which involves inserting the cuff through the corporal bodies to avoid perforating the dorsal aspect of the urethra, can be particularly useful for patients with prior radiation or urethral erosion; however potency if present may be compromised. Some have advocated tandem cuffs not only as a salvage procedure, but also as a primary procedure for men with severe incontinence [273, 274]. However, O’Connor et al. reported no difference in continence outcome and a higher revision rate in patients undergoing double-cuff implant versus single-cuff after longer follow up [275].

An increased revision rate has been reported for patients who received pelvic radiation [254,27] but was not found in a recent series [252]. The results for continence for radiated patients are variable with some studies showing lower success rates [251,276] while others do not [266]. It has been recommended that such patients have a lower pressure reservoir and/or longer period of deactivation time [254].

**CONCLUSION**

The AUS remains the gold standard for the treatment of PPI secondary to sphincteric insufficiency in patients with severe incontinence, in those who...
have had external beam radiation treatment and in those who have had prior AUS placement. It has the largest body of literature reporting long-term success. The long term success rates and high patient satisfaction seem to outweigh the need for periodic revisions in some patients. Intermediate term data with the male sling demonstrates that the sling is an alternative to the AUS in patients with mild-moderate SUI, provided that those patients have not failed previous AUS surgery, have not had radiation treatment, and have normal bladder contractility. Overall, the AUS remains the reference standard to which all other treatments must be compared. (Level of evidence 2; Grade of recommendation B)

5. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of PPI, either with benign or malignant disease. Therefore, at present guidelines as to timing of the surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. Observational studies of men following prostate cancer surgery typically demonstrate improvement in continence from the early post-operative period until the end of the first year [114]. In addition, it is common for clinical trials of nonoperative management to follow patients for up to 12 months post-operatively, usually with improvement in both the intervention and the control groups during that year of follow up [150].

In a prospective cohort study of men undergoing RRP, Lepor and Kaci [76] demonstrated continued recovery of continence up to 24 months post-operatively, from 80.6% at 3 months to 95.2% at 12 months, reaching a plateau at 98.5% at 24 months. Other cohort studies have demonstrated a plateau in continence rates at 12 months [277, 278]. Since continence may improve up to 12 months post-operatively, and possibly even until 24 months, it is generally recommended that behavioral/conservative management be utilized during the first year after prostate cancer surgery.

There have been some studies evaluating the effect of early interventional treatment for incontinence. Schneider and colleagues [279] demonstrated a beneficial effect on the earlier return to continence with early injection of periurethral bulking agent. Results were better in the subgroup of 34 patients that were injected early (mean 23 days post-operatively) compared to 10 patients treated at a mean of 26 months post-operatively. It could not be demonstrated, however, that long-term continence is improved by early injection of bulking agent. Similarly, Jones and colleagues [280] demonstrated in a comparative cohort study of RRP patients treated either with or without a simultaneous suburethral sling, that sling placement at the time of RRP resulted in an earlier return to continence. There was no difference after 24 months.

(Level of evidence 3-4; Grade of recommendation C)

IV. INCONTINENCE AFTER PROSTATECTOMY FOR BENIGN DISEASE

1. INCIDENCE AND RISK FACTORS

The incidence of urinary incontinence after prostatectomy for benign disease has been reviewed and described in the AHCPR “Benign Prostatic Hyperplasia” Clinical Practice Guidelines [281]. The following percentages for stress incontinence and total incontinence, respectively, were reported:

- Open surgery (retropubic or transvesical prostatectomy): 1.9% and 0.5%.
- TUIP (transurethral incision of the prostate): 1.8% and 0.1%.
- TURP (transurethral resection of the prostate): 2.2% and 1.0%.

These figures were based on studies reported before 1990. Several other series were published after 1990. These series were reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [4, 282, 283]. A clear description of the method of follow-up and assessment of the continence status was indicated in only about one third of these studies. The incidence of incontinence after open surgery, TURP, TUIP and HoLEP is low: the reported percentages ranged between 0 and 8.4%. Since the method of assessment of the continence status and the definition of incontinence is rarely stated in these studies, it is actually not possible to make a distinction between simple stress incontinence and total incontinence. There is generally no clear indication that the incidence is affected by patient age or (resected) prostatic volume. [282] However, a recent study out of Brazil did demonstrate that the rate of urinary incontinence following BPH surgery is higher in older patients. However, most of the increased incidence in incontinence was due to bladder dysfunction rather than to sphincter insufficiency. In a retrospective chart review from Wendt-Nordahl and colleagues [284], the incidence of incontinence following TURP was reported to have decrease over 17 years, from 3.3% in 399 patients operated on between 1987 and 1997, compared to 1.3% in 550 patients operated on from 1997-2004. It is not clear whether this statistically significant (p< 0.05) difference was due to improvement in surgical technique or patient characteristics. However both the earlier and later incontinence rates are consistent with those in the AHCPR and AUA guidelines reports.
In 2003, the AUA published guidelines for the management of “benign prostatic hyperplasia” [285]. The estimated frequency of incontinence following TURP was 3% (from 19 trials that included > 5000 patients). However, the Veterans Affairs Cooperative Study, reported an incontinence rate of only 1% in TURP patients, which was not different from the watchful waiting arm [286]. The AUA conducted meta-analysis of RCTs comparing TURP with TUIP or transurethral electroderevaporization did not reveal any statistically significant differences in incontinence rates. [285, 287-291] The 2010 AUA updated guideline provided no additional information [292].

Over the past decade, transurethral holmium laser enucleation of the prostate (HoLEP) has become a standard treatment for BPO. Review of RCTs by the AUA as well as a meta-analysis of RCTs comparing TURP with HoLEP did not reveal any significant differences in incontinence rates [285,291,293-299]. While incontinence did not increase with age in men undergoing HOLEP with morcelation, it was noted that the overall complication rate - including bladder mucosal injury, urethral stricture disease, and bladder neck stenosis = was higher in patients with prostate volumes > 50 g [300]. Moreover, it does not appear that either bipolar resection of the prostate or photovaporization of the prostate are associated with a substantially different rate of urinary incontinence than are other BPO surgeries [301]. While incontinence following PVP is comparable to that of other BPO surgeries, and more often than not improves over 12-36 months postoperatively with conservative management, the rate of post-operative dysuria is higher than that of TURP, recently reported at a rate of 10.1% [302].

In summary, the incidence of urinary incontinence after open surgery, transurethral resection of the prostate, transurethral incision of the prostate, and holmium laser enucleation of the prostate is low, and does not differ appreciably among the various techniques.

2. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of incontinence, as mentioned above in the section on post-radical prostatectomy. Therefore, at present guidelines as to the timing of surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. (Level of evidence 3-4; Grade of recommendation C)

3. SURGICAL TREATMENT OPTIONS

a) Artificial Sphincter

The literature on this subject was reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [4, 282, 283]. Candidates for treatment with the artificial urinary sphincter (AUS) are patients with incontinence due to intrinsic sphincter deficiency that have normal bladder compliance [303]. Detrusor overactivity is not a contraindication [268]. The AUS has been placed around the bulbar urethra via a perineal route or transverse scrotal routes [304] or around the bladder neck [4, 282, 283]. The above mentioned review of the results obtained with the AUS indicated that more than 70% of the men treated with the AUS for this indication are dry or almost dry after a follow-up of more than 2-3 years. However, most series on the AUS include both post-prostatectomy incontinence for benign and malignant disease [282].

In summary, the AUS is a successful surgical treatment option for post-prostatectomy incontinence. It is the most commonly performed surgery for post-prostatectomy incontinence, with the longest follow-up and therefore longest record of success. (Level of evidence 2; Grade of recommendation B)

b) Injectable Agents

Most series include post-prostatectomy incontinence after treatment for benign and malignant disease, with the majority after prostate cancer surgery. For collagen, "success rates" range from 36-69%, with 4-20% of patients reporting being dry. [157-164] Study results are inconsistent with both TURP [305] and radical prostatectomy [306] showing better outcomes.

Other bulking agents such as polydimethylsiloxane (PDMS (Macroplastique®)) have shown some initial success, but results also deteriorate over time. Bu
gel and co-workers treated 15 patients. They noted rapid deterioration of initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months respectively [168]. As mentioned previously in the section on post-radical prostatectomy incontinence Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively [169]. Follow-up, however, was only 3 months. In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI following BPO surgery, with less than1/3 of the cohort suffering from SUI following RP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. [52] There has also been some initial work with sphincteric injections of muscle stem cells.[173,174]

Bulking therapy fails in up to 75% of men. Of those who are improved only a minority actually becomes
dry with short-term follow-up. Although bulking therapy may be slightly more efficacious in treating SUI following TURP compared to SUI following prostate cancer surgery, bulking is of limited value in those men with all but minimal SUI. (Level of evidence 3; Grade of recommendation C)

c) Male Sling Procedures

Since Frangenheim described his first successful urethral sling suspension for post-traumatic stress urinary incontinence in 1914, various sling materials and surgical methods have been reported [307]. Rectus fascia, as described by Frangenheim, has distinct advantages over alloplastic materials with respect to erosion and infection risks. Allograft off-the-shelf-materials like lyophilized fascia lata have a higher infection risk than does autologous fascia, whereas the use of synthetic materials like polypropylene mesh or polytetrafluoroethylene slings are associated with a higher incidence of urethral erosion [308]. According to various published techniques, the sling can be placed either underneath the bladder neck, the urethral bulb or the membranous portion of the urethra. The principle of continence support is similar for all sling procedures and comprises passive compression of the urethra, which is dependent on the applied sling tension [219]. This mode of action favours sling procedures as a treatment option for intrinsic sphincter deficiency. However, the sling tension needed for restoration of continence has not been standardized, with tensioning techniques ranging from perfusion sphincterometry, to a cough test, to visual approximation, [193, 309] and therefore the success of the procedure probably depends heavily to the surgeon’s experience and the degree of sphincteric incompetence. Overcorrection with consequent urinary retention (especially in the setting of detrusor underactivity) and undercorrection with persistent or recurrent incontinence are certainly possible, which may adversely affect continence, bladder emptying, and patient satisfaction. Most series of sling surgeries deal with a preponderance of men following prostate cancer surgery. Therefore, it is difficult to draw conclusions about any differences in sling efficacy between those with SUI following BPH surgery versus those with SUI following RP due to small numbers of BPH patients most the cohort series.

V. INCONTINENCE AFTER EXTERNAL BEAM RADIOTHERAPY ALONE AND IN COMBINATION WITH SURGERY FOR PROSTATE CANCER

The risk of incontinence after external beam radiotherapy (EBRT) for prostate cancer is variable and ranges from 0 to 18.8%. Lawton et al. [310] reported a risk of urinary complications of 7.7% in more than 100 patients, proportional to dose. Perez et al. [311] found incontinence in only 5 of 738 patients. Shipley et al. [312] reviewed more than 2500 cases with an incontinence rate of 0.5%. Similar incidences have been reported in more recent series. Madalinska et al. [77] reported an incidence of 6-7%. With three-dimensional conformal radiotherapy, Weil and colleagues [313] reported no incontinence in 168 consecutive patients and Hanlon et al. [314], in a series of 195 men, found that post treatment urinary symptoms were no different from a control group without cancer. With conformal radiotherapy, Sandhu et al. [315] reported a 9% incidence of stress incontinence in 110 patients. The impact of EBRT followed by prostatic boost, for a total of 66-70 Gy, was evaluated. Scalliet and co-workers [316] reported urinary incontinence in 16% of 230 patients, however, Fransson and colleagues [317] reported an increase in urinary incontinence on a patient-administered symptom bother scale 3 years after treatment in 153 men compared to pretreatment status. The increase was from a mean of 0, at the start to 2 out of 10 at 3 years. Ponholzer et al. [318] reported incontinence in 18.8% of a group of 82 men who were surveyed 4.4 year after EBRT for prostate cancer. Furthermore urinary incontinence worsened from year 2 to year 6 in a cohort of 147 men treated with 3D conformal RT. [319] Budaus et al. [320] conducted a review of radiation series published from 1999-2010 and concluded that early storage symptoms are commonly reported but long-term incontinence is not.

Pre-radiotherapy transurethral prostatectomy may be a risk factor for incontinence. Jonler et al. [321] reported an incontinence rate of 11% with pretreatment TURP. Green et al. [322] and Lee et al. [323] also reported a higher risk of incontinence with pretreatment TURP versus those without with 5.4% and 2% respectively. There are no series reported on the treatment of patients who only have incontinence after EBRT.

Salvage or adjuvant radiotherapy is frequently given after radical prostatectomy and the impact on continence is controversial. Petrovich et al. [324] reported no difference in incontinence in 2 cohorts of patients, one with and one without adjuvant radiation. In a follow-up study the same group reported no late toxicity. [325] Fontaine et al. also reported no change in continence status in 16 of 17 men after salvage radiation. [326] However, Petroski et al. reported that postoperative radiotherapy worsened continence in 26% of 129 patients followed for a median of 5 years. [327] On the other hand salvage radical prostatectomy following external beam radiotherapy has been generally reported to have a high incidence of urinary incontinence [328-330] possibly because of radiation induced fibrosis of the external sphincter. [329] Cozzarini et al. demonstrated that older age and greater radiation dose in the salvage setting and younger age and hypertension in the adjuvant setting resulted in worse urinary toxicity. [331]
1. SURGICAL TREATMENT

Results of surgical treatment of incontinence in this setting are based on retrospective clinical series. In the past the most commonly published treatment modality was the artificial urinary sphincter as therapy for sphincter damage. As discussed and referenced in the following paragraphs, the series published contain both patients who had and had not received radiotherapy and collagen injections have also been reported in case series.

There has been a higher reported revision rate for the artificial sphincter following radiotherapy (Table 7) [251, 252, 254, 262, 265, 276, 332, 333] compared to low risk patients, 38% versus 22%. Although recent reports dispute the higher rate [252, 262]. However, generally this is due to a higher incidence of erosion and infection as well as urethral atrophy, possibly secondary to radiation induced vasculitic fibrosis of the urethra.254 Radiation may also induce detrusor overactivity or poor compliance leading to urgency incontinence. Recurrence of bladder neck contracture may be more common. [262] Radiation was also identified as a co-morbidity associated with erosion [334] and infection. [335] However, good results are reported, and it is generally recommended that the cuff be inserted outside the radiated field. [336]

Collagen injection has also been reported for incontinence after radical prostatectomy and adjuvant radiation [159,163,305,337-339] or after salvage radical prostatectomy following radiotherapy [166,340] Continence results are poorer compared to those without radiation. [306] Very few patients have been reported on with the use of Macroplastique following radical prostatectomy and adjuvant radiotherapy.

The male perineal bone-anchored sling has been reported in patients following adjuvant RT. In Comiter’s group with the perineal compression sling 3/21 with radiation had no adverse sequelae.166 Similarly in the series of Onur et al. radiation did not cause a worse outcome.[193] However, Schaeffer et al. reported that prior irradiation was the only identified factor that predisposed to failure. Their success rate following a single sling procedure was only 29% (2 of 7) for irradiated patients, and the corresponding rate for nonirradiated patients was 68% (39 of 57). [184] They postulated that the sling acts by compressing and elevating the urethra, thereby increasing urethral resistance to abdominal pressures. Theoretically, radiation-induced fibrosis of the urethral and periurethral tissues would make compression and elevation more difficult by reducing tissue compliance and mobility. As mentioned above, the results of AdVance slings, adjustable slings, and adjustable balloons are adversely affected by radiation.

In summary, despite the frequently reported higher incidence of complications of the artificial sphincter in post-prostatectomy patients after adjuvant radiation, it has provided acceptable treatment benefits. Injectable agents have yielded poor results. Other techniques are adversely affected by radiation. (Level of evidence 3; Grade of recommendation C)

VI. INCONTINENCE AFTER OTHER TREATMENT FOR PROSTATE CANCER AND NEOBLADDER FOR BLADDER CANCER

1. BRACHYTHERAPY

Brachytherapy is a form of radiation therapy in which radioactive materials are placed directly into the prostate gland. The incidence of incontinence following this modality is given in Table 8 [341-353] and was previously related to the treatment of post-brachytherapy retention of urine. Numerous series have reported retention to be associated with larger initial prostate volumes. [354] In a systematic review of brachytherapy series, Crook et al. [350] reported the incidence of retention to be 1-14%. Many patients require prolonged or permanent alpha blocker or TURP. The main risk factor for incontinence after brachytherapy is TURP. Hu and Wallner [347] reported on the incidence of urinary incontinence after TURP/TUIP following prostate brachytherapy for prostate cancer. Of the 10 patients who underwent the outlet relaxing procedures for refractory urinary obstruction, 7 developed some degree of permanent urinary incontinence. They surmised that the cause may be multifactorial and may include physical damage to the urinary sphincters and the radiation dose to the urethral region. Surgical therapy when required has included the artificial sphincter. [348] High dose brachytherapy that is administered over a short period of time may have reduced toxicity. [355] Urethrectal fistula is another complication that has been reported in 1.8% of patients in a large U.S. medicare retrospective review. [348] Salvage brachytherapy leads to a higher rate of urinary tract complications. [330]

2. CRYOSURGICAL ABLATION OF THE PROSTATE

Cryosurgical ablation of the prostate is used for clinically localized prostate cancer either as primary treatment or after unsuccessful external beam radiation therapy. The frequency of the main lower urinary tract complications are listed in Table 9 [356-369]. The artificial sphincter has been mentioned as one of the treatments for incontinence. [367] Cryotherapy is an adverse factor for collagen injections. Urethrectal fistulae can also occur in up to 5% of treated patients. Severe incontinence and fistulae that occasionally results may have to be treated with extirpative surgery and diversion. [370]

3. HIGH-INTENSITY FOCUSED ULTRASOUND (HIFU)

Transrectal high-intensity focused ultrasound is another minimally invasive treatment for prostate

HIFU destroys prostate cells by coagulative necrosis of the tissue without damaging the structures intervening between the transrectal probe and the target tissue [371]. Reports of efficacy also include morbidity. In a systematic review involving 37 articles/abstracts Rebillard et al. [372] reported that stress incontinence occurs in 6-28%, urethra/bladder neck stenosis in 1-31%, and rectourethral fistula in 0-3% of treated patients. With improvements in techniques the risk of complications is decreasing [372]. In a recent systematic review from 2000-2011, Cordeiro et al. noted that the rate of incontinence ranged from <1-34.3% [373].

4. INCONTINENCE AFTER NEOBLADDER CONSTRUCTION

The incidence of incontinence after neobladder construction following radical cystectomy for bladder cancer ranges from 85 to 100% during the day and 55 to 100% at night Table 10 [374-386]. Most patients achieve daytime continence after one year and nighttime continence after 2 years. Most of the published reports do not comment on specific surgical management and imipramine is mentioned as treatment only occasionally. Martins and Boyd [254] reported on 8 patients treated with the AUS for persistent sphincter weakness incontinence. Six of these underwent revisions, 3 for infection and/or erosion and 3 for inadequate cuff compression. They cautioned against the use of the AUS and suggested alternatives such as intermittent catheterization at night. However, O’Connor and colleagues [387] reported a successful outcome, after AUS, with no complications in 5/5 men with incontinence after neobladder, with a mean follow-up of 22 months and Simma-Chiang et al. [388] reported success in 11/12 men 22 months after AUS implant. The bone-anchored sling has been reported for one case [389] and the Advance sling for 2 cases [226] Collagen has only been reported in women following neobladder construction.[390]

In summary there are not enough data upon which to recommend definitive surgical therapy, although the artificial sphincter is reasonable. (Level of evidence 3; Grade of recommendation C-D)

VII. TRAUMATIC INJURIES OF THE URETHRA AND PELVIC FLOOR

Incontinence following posterior urethral injuries occurs in 0-20% of patients [391,392] and is thought to be due to the extent of injury rather than to the method of management.

The data on surgical treatment are all retrospective case series and the most commonly published surgical therapy is the AUS. The series published contain both patients with and without traumatic injuries. Perez and Webster [251] reported on 27 patients after urethral or bladder neck strictures. The revision rate was 41% and the continence rate was 85%. In a subsequent report from this centre on reoperations the patients with traumatic injuries were not discussed separately. [393] In Montague’s series 22 out of 166 patients had incontinence after trauma. He did not separate the results of this group from those of the other patients. Martins and

Bladder neck reconstruction by excising the scar and narrowing the calibre was reported by Iselin and Webster [395] in 6 patients who had incontinence with an open bladder neck on cystourethrography, following urethroplasty for traumatic strictures. Bladder neck closure with a Mitrofanoff catheterizable abdominal stoma has also been reported as treatment following severe urethral or bladder trauma. [396] (Level of evidence 3; Grade of recommendation C)

For patients with severe bladder neck strictures and incontinence after prostate surgery Meulen et al. [397] and the group from Baylor [262, 398] reported on the use of a Urolume stent with a bulbar artificial sphincter. Alternative management with perineal urethroplasty and subsequent artificial sphincter placement in 6 patients was reported by Simonato et al. [399] (Level of evidence 3; Grade of recommendation C)

In summary, the AUS provides a reasonable outcome in appropriate cases. Since there are so few reports of alternative therapies the C recommendations were based primarily on expert opinion as to what is reasonable surgical therapy in very difficult cases.

In exstrophy, the bladder plate at birth is smaller than a normal bladder. It is uncertain whether that which does exist is normal. It has been shown that the muscarinic cholinergic and other neuropeptide receptors in exstrophy detrusor muscle are the same as in controls [400, 401]. Microarray analysis shows that the bladders are developmentally immature [402]. The number of number of myelinated nerve fibers in the detrusor is reduced in new born exstrophy bladders compared to that of neonates who had died from cardiac causes (controls) [403]. It seems probable that the spectrum of neurological and morphological changes seen in exstrophy bladders beyond the neonatal period, are largely secondary to the medical management [404].

Control of the bladder outlet depends on proper function of the pelvic floor musculature and of the urethral sphincters. In exstrophy infants who have not had an osteotomy, the pelvic floor muscles have normal bulk, but abnormal orientation, especially in their relationship to the urethra. They are unable, therefore, to contribute very much to urethral continence [405]. The prostate is a flat plate of normal size, lying behind the urethra. It is not wrapped around the urethra [406]. Growth of the prostate at puberty will not improve continence.

The existence of the urethral sphincters is also uncertain. There is no histological study to show their presence or innervation. However, electromyographic studies of continent children have shown normal electrical traces [407].

Epispadias is a very rare condition. There are very few data on the bladder and sphincters for this diagnosis alone. In general the bladder is of better volume and there may be some active sphincter function in those at the better end of the spectrum.

Storage of urine in children with exstrophy depends on creating sufficient bladder outflow resistance that there is a leak point pressure great enough to stretch up the bladder volume. Voiding depends on the ability, either by detrusor or by abdominal wall contraction, to generate enough pressure to overcome a fixed outlet obstruction.

The pediatric literature often refers to patients with exstrophy having a ‘dry interval’ of so many hours. The implication of this is that the bladder has a fixed capacity beyond which the pressure becomes higher than that of the fixed outflow resistance. Providing the child recognizes this point, a visit to the lavatory will avoid incontinence. Patients in many clinical situations to avoid a ‘social or hygienic problem’ use this technique of timed voiding but it does not constitute continence as would be understood by a ‘normal’ person. It is a means of managing poor bladder control. It is rare to find literature on the long-term follow-up of patients with this complex describing ‘normal’ continence. The evidence base is level 3 at best.

1. EARLY MANAGEMENT OF EXSTROPHY AND EPISPADIAS

The early reconstruction of bladder exstrophy is clearly important but not a subject for this chapter. Only an outline will be considered as a basis for discussing problems of continuing incontinence in adolescence and adulthood. Techniques have gradually evolved over the last 100 years since the first (transiently) successful closure described by Trendelenberg in 1906 [408]. The most important development, at least in Western countries, is the concentration of cases in a small number of centers. In the United Kingdom, for example, it is estimated that 12 babies a year are born with exstrophy and all are cared for in two centers.

Broadly, there are three approaches to early reconstruction —
• Staged repair, originally described by Jeffs [409]. Here the principle is to close the bladder in the first operation. The bladder neck and epispadias repair are then done as a second stage.

• Complete primary repair of bladder exstrophy (CPRE) often attributed to Mitchell [410]. The objective is to close the bladder and bladder neck and to repair the epispadias in one operation. Although more than one operation is often needed, the important principle is to create bladder outflow resistance as early as possible. This should allow proper development of bladder volume and compliance. A subsequent bladder neck reconstruction may be needed in up to 40% of children [411].

• Single stage radical soft tissue mobilization (RSTM), usually called the Kelly operation [412]. The entire anterior pelvic contents with blood and nerve supply are mobilized from the pelvic sidewall, reconstructed and repositioned more posteriorly in the pelvis. There is no osteotomy, but the radical mobilization allows abdominal wall closure without osteotomy.

Each of these is subject to many modifications by different surgeons, which makes comparison of results difficult. Not surprisingly, there are no controlled trials. Outcomes have been described from specialist centers with good results and from generalists with, usually less good results.

At the longest follow-up available, the results of these three approaches are very difficult to determine, at least as far as bladder function is concerned. Data beyond the age of 18 are limited, especially for RSTM. Definitive reports in peer-reviewed journals of long-term outcomes from the centers that specifically champion these techniques are lacking. There are reports from other centers of small numbers of patients, but often without the use of a consistent technique.

Approximate figures are given in Table 11. Sadly, the results in the world at large are much worse. There are also differences in outcomes in relation to the condition of the kidneys, genitalia, cosmetic appearance and sexual function that are beyond the scope of this chapter.

2. LATE BLADDER FUNCTION

If the figures for continence shown in the table are maintained into adult life and ‘partial continence’ is not acceptable, no more than 70% of patients will have a native bladder and normal voiding. In reality, this figure is rather optimistic and may be as low as 7% [413].

For the children who have done well, there is some evidence that continence may not be maintained into adulthood. In a follow-up of 56 patients for a minimum of 20 years, 13 were found who were continent and voiding naturally at 10 years old. However, by 20 years old, only three were still in this situation. The remainder were augmented or on CIC or both. The patients had been operated in the 1960s and early 1970s by older techniques than are currently used [414].

Late failure has several possible causes. Possibly the most important is that the outflow resistance generated by bladder neck reconstruction is not sphincteric, but fixed. Voiding is, therefore, always against obstruction. Deterioration in bladder function would come either from detrusor failure or from overactivity. Borer et al. found detrusor overactivity in six of 13 children (46%) who had had a staged repair but in none of 19 who had had CPRE [407].

Another problem was identified by Yerkes et al. [415] In an investigation of 18 children who were said by themselves and their parents to be ‘continent and voiding well’, none were, in fact, voiding normally. Apart from infections, stones and a dry...
interval of two hours, there were major objective bladder dysfunctions in all patients. Seventy two percent had a residual urine of at least a third of bladder capacity; 70% had a flow rate below 10ml/sec; 30% had staccato stream; and 36% voided by Credé’s maneuver.

Finally, there is the problem of the definition of continence. The disciplined life of a closely supervised child may well make a three-hour dry interval seem like continence. It fits in well with the school routine. It does not lie well with the life style of an adolescent. It quickly becomes apparent that the coffee, soda, and alcohol that soon become a part of an adolescent’s life expose the fact that they have to make far more visits to the lavatory than their peers or risk being wet. It has been shown that one of the prime desires of exstrophy adolescents is to be ‘normal’. This includes being treated as normal and having normal lavatorial habits [416]. This difference from normality may drive some young adults to seek continence surgery even though, by pediatric criteria, they had been classified as continent.

3. MANAGEMENT OF INCONTINENCE

a) Investigation

Standard investigations for incontinence are appropriate for patients with exstrophy. Urodynamic studies have been used to clarify the etiology and have clinical value in management [407,415]. Dave et al [417] investigated 31 children one year after a modified bladder neck reconstruction. Fifteen had satisfactory continence defined as a dry interval of two hours or more, no stress incontinence and no more than two episodes of nocturnal enuresis per week. The continent children had a better bladder capacity at 162 ml compared to 113ml for those with poor continence or 55ml for the totally incontinent. End filling pressure was around 31cm H2O for the continent children versus 48 or 41cm for the other two groups. However, involuntary detrusor contractions were seen in a third of the continent group and were associated with a lower than average bladder capacity and less good compliance than the other continent children.

It has been pointed out by Hollowell et al. [418] that even in severely incontinent children who appear to drip continuously, leakage is often due to detrusor overactivity. They found that a leak point pressure (LPP) of at least 10 cmH2O was necessary to allow bladder expansion. However, in some children with a higher LPP than 10, bladder expansion did not occur because detrusor contractions were constantly emptying it.

As in other conditions of bladder abnormality, end filling pressures over 40cmH2O were associated with hydronephrosis (two thirds of patients) [417].

The role of electromyography (EMG) of the sphincters has been reported but not correlated with management or outcomes [407]. In Dave et al’s [417] patients only 12 children voided with sustained detrusor contractions and only five voided effectively. Ten children had persistent EMG activity during voiding but no other detectable neurological abnormality. Eight of them had significant residual urine volumes.

Some authors stress the importance of examination under anesthesia. In the assessment of incontinence, the volume of the bladder has some predictive value and is most accurately measured under general anesthesia. Although not statistically significant, children with a bladder capacity before bladder neck reconstruction of less than 25ml do less well than those with larger bladders [407]. Secondly, a transverse oval appearance of the bladder neck is associated with its incompetence and hence incontinence [411].

Complete objective evaluation of bladder function in this manner is particularly important in exstrophy as the description by patients and parents is unreliable [415].

b) Medical Management

The apparent normality of the detrusor muscle at least in infants born with exstrophy, suggests that standard anti-muscarinic drugs should be effective in detrusor overactivity [400]. There have been no disease specific controlled trials, least of all in adults. In children, there has been an uncontrolled trial of imipramine using both clinical and urodynamic criteria to assess response [419]. All of 17 children (mean age 7.9 years) had urodynamically proven detrusor overactivity, small poorly compliant bladders and incontinence. Imipramine 1.5 – 2.0mg/kg was given for a mean of 9.5 months. There was a 40% increase in bladder capacity and a 25% reduction in end filling pressure. Eleven of 17 children had a clinically significant improvement in continence; all of eight children with partial continence (1-2 hr dry interval by day but enuretic) became dry day and night with a dry interval of more than 2 hours. Three of nine children with severe incontinence improved. Hydronephrosis improved in three of nine patients. In an editorial comment on this paper, Gearhart stated that he used oxybutynin 0.5mg/kg in combination with imipramine, which ‘gave even better results’. No further data were given.

c) Bulking Agents For The Bladder Outflow

In patients with exstrophy who have bladder outflow weakness, there is logic in using injectable bulking agents to increase resistance. Although not mentioned in the literature on this subject, the obvious drawback is that there will be even greater fixed outflow resistance that may limit the opportunity for the action of any active sphincter.
Burki et al. [420] reported the use of polydimethylsiloxane (macroplastique™) in 34 children with exstrophy and 18 with primary epispadias. Apart from bladder neck reconstructions eight had had augmentations. In addition, 14 relied on a Mitrofanoff for self-catheterization. There was no standard technique of injection and the objective seems to have been to put in enough of the bulking agent to produce visual occlusion of the bladder neck area using 2.5 to 7.5 ml. Twenty patients had one injection and the rest had an increasing number up to seven. The follow-up assessment was entirely clinical and there were no urodynamic data. Only 17% were completely dry at a mean of 4.6 years; 33% were reported to be significantly improved. The milder the initial incontinence the better the result, however four of 36 patients who were totally wet did become totally dry. The continence rate was improved by up to four injections but only one patient became dry after more than four (he became dry after six injections). Other bulking agents have been reported including Teflon and collagen but in series of patients with different diagnoses including exstrophy and epispadias.

**d) Surgical Management**

Adults with exstrophy who have failed to become dry after initial reconstruction and the relatively conservative management of medication and bladder neck bulking have a difficult decision to make. The most elusive outcome is to create a bladder that is continent and from which there is spontaneous voiding. It will be seen that the choice to achieve this result is a second bladder neck reconstruction or insertion of an artificial sphincter. Both of these require a natural bladder of adequate capacity and which retains normal detrusor function. If the bladder is small or of high pressure, there may be some improvement when outflow resistance is increased with a successful bladder neck procedure, though, again, the data come from studies in children and may not be applicable to adults [407]. Otherwise, augmentation will be necessary. The options for augmentation, with or without a Mitrofanoff, are considered elsewhere in this chapter. A more realistic objective if the urethra is to be used for urinary drainage would be to accept CIC for bladder emptying. If the bladder is inadequate, it can be augmented. However, this option depends on having a urethra that can be catheterized. This may be difficult after repair of the epispadias and bladder neck initially; after a second bladder neck reconstruction, it may be more difficult.

a) Bladder neck reconstruction: In children who have had a bladder neck reconstruction and failed to become dry, the results of further reconstruction are poor. In adults, data are very limited. In a group of older children (3.2y – 15.5y) the group at the Hospital for Children, Great Ormond Street reported very modest results. There were 20 boys and ten girls most of whom had had several operations apart from the initial bladder neck reconstruction, including injection of bulking agents, augmentation and Mitrofanoff procedures and yet still remained wet. Sixty percent became dry by day (80% of girls but only 50% of boys), but only 50% by night. None could void urethrally and only five performed CIC urethrally. Urethral catheterization was difficult in eight. The authors acknowledged that the outcomes were not good and suggested that closure of the bladder neck might be a better option [421]. In an earlier series from Johns Hopkins all of eight patients achieved a dry interval of three hours or better with a re-do Young-Dees operation but all required CIC [422]. Although these data cannot directly be extrapolated to adults, it seems likely that they are representative of patients with failure of the initial bladder neck reconstruction.

b) Artificial urinary sphincter (AUS): The patient with exstrophy has, by definition, a reconstructed bladder neck and urethra. Such structures are not well suited to the support of an AUS cuff. It is also common for incontinent patients to carry a residual urine and so, with an AUS, would need to use CIC. Even in the earliest reports of the AMS 800 AUS, the results in patients with exstrophy were poor [423]. Again, data on this procedure in adults with exstrophy are limited and often included in series of patients with different diagnoses. In one series of 112 patients without spina bifida, there were 12 with exstrophy and four with epispadias aged four to 17 years old. The AMS 880 AUS was used with 5.5 to 7.5 cm cuffs and 61–70 cm water balloons. The cuff eroded in three of 12 exstrophy patients. Only four were dry and able to void spontaneously all of the time [424]. Herndon et al reported a 20% erosion rate in patients of any diagnosis who had had a bladder neck repair [425].

e) Diversion:

It is beyond the remit of this section to consider urinary diversion for exstrophy in detail. There is a school of thought that the results of exstrophy reconstruction in the long run are so poor that early diversion should be the initial management [426]. The original diversion of choice was a ureterosigmoidostomy, however the results before antibiotics and an understanding of hyperchloremic acidosis were very poor with 50% of children dying before ten years old [427]. With modern management and the use of a de-tubularized rectal pouch, such as the Mainz II, the results are very good and continence rates of 95% day and night are reported [428, 429]. This would certainly be the
management of choice in countries with limited facilities for reconstruction [430]. Surveillance for the development of anastomotic neoplasms from the tenth year after construction is mandatory [431].

Even in exstrophy patients who are continent, very many will have had an intestinal augmentation procedure. If the urethra is continent it may be used for self catheterization. When the urethral reconstruction has failed, either because it is wet or impossible to catheterize, a supra-pubic catheterizable channel, such as a Mitrofanoff, should be formed. The wet urethra is closed at bladder neck level to allow continued seminal ejaculation. If the bladder is too small or of too high pressure, it is augmented with intestine.

In the large series from Baltimore, 91 of 704 (13%) of exstrophy children required such procedures [432]. Of the reconstructed patients, 65% had a bladder neck closure. At a mean follow-up of six years, 93% were continent.

There are no data on the use of these techniques in adults specifically with exstrophy. However, as there are no other alternatives, a reconstruction based on the bladder is the recommended option. Long-term follow-up of intestinal diversions in other situations suggests that stone formation, stomal stenosis, hyperchloremic acidosis are common. Spontaneous rupture, an acute and life-threatening complication is rare. Renal function is preserved at least to ten years [433].

A long-term problem unique to exstrophy patients with a retained bladder is the risk of cancer. At the age of 40, exstrophy patients have a 640 fold increased risk over the normal population of that age. The reported tumors are aggressive and frequently fatal. Histologically, they are a mixture of transitional, squamous and adenomatous, most commonly arising on the bladder neck [434]. To date, the reported cases have been in those whose bladder reconstructions were done in early childhood; it remains to be seen whether those with reconstructions done in the first few days of life will have the same risk. It is important to pay urgent attention to the standard symptoms suggestive of bladder cancer even in young adults with exstrophy.

If the bladder is too small to be useful, or has been removed, one of the standard supra-pubic diversions such as a colonic reservoir can be used. The Mainz II rectal reservoir is an alternative. Ileal conduit is almost never indicated. However, the risk of bladder cancer remains, even if the only remaining part is the bladder neck.

4. RECOMMENDATIONS

The published studies to date are retrospective case series with levels of evidence at best 3 with a Grade of Recommendation of C and Level of Evidence 3. The expert opinion of the Committee has resulted in the following recommendations regarding the evaluation and treatment of persisting incontinence in adulthood. (C)

• Anti-muscarinic drugs are the first option for detrusor overactivity although there are no data specifically related to exstrophy patients.
• Standard techniques for enlargement of a small or high-pressure bladder are appropriate.
• Bladder neck bulking agents may be effective but continence is unlikely to be achieved if 4 injections have failed
• Re-do bladder neck reconstruction has a high failure rate, and is very unlikely to allow complete, spontaneous voiding. Urethral CIC may be difficult or impossible.
• AUS also has a poor outcome because of erosion, chronic retention and CIC difficulties.
• Supra-pubic continent diversion with or without augmentation and with or without bladder neck closure is the best choice for exstrophy patients with urethral failure. Rectal diversion (eg a Mainz II pouch) should be considered especially in countries with limited medical facilities.
• Patients with exstrophy-epispadias complex should be evaluated and managed in specialized centers
• A universal definition of continence should be established
• Persisting incontinence should be evaluated with urodynamics and its treatment should be individualized based on urodynamic findings
• Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications
• Comparative studies, including quality of life and psychological assessment, should be undertaken if possible.

IX. DETRUSOR OVERACTIVITY AND REDUCED BLADDER CAPACITY

1. REFRACTORY URGENCY INCONTINENCE AND IDIOPATHIC DETRUSOR OVERACTIVITY

The overactive bladder (OAB) syndrome refers to the symptoms of urgency, with or without urge incontinence, usually with frequency and nocturia [435]. Detrusor overactivity (DO) indicates the urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. Idiopathic Detrusor Overactivity (IDO) exists when there is no defined cause. Neurogenic Detrusor Overactivity (NDO) is seen when there is a relevant neurological condition. Ahlberg et al found that 82% of patients initially considered idiopathic on careful searching actually had pathology potentially leading to the problem [436].
Idiopathic detrusor overactivity is a normal situation early in life. Children have urgency incontinence as a stage in acquiring bladder control. The incidence of detrusor overactivity during mid-life years (20 to 60) has been estimated as 10% [437]. In the asymptomatic elderly, detrusor overactivity once again becomes common, occurring in 50% of men over 70 [438]. In the symptomatic elderly, over 75 years old, it can reach 90% in men [439]. Detrusor overactivity may be a cause of severe storage symptoms such as frequency, nocturia, urgency and urgency incontinence. Conservative treatment of these symptoms such as bladder training and pharmacotherapy is discussed in other sections.

Magnetic stimulation has been reported as a non-invasive treatment of DO [440,441]. Bradshaw et al. demonstrated an effect on cystometry with magnetic stimulation and found an improvement in urodynamic parameters but no consistent change in OAB symptoms [442]. Almeida et al.[443] in a prospective urodynamic controlled study of 91 women with UI, found an improvement on DO only in patients with initial bladder contractions greater than 15 cm H2O. There are no other specific data available [444].

The use of intravesical neuromodulatory drugs such as capsaicin and resiniferatoxin was extended to DO of non-neurologic origin after the suggestion that its etiology involved the enhancement of the C-fiber mediated spinal micturition reflex [445] and emerged as a minimally invasive procedure: the results are shown in Table 12 [446-453]. In spite of promising and controversial results, it is still

Table 12. Intravesical capsaicin and resiniferatoxin for detrusor overactivity (males and females)
considered experimental and more clinical studies are necessary for it to be licensed [454].

The mechanism of action is still under study. The mean bladder perception threshold is increased only in patients with clinical improvement [455]. The complexity of the mechanism is demonstrated by the presence of vanilloid receptors not only on sensory fibers but also in bladder urothelium and smooth muscle cells [452] and by ineffectiveness in treating an overactive bladder from idiopathic causes or suprapontine lesions with no vanilloid-sensitive fiber-mediated reflex [456]. It has been suggested that over expression of transient receptor potential vanilloid subfamily 1 in the bladder predicts the response [457]. A well designed double-blind placebo-controlled study revealed no difference between placebo ethanol 10% saline solution and 50 nM resiniferatoxin, nevertheless both treatments showed improvement in symptoms of women with IDO [453]. Some placebo-controlled studies either did a quasi randomization458 or did not explain how it was done [452]. Patients with increased bladder sensation without DO presented some improvement in symptoms in a small non placebo controlled series [459]. There are no recent clinical series published and at present time, the use of resiniferatoxin has been restricted to animal studies [460,461].[levels of evidence 1 – 4; Grade of recommendation D, two level 1 studies have contradictory conclusions. [452,457])

For symptoms that are refractory to conventional means, 3 interventional treatments have been reported: botulinin-A toxin detrusor injections, neuromodulation, and bladder augmentation.

a) Botulinum toxin A injection in the bladder

The minimal invasiveness of this method makes it very attractive but long-term results in IDO are lacking Table 13 [462-478]. The effects of its use are still not fully recognized [479], with possible systemic consequences [480-482], such as generalized muscle weakness in a number of patients treated for neurogenic bladder overactivity, and the development of resistance to the drug [483-485]. The FDA conducted a safety review of botulinum toxin products and issued a report that included a “Boxed Warning” highlighting the possibility of life-threatening distant spread of the toxin, a Risk Evaluation and Mitigation Strategy (REMS) with a medication guide to help patients understand the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding of the risks and benefits, and changes to the established drug names to reinforce individual patients’ understanding

Most of the initial experience comes from its use in neurogenic bladders [487-490]. In 2011, OnabotulinumtoxinA was approved by countries in North and South America and Europe for treatment of urinary incontinence in people with neurologic conditions as spinal cord injury or multiple sclerosis. Information about its use in children is scarce [491]. DasGupta et al. [492] published a systematic review on its use in children. They found 225 children in 10 peer-reviewed publications with 165 pediatric patients with neurogenic overactivity (6 studies), 21 patients with idiopathic overactivity (1 study) and 39 patients with voiding dysfunction (3 studies). Only 11 male children with idiopathic OAB were included, limiting conclusions on this subject.

A randomized study comparing the results of botulinum toxin A injections to intravesical resiniferatoxin in NDO showed superior clinical and urodynamic benefit with the use of botulinum toxin [490]. The need for reinjections seems to be overcome by the significant improvement in quality of life of these patients [493-495]. Cost-effectiveness with botulinum toxin A in patients with detrusor overactivity is becoming an important issue with its increasingly widespread use [496]. The number of BTx treatments in the UK has increased dramatically from around 50 in 2000 to 4088 in 2010, making costs an important matter to be considered [497-499]. A 3-year cumulative cost analysis of BTx versus augmentation cystoplasty favoured botulinum toxin injections [500], but longer follow up may change this.

The use of botulinum toxin B (Myobloc – RimabotulinumtoxinB) is less efficient, with duration of action of about 10 weeks [501].

The optimal site of injections, including or not including the trigone, is still under debate [502]. In 2007, Kuo [474], published a study comparing the injections into the detrusor, suburothelial area, and bladder base, with the last location improving urgency but not increasing capacity. Recently Kuo did a single blind, randomized, parallel, actively controlled trial testing 100 U of OnabotulinumtoxinA with patients assigned to receive injection into one of the three following sites: bladder body, 100 U; bladder body, 75 U plus trigone, 25 U; and bladder base, 50 U and trigone, 50 U. He concluded that the injections are a safe and effective treatment for IDO regardless of the injection site [503]. Manecksha et al [504] performed a study with 500 U of AbobotulinumtoxinA in 22 patients randomized to trigone-included or trigone-sparing detrusor injections. Benefits of trigone included injections were superior to trigone sparing injections for the treatment of refractory IDO and did not cause VUR in this study. A case series of 56 women with IDO underwent submucosa-only injection of 200 U of OnabotulinumtoxinA at 30 sites, showed success in 85.7% at 2 months and 54.3% at 12 months [505]. Initial results of bladder instillation of 300 units of OnabotulinumtoxinA and 50 mL of 50% DMSO in aqueous solution in women with IDO, showed safety and some efficacy that merit further research [506].

Many studies on idiopathic overactive bladder have been done in women [468, 469]. Data are still lacking on dose, concentration, site(s), numbers of injections, long-term efficacy and side effects. Attempts

Table 13. Botulinum Toxin A detrusor injection results
to determine whether poor responders could be predicted from preoperative urodynamic parameters showed only a very high maximal detrusor pressure over 110 cm H2O as an unfavorable predictor when using 200 units [476]. Studies in women suggest a longer duration of action than its mere motor-nerve blocking potency can explain [469]. Therefore, a dual mechanism of action has been proposed: in addition to binding to cholinergic terminals, it might also affect afferent nerve transmission, thereby decreasing urgency [504]. Kuo evaluated retrospectively the results of 100 U OnabotulinumtoxinA injection in 174 patients (89 males) [509]. Patients who had sensory effects had significantly greater long-term success rates compared to those with motor effects alone. He concluded that improvement of urgency severity seems to be significantly associated with the long-term success of BoNT-A treatment for IDO.

There are two commonly marketed forms of botulinum toxin-A: Botox (Allergan Pharmaceuticals, Irvine, CA, USA), now referred to as OnabotulinumtoxinA, and Dysport (Ipsen Biopharm Ltd., Wrexham, UK), referred to as AbobotulinumtoxinA, as recommended by the US Food and Drug Administration. They require different doses to achieve similar results, in a proportion of approximately 1:3 [510,511]. Other forms of botulinum toxinA do not have enough data in urology to be considered for this report, including Xeomin (IncobotulinumtoxinA) (Merz, Germany), Prosigne (Lanzhou Institute of Biological Products, China) [512], and Neuronox (Medy-tox, South Korea).

AbobotulinumtoxinA for refractory IDO was published in 2007 with similar results to OnabotulinumtoxinA [468]. Recently, a series of 22 patients with IDO underwent injection of 500 U of AbobotulinumtoxinA and were randomized to injections including or excluding the trigone [504]. Similar results were obtained regarding side effects (16% retention and no reflux) with the trigone-included group showing better results. Another large case series of 234 patients either with various types of neurogenic bladder dysfunction (NBD) or IDO underwent respectively 500 U and 250 U of AbobotulinumtoxinA including 57 men with IDO. Success was 91% for NBD and 93% for IDO, with 12% retention only in the male patients [513]. In a study using a type A neurotoxin, produced in a medium containing lactose gel column, Lee at al. [471] reported improvements in 89% of patients treated for incontinence due to IDO and NDO. Mangera et al. [514] did a systematic review on management of lower urinary tract diseases comparing OnabotulinumtoxinA and AbobotulinumtoxinA. They identified good-quality

Table 13. Botulinum Toxin A detrusor injection results (continued)
studies for OnabotulinumtoxinA in adults and lack of such studies for AbobotulinumtoxinA, although this does not imply that OnabotulinumtoxinA is more effective than AbobotulinumtoxinA.

Many studies with botulinum toxin detrusor injection use different outcome measures for results and are variable in reporting the presence of residual urine and the need for intermittent catheterization, but 6-75% of cases may develop a high post void residual urine [469,471,473,476]. A retrospective study looking at risk factors for adverse events in a series of 217 patients treated with OnabotulinumtoxinA showed an overall 63.3% success, with male gender, base line PVR >100 ml and dosage >100U as predictors of urinary retention or difficulty voiding. Besides being an alternative for treatment of refractory DO, currently available data do not support superiority of any specific treatment plan, and therapy options should be tailored to the specific patient and physician preference [515]. Higher doses such as 200 units in IDO resulted in incomplete emptying, necessitating intermittent catheterization in 6 out of 16 patients (37.5%) in one study [476]. Sahai suggests a careful follow up of the patients after the injections, starting IC in symptomatic patients if post void residual urine is more than 100-150 ml [516].

Many reports do not separate genders and mix urogenic and idiopathic etiologies. A large number of publications are reviews of the literature [517-535]. There is a randomized double blind OnabotulinumtoxinA placebo controlled trial showing favourable difference against saline injections for frequency and incontinence, but not for urgency [476]. Quality of life analysis showed improvement even with the occurrence of 38% of urinary retention [536]. In a dose-finding randomized double blind placebo controlled study with a total of 313 IDO patients of both sexes, all OnabotulinumtoxinA dosages (50-300U) were better than placebo, but the 100 and 150 U dosages were best in regard to the balance between efficacy and side effects [537,538]. In women, a placebo controlled randomized study with 200U of OnabotulinumtoxinA for IDO showed a 60% clinical response but was terminated early due to 43% of patients having increased PVR [539].

Conclusions

Efficacy of botulinum toxin A for IDO: level 1 of evidence, Grade of recommendation A (for OnabotulinumtoxinA). Fewer studies for AbobotulinumtoxinA and the lack of studies for other A toxins do not allow similar recommendation.

Dosage of botulinum toxin A for IDO: between 100 and 150 U (for OnabotulinumtoxinA). No studies for other types. Level 1 of evidence; Grade of recommendation A.

Location of injection: the majority of studies use 20 or 30 injections, and spare the trigone (Table 13). Alternative sites such as submucosal or including the trigone, have levels 2 and 3 of evidence. Grade of recommendation C.

Predictability of complications: Risk factors for retention or difficulty voiding are: male gender, baseline PVR>100ml and a dosage >100U. Level 3 of evidence; Grade of recommendation C (for OnabotulinumtoxinA – for other types, no conclusion possible).

The committee cautions that although the efficacy and safety of botulinum toxin A for IDO is being established there are still concerns regarding the data. Its use in men is not as widely reported as its use in woman; the issue of voiding difficulty and the need for intermittent catheterization has not been addressed in men. There are no long-term or cost effectiveness studies compared to alternatives. Furthermore the recommendations cannot be extended to other toxins due to lack of studies.

b) Electrical stimulation and neuromodulation

Electrical stimulation of the genital area was first used to control incontinence due to DO of different etiologies on an empirical basis [540]. Later, it was suggested that sphincteric contraction induced by electrical stimulation can promote an inhibitory effect on detrusor activity, thus suppressing DO [541]. Many studies of external electrical stimulation for bladder inhibition of idiopathic urgency incontinence have been published, mainly in female patients [542-549]. The results vary from 45% to 85% success, with a mean of 38%, and 26% improved. Electrodes implanted in the pelvic floor, have not yielded good results [547].

Sacral neuromodulation has been reported as alternative therapy for urgency incontinence, urinary retention, chronic pelvic pain, and for simultaneous urinary and fecal incontinence [550]. Good results have also been published in treating neurogenic bladder dysfunction [551,552]. The working mechanism of neuromodulation in the treatment of lower tract dysfunction is still unknown [553,554]. A suggested mechanism is somatic afferent inhibition of sensory processing in the spinal cord [555,556], therefore it may be a centrally acting treatment modality that is different from botulinum toxin, which is an end-organ therapy that specifically targets the bladder [557].

Long-term results suggest a sustained effect on restoring voiding in appropriately selected cases, but a revision rate of 42% at 5-year follow up remains a problem [558]. The 14-year revision rate from a single center was 39%, which decreased after the introduction of new materials [559]. On-demand use, as suggested by Oerlemans et al. [560] may improve this revision rate by prolonging battery life. Its use in refractory idiopathic urgency incontinence has been limited to relatively few patients, mostly women. Bosch and Groen [561] presented results of chronic implantation in 15 women and 3 men, with

1263
an average age of 46 years. Significant improvements in voiding frequency, average voided volume, number of incontinence episodes and number of pads used were found, with no deterioration in response to stimulation with time. However, with subsequent experience in 14 men only 2 patients had a partial response and the rest ultimately failed [562]. Shaker and Hassouna [563] implanted 18 patients with refractory urinary urgency incontinence, but only 2 were in men. Groen, Bosch and van Mastrigt reviewed 33 implanted women and found no effect on urethral resistance and bladder contraction strength, thought to be due to the depressant effect of sacral (S3) nerve neuromodulation on detrusor overactivity [564]. Groenendijk et al in a retrospective study for the Sacral Nerve Stimulation Study Group, reported urodynamic aspects of 111 patients implanted, but only 8 men were included [565]. They found a better result on urgency incontinence in patients without DO. The difference was not significant. This tendency was also found by South et al. in 67 women implanted [566]. Clinical or urodynamic values to predict the outcome of sacral nerve stimulation has been difficult to define. Evaluation of 19 women suggested that urethral overactivity seemed to be a good parameter to predict a favourable outcome [567]. Some studies do not specify the etiology of the DO and neurogenic and non-neurogenic causes are grouped together [563]. Some reports focus on technical or specific aspects of the procedure and the same patients may be included in different publications [565,568-570]. Implantation in children may be feasible in selected cases [571,572] and poorer results are expected in older women [102]. The outcome in older men is unknown since there are no reports.

**Table 14** [478,558,573-582] shows recent studies.

Some reports are literature reviews [554,583-585] or detail technical modifications [586,587]. There is one systematic review on efficacy and safety of sacral neuromodulation for urgency incontinence, but 13 of the articles analyzed are abstracts and it is also difficult to ascertain whether the same patients are included in different publications [588].

There are some publications with level [1573,574 or 2562,576,577] evidence and with a grade of recommendation of B. However, due to relatively few men in the clinical trials, and poor results in one of the prospective trials, its general applicability to men with urgency incontinence may be limited. The scenario remains unchanged after about 26,000 patients implanted [589]. In a recent review, Apostolidis [590] concluded that further research is needed to improve patient selection, identify prognostic fac-

**Level of evidence 3. Grade of recommendation C.**

c) Surgical treatment by detrusor myectomy and augmentation

Previously used treatments of surgical bladder denervation, open bladder transection, cystolysis, endoscopic phenol injections, hydrostatic bladder distention did not yield good results.

Bladder autoaugmentation or detrusor myectomy has been reported as an alternative to augmentation in neurogenic and non-neurogenic dysfunction. **Table 15** [591-593] shows results of this treatment in patients with non-neurogenic detrusor overactivity. There are few long term results available [593]. The use of silastic intravesical balloon as a scaffold after myectomy seems to improve results in neurogenic patients but was not tested in IDO [594]. Additional and longer-term experience is still required to properly assess this procedure. **(Level of evidence 3; grade of recommendation C-D)**

Enterocystoplasty results are detailed in **table 16** [592,595-601], which includes both male and female patients. Some publications are not clear about the type of surgery specifically done in IDO and about the gender. Good results vary from 58% to 88%, with an average of 77%. Approximately 10 to 75% of patients require intermittent catheterization for bladder emptying. Ileum was the most frequently used bowel segment followed by sigmoid colon, although no scientific reason for the use of any particular segment was given. The surgery, as reported in other sections, has a significant complication rate and should be considered carefully when applying it to these patients. **(Level of evidence 3; grade of recommendation C)**

### 2. REDUCED BLADDER CAPACITY

Fibrosis of the wall produces a low-volume low-compliant bladder, leading to diminished functional capacity. Symptoms of frequency and nocturia occur as a result of progressive decrease in bladder volume, but urinary incontinence may also be the consequence of a very small capacity, especially if accompanied by urethral weakness. The diagnosis can be suggested by the micturition chart, and confirmed by urodynamics. The causes can be congenital or acquired. Acquired causes include multiple surgeries, inflammatory processes (chronic cystitis, interstitial cystitis, tuberculosis, schistosomiasis, and chemical cystitis) or following radiation.

Bilharzial contracted bladder is a problem that is primarily limited to endemic areas in Africa and the Middle East. Schistosoma haematobium migrates to the veins of the vesical and pelvic plexuses, where the female begins to lay eggs, promoting a initial inflammatory response. As a result, granulomatous lesions form in the lamina propria. Mucosal reactions vary from hyperplasia to polypoid cystitis. A contracted bladder occurs in 2% of cases [602]. Bladder augmentation seems to offer reasonable results in these cases.

Similarly, small fibrotic bladders due to other etiologies can be treated successfully with enterocystoplasty. The results of this surgery are presented in Table 17 [603-631]. The results are similar in all etiologies except for radiation. The poorer results after radiation may be due to other tissue damage in the surgical area. New conformal techniques for radiation may improve results in the future, so that the need for augmentation cystoplasty decreases.

Almost all of these studies do not distinguish bowel segments or separate males from females in reporting results. Therefore, it is not possible to correlate any particular aspect with the chance of success or failure. However, overall the results seem reasonably good with the exception of patients who have undergone radiation. (Level of evidence 3; Grade of recommendation C)

X. URETHROCUTANEOUS AND RECTOURETHRAL FISTULAE

Urethrocutaneous or rectourethral fistula may have congenital, inflammatory, neoplastic or traumatic origins. It is important to recognize the varying etiologies because each type may require a different surgical strategy. All reports except one are retrospective case series. The report by Shakespeare et al. [632] is from a prospectively collected data base of patients treated with radiotherapy for prostate cancer. (Level of evidence 3; grade of recommendation C).

1. URETHROCUTANEOUS FISTULA (UCF)

a) Acquired UCF

Hidden foreign bodies have been described as a rare cause of both strangulation of the glans penis and urethrocutaneous fistula. Tash and Eid [633] presented the case of a 30-year-old man who developed a urethrocutaneous fistula and penile shaft necrosis after a condom broke during intercourse. Neither the patient nor several physicians could identify the retained ring of condom, which had been buried under newly epithelialized skin. He underwent removal of the foreign body under general anaesthesia, followed 5 months later by a formal urethrocutaneous fistula repair.

Urethroperineal fistula, as a complication of open perineal prostate cryosurgery, occurs as an immediate perioperative complication in 10.7% [634]. Thomas et al. [635] retrospectively evaluated 250 patients after radical perineal prostatectomy and revealed only 1 (0.4%) urethroperineal fistula. Fahal et al. [636] published an unusual complication of mycetoma. The patient had an infection with Actinomadura madurae that involved abdominal wall, perineum and urethra. This resulted in urinary extravasation with a urethrocutaneous fistula.

b) Management of UCF

The diagnosis of UCF is made by physical examination, retrograde urethrography (Figure 3), urethroscopy, fistulography, urethral ultrasound or color Doppler imaging. Urethral sonography provides additional information about any involvement of the surrounding tissue, location of vessels and associated abnormalities such as a periurethral abscess [637].

Treatment of UCF usually requires urethroplasty techniques with modifications involving fistula excision and multiple layer closure [638]. (Level of evidence 3; Grade of recommendation C)

2. RECTOURETHRAL FISTULAS (RUF)

Culp and Calhoon described five basic groups of RUF according to the etiology [639]: congenital, iatrogenic, traumatic, neoplastic, and inflammatory. (Level of evidence 3; grade of recommendation C)

**a) Congenital RUF**

Endo et al. [640] described the results of the Japanese Study Group of Anorectal Anomalies (JSGA) to determine the relative incidence of specific types of these anomalies in Japan. They included discussion of RUF regarding the relationship between the fistula levels and the blind end of the rectum, low type deformity, rare types, and associated anomalies. A total of 1,992 patients (1,183 boys and 809 girls) registered from 1976 to 1995 were analysed according to the pathogenesis of anorectal malformation in the field of molecular genetics. They reported that more than 20% of RUF should be categorized as intermediate or low deformity from the position of the rectal pouch. A significant preponderance of Down’s syndrome in the deformities without fistulae suggests that investigation of associated anomalies and congenital diseases may provide further insights.

The purpose of Rintala’s study was to compare the long-term outcome of sacroperineal-sacroabdominoperineal pull-through (SP-SAP) to that of posterior sagittal anorectoplasty (PSARP). In boys with high anorectal anomalies, PSARP was superior to SP-SAP pull-through in terms of long-term bowel function and faecal continence [641].

**b) Acquired RUF**

Acquired RUF may occur after pelvic trauma, surgery of the prostate or rectum, pelvic cancer, radiation (either external beam or brachytherapy),
cryosurgery, prostatic hyperthermia, prostatic high intensity focussed ultrasound (HIFU), inflammatory bowel disease affecting rectum, or rarely prostatic inflammation.

Benchekroun and co-workers [642] report a series of 11 RUF observed over a 25-year period. The etiologies were surgical trauma (5 cases), fracture of the pelvis (2 cases), inflammatory lesions (3 cases), and one fistula was congenital. Colostomy was performed in 2 patients, surgical closure of the fistula was performed in 7 patients: abdominoperineal (3 cases), perineal (2 cases), transperitoneal (1 case) or by transansphincterincision (1 case).

In 1972 Smith and Veenema [643] reported their 20-year experience with 160 patients undergoing radical retropubic prostatectomy (RRP) with an incidence of 15 rectal injuries. Only 4 fistulas developed in this group.

Roberts et al. [644] published a series of 11,452 men who underwent open (RRP) or laparoscopic (LRP) radical prostatectomy. Rectal injury occurred in 18 men -12 in the RRP group (0.12%) and 6 in the LRP group (0.47%). When recognized intraoperatively and primarily repaired, rectourethral fistula was prevented in 87.5% of men. Primary repair performed with vascularized tissue interposition prevented rectourethral fistula development. In men with unrecognized rectal injury, the rectourethral fistula tended to persist and eventually required delayed surgical repair. Thomas et al. [645] reported that 23 (3.9%) rectal injuries during 589 RRP and cystoprostatectomy procedures. Eastham and Scardino [648] summarized the incidence of rectal injury during RRP in 30 patients with an average of 0.7% (range 0.2-2.9%). The incidence of RUF, as an immediate perioperative complication of open perineal prostate surgery, is 1.4%.

Nyam et al. [649] reviewed records of all patients who were diagnosed with RUF between January 1981 and December 1995 and 16 males were identified. All patients were interviewed by telephone for follow-up. The mean age was 68 years and the mean follow-up was 80 months. Adenocarcinoma of the prostate in 15 patients and recurrent transitional cell carcinoma of the bladder in one patient were the underlying malignant diseases. Nine patients had had a RRP with 2 fistulas after radiation, 2 after brachytherapy, and 3 after a combination of radiation and brachytherapy. One patient formed a fistula after cystectomy and dilatation of a stricture. This heterogenous group of patients received multiple therapies including initial colostomy (7 patients), transanal repair (2 patients), perineal repair (2 patients), coloanal anastomosis (3 patients), and muscle transposition (3 patients). Four of the patients required a permanent stoma.

Badalament et al. [650] managed one patient (0.4%) with a urethrectal fistula after cryoablation therapy for prostate cancer. Zippe [651] reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF. Porter 634 found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroprostate fistulae. Ismail et al. [652] reported the experience of using salvage targeted cryoabl...
a urinary fistula. Of 20 patients meeting inclusion criteria, 30% received external beam RT alone, 30% received brachytherapy and 40% had received combined external beam RT/brachytherapy. Most fistulas (80%) were from the rectum to the urinary tract with an average diameter of 3.2 cm. Of patients with rectal fistulas 81% had a history of rectal stricture, urethral stricture, rectal biopsy, rectal argon beam therapy or transurethral prostate resection after radiation. All patients with rectourethral fistulas who achieved symptomatic resolution required urinary and fecal diversion.

Shakespeare et al. [632] reviewed the potential factors in fistula development and identified three cases (0.2%) of RUF among 1455 patients treated with prostate brachytherapy (BT), occurring at 19-27 months following BT. All these patients had BT monotherapy and had been investigated with endoscopy and low rectal biopsy. They concluded that gastrointestinal specialists should not perform biopsy of the anterior rectum in patients who have had BT unless there is a very high clinical suspicion of malignancy. Marguet et al. [659] described 6 cases of RUF in patients treated with brachytherapy plus external beam radiotherapy for localized prostate cancer and subsequent rectal biopsies or rectal surgery. Four patients underwent hyperbaric oxygen therapy, which failed. Three patients underwent fecal diversion with gracilis interposition flaps, and two underwent pelvic exenteration. They also concluded that biopsy of rectal ulcers in the clinical setting of combined radiotherapy should not be performed.

Chang et al. [660] published a case of prostatic malakoplakia masquerading as a rectal tumor due to formation of a fistulous tract to the rectal muscular layers. Cools et al. [661] reported a very uncommon type of fistula between the large bowel and the prostatic urethra due to Crohn’s disease. Felipetto et al. [662] described a prostatocutaneous fistula as a complication of pseudomonas prostatitis.

Transrectal high-intensity focused ultrasound (HIFU) destroys prostate cells by coagulative necrosis of the tissue. Recent reports of efficacy also include morbidity. Rebillard et al. [372] reported RUF in 0-3% in a review involving 37 articles/abstracts.

Buckley et al. [663] concluded that there has been a major shift in the cause of RUF from primarily surgical to approximately 50% resulting from radiation/ablation therapy. Surgically induced RUFs typically are small, located in bladder neck/trigonal region and can be closed primarily. Radiation/ablation induced fistula are large (>2 cm), involve the prostatic urethra and are fibrotic often requiring a combination of onlay grafting and interposition muscle flap for closure. The anterior, perineal sphincter-sparing approach may be the optimal approach for closure of most RUF (simple or complex). Lacarrière et al. [664] noted that the use of radiotherapy had a major impact on its prognosis. The flap, which seemed to have the best results, was the gracilis muscle flap.

c) Diagnosis of RUF

RUF may be strongly suspected from the patient’s history (fecaluria, abnormal urethral discharge, pneumaturia, leakage of urine from the rectum during micturition). Rectal examination, proctoscopy, careful urethroscopy, intraurethral injection of methylene blue dye, radiopaque contrast agent placed into the bladder and then voided usually appears in the rectum on X-ray, are the most important diagnostic steps [637,665] (Figure 4).

d) Therapy of RUF

Small fistulae may resolve spontaneously with urinary and/or fecal diversion. Therefore, an initial trial of conservative therapy is reasonable. Selected patients with chronic fistulas who are poor surgical candidates may also be managed conservatively with antibiotics, pads and symptomatic care. Timing of repair is often individualized, mainly according to the etiology, delay in diagnosis, size of fistula, whether it is the first or subsequent repairs, and the general condition of patient.

Diversion of urine (suprapubic cystostomy) is generally recommended as well as correction of any urethral stricture distal to the fistula. Fecal diversion, with colostomy is used by some as a mandatory part of double diversion or selectively by others [645]. Gibbons 666 stressed the need for a diverting colostomy for 3-4 months.

![Figure 4. Cystogram demonstrates a rectourethral fistula that occurred after a laparoscopic radical prostatectomy](image-url)
However, as surgeons obtained more experience, bowel preparations became standardized, and effective antibiotics were developed, and the enthusiasm for colostomy diminished. Currently, colostomy is recommended in circumstances where antibiotics alone cannot control the inflammation and infection associated with the fistula or when the fistula involves radiated tissue. Low residue diet is also useful for healing. Suitable drainage (perineal and urethral splinting) is stressed.

e) Surgical Approaches

Surgical management for rectourinary fistulas remains a reconstructive challenge. Two-layer closure of the urethra and rectum with suture lines at right angles and with interposition of soft tissue (eg. omentum [667], gracilis muscle [668], or scrotal flap [669]) has been described. Surgical approaches include transabdominal, transvesical, or direct exposure of the RUF.

There are only a few guidelines to direct the surgeon to the most successful and least morbid technique. Rivera et al. [670] staged RUF as: stage I, low (less than 4 cm from anal verge and nonirradiated); stage II, high (more than 4 cm from anal verge and nonirradiated); stage III, small (less than 2 cm irradiated fistula); stage IV, large (more than 2 cm irradiated fistula); and stage V, large (ischial decubitus fistula). Diverting colostomy was performed for stages III to V 6 weeks before definitive therapy. Some of the patients in addition to the RUF will also have urethral strictures that have to managed. Reconstruction of both aspects to restore functional anatomy is possible with complex reconstructions. [671]

The surgical approaches including the numbers of reported patients are listed in Table 18 [639, 642, 643, 646, 647, 655, 665, 669, 672 - 688]

1. Perineal Approach

In 1926, Young [672] dissected the rectum away from sphincters, divided the fistula, closed the urethra, and mobilized the rectum further cephalad in such a fashion as to pull the affected rectum caudally out of the anus where it was then transected and discarded, suturing the proximal rectum to the anal skin. Subsequently Lewis, in 1947 [673], described suturing the levator muscle fibers together in the anterior midline when possible.

Goodwin et al. [674] reported a series of 22 RUF approached perineally. They extensively mobilized the rectum posteriorly and the bladder anteriorly through wide perineal exposure allowing interposition of the levator ani muscles between the urinary tract and rectum. Singh et al. [689] described the management of a delayed post-traumatic RUF repaired via transperineal access without rectal or sphincteric transgression. An example of a preoperative and postoperative urethrogram is in Figure 5. Pratap et al. [690] described a simultaneous perineal and abdominal approach in a series of 8 patients with traumatic perineal injuries who had both complex urethral disruptions and RUF.

![Figure 5A. Cystogram demonstrates RUF caused by a TURP. Negative shadow from Foley catheter is seen in the bladder.](image1)

![Figure 5B. Retrograde urethrogram after transperineal closure of RUF](image2)

Samplaski et al. [691] reported transperineal repair with gracilis muscle interposition in 13 patients with complex RUFs of varying etiologies. One patient developed recurrence. They demonstrated low morbidity, high success rates, and reasonable bowel and bladder function postoperatively.

### 2. Posterior Sagittal Approach

Kraske in 1885 [692] described a posterior midline incision extending to the left paramedian aspect of the coccyx and sacrum that involved partial removal of the sacrum in addition to coccyxectomy. His method did not involve division of the sphincters, but rather sweeping the rectum laterally to ultimately facilitate resection and reanastomosis of a tumour-bearing rectal segment, thereby preserving fecal continence. In 1962, Kilpatrick and Thompson [677] used this approach when the rectum was completely mobilized circumferentially proximal and distal to the fistula. The RUF was then divided, sparing as much as possible on the urethral aspect. The rectal part of the fistula was excised and closed in two layers, and the urethra was repaired and stented with a catheter.

### 3. Posterior (Parasacroccocygeal) Transssphincteric Approach

In 1969 Kilpatrick and Mason [679] updated this method and advocated a more radical method of dividing the rectal sphincters to give direct access to the RUF. The procedure (the York-Mason approach) is simpler than some complicated trans-
abdominal or transperineal approaches to RUF. It is still used because it allows direct visualization of the fistula via parasacrococcygeal (transsphincteric) incision especially to fistulae in the mid to lower rectum [655]. After the skin incision the mucocutaneous junction is marked with sutures and the internal sphincter is exposed. Division of the sphincter mechanism and posterior rectal wall allows exposure of the fistula. Each sphincter muscle is tagged with color-coded sutures. The next step of this procedure is the incision around fistula, followed by excision of the fistulous tract exposing the catheter in the prostatic urethra. The undermining of rectal wall allows sufficient mobilization. After closure of the prostatic urethra it is recommended that the full-thickness rectal wall flaps are close in a “vest over pants” technique (Figure 6). It is important to make sure that the suture lines do not overlie each other. The procedure is completed by suture of the rectal wall and approximation of the sphincter muscles (Figure 7). Fengler and Abcarian [655] reported healing of RUF in all of 8 patients with the York-Mason approach. Bukowski et al. [681] managed 7 acquired recurrent RUF (3 after prostatectomy, 3 after trauma and 1 after perineal abscess) using York-Mason technique and a similar experience was described by Fournier et al. [680] in the management of a case of the urethroprostato-rectal fistula after a gunshot wound.

Stephenson and Middleton [678] modified the York-Mason repair and reported their experience with posterior sagittal, transanal, transrectal repair of RUF in 15 patients. The transsphincteric, transanal surgical approach provides many advantages, including easy access and identification of the fistula tract, good surgical exposure, adequate resection back to well vascularized tissue, and access to several vascularized flaps for interposition between the repaired urinary and gastrointestinal tracts.

Culkin [684] reported preliminary experience with the transsphincteric, transanal surgical approach to correct acquired urethral fistula in five men. Mean patient age was 56.6 years (range 37 to 72). The etiology was surgical (radical prostatectomy) in 3 cases, traumatic in 1 and idiopathic in 1. The time from the diagnosis of urethral fistula to surgery was 4 weeks to 4 years. Five men underwent excision and closure of a urethral fistula with diverting colostomy. In 4 men (80%) urinary continence subsequently returned with adequate sphincter tone, while in 1 (20%) with perineal trauma and active proctitis the fistula recurred 6 weeks after surgery.

Dal Moro et al. [693] reviewed a 15-year experience using the York-Mason posterior sagittal transrectal approach to iatrogenic RUF in 7 patients. In one patient with Crohn’s disease the fistula recurred 11 years after the first surgery. The colostomy remained in place only in one patient with Crohn’s disease and in another with ulcerative rectocolitis.

Erickson et al. [694] reported a novel surgical technique used to repair a rectourethral fistula associated with two short-segment urethral strictures located in the anterior and posterior segments of the urethra in a patient with prior unsuccessful repairs. The anterior urethral stricture was reconstructed with a ventral onlay of buccal mucosa in the ex-

aggerated lithotomy position. In a modified prone position, the rectourethral fistula was repaired using the transrectal transsphincteric (York-Mason) technique and the posterior urethral stricture with a radial forearm fasciocutaneous free flap which was anastomosed to the inferior gluteal artery and vein. The coexistence of a rectourethral fistula and distal urethral stricture requires simultaneous repair, because the urethral pressure from the distal obstruction may compromise fistula closure.

Lorente et al. [695] reported early successful closure in 10 patients with the posterior transsphincteric York-Mason technique, with good recovery of urinary and fecal continence. Pera et al. [696] reported on 5 patients successfully treated after RP with the York Mason technique. They reported minor morbidity and no impairment of continence.

4. Transanal Approach

Parks and Motson [683] popularized the addition of a full thickness local flap of anterior rectal wall as an adjunct to fistula repair through the intact anal canal (Figures 8 [697] and 9). They modified the transanal technique by denuding the rectal mu-

cosa lateral and distal to the fistula, and mobilized the rectal wall away from Denonvilliers’ fascia proximal to the fistula for four centimeters. Tiptaft et al. [646] also used a special anal retractor for this surgery.

With the Latzko procedure the RUF is closed in three layers with absorbable suture. A transurethral catheter is placed for 3 weeks. Noldus et al. [647] reported 23 patients (3.9%) with rectal injury during 589 RP and cystoprostatectomies. Of these 23 patients, 12 developed a RUF. Seventeen fistulas closed spontaneously with prolonged catheter drainage. The remaining 5 fistulas were all successfully closed with the transanal Latzko procedure.

Al-Ali et al. [665] treated 30 men with RUF caused by war wounds. He used the method of posterior transsphincteric anterior rectal wall advancement as the treatment of choice. Double diversion (end sigmoid colostomy and suprapubic cystostomy) for one month was performed in all patients. Double diversion alone resulted in ‘spontaneous’ RUF healing in 47% of patients but 53% required reconstruction. Early repair was recommended for large fibrous fistulas. Undiversion was done after two months when the urethra and anorectal canals were normal.

5. ANTERIOR TRANSSPHINCTERIC, TRANSANAL SURGICAL APPROACH (ASTRA)

In 1973 Gecelter [685] performed a midline perineal incision to gain access to the urinary tract after placing the patient in exaggerated lithotomy position. The anal sphincter was incised anteriorly, tag sutures carefully placed, and the rectal incision was carried to the fistulous tract, which was excised and repaired in multiple layers with transposition of tissue as available. Castillo et al. [698] reviewed their first 110 consecutive laparoscopic extraperitoneal radical prostatectomies and reported 3 RUF. Only one was cured with conservative management. The other 2 patients were repaired by anterior transspincteric, transanral surgical approach (ASTRA).

6. ENDOSCOPIC APPROACH

Wilbert et al. [687] reported two patients with RUF who were repaired endoscopically transanally. The patients were positioned prone and the rectoscope mounted to the operating table was inserted into the rectum. The fistula was visualized and the opening excised to the level of the perirectal tissues with cautery. The rectal wall was mobilized full thickness with scissors and closed primarily in two layers with a microscope. The patient was then placed in lithotomy position and the urethral side of the fistula was coagulated and injected with fibrin.

Bardari et al. [688] used cyanoacrilic biological glue to close one prostato-perineal fistula complicating an abdominoperineal resection of rectum and one persistent neobladder-ileal fistula. The biologic sealant was administered endoscopically through an open-end 6F ureteral catheter. Quinlan et al. [699] presented the case of an iatrogenic fistula in a 71-year-old man treated by a transanal endoscopic microsurgical (TEM) approach, without recourse to a stoma. Bochove-Overgaauw et al. [700] reported successful repair of 1 of 2 RUF with transanal endoscopic microsurgery (TEM): the RUF occurred after laparoscopic radical prostatectomy. Pigalarga et al. [701] described a case of successful repair of iatrogenic RUF through a multidisciplinary approach consisting of cystoscopy, urethral stent placement, colonoscopy, and transanal endoscopic microsurgery assisted rectal advancement flap.

7. OTHER MODIFICATIONS

Youssef et al. [675] successfully treated 12 male patients who presented with RUF from 1990 to 1997 using the perineal subcutaneous dartos flap procedure. The RUF resulted from crushed pelvic injury in 6 cases, gunshot wounds in 2, and post prostatectomy in 4. The fistula was associated with a urethral stricture in 4 cases. A perineal approach was used and combined with a transsymphyseal approach in the 4 patients with posterior urethral stricture. They interposed a subcutaneous dartos flap as a tissue flap between the repaired rectum and urethra. No leakage or perineal collection developed and there was no fistula recurrence. Follow-up ranged from 9 to 42 months. This technique of a perineal subcutaneous dartos flap may fulfill the principles for successful repair of RUF. Varma et al. [702] also concluded that dartos muscle interposition is a straightforward technique that can result in successful fistula repair, but should not be used in immune-compromised patients or after radiation therapy.

Felipetto et al. [662] used human fibrin sealant (Tissucol) to close a prostato-cutaneous fistula (as a complication of pseudomonas prostatitis). Venkatesh and Ramanujam [703] prospectively studied the efficacy of autologous fibrin glue for closure of recurrent anorectal fistulas. Overall success rate was 60% however patients with acquired immunodeficiency syndrome who had fistulas associated with the urinary tract failed to respond. Verriello et al. [704] used fibrin sealant (Quixil) to inject it into the fistula tract and a rectal mucosal flap was used to close the internal opening. The fistula healed in few weeks, and the patient remained symptom free after 1 year of follow-up.

Chirica et al. [705] reported their experience with coloanal sleeve anastomosis (Soave procedure) as a salvage procedure for complex
rectourinary fistulas after radical prostatectomy or following anterior resection for rectal cancer after radiochemotherapy. All eight patients had a temporary ileostomy, which was successfully reversed in 7. Lesser et al. [706] reported a case of radiation and salvage cryoablation induced RUF after treatment of prostate cancer which was successfully repaired with a combined endorectal advancement flap with an Alloderm graft.

1) Summary

A review of recent literature shows an increasing number of papers describing treatment. All available studies are retrospective cases and case series (level 3 evidence). There are many causes of these fistulas described in the literature but there is a lack of valid epidemiologic data about the incidence of UCF and RUF. The diagnostic algorithm has not changed in many years.

The aim of the surgical approach is the closure of all types of fistulas. While spontaneous closure and success with a one-stage procedure has been reported, most cases to date involve 3 stages (double diversion, closure technique, and undiversion). An endoscopic approach using biological sealants is promising. Only a few urologists and general surgeons have gained wide experience in the management of UCF or RUF, and the management of these difficult conditions should remain in the hands of experts working in tertiary referral centres. No single procedure has yet proved to be best or universally applicable. Conservative treatment is generally ineffective in the management of large RUF. Surgical intervention offers symptomatic relief and improved quality of life in most patients.

All reports are still only retrospective case series (Level of evidence 3; grade of recommendation C).

XI. THE ARTIFICIAL URINARY SPHINCTER (AUS)

Different devices designed to control urinary incontinence in the male began to appear in the middle of the 18th century [707]. The gold standard today is the artificial urinary sphincter (AUS) designed by F.B. Scott, W.E. Bradley, and G.W. Timm in 1973 [708]. The original model underwent a number of modifications, but the basic principle remained the same. It consists of a fluid filled hydraulic system with a cuff around the urethra, a pressure regulating balloon and an activating device, the pump, placed in the scrotum.

1. AVAILABILITY AND COST

The use of the AUS has increased dramatically since its introduction in 1975 when 90 AUS devices were implanted until 2008 when 4818 procedures were done, with 61% implanted for PPI. [709, 710] In 2005, just over 10% of US urologists perform AUS surgery with the vast majority (92%) performing 5 or fewer surgeries a year and there were only 8 surgeons who implanted 21 or more AUS devices per year. [710]

The results of an e-mail survey among urologists and gynecologists were previously published in the 3rd ICI, whereby members of the International Continence Society were asked if the AUS was available in their country; and if so, what was the price of the device (in US dollars). About 10% of the members responded by email from 31 countries. The high price in some countries at the time (Georgia, Hong-Kong, Romania and Saudi Arabia) precluded its use. Very few gynecologists implant the AUS, probably since the majority of patients receiving the device are male.

2. INDICATIONS

The indication for AUS placement is for the treatment of SUI that is persistently bothersome despite 6-12 months of active conservative management. As the most common cause of SUI in men is iatrogenic injury during prostate cancer surgery, it follows that the most common indication for AUS is post-prostatectomy incontinence (PPI). The use of the AUS for the treatment of PPI varies regionally. For example, within the United States, state-by-state use of the AUS ranges from 1% to 10% of all RRP patients, with an average of 6% of RRP patients ultimately undergoing AUS implantation.[711]

Previous radiotherapy to the pelvis is not a contraindication for AUS placement in males,712 as the ultimate outcome seems to be similar in men whether or not they have received radiation therapy [713], although a higher incidence of urethral atrophy, erosion and infection requiring surgical revision has been reported in irradiated patients compared to those not irradiated (41% vs 11%). Despite this observation, long term continence and patient satisfaction appear not to be adversely affected in the irradiated male patient [713].

The compressive effect of the AUS is temporarily relieved when the patient squeezes the scrotal pump, transferring fluid from the urethral cuff to the pressure-regulating balloon. Subsequently, the bladder can then empty either by bladder contraction and/or by abdominal straining. Accordingly, patients voiding with the Valsalva maneuver because of an underactive or neurologically acontractile bladder, do not seem to be at an increased risk of complications [714]. It should also be noted that patients with previous anti-incontinence procedures show a significantly higher explanation rate [715].

Clinical experience suggests that enterocystoplasty or gastrocystoplasty can be done simultaneously
with the implantation of the AUS [716,717]. However, AUS placement at the time of cystoplasty is associated with earlier infections, especially during the first 3 years post-operatively [718]. In the long-term (> 3 years) the infection rate is the same whether the AUS is implanted after or at the time of cystoplasty. AUS can also be successfully implanted in patients after bladder substitution [387], and in those with locally recurrent prostate cancer with a relatively good prognosis [719], or those with severe post-radical prostatctomy anastomotic stricture in whom a stent has been placed previously [398].

Finally, advanced age is not a contraindication to AUS placement. A retrospective analysis by O’Connor and colleagues of a cohort of men over age 75, revealed excellent success rates, with 21 of 29 men (72%) achieving successful continence. Revision rate was 14% at an average of 5 years follow-up, with 14% requiring explantation, and 21% requiring device deactivation due to deterioration in overall health precluding proper use of the AUS at an average of 47 months after placement [720].

3. SURGICAL TECHNIQUES

The original technique of implantation is illustrated in Figure 10. The cuff of the sphincter is placed around the bulbar urethra via a midline perineal incision, while the pressure regulating balloon and the scrotal pump are inserted via a separate inguinal incision. The inguinal incision is carried through the fascia, above the level of the ligament and an area in the prevesical space is bluntly cleared. The pressure-regulating balloon is placed there and filled with 23 cc of saline or contrast after which the fascia is closed. A tunnel is made under Scarpas fascia into the scrotum deep to the dartos fascia where a pocket for the pump is developed. The cuff tubing is transferred from the perineum to the inguinal incision after which the excess tubing is cut off and the appropriate connections are made with the quick connect system.

Another surgical approach has been described using a single, upper transverse scrotal incision which allows the placement of all 3 components of the system, the cuff, the pump in a scrotal pouch, and the reservoir behind the fascia transversalis [304]. Alternatively, the pressure-regulating balloon may be placed through a separate inguinal incision, with the cuff and control pump placed via a single trans-scrotal incision, with the connections among scrotal pump, balloon reservoir, and urethral cuff tubing made in the usual inguinal incision. While the trans-scrotal approach potentially minimizes the invasiveness of the AUS surgery, by limiting the surgical approach to a single incision [304], a few reports have revealed that surgical success might be diminished compared with perineal cuff placement and abdominal balloon reservoir placement [721,722]. A multicenter retrospective study by Henry et al of 158 patients operated on at 4 centers noted that in patients treated with a perineal versus trans-scrotal AUS the perineal group had a completely dry rate of 44%, versus 28% in the scrotal group (p<0.03) and had much higher rates of “social continence” as well. Thus the perineal approach for initial artificial urinary sphincter implantation appears to control male stress incontinence better than the trans-scrotal approach.

The trans-scrotal approach appears particularly useful for simultaneous placement of an AUS and inflatable penile prosthesis through a single incision, with Kendirci and colleagues [723] reporting a urethral erosion rate of 9%, an overall revision rate of 14%, and a social continence rate of 100% in 22 patients at 17 months average follow-up. Sellers, et al. [724] recommend the simultaneous surgery for cost-efficacy. They demonstrated a $7,000 cost savings when both devices were implanted simultaneously through a scrotal approach, compared to staged implantation with 2 separate surgeries.

Recent experience with the relatively new 3.5 cm cuff has demonstrated significant efficacy with no increase in complications during 14 months of study at one site [725]. The 3.5 cm cuff has become the predominant size used for primary and revision surgery at that center.

4. COMPLICATIONS

Complications following implantation of the AUS can be divided into the categories of incontinence, erosion and/or infection, and unusual complications. While the number of AUS procedures performed varies geographically throughout the world. Certain “centers of excellence” perform substantially more procedures than do community hospitals [711]. However, the total number of procedures done in a given center does not seem to be a determining risk factor for complications. Comparable erosion/infection rates have been reported from centers with fewer than 50 or more than 100 cases [282]. This suggests that erosion and infection may be more closely related to the physiologic state of the patient rather than the experience of the surgical team, provided standard precautions are strictly applied. Nevertheless, as experience with the AUS has grown the overall revision rate has reportedly decreased [710].

a) Incontinence

Incontinence following implantation of an AUS can result from (1) alteration in bladder function, (2) atrophy of the urethra, or (3) mechanical failure of the device. These causes may co-exist.

1. Alteration in bladder function

Lai and Boone noted that based on postoperative patient symptoms and the need for anticholinergic medication up to 23% of men undergoing AUS for PPI can develop denovo OAB [268]. UDS were not repeated postoperatively to define the bladder changes associated with this.
A. With the patient in lithotomy position, a perineal incision is made behind the scrotum to expose the bulbar urethra.

B. The urethra is mobilized circumferentially within the bulbospongiosus muscle and the measuring tape is used to obtain the cuff size.

C. The belt-like cuff is positioned around the urethra.

D. A right lower quadrant (RLQ) abdominal incision is made and the extraperitoneal space is entered lateral to the rectus muscle for insertion of the reservoir.

H. Connectors are placed to join the tubes from the cuff and reservoir to the corresponding tubes from the pump in the RLQ incision.

Figure 10. Artificial Sphincter Technique
Alteration in bladder function has been reported principally in patients with neurogenic bladder dysfunction, especially in children [726-731]. These changes include de novo involuntary detrusor contractions, decrease in bladder compliance, and the development of a high-pressure system, causing incontinence, hydronephrosis and ultimately renal failure. Modifications in detrusor behavior (including its consequences on the upper urinary tract) occur in up to 57% of such cases [726-737]. It should be pointed out, however, that there has never been a published report of hydronephrosis following implantation of an AUS for incontinence after prostatectomy [738]. While the ideal candidates for sphincter implantation are those with an incompetent urethral sphincter, and a low pressure, relaxed, and compliant bladder [735], data described earlier demonstrated that even those with "unfavourable" urodynamic factors may have a good outcome after AUS placement [58].

2. Atrophy of the urethra

Urethral atrophy may occur at the cuff site secondary to long-term mechanical compression of the periurethral and urethral tissues. However, some authors do not mention it as a possible cause of AUS failure [336,738,739]. About 4 months following implantation, cuff efficiency diminishes, presumably because pressure atrophy occurs in every patient to some extent 740. The incidence of urethral atrophy leading to revision varies from 3% to 9.3% [253,259,262,423,736-743]. Atrophy can be lessened with nocturnal deactivation of the cuff [744].

b) Mechanical failure

The causes include perforation: of one of the components with loss of fluid from the system, air bubbles or organic debris within the system causing inadequate function of the pump, disconnection of one of the tubes, or kinking of a tube. Introduction of "kink-free" tubing has virtually eliminated this last complication. The incidence of these complications varies widely and ranges from 0% [741] to 52.5% [269] with the longest follow-up. In this latter study, the cuff seemed to be the most vulnerable part of the system (22 cuff failures in 18 patients, most of them occurring during the first 2 to 3 years following implantation), followed by pump failure (6 times in 4 patients). Blockage is an exceptional event, occurring only once in 61 patients followed from 10 to 15 years [269]. In a publication from Baylor [262], chronicling a 13-year experience with the AUS, mechanical failure occurred at an average of 68.1 months postoperatively. An unusual mechanical complication has been reported. The locking tab became displaced distally into the cycling portion of the cuff preventing the fluid from flowing into the cuff surrounding the urethra.[745]

c) Erosion and/or infection

Erosion and infection are two major complications that almost invariably necessitate removal of the prosthesis. Their incidence may be reported separately, or more commonly together as a single complication. The incidence of these complications varies from 0% to 24.6% [253,336,423,729,735,736,741-743,746,747]. Most recent large series report an incidence of infection and erosion generally less than 8% [56,261,262,274,738,739,748,749]. As would be expected, the highest incidence has been reported with the longest follow-up (10-15 years) [253]. Lai and colleagues [262] from Baylor reported that erosion occurred at an average of 19.6 months postoperatively rather than in the peri-operative period. Previous surgery [750] at the site of cuff placement increases the risk of erosion. This, however, may be decreased by delayed cuff activation [751]. A recent study by Lai et al. [752] noted that patients undergoing a "secondary" implant (after a prior explant for erosion or infection) had a four-fold higher erosion rate compared to "virgin" cases. Some authors, however, did not find an increased incidence of complications when a new cuff was implanted at the site where several months before, a cuff has been removed for infection or erosion [753]. Other risk factors include urethral catheterization and urethral endoscopic manipulations with an activated sphincter in place [754]. This point is important and it is crucial that patients with an AUS understand that if they are to have a catheter placed they should ask their physician to have a urologist deactivate the AUS first.

A likely etiology of early erosion is intra-operative laceration of the urethra when dissecting it from the corpora cavernosa, where a difficult anatomical plane exists. Intraoperative recognition of urethral injury can be facilitated by retrograde perfusion sphincterometry using a flexible cystoscope35. While recognition of a urethral injury may alert the surgeon to the necessary termination of the procedure, urethral erosion may still occur without a known urethral laceration [755].

As mentioned above, while the majority of authors consider previous radiotherapy a risk factor for increased infection and erosion, it is not a contraindication to implantation of an AUS in the male patient with PPI [252,254,276,332,713,739,756]. Overall patient satisfaction is similar in those who have been irradiated, compared to those who have not been [252,263,713]. Furthermore, the degree of satisfaction does not diminish with an increased number of surgical revisions [267,757].

d) Rare complications

Several unusual and rare complications have been reported in the literature, such as the intravesical migration of the reservoir with secondary stone formation in the bladder [758], or a giant urethral diverticulum at the site of a previously removed cuff because of erosion and urinary extravasation [759].

5. DURABILITY OF AUS COMPONENTS

When defining durability of one of the components or the AUS as a whole, one should distinguish
between explantation of the device due to device malfunction (e.g. leak in one of the components) or complications caused by an otherwise properly functioning sphincter unit (e.g. cuff erosion, infection at the site of implantation, etc.). This distinction is rarely made in the literature. Durability of a device is defined as time elapsed during which no mechanical problem alters the normal function of the device. This should exclude the second group from further analysis.

There are very few references in the literature pertaining to the length of time a device functioned normally before its removal due to mechanical failure. In a multicenter trial, for neurogenic bladders, conducted in France [736], the authors mention that the “mean operational life” of the sphincter was 56 months (range 3-118 months). Haab et al [259] analyzed 68 patients and noted that the mechanical failure rate dropped from 44.4% to 12.4% since modifications were made to the device, mainly the cuff component. Survival time of these components was not provided. Similar conclusions can be drawn from a series from the Mayo Clinic [265] where the modification of the cuff design (narrower back) resulted in a substantial drop of the reoperation rate at 5 years. In the “narrow back” group 17% (31/184) required reoperation. In that cohort, non-mechanical failure decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff [265]. Mean time to reoperation was 26.2 months (mean 2-68 months). Using Kaplan-Meier statistical analysis for this group of patients, the overall 5-year expected product survival was 75%. In Lai’s report regarding Baylor’s 13-year experience with the AUS, only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years [262]. In a review, Venn et al. [336] analysed the outcome of 100 patients in whom an artificial urinary sphincter was implanted for more than 10 years. Thirty-six percent of them still had the original sphincter and were continent at a median follow-up of 11 years. The bulbar cuff, as compared to the bladder neck cuff provided a slightly better continence rate at 10 years, 92% and 84%, respectively. The lowest erosion rate occurred with the bulbar cuff. Device survival rate at 10 years was 66% in this series.

In a series of 30 boys with spina bifida Spiess et al. [760] found that the mean lifetime of all AUS was 4.7 years, with no statistically significant difference in sphincter survival of those inserted at the bladder neck or the bulbous urethra (4.6 and 4.9 years, respectively). A sharp drop was observed at 100 months with only 8.3% of the original sphincters still functioning beyond this point. In a series of 35 adolescents with neurogenic voiding dysfunction implanted with a bladder neck cuff over an 11-year period, with an average follow-up of 5.5 years, Lopez Pereira and colleagues [761] reported a 20% mechanical failure rate, with an additional 8.6% erosion rate. Adverse bladder storage changes developed in 31.8% of patients, who thereby required augmentation cystoplasty. However, continence was achieved in 91.4% of individuals.

In other series, the global long-term (2 to 7.7 years) revision rate, for any of the above mentioned reasons varies between 16% and 50% [261,262,266,267,424,757,761-763]. In Webster’s report [757] of 554 implantations over a 10 year period, (i.e. performed since the 1987 device modification), he noted a mechanical failure rate of only 31/554 (5.5%). Non-mechanical failure was 88/554 (15.9%), with 63/554 (11.3%) due to urethral atrophy and 21/554 (3.8%) due to cuff erosion. Of the total cohort, 21.4% required at least one revision surgery, while 78.6% did not. Of those 119 patients who required reoperation, 76.5% required no further treatment (similar to the non-reoperation rate of the initial cohort), while 23.5% required re-operation for either mechanical or non-mechanical failure. Five-year durability of the AUS following primary or secondary implantation was comparable, with 80% for the initial placement, and 88% following revision surgery. Similarly, continence status was comparable, with 90% of primary and 82% of revision patients achieving 0-1 pad per day urinary control. Patients with neurologic deficits seem to have a higher risk of non-mechanical failure and the overall continence rate may be lower compared to non-neurologic patients [32].

6. DIAGNOSTIC PROCEDURES RELATED TO ARTIFICIAL SPHINCTER FAILURE

The diagnostic evaluation of urinary incontinence after the placement of the AUS is critical for the management of these patients and represents a challenging problem for the urologist. Several diagnostic and management algorithms have been proposed, some relatively simple, others more complex [32, 33, 276, 282, 737, 764-766]. Figure 11 shows an algorithm to investigate and treat the male patient with a previously functioning AUS who becomes incontinent.

Physical examination should exclude infection at the site of the cuff or the scrotal/labial pump. Difficulty compressing the pump suggests tube kinking, fluid loss or an obstructed system. Loss of fluid from the system may be suggested by the inability of the pump to appropriately refill after just one or two pumps.

Plain X-rays of the abdomen or pelvis may show fluid loss, if the system is filled with radiopaque solution [767, 768] (Figure 1). Alternatively, sonography of the pressure-regulating balloon may show volume loss. One should obtain a baseline plain film after the primary implantation when the reservoir is filled with contrast for subsequent comparison as radio-
Figure 11. Algorithm for managing incontinence after AUS placement.

Figure 12. Endoscopic view of AUS cuff erosion into the bulbar urethra. The patient had undergone radiation after radical prostatectomy.
graphic imaging of the balloon does not detect changes until at least 50% of its volume has been lost [15]. Cystometrogram or complete urodynamic study will demonstrate changes in bladder behavior following insertion of the AUS as described above. Cystourethrogram could eventually demonstrate a urethral diverticulum at the site of previous cuff erosion (Figure 2). Endoscopy will disclose any urethral erosion by the cuff (Figure 12).

Retrograde perfusion sphincterometry has been reported to diagnose the loss of compressive pressure in the urethral cuff [32]. It is done by infusing fluid from the meatus in a retrograde fashion. If the AUS cuff is functional and the urethral is intact there should be no flow when the pressure equals the AUS balloon pressure. This technique can also be used intraoperatively to detect urethral perforation or to adjust the pressure in the cuff [35]. This seems to be more useful than urethral pressure profile (UPP) [733].

Intraoperative electrical testing, using an ohmmeter [747,765] has been described to determine the site of fluid leakage from the system. This test can be helpful to avoid the need to change the whole system, and allow replacement of the leaking part only.

7. TREATMENT OF COMPLICATIONS

As outlined above, complications directly related to the presence of an artificial sphincter can be divided into categories: de novo OAB (which is typically treated as OAB), urethral atrophy, and/or mechanical failure, and infection/erosion. The treatment of these complications deserves comment, as no detailed reference can be found in the literature dealing exclusively with the treatment of these complications.

a) Atrophy of the urethra

Several therapeutic options exist to increase cuff pressure around the atrophied urethral wall: changing the balloon reservoir for one generating a higher pressure, downsizing the cuff diameter [15, 254, 769], or increasing the amount of fluid in the system. The most common approach is downsizing of the cuff. Another approach consists of placing the cuff inside the corporal tunica albuginea on the dorsal aspect of the urethra (transcorporal). This allows a safer mobilization of the urethra and adds some supplementary bulk of tissue to the circumference of the urethra, possibly decreasing the risk of erosion [272]. It should be mentioned, however, that there is a risk of reduced erectile function with this technique. The vast majority of such patients, however, already suffer from erectile dysfunction secondary to the prostate cancer surgery.

The implantation of a double-cuff AMS 800 had a recent period of increased popularity, as a primary procedure in the totally or severely incontinent patient [273,770], or as a salvage procedure, by adding a second cuff, following a failed previous single cuff [270,271,770]. Dimarco’s group [271] and others showed excellent results with the addition of a second urethral cuff, placed 1.5–2.0 cm distal to the primary cuff. Alternatively, a circumurethral wrap of an organic bulking agent can be fitted, with subsequent placement of the AUS cuff over the biologic external urethral bulking agent [771]. Early reports of primary double cuff placement did not demonstrate any significant increase in morbidity with the double-cuff as compared with the single cuff system [273], and patient satisfaction also seemed to be higher [274] at an average of 21-41 months follow-up. However, O’Connor et al. [275] recently described their experience with 28 men who underwent double cuff placement and in contrast to an earlier report of theirs found that with longer follow-up there was no difference in continence between those men and 28 who underwent single cuff placement. In addition those who had the double cuff placement had a higher rate of additional surgery due to complications.

b) Mechanical failure

As with any device, mechanical failure can be expected with the AMS 800 AUS. The treatment involves surgical replacement of the failed component and reconnecting the system.

c) Infection

With overt infection the accepted treatment option is removal of the entire device and appropriate antibiotics. A second system can be subsequently implanted with equally good results [751]. It has been demonstrated, however, that immediate reimplantation of a new AUS after the removal of an infected, but not eroded, prosthesis can be a valid option with an overall success rate of 87% [772]. In 2007, AMS introduced the InhibiZone-coated artificial urinary sphincter (rifampin and minocycline hydrochloride coating) [773].

d) Erosion

In cases of urethral cuff erosion, the “offending” cuff must be removed. No clear guidelines exist whether removal of the whole system is superior to removal of the cuff alone but it must be assessed for infection and if present the whole device should be removed. When in doubt remove the entire system. Reservoir erosion into the bladder has been described following the removal of an eroded cuff [758]. Furthermore, it is not known whether it is nec-
necessary to allow the urethra to heal over a catheter versus surgical repair. Most though would leave a catheter to allow for spontaneous healing and wait at least 4-6 months before placing another cuff. When a new cuff is placed it should be positioned away from the erosion site. In case of the erosion of one of the cuffs of a double system removal of the eroded cuff can successfully convert a double-cuff system into a single cuff system [774]. It is logical that intra-operative urethral injury may precipitate cuff erosion if unrecognized.

8. CONSENSUS PROTOCOL FOR FOLLOW-UP OF PATIENTS WITH AUS

As complications continue to be seen for years after implantation [775], it is helpful to have a structured follow-up plan. However, no standardized recommendations are available in the literature.

The consensus upon which the members of this subcommittee agreed and which is based on expert opinion are as follows:

1. Perioperative antibiotics are required. Gram-negative enteric bacteria and Staphylococcus epidermidis are the most frequently encountered microorganisms in infected prostheses [754].

2. Hospital stay should be kept to a minimum.

3. Urethral catheters, if inserted, should be withdrawn within 24-48 hours of surgery and the preoperative continence management continued.

4. The sphincter device should not be activated immediately postoperatively. In the initial period scrotal edema and pain prevent patients from manipulating the pump adequately. When this subsides after 6 to 8 weeks the device can be activated. Earlier activation may also be acceptable. Irradiated patients may benefit from a longer initial period of deactivation, up to 12 weeks [254]. Nocturnal deactivation should be considered in high-risk patients [253].

5. Patients are reviewed at 3 months after activation to ensure the device is working adequately, and to assess the continence status.

6. Long-term follow-up is different in the neurogenic and non-neurogenic patient. With time, alteration in bladder function may jeopardize renal function in the neurogenic patients. Periodic ultrasound evaluation of the upper urinary tract and monitoring of renal function is essential. If changes occur, urodynamic studies should be done to rule out detrusor overactivity. In non-neurogenic patients, periodic ultrasound may not be necessary.

7. When changes in the continence status occur diagnostic procedures depicted in Figure 11 should be considered. (Level of evidence 3; Grade of recommendation B-C)

XII. SUMMARY AND RECOMMENDATIONS

1. EVALUATION OF MALE INCONTINENT PATIENTS

Prior to surgery a basic patient evaluation should consist of history and physical examination, urinalysis and postvoid residual urine (Level of evidence 1-2: grade of recommendation A).

- A voiding diary is helpful to assess functional capacity and total urine output (Level of evidence 1-2: grade of recommendation B).

- Pad tests may be useful in certain circumstances (Level of evidence 1-2: grade of recommendation B).

- Blood testing (BUN, creatinine, glucose) is recommended if compromised renal function is suspected or if polyuria or poor urinary concentrating ability (in the absence of diuretics) is documented.

- Additional testing with cystoscopy and appropriate imaging of the urinary tract may be helpful in guiding therapy (Level of evidence 2-3: grade of recommendation B).

- The committee felt that multichannel urodynamics may be useful prior to invasive treatment for incontinence. (Level of evidence 3: grade of recommendation C)

2. INCONTINENCE POST-PROSTATECTOMY FOR BPO AND POST-RADICAL PROSTATECTOMY FOR PROSTATE CANCER

After a period of conservative management, which may also be from 6 to 12 months (Level of evidence 3-4; grade of recommendation C):

- The artificial sphincter is the preferred treatment for properly selected men who have stress incontinence after radical prostatectomy with the longest record of safety and efficacy. The AUS has been reported extensively for men with moderate to severe incontinence. (Level of evidence 2-3; grade of recommendation B)

- Male slings are an alternative approach with intermediate data supporting their safety and efficacy in men with more moderate degrees of PPI. Long-term data are beginning to accumulate. However,
the literature contains results on many different kinds of slings. (Level of evidence 3; grade of recommendation C)

- Injectable agents are an inferior option. (Level of evidence 3-4; grade of recommendation C)
- Adjustable balloons have also been reported. (Level of evidence 3; grade of recommendation D (no recommendation possible))

3. INCONTINENCE FOLLOWING OTHER TREATMENTS FOR PROSTATE CANCER

- The artificial sphincter is most widely used but radiation may be a risk factor for an increase in complications. (Level of evidence 3; grade of recommendation B)
- Slings have variable results after radiation. (Level of evidence 3; grade of recommendation C)
- Injectable agents (Level of evidence 3-4; grade of recommendation C)
- Adjustable balloons have not been successful in this setting. (Level of evidence 3; grade of recommendation D (not recommended))

4. INCONTINENCE FOLLOWING PELVIC TRAUMA (Level of evidence 3; grade of recommendation C)

- The artificial sphincter is most widely reported.
- Lower urinary tract reconstruction has also been reported on a limited basis.

5. INCONTINENCE IN ADULT EPISPADIAS-EXTROPHY COMPLEX (level of evidence 3; grade of recommendation C)

- Patients should be treated in centres of excellence.
- A patient-directed approach should be taken.
- The choices include further bladder neck reconstructive surgery, bladder neck closure, bladder reconstruction or diversion with bowel.
- The data are insufficient for a specific recommendation.
- Transition is important between the pediatric and adult urologist.
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications

6. REFRACTORY URGENCY INCONTINENCE AND DETRUSOR OVERACTIVITY

- Botulinum toxin-A bladder injection is a minimally invasive treatment with efficacy (Level of evidence 1-2; grade of recommendation B).
- Neuromodulation is a treatment option with success reported in a limited number of male patients. (Level of evidence 3; grade of recommendation C)
- Detrusor myectomy has also been reported to be successful in a small number of male patients. (Level of evidence 3; grade of recommendation C)
- Augmentation cystoplasty is potentially successful in controlling symptoms but may be associated with unacceptable side effects. (Level of evidence 3; grade of recommendation C)
- Urinary diversion is a final option. (Level of evidence 3; grade of recommendation C)

7. REDUCED CAPACITY BLADDER

- Augmentation cystoplasty has been successful in most etiologies. (Level of evidence 3; grade of recommendation C)

8. URETHROCUTANEOUS FISTULA AND RECTOURETHRAL FISTULA (Level of evidence 3; grade of recommendation C)

- Etiologic factors causing acquired urethrocutaneous fistulae are demonstrated by clinical, endoscopic and imaging studies.
- Similar diagnostic maneuvers are applied to rectourethral fistulae.
- Surgical reconstruction is applied as required.
- In those that do not close with or without temporary urinary and fecal diversion, surgical reconstruction may be carried out.
- Most repairs are now carried out after prior fecal diversion.
- Various techniques are available for closure and can be done in collaboration with colorectal surgeons.

9. MANAGEMENT OF AUS COMPLICATIONS (Level of evidence 3; grade of recommendation C)

- Incontinence may result from alteration in bladder function, urethral atrophy, or mechanical malfunction.
- Infection and/or erosion of components demand surgical removal of all or part of the prosthesis.
- A treatment algorithm is presented to aid in management and in follow-up of patients.
10. NEW TECHNOLOGIES (Level of evidence C; grade of recommendation D)

- Tissue engineering has not been widely reported in males apart from isolated reports of preliminary studies. [776, 777]
- A new one-piece adjustable artificial sphincter has been reported with social continence (0-1 pads/day) in 28/36 men at 6 months after device activation. [778] The removal rate was 11% for erosion/infection.

FUTURE RESEARCH DIRECTIONS

- New technologies, bulking agents, sling materials, prosthetic devices should continue to be evaluated
- Accuracy in reporting of early research results is mandatory
- Mechanisms of post-prostatectomy incontinence and device effects need further research

CLINICAL TRIAL RECOMMENDATIONS

- Randomized trials (AUS and slings)
- Standardized workup and outcome measures including QoL
- Evaluation of the role of urodynamics in the workup
- Complete reporting of complications and outcomes especially those of slings
- Standardised definitions of cure/improved/unchanged/worse
- Reporting of procedures to salvage failures
- Long-term results (>2 years)
- Standardized reporting of durability

IX. CLINICAL TRIAL OUTCOMES USED IN STRESS URINARY INCONTINENCE RESEARCH

REFERENCES
A. Introduction

This chapter is intended to present a further assessment of surgical interventions for urinary incontinence in women. The intent of this chapter is to build upon data that were previously collated for the ICUD Report of 2009. This chapter updates the current status of surgical interventions for stress urinary incontinence and includes additional data that have been forthcoming regarding new interventions (such as transobturator tapes and single incision slings).

The further enhancement on sections related to clinical research and specific outcomes reporting on clinical trial design has been updated with experience from recently reported multi-institutional trials which assess surgical interventions for incontinence.

SEARCH STRATEGY

Material collected for this chapter was based on electronic searches of Medline, EMBASE, Cinhais, Cochrane Database of Systematic Reviews and the NICE website (www.nice.org.uk). Review papers were separately searched for additional references not identified by initial database search. Individual papers where then selected from April, 2008 to present in European, UK and North American journals of Urology, Gynecology, and Urogynaecology. Additionally, conference preceedings from 2008 were also reviewed inclusive of ICS, IUGA, AUA, AUGS. Hence, some more recent abstracts are included in the following reviews based upon time to press and non-identification of associated publications with those abstracts. Approximately 454 articles were identified for inclusion in addition to the original 762 which were included in the 2009 chapter. Search terms included; Urinary incontinence: stress, mixed, urge. Surgical procedures; minimally invasive, urogenital, gynaecologic, urologic, urinary tract, urethra, vagina, bladder, ligaments; colposuspension, vesicosuspension, urethrosuspension; vesicourethral or urethrovesical; colpourethrosuspension; colpofixation; Burch; Marshalls, Marchetti, Krantz; paravaginal, pubococygeal, obturator; bladder, neck needle; ligament fixation; colporraphy; anterior or vagina; Surgical mesh; sling, bladder, surgical or synthetic, or biological or autologous; tape; urethra, suburethra, midurethra, transurethra, pubovesical; retropubic, suprapubic; pubovaginal, implant: Bologna, Ingelman, Sundberg; Prostheses: injections; bulking agents, Contigen; collagen; Macroplastique, silicones; microparticulate; hyaluronic acid; carbon particles; polytetrafluoroethylene; biocompatible materials; urinary sphincter, artificial.

Since the last review more high quality evidence is available based upon randomised controlled trials at multi-institutional programs. Level I, Level II and Level III evidence are included in the current publication. Additionally, systematic reviews where appropriate have also been included to update those referenced in the 2009 chapter. Additionally, national and international guidelines such as the National Institute for Health and Clinical Excellence (NICE) in the UK were also included where appropriate for complete summation of current status of interventions for stress urinary incontinence in women. It is to be noted that transobturator tape data are now of sufficient maturity to be included at length in addition to other midurethral data, both regarding standard retropubic as well as single incision approaches.

I. SURGERY FOR STRESS INCONTINENCE (INCLUDING COMPLICATIONS)

1. URETHRAL BULKING AGENTS

Since the last International Consultation, bovine collagen (Contigen®) has become obsolete due to manufacturing cessation. Currently available agents include; calcium hydroxyl apatite (Coaptite®), carbon coated Zirconium (DuraspHERE®), polydimethylsiloxane elastomer (Macroplastique®) and polyacrylamide hydrogel (Bulkamid®). Additionally limited data has been published regarding non-animal stabilized hyaluronic acid/dextranomer NASHA-dx (Zuidex®). Recent experience has also been reported with adult stem cells for the indication of stress urinary incontinence.
Urethral bulking agents may be injected either transurethrally or periurethrally in a retrograde manner, using either ultrasonographic, direct cystoscopic or implacer-guided device implantation. Device implantation optimally occurs in the proximal urethra, either single or multiple injections with strategic planning for reinjection at some point after initial injection. Clinical trials have defined specific injection schedules (usually three injections) as part of trial therapeutic algorithms. Optimal injection technique has yet to be standardized, although it does appear that urethral mucosa visualization at procedure completion is not predictive of final outcome. Prior systematic reviews have formed the basis of NICE guidance [National Collaborative Center for Women’s and Children’s Health, 2006, National institute for Health and Clinical Excellence, 2006b]. Methodologic problems with most non-regulatory trials limit the ability to generalize the results of those trials to clinical experience.

Ghoniem, et al [2009][1] reported a randomized controlled trial of polydimethylsiloxane elastomer versus Contigen in 247 women. Repeat injection was allowed at three months after initial delivery for persistent incontinence. Efficacy was determined at one year post last injection using Stamey Grade scoring, pad weight change and quality of life assessment. 122 patients received polydimethylsiloxane elastomer. Additionally, 125 patients received Contigen. At one year post treatment, 61.5% of patients who received polydimethylsiloxane elastomer had improved by one Stamey Grade as compared to 48% of controls. The cure rate at one year was 36.9% of the Macroplastique group and 24.8% in the Contigen group, which was statistically significant. Pad weight changes (one hour pad weight) were 25.4 mL from baseline in the polydimethylsiloxane elastomer group and 28 mL in the Contigen group. Both groups had improvement in quality of life assessments (28.7% and 26.4% respectively).

Ghoniem, et al recently reviewed clinical outcomes associated with the use of polydimethylsiloxane elastomer as a bulking agent for stress incontinence. They identified a total of 958 patients in 23 cohorts in their review. Overall, short term (defined as less than six months) improvement rates were 75% with 64% improvement rates long-term (greater than 18 months). Cure rates were 43% at less than six months and 36% at greater than 18 months using a variety of definitions including pad weight, number of pads used and subjective reporting. The authors noted that as re-injection rates increased, there was improvement in long-term stress incontinence outcomes. Safety events associated with injection included retention, irritative voiding symptoms, dysuria, and urinary tract infection. [Ghoniem, 2012] [2]

The same study population was assessed at 24 months from last injection in subsequent publication. At that time, 67 patients in the polydimethylsiloxane elastomer arm were available for follow-up of whom 45 or 67% were continent. Of those patients who were dry at 12 months [38], 33 remained dry at 12 months. Additionally, 12 of 29 patients improved at 12 months, progressed to urinary incontinence at 24 months. Global quality of life scores and subscales all were statistically improved from baseline. Pad weight changes decreased from 24 grams at baseline to 4 grams at 12 and 24 months. There was no long-term complication noted in this population. [Ghoniem, 2010][3]

Polyacrylamide hydrogel has also been reported as a potential agent for bulking. Lose, et al [2010],[4] reported on the use of polyacrylamide hydrogel in 135 women with urinary incontinence (either stress or mixed) who were followed-up for 12 months after injection. Of that group, 47 (35%) required repeat injection. At one year, overall subjective response rate was 66%. Incontinence episodes per 24 hours decreased from baseline of 3 to 0.7 at one year. Additionally, overall urine leakage by pad gram weight decreased from 29 grams at baseline to 4 grams at end of trial. Overall ICIQ demonstrated improvement in quality of life. The most frequent adverse event in this trial was urinary tract infection (10 patients).

Tooze-Hobson, et al, [2011][5] reported a two year follow-up of polyacrylamide hydrogel in 135 women. At twenty four months, 64% of patients remained responders (as compared to 67% at twelve months). Responder was defined as subjective improvement. Overall decreases in urinary incontinence episodes and volume of urine incontinence (pad weight) were stable as compared to twelve months evaluation, as were other objective outcomes and quality of life data.

Gopinath [2011][6] reported a periurethral abscess associated with the use of this agent which required surgical drainage.

Non-animal stabilized hyaluronic acid/dextranomer has been compared to bovine collagen by Lightner, et al [2009],[7] This trial utilized an implanting device for non-animal stabilized hyaluronic acid/dextranomer injection. Bovine collagen was delivered endoscopically under direct vision. This trial failed to demonstrate equivalence of non-animal stabilized hyaluronic acid/dextranomer to direct vision injected bovine collagen in all primary and secondary outcome variables. 84% of women who were injected with bovine collagen experienced a 50% reduction in urinary incontinence in provocative testing versus 65% in the non-animal stabilized hyaluronic acid/dextranomer group. Of note, non-animal stabilized hyaluronic acid/dextranomer was associated with injection site sterile abscesses in 8.4% of patients, injection site mass in 4.4% of patients and pseudo cyst formation in 2.2% of patients. Irritative voiding
symptoms and injection site pain were more common with non-animal stabilized hyaluronic acid/dextranomer than with bovine collagen.

Lightner, et al. [2010][8] reported a single institutional review of 56 patients who underwent implantation with non-animal stabilized hyaluronic acid/dextranomer. This trial included 35 women and 6 men. Of the women, 4 developed pseudo abscess formation requiring multiple operative interventions also associated with a high rate of failure amongst all women with ISD.

Mohr, et al [2012][9] reported a large series of 514 women treated with bulking therapy with either collagen, hyaluronic acid, ethylene vinyl alcohol (no longer marketed) or polyacrylamide hydrogel. Outcomes were reported using standardized pad tests, visual analogue score for severity of incontinence and Kings Health Questionnaire. 61 patients in the entire study were lost to follow-up. Overall pad testing was negative in 73.2% of women after bulking therapy with statistical improvement in both pad weight and visual analogue score changes for each of the agents used at one year post implantation. Re-injection was permitted six weeks after initial injection in this study.

The role of bulking agents as salvage therapy for women who undergone prior mid-urethral sling procedures and were not satisfied with postoperative results was assessed by Lee, et al [2009].[10] The authors reported 23 women who had undergone mid-urethral slings who then received therapy with polydimethylsiloxane elastomer or carbon coated zirconium beads. They noted a cure rate of 34.8% at a median follow-up of ten months and improvement in secondary outcomes. Overall, 92% of patients reported benefit from therapy and the authors reported no complications.

Recently an update to the Cochrane Analysis of Urethral injection therapy has been published [Kirchin, 2012]. [13] This analysis identified 14 further trials for non-injectable agents. The Cochrane Analysis concluded there was no difference in manner of delivery (peri- versus trans-urethral injection) method, although there was a trend towards higher early complications with peri-urethral injection. Additionally, weak evidence supports mid-urethral injection resulting in improved patient satisfaction compared to bladder neck injection. The Cochrane analysis also concluded that all bulking agents appeared to provide similar overall improvements as compared to bovine collagen. Non-animal stabilized hyaluronic acid/dextranomer appeared to be associated with higher rates of injection site complications (15% with non-animal stabilized hyaluronic acid/dextranomer as compared to none with bovine collagen). In the few trials that have compared injection therapy with surgical management, better overall objective cure was obtained in surgical as compared to the injection groups.

The overall conclusion of the Cochrane analysis was that the evidence base remained insufficient to guide practice, specifically regarding optimal choice regarding bulking device, mechanism delivery, or identification of the optimal patient for bulking.

Research in autologous stem cell based urethral bulking continues. To date, no large scale randomized trials have been published, although, abstracts have been presented at various meetings. Durability and length of follow-up will be critical to assess the contribution of this possible bulking option. [Du,2012][14]

**Recommendation**

Bulking agents provide an option in the management of women with stress incontinence. Optimization of results is dependent upon repeat injections to achieve and sustain efficacy. Additionally, efficacy with at least some bulking agents appears to diminish with time and may be inferior to surgical interventions. Overall complication rates associated with bulking agents appear to be relatively low (Grade B). Continued development of new materials for injection should be under strict regulatory guidance and evaluation using RCT design construct and long-term follow-up (at least 12 months after last injection) (Grade D) (Evidence level II/III).

2. RETROPUBIC MID-URETHRAL SLINGS (MUS)

The tension-free vaginal tape (TVT) procedure for treatment of female stress urinary incontinence was first introduced by Ulmsten et al. in 1996. [15] The development of the TVT operation was an attempt to support the middle portion of the urethra, instead of restoring anatomy and correcting urethral hypermobility at the bladder neck. The idea of supporting the “mid-urethra” has been derived from the results of several research projects conducted during the last thirty years. The work of Zaccharin in 1968 and Delancey in 1994 had already shown that the pubourethral ligaments inserted at the mid-urethra and that the urogenital diaphragm also was closer to the middle portion of the urethra than the bladder neck. [16, 17] In 1978, Owman et al. found that the most densely innervated portion of the urethra was the middle part and Huisman in 1983 showed in histological studies that the mid-urethra had the most abundant vascularisation. [18] Additionally, Westby et al. in 1982 showed in radiographic studies how the urine stream was interrupted at the mid-urethra.
on holding in continent women and Asmussen et al. in 1983 showed that the maximal urethral closure pressure was situated at the midurethra.[19, 20] It quickly became apparent that focusing on the mid-urethra might bring improvement in the performance of incontinence surgery.

Prospective observational cohort studies revealed that placing a macroporous, monofilament polypropylene tape at the mid urethra resulted in cure rates between 80-90% in primary cases of SUI [Ulmsten et al., 1996; Ulmsten et al., 1998; Nilsson, 1998; Ulmsten et al., 1999; Nilsson et al., 2001], [15, 21-24] in recurrent cases [Rezapour and Ulmsten, 2001; Kuva and Nilsson, 2003],[25, 26] in mixed incontinence cases [Rezapour and Ulmsten, 2001], [25] and in an unselected group of women including primary, recurrent and mixed incontinence as well as women with intrinsic sphincter deficiency [Nilsson and Kuva, 2001]. [24] Since those initial reports of success, several groups have reported long-term outcomes exceeding 5 years [Ankardal et al., 2006; Doo et al., 2006; Deffieux et al., 2007; Chene et al., 2007; Song et al., 2009] and 10 years after the TVT procedure [Nilsson et al., 2008; Olsson et al., 2010][27] [28] A variety of follow-up regimens and definitions of success reveal that the effects of the TVT on resolution of SUI are durable over the long-term.

Since the last ICI review was conducted, the literature regarding the TVT and other retropubic MUS procedures has expanded at an almost exponential pace. As an example, only 12 RCTs comparing MUS to other procedures were available for review and most of these were small (<50 patients in each arm) and underpowered. The number of RCTs and large cohort studies available today significantly exceeds the previous review, and, unless otherwise mentioned, only fully-published studies have been included herein.

**a) Retropubic MUS vs. no treatment (table 1)**

A multicentre, prospective RCT performed by Campeau et al. enrolled 69 elderly who initially consented to be randomised to either undergo immediate TVT surgery or to wait for 6 months before submitting to the same surgery (control group). [29] The main outcomes measured at every visit (pre-randomisation, 8-12 weeks and 6 months) consisted of the Incontinence-Quality of Life (I-QOL) Questionnaire, the Patient Satisfaction Questionnaire and the Urinary Problems Self-assessment Questionnaire. The analysis included 31 patients in the immediate surgery group and 27 subjects in the control group. Perioperative complications in the immediate surgery group were bladder perforation (22.6%), urinary retention (12.9%), urinary tract infection (3.2%) and de novo urgency (3.2%). At 6 months, the mean scores on each questionnaire were significantly in favour of the TVT group. [EL=1/2]

**b) Retropubic MUS vs. open colposuspension (table 1)**

Since the ICI-4 review, only 3 additional studies have published comparing TVT and open colposuspension [McCracken et al., 2007; Tellez Martinez-Fornes et al., 2009; Wu et al., 2010]. [30-32] In a non-randomised trial with significant failed-to-complete follow-up, McCracken et al. found no difference in subjective success rates via questionnaire between colposuspension and TVT at 5 to 10 years. [30] In an RCT randomising 49 women to TVT or colposuspension, Tellez Martinez-Fornes found no significant difference in subjective success rates (cured/improved) between the 2 procedures at follow-up periods of 6, 12, and 36 months. [31] In a retrospective, non-randomised trial comparing 105 women who underwent TVT with 81 women who underwent MMK, the authors found that while the short-term success rate of the MMK was 89%, the rate fell to 68.2% at 5 years and 32% at 10 years. [32] In comparison, the short-term success rate of the TVT was statistically similar to the MMK (90%) but decreased only to 84.3% at 5 years. Women who underwent TVT also experienced shorter operative time, less blood loss, and shorter hospital stay. [EL=3/4]

Four of the studies from ICI-4 comparing TVT with open colposuspension used objective outcome measures for defining cure: 1 hour pad test [Ward et al., 2002; Liapis et al., 2002; Wang et al., 2003; Ward et al., 2004; Ward et al., 2008], [33-37]cystometry [Ward et al., 2002], [33] and a cough-stress test [Ward et al., 2002; Ward et al., 2004; Bai et al., 2005].[33, 36, 38] One study only used subjective outcome measures [El-Barky et al., 2005]. [39] None of these studies found any statistical differences in objective cure rates between the two operations. The cure rate ranged between 63 and 87% in the TVT groups and between 51% and 90% in the open colposuspension groups. The time period of follow-up was between 3 and 24 months in all five trials except the 5-year extension of the U.K. & Ireland TVT Trial Group [Ward et al., 2008]. [37] These 5-year outcome data are hampered by a significant lost to follow-up rate (58% in the TVT group and 67% in the colposuspension group). The criteria of subjective cure were for the most part poorly defined and validated QOL questionnaires were only used in the 2002 study.[33] There was no difference in subjective cure between the TVT and the colposuspension groups. [EL=1/2]

As in the study by Tellez Martinez-Fornes, operative time, hospital stay and time for resuming normal activity was significantly shorter in the TVT groups [Ward et al., 2002; Liapis et al., 2002; El Barky et al., 2005].[33, 34, 39] Ward et al. [2002] found that the percentage of intra-operative bladder perforations was significantly greater in the TVT group (9%) than in the colposuspension group (3%), while El Barky et al.

*: Included in ICI-4  
^: Included in Systematic Review (Novara, 2010)  
†: Included in Cochrane Review (Ogah, 2011)

Key: RP MUS=retropubic midurethral sling; F/U=_follow-up (months); LE=level of evidence; TVT=tension-free vaginal tape; o=objective; s=subjective; N/A=not available; OC=open colposuspension; LC=laparoscopic colposuspension; ITT=intention to treat
reported no perforations in the colposuspension group and two in the TVT group (p < 0.05). [33, 37] Wound infections were more common in the colposuspension group (p < 0.05). Significantly more patients experienced delayed voiding in the colposuspension group in the Ward et al. [2002] study and in the 2 years follow-up report of the same study there were significantly more patients in the colposuspension group needing intermittent self catheterisation (p < 0.0045) and surgery for pelvic organ prolapse (p < 0.0042). [33, 36] [EL=1/2]

The Cochrane review comparing the outcomes of minimally-invasive suburethral sling operations with open colposuspension included 9 trials, and included 5 of the trials mentioned above [Ward et al., 2002; Liapis et al., 2002; Wang et al., 2003; Bai et al., 2005; El Barky et al., 2005].[40] The remainder of the studies were either in abstract form or provided a comparison between transobturator MUS and colposuspension. A total of 729 women studied within the first 12 months after surgery showed subjective cure rates of 79% with MUS and 82% after open colposuspension. This difference was not statistically significant (RR 0.96, 95% CI 0.90 to 1.04). In 2 trials [including Ward et al., 2004] follow-up at 2 years also failed to show a statistically significant difference (RR 1.11, 95% CI 0.91 to 1.34). In the 3 trials evaluating objective cure rates [including Liapis et al., 2002, and Wang et al., 2003], there was no significant difference at 12 months (RR 1.04, 95% CI 0.94 to 1.14), after 2 years (RR 1.01, 95% CI 0.92 to 1.11) and after 5 years (RR 0.90, 95% CI 0.77 to 1.10). [EL=1/2]

A limitation to the conclusions that can be drawn from the aforementioned study results is the fact that most of the trials include fewer than 50 patients in each arm and lacked any mention of power calculations. The trials by Ward et al. enrolled a greater number of patients and included power calculations, but did not reach the required number of patients. [33, 36, 37]

c) Retropubic MUS vs. laparoscopic colposuspension (table 1)

Four of the 12 RCTs in ICI-4 comparing retropubic MUS with traditional incontinence procedures compare TVT with laparoscopic colposuspension [Persson et al., 2000; Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004]. [41] [40] [39] [38] [37] [36] [35] [34] [33] [32] [31] [30] [29] [28] [27] [26] [42] [43] Two additional trials have been published since that review [Foote et al., 2006; Tong et al., 2008] as well as an update of the Paraiso et al. study [Jelovsek et al., 2008]. [44-46] The Cochrane review included 5 fully-published manuscripts [Persson et al., 2000; Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004; Foote et al., 2006] along with 2 abstracts. [40]

In the studies comparing TVT or Supra Pubic Arc Sling (SPARC; a monofilament polypropylene MUS placed through a top-down approach) with laparoscopic colposuspension objective cure was assessed by a pad test in 2 of the 6 studies [Persson et al., 2000; Valpas et al., 2004], [43, 47] and by a cough-stress test in 3 of the studies [Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004]. [41, 42, 47] The criteria for cure or improvement were unclear in the study by Foote et al. [44]. The trial by Valpas et al. with the greatest number of patients enrolled showed a significantly higher objective and subjective cure rate in the TVT group than in the laparoscopic colposuspension group (p < 0.0001), [47] while the other studies showed similar cure rates for both procedures ranging between 72.9% and 96.8% in the TVT groups and between 58.8% and 87% in the laparoscopic colposuspension groups. It was thought that the Valpas et al. trial may have shown a significant difference in outcomes in favour of TVT due to a difference in laparoscopic technique (using mesh rather than sutures to perform colposuspension). [40] In their trial, Paraiso et al. performed postoperative multichannel urodynamic studies in 32 laparoscopic Burch colposuspension and 31 TVT patients showed a higher rate of urodynamic stress incontinence at 1 year in the laparoscopic Burch colposuspension group, 18.8% versus 3.2% (p = 0.056). [41] There was a significant improvement in the number of incontinent episodes per week and in UDI and IIQ scores in both groups at 1 and 2 years after surgery (p < 0.001). However, postoperative subjective symptoms of incontinence (stress, urge, and any urinary incontinence) were reported significantly more often in the laparoscopic Burch colposuspension group than in the TVT group (p < 0.04 for each category). At long-term follow-up of the previous study, Jelovsek et al. confirmed that the TVT has similar efficacy to the laparoscopic Burch for the treatment of SUI. [100] While not always bothersome, the authors cited a substantial number of women in either group who had some degree of incontinence 4 to 8 years after surgery. Although laparoscopically-performed colposuspension is regarded as a less-invasive operation than the open colposuspension the MUS procedures had significantly shorter operating time, hospital stay, and time for resuming normal activity than the laparoscopic colposuspension. [40] [EL=2]

As with the studies comparing open colposuspension with MUS, the conclusions of studies comparing MUS with laparoscopic colposuspension may be limited due to underpowering. Dean et al. performed a systematic review of laparoscopic colposuspension (n = 264) and TVT (n = 290) which included 7 trials. [101] There was no statistically significant difference in the reported subjective cure rate between laparoscopic colposuspension and TVT within 18 months (RR 1.12, 95% CI 0.98 to 1.29). However, within the same time period, the overall objective cure rate was statistically significantly higher for TVT (RR 1.16, 95% CI 1.07 to 1.25). There were no significant differences be-
between the two procedures with regards to perop-
erative complications, de novo detrusor overactiv-
ity, voiding dysfunction, procedural costs and QoL
scores. The authors confirmed that the TVT pro-
dure was quicker to perform and was associated
with a shorter hospital stay. [EL=1/2]

A systematic review by Novara et al. evaluated
open and laparoscopic colposuspensions together
with retropubic MUS. [48] Women receiving MUS
had significantly higher overall (OR 0.61; 95% CI
0.46 to 0.82, p=0.00009) and objective (OR 0.38;
95% CI 0.25 to 0.57, p<0.0001) cure rates than
those receiving colposuspension. A clinical and
economic subanalysis of the Valpas et al. study
suggested that over a follow-up period of 1 year the
TVT is more cost-effective than laparoscopic mesh
colposuspension as a primary treatment for female
SUI. [103] [49][EL=1/2]

d) Retropubic MUS vs. traditional sling

This comparison will be addressed in the section on
traditional pubovaginal slings.

e) Retropubic MUS vs. retropubic MUS (table1)

The favorable results obtained with the TVT opera-
tion have resulted in several modifications of the
procedure and the use of different tape materials.
These retropubic modifications have been poorly
clinically evaluated and only 6 randomised stud-
ies comparing these with the TVT have been pub-
lished. The meta-analysis by Novara et al. did not
evaluate the comparison between different types
of retropubic MUS procedures. [48] In ICI-4, 3
RCTs compare the TVT with the SPARC [Andonian
et al., 2005; Tseng et al., 2005; Lord et al., 2006].
[50-52] The study by Lord et al. included 147 TVT
and 154 SPARC cases and showed no statisti-
cal difference in estimated blood loss of >100 mL
(TVT, 21.8% vs. SPARC, 18.2%), de novo urgency
(TVT, 40.5% vs. SPARC, 42.4%), objective cure
(TVT, 97.3% vs. SPARC, 97.4%) or vaginal mesh
extrusion (T VT, 4.8% vs. SPARC, 10.5%). [51]

Acute urinary retention (TVT, 0% vs. SPARC 6.5%;
OR =, 95% CI 2.2-∞; p=0.002) and subjective cure
(TVT 87.1% vs. SPARC 76.5%; OR 2.07, 95% CI
1.13-3.81; p=0.03) were statistically significantly
different. Tseng et al. reported a 12.9 % of blade
perforation in the SPARC group with none in
the TVT group. [52] While the difference did not
reach statistical significance in this small study (31
patients in each group), the authors felt it to be
clinically significant. [EL=1/2]

Four additional non-randomised studies compared
TVT with SPARC [Dietz et al., 2004; Gandhi et al.,
2006; Kim et al., 2006; Paick et al., 2008].[53-56]
In the Dietz et al. study, there were no significant
differences for subjective cure/improvement, patient
satisfaction, or symptoms of incontinence. [56] The
cough-stress test was positive in 8 of 37 women
who underwent SPARC compared to 4 of 69 TVT
patients ( p=0.019). The TVT had a more negative
effect (p=0.001) on postoperative voiding. In the
Gandhi et al. study, 107 of 122 women returned for
objective postoperative evaluation after surgery.
[55] The TVT procedure was associated with higher
subjective (86% vs. 60%, p=0.001) and objective
(95% vs. 70%, p<0.001) SUI cure rates, while there
was no difference between the TVT and SPARC
groups in the resolution of subjective and objec-
tive UUI. Kim et al. found no difference in objective
cure rates at 1 year of follow-up and complication
rates were similarly low. [54] Paick et al. found no
significant difference in cure of SUI or cure of all in-
continence between TVT and SPARC at 6 months.
[53] [EL=3/4]

In ICI-4, 3 RCTs compared TVT with the intra-
vaginal slingplasty (IVS) procedure, which util-
ises a multifilament, miniporous polypropylene
tape material [Rechberger et al., 2003; Lim et
al., 2005; Meschia et al., 2006]. [57-59] Only the
study by Lim et al. was included in the Cochrane
analysis. [40] In the study by Meschia et al. that
included 95 patients in each group, the objective
cure rate was 85% for the TVT and 72% for the
IVS and the subjective cure rate was 87% and
78%, respectively, with no difference between
groups. [58] There was a 9% vaginal extrusion
rate during the 2 years of follow-up in the IVS
group, and 0% extrusion in the TVT group.
Re-
chberger et al. found no significant difference
in cure rates between the groups at a mean of
13 months of follow-up.[57] Lim et al. compared
TVT with both IVS and SPARC, with 65 patients
in each group. [58] The subjective cure rates be-
tween 6 and 12 weeks of follow-up were 87.9%
in the TVT group, 81.5% in the IVS group and
72.4% in the SPARC group, the differences not
being significant. Interestingly, the authors found
a significantly greater rate of tape extrusion in
the SPARC group compared to both TVT and IVS
(p<0.04). An additional retrospective study found
a significant difference in favor of TVT in objec-
tive SUI cure rate at 3, 12, and 60 months com-
pared with IVS, while the subjective cure rates
did not differ significantly at any of those time
intervals [Prien-Larsen & Hemmingsen, 2009].
[60] Vaginal extrusions were found in 11.8% of
the women in the IVS group compared with 0% in
the TVT group. [EL=1/2]

Most concerning is the report by Balakrishnan et
al. in which they followed the subgroup of IVS pa-
tients of the Lim et al. study for up to 30 months
and found that 13% had sling extrusions requiring
sling removal. [61] Additionally, of the 29 patients
(47%) of the initial IVS group who were seen 12 to
34 months post-operatively, 24% experienced sling
erosion with sinus formation requiring sling remov-
al. Further infectious complications, like retropub-
ic abscess and pyogenic granuloma associated with
vaginal extrusion, indicate that the IVS may behave clinically like microporous synthetic materials rather than other polypropylene slings.[62, 63] [EL=3/4]

Two additional studies compared TVT against other retropubic midurethral MUS procedures. Agarwala found no difference in subjective (94% vs. 92%) and objective (96% vs. 94%) cure rates in 96 women consecutively assigned to TVT or to Lynx mid-urethral sling (Boston Scientific; monofilament polypropylene), respectively. [64] Yoon et al. compared TVT to the IRIS (innovative replacement of incontinence surgery) with a follow-up of 3 years. [65] The instrument of the IRIS system is comprised of a nondisposable metal handle to which two metal needles can be attached. The needles have an outer diameter of 5-6 mm and the non-absorbable polypropylene tape, which is 11 mm wide and 450 mm long with a plastic sheath cover, is fixed to the needles. The tape of the IRIS system is polypropylene monofilament mesh (Trelex; Meadox Medicals, Oakland, NJ/Boston Scientific, NJ, U.S.A.), and the diameter of the pore size is greater than 75 µm such as the tape of TVT. Success rate encompassing both objective and subjective criteria were not statistically different between the 2 procedures at 12 and 36 months. Likewise, the incidence of perioperative complications and postoperative voiding dysfunction was not statistically different. [EL=3]

The Cochrane review encompassing 4 aforementioned RCTs [Andonian et al., 2005; Lim et al., 2005; Tseng et al., 2005; Lord et al., 2006] and an abstract, found that, in 492 women studied within the first 12 months after surgery, women were significantly more often subjectively dry with the TVT than SPARC (85% vs. 77%; RR 1.10, 95% CI 1.01 to 1.20). [40] In a total of 636 participants, women were statistically significantly more likely to be objectively cured with the TVT than SPARC or IVS (92% vs. 87%; RR 1.06, 95% CI 1.01 to 1.11). There were significantly fewer women experiencing bladder punctures during trocar passage after TVT compared with SPARC (4.7% vs. 8.5%; RR 0.55, 95% CI 0.31 to 0.98), as well as fewer vaginal extrusions (RR 0.27, 95% CI 0.08 to 0.95). No statistically significant difference was seen in overall perioperative complications, but the confidence interval was wide (RR 0.98, 95% CI 0.53 to 1.84). There were no statistically significant differences between the 2 groups with respect to postoperative de novo urgency symptoms and UUI, as well as urodynamic detrusor overactivity. Finally, there were no statistical differences in QoL indices between the 2 procedure groups. [EL=1/2]

The Cochrane review also evaluated 3 of the aforementioned RCTs [Rechberger et al., 2003; Lim et al., 2005; Meschia et al., 2006] that compared TVT to IVS.[40] At 12 months, the higher subjective cure rates seen with TVT did not reach statistical significance (83% vs. 77%; RR 1.08, 95% CI 0.98 to 1.19). Objective cure for the TVT was significantly higher than for the IVS (83% vs. 72%; RR 1.15, 95% CI 1.02 to 1.30). There were few perioperative complications and the combined results from 2 small trials did not show a statistically significant difference (RR 1.16, 95% CI 0.36 to 3.69). However, the confidence intervals were wide. There were no statistically significant differences in the rates of de novo urgency symptoms and UUI, detrusor overactivity, and postoperative voiding dysfunction. [EL=1/2]

f) Retropubic MUS vs. transobturator mus (table 2)

A unique complication of the retropubic MUS procedures has been inadvertent puncture of retropubic and, on occasion, intra-abdominal viscera or neurovascular structures. The most common organ punctured is the bladder and the rates of puncture have varied between 0.8% and 21% in different reports [Wang et al., 2004; Andonian et al., 2005]. [50, 66] Two systematic registries on the rates of complications associated with the TVT operation have been published, one from Finland including the first 1455 operations performed nation-wide and one from Austria including 2795 operations [Kuva and Nilsson, 2002; Tamussino et al., 2001]. [26, 67] The rates of bladder perforation were 3.8% and 2.7%, respectively. In an effort to minimise the incidence and morbidity of bladder injuries, Delorme in 2001 introduced a modified tape procedure in which the tape was brought to support the mid-urethra from inside the thighs through the obturator foramina on both sides.[68] De Leval further modified the outside-in transobturator tape procedure (TOT) procedure to be an inside-out procedure, now called the tension-free vaginal tape-obturator (TVT-O). [69]

The comparison between the retropubic and transobturator MUS procedure has become the most-documented topic in sling surgery over the last 5 years. ICI-4 reported on a total of 9 RCTs comparing RP with TO midurethral slings. TVT was compared with the inside-out TVT-O in 6 randomized trials [Liapis et al., 2006; Laurikainen et al., 2007; Meschia et al., 2007; Zullo et al., 2007; Araco et al., 2008; Rinne et al., 2008], [70-75] and with the outside-in TOT in 2 trials [Andonian et al., 2007; Porena et al., 2007]. [76, 77] Wang et al. compared the TOT with SPARC and found no difference in cure rate or rates of complications between the group of 31 TOT patients and 29 SPARC patients.[78]

The studies evaluated in ICI-4 were quite heterogeneous. Five of the studies comparing TVT with TVT-O included power calculations either for detection of differences in cure rates and complication rates [Meschia et al., 2006; Laurikainen et al., 2007; Rinne et al., 2008], [70, 71, 75] or only for detection of differences in complications [73]. The study by Liapis et al. reported no power calculations. [70] No differences in the overall objective or subjective cure rates were seen between the TVT and the TVT-O procedures.

†: Included in Cochrane Review (Ogah, 2011)
during follow-up periods of 6 to 12 months. The only statistically significant difference in objective cure rate was seen in the Araco et al. report where stratification between mild and severe stress incontinence had been made.[74] They found a significantly higher cure rate in the TVT patients with severe SUI than in the TVT-O patients with the same condition: 100% versus 66% cure respectively ($p<0.001$). [EL=1/2]

The trials presented contradictory results concerning postoperative complications. The reports by Meschia et al. [71] and Laurikainen et al., [70] including 3-4 times more patients than the reports by Zullo et al. [73] and Liapis et al. [79] show either no differences in the overall number of complications or a significantly higher rate of overall complications in the TVT-O group (Laurikainen et al.). It is not clear from the Zullo et al. study, which showed a higher complication rate for the TVT, how the overall complication rate was calculated. The two trials comparing TVT with TOT [Andonian et al., 2007; Porena et al., 2007] found no difference in cure rates between the procedures. [76, 77] There were no differences in complication rates between the procedures in the Porena et al. study, while Andonian et al. reported significantly greater rates of complications in the TOT than in the TVT group. [EL=1/2]

As an example of the continued and exponentially-increasing interest in these procedures, the Cochrane systematic review evaluated 16 fully-published RCTs and 7 additional meeting abstracts. [40] The published studies included the following: Enzelsberger et al., 2005; Kim et al., 2005; Wang A et al., 2006; Liapis et al., 2006; Andonian et al., 2007; Darai et al., 2007; Lee et al., 2007; Meschia et al., 2007; Porena et al., 2007; Zhu et al., 2007; Zullo et al., 2007; Araco et al., 2008; Barber et al., 2008; Barry et al., 2008; Rinne et al., 2008; Schierlitz et al., 2008. [71, 73-87]. Three of the abstracts included in the Cochrane review have since been published as full manuscripts [Rechberger et al., 2009; Defieux et al., 2010; Teo et al., 2011].[88-90] while the population in the study by Rinne et al. has recently been updated with long-term outcomes. [91]

The Cochrane review reported subjective cure within 12 months in 10 trials with a total of 1281 participants. [43] Assessment of cure was self-reported by participants and by responses to symptom based questionnaires. The combined results from the 10 trials showed no statistically significant difference in the subjective cure rates between the RP and TO routes (RR 1.00, 95% CI 0.96 to 1.05). Subjective cure rate in each group was approximately 83%. In this instance, the confidence interval is narrow and may not include a clinically significant difference. The confidence interval is compatible with the cure rate for the transobturator route being 6% better, or being 3% better for the retropubic route. [EL=1/2]

Objective cure was assessed by 17 studies with 2434 participants using a variety of measures such as urodynamic assessment, negative cough-stress test, 1-hour pad test of ≤ 2 g, 1-hour pad test of ≤ 1 g, and 24-hour pad test of ≤ 5 g. [40] The cure rate using the obturator route was significantly lower at 84% versus 88% for the retropubic route (RR 0.96, 95% CI 0.93 to 0.99). However, the confidence interval was narrow and the difference between the groups (4%) may not represent a clinically significant difference in the short term. There was no significant difference in women whose improvement and cure rates were demonstrated objectively (RR 0.96, 95% CI 0.91 to 1.02). [EL=1/2]

In 14 trials, there were no statistically significant differences in the rates of tape erosions (RR 1.58, 95% CI 0.83 to 3.00) or, in 5 trials, the need for repeat incontinence surgery (RR 1.52, 95% CI 0.90 to 2.59). [40] However, once again, the confidence intervals in both cases could include a clinically significant difference favouring the RP approach. There was significantly higher occurrence of groin pain (12%) in women with a TO approach compared with suprapubic pain in women with a retropubic sling (1.7%, RR 6, 95% CI 3 to 11). There was no statistically significant difference between the groups in terms of detrusor overactivity (RR 1.22, 95% CI 0.56 to 2.63) in 3 trials, or de novo urgency and urgency incontinence (7% with the TO route versus 6% via the RP route (RR 1.08, 95% CI 0.75 to 1.56) in 14 trials, but the confidence intervals were wide because these were relatively rare events and clinically significant differences could not be ruled out. However, postoperative voiding dysfunction occurred significantly less frequently in the TO route group (4% versus 7%, RR 0.63, 95% CI 0.44 to 0.89). [EL=1/2]

The systematic review by Novara et al. included 13 RCTs that compared classic TVT with inside-out TOT: TVT-O in 10 studies [71-75, 84, 89, 90, 92-96] and a less invasive free tape in a single study [Nau mann et al., 2006 (abstract only)].[48] Nine studies compared TVT to outside-in TOT: ObTape in 3 studies, [76, 77, 80] Monarc in 4 studies, [86, 87, 97], Freeman et al., 2008 (abstract only) Iris-TOT in a single study, [Kim et al., 2004 (abstract only)] and Obtryx in a single study. [98] The implanted devices were not specified in a single study.[99] A single trial compared TVT to both TVT-O and Monarc. [Schein er et al., 2009 (abstract only)] a single trial compared retropubic IVS to outside-in IVS, [142], and 2 trials compared SPARC sling to Monarc.[78, 81]

Overall (OR: 1.02; 95% CI OR: 0.78 to 1.33; $p = 0.90$), and subjective (OR: 0.97; 95% CI OR: 0.75 to 1.24; $p = 0.80$) continence rates were overlapping in the two procedures. [48] Among the studies providing subjective outcomes using validated questionnaires, postoperative UDI-6 (WMD: 0.07; 95% CI: -0.39 to 0.53; $p = 0.76$) and IIQ-7 (WMD: 0.01; 95% CI: -0.22 to 0.24; $p = 0.95$) scores were
similar. Notably, retropubic MUS were followed by significantly higher objective continence rates (OR: 0.80; 95% CI OR: 0.65 to 0.99; \( p = 0.04 \)). Moreover, a statistically significant difference in favour of TVT was shown when comparing objective continence rates between TVT and inside-out TOT (OR: 0.71; 95% CI OR: 0.52 to 0.96; \( p = 0.03 \)), whereas no difference was found comparing TVT to outside-in TOT (OR: 0.90; 95% CI OR: 0.66 to 1.22; \( p = 0.51 \)). Sensitivity analyses limited to studies of higher methodological quality showed only a nonstatistically significant trend in favour of TVT with regard to objective cure rate (OR: 0.74; 95% CI OR: 0.54 to 1.01; \( p = 0.05 \)). No differences in subjective and overall continence rates were found in the other sensitivity analyses. [EL=1/2]

With regard to complications, bladder or vaginal perforations (OR: 2.5; 95% CI OR: 1.75 to 3.57; \( p < 0.0001 \)) were significantly more common following retropubic MUS, without any significant difference between inside-out and outside-in TOT.[48] Again, as expected, the prevalence of postoperative haematoma was significantly more common following placement of retropubic MUS (OR: 2.62; 95% CI OR: 1.35 to 5.08; \( p = 0.005 \)). In fact, the rates of vaginal extrusion were slightly higher following TOT (OR: 0.64; 95% CI OR: 0.41 to 0.97; \( p = 0.04 \)), due to the studies using ObTape, a device removed from the market due to a high risk of erosion and extrusion. Finally, the risk of urinary tract infections (OR: 0.95; 95% CI OR: 0.69 to 1.31; \( p = 0.74 \)), the need for clean intermittent catheterisation or re-catheterization (OR: 1.16; 95% CI OR: 0.84 to 1.59; \( p = 0.37 \)), and the reoperation rate (OR: 1.1; 95% CI OR: 0.75 to 1.59; \( p = 0.62 \)) were not significantly different between retropubic and transobturator MUS.

Interestingly, the prevalence of storage LUTS was significantly higher in those patients randomised to RT (OR: 1.35; 95% CI OR: 1.05 to 1.72; \( p = 0.02 \)), without any significant difference between inside-out and outside-in TOT. A nonstatistically significant difference in favour of TOT was found for voiding LUTS (OR: 1.56; 95% CI OR: 0.97 to 2.5; \( p = 0.07 \)). In sensitivity analyses limited to studies of higher methodological quality, only a nonstatistically significant trend in favour of TOT was found for storage LUTS (OR: 1.44; 95% CI OR: 0.99 to 2.09; \( p = 0.06 \)) and voiding LUTS (OR: 1.59; 95% CI OR: 0.85 to 2.97; \( p = 0.15 \)). Similarly, with regard to the risk of all the other complications and reoperation, no differences were identified in the other sensitivity analyses. [EL=1/2]

The largest RCT to date comparing retropubic and transobturator MUS was recently published by Richter et al.[37] This was a multicentre, randomised equivalence trial with the primary outcome being objective (a negative stress test, a negative pad test, and no retreatment) and subjective (self-reported absence of symptoms, no leakage episodes recorded, and no retreatment) success at 12 months. The predetermined equivalence margin was ±12% points. A total of 597 women were randomly assigned to a study group and 565 (94.6%) completed the 12-month assessment. The rates of objectively assessed treatment success were 80.8% in the RP group and 77.7% in the TO group (3.0%-point difference; 95% CI: −3.6 to 9.6). The rates of subjectively assessed success were 62.2% and 55.8%, respectively (6.4%-point difference; 95% CI, −1.6 to 14.3). The rates of voiding dysfunction requiring surgery were 2.7% in the RP group and 0% in the TO group (\( P = 0.004 \)), and the respective rates of neurological symptoms were 4.0% and 9.4% (\( P = 0.01 \)). There were no significant differences between groups in postoperative urgency incontinence, satisfaction with the results of the procedure, or quality of life. Thus, the success rates met the predetermined criteria for equivalence of the 2 procedures. [EL=1]

There have been numerous additional, non-randomised trials published in peer-reviewed literature. [100-118] The majority of these concluded that there is no statistically significant difference in subjective or objective outcome measures between retropubic and transobturator MUS procedures. As concluded in the RCTs, postoperative complications are more common in the retropubic MUS group. [EL=3/4]

**g) Other studies**

Two additional topics deserve mention. Pelvic floor muscle training (PFMT) with or without biofeedback is a recognised and effective treatment for various pelvic floor conditions, including SUI, UUI, and pelvic pain. While a trial comparing MUS procedures and PFMT has not been published, there is a design for a prospective RCT in place to address this question [Labrie et al., 2009]. [58] This multi-centre RCT will be include women between 35 - 80 years old with moderate to severe, predominantly SUI, who have not received specialised PFMT or previous anti-incontinence surgery. Women will be assigned to either PFMT for a standard of 9-18 sessions in a 6-month period or TVT-O surgery. The main endpoint of the study is the subjective improvement of urinary incontinence. Objective cure, a secondary outcome, will be assessed from history and clinical parameters. Subjective improvement in QoL will be measured by generic (EQ-5D) and disease-specific (UDI & IIQ) QoL instruments. The economical endpoint is short term (1 year) incremental cost-effectiveness in terms of costs per additional year free of urinary incontinence and costs per Quality Adjusted Life Years gained. Finally, treatment strategy and patient characteristics will be combined in a prediction model, to allow for individual treatment decisions in future patients. Four hundred female patients will be recruited from over 30 hospitals in the Netherlands.

Finally, single-incision mini-slings (SIMS) have emerged as an additional option for the woman
with SUI. These procedures theoretically require minimal anesthesia and may be performed entirely under local anesthetic. While most outcomes and comparisons between SIMS and traditional MUS procedures have not yet reached medium-term follow-up, a recent abstract at the 2011 International Continence Society Annual Meeting presented a systematic review and meta-analysis of SIMS and MUS procedures [Abdel-Fattah et al., 2011]. Nine studies were included, comparing TVT-Secur (6 studies; n=548), Mini-arc (2 studies; n=160) and Ophira (one study; n=50) to traditional MUS. A total of 758 women were included and 60 women were lost to follow-up (MUS n=23, vs. SIMS n=37). The meta-analyses showed a significantly lower patient-reported cure rate with SIMS when compared to MUS, specifically TVT-O (RR 0.84, 95% CI 0.71 to 0.99), however a non-significant difference in favour of TVT was seen (RR 0.79, 95% CI 0.37 to 1.67). These results were supported on sensitivity analysis when studies of unclear quality were excluded. SIMS were associated with significantly lower objective cure rates when compared to MUS, specifically TVT-O (RR 0.88, 95% CI 0.77 to 0.99). In addition there was a significant difference in favour of TVT when compared to SIMS. This was also confirmed on sensitivity analysis when studies of unclear quality were excluded. A shorter operation time was associated with SIMS (WMD -8.67 minutes, 95% CI -17.32 to -0.02), and this was due to the significant difference in operation time in the single TVT comparison. There were significantly lower day-one pain scores in the SIMS group (WMD -1.74, 95% CI -2.58 to -0.09). Repeat continence surgery was significantly higher in the SIMS group (RR 6.72, 95% CI 2.39 to 18.89). Tape erosion and de-novo urgency incontinence were significantly higher in the SIMS group (RR 3.86, 95% CI 1.45 to 10.28 and RR 2.08, 95% CI 1.01 to 4.28, respectively). There were non-significant differences between both groups in respect to post-operative voiding difficulties (RR 1.47, 95% CI 0.78 to 2.74) and other minor (postoperative wound infection, haematoma, UTI, and haematuria) post-operative complications (RR 1.59, 95% CI 0.74 to 3.45). There was no significant difference in the QoL scores between the groups (WMD -33.46, 95% CI -87.55 to 20.62). Statistical heterogeneity was found throughout the analysis and was highest in patient reported cure rate, QoL scores, and operative time. [EL=1/2]

h) CONCLUSIONS / RECOMMENDATIONS

There is evidence that the retropubic TVT is more effective than colposuspension and is equally effective as traditional autologous fascial sling operations. [EL=1/2] Operation time, hospital stay, and time to resume normal daily activity is shorter with the TVT than with colposuspension. Post-operative voiding problems and need for urogenital prolapse surgery are more commonly associated with colposuspension, while bladder perforation is more commonly associated with TVT. [EL=1/2] TVT is more effective than the IVS and the SPARC procedure; however, the studies are heterogeneous. Inadvertent bladder puncture during SPARC (top-down) placement is more common than bladder puncture during TVT (bottom-up). [EL=1/2] Overall, retropubic and transobturator MUS procedures perform equally at a short term follow-up of 6 to 12 months. (Level 1/2) The rate of complications, including bladder puncture, vaginal extrusion, and hematoma formation are higher for the retropubic MUS. [EL=1/2]

Retropubic MUS is recommended as an effective treatment for stress urinary incontinence, which has longevity. [Grade A] Outcomes using subjective and objective criteria indicate that the retropubic MUS is at least equivalent, and usually superior, to other anti-incontinence procedures. [Grade B]

3. TRANSOBTURATOR MID-URETHRAL SLINGS

a) Evolution of the TOT including proposed advantages

The introduction of the tension-free vaginal tape (TVT) in 1995 [171] as well as the[172] development of other retropubic mid urethral slings, changed the way stress urinary incontinence (SUI) is treated. These procedures, although effective, were not without complications. Beyond voiding phase dysfunction, complications including bladder perforation, bowel perforation and vascular injury were described. [26, 173, 174] [175] The majority of serious complications reported from these procedures were thought to be related to penetration of the retropubic space. [176]

In 2001, Delorme first described placement of a synthetic sling avoiding the retropubic space by placing the sling through the obturator foramina.[68] Thus the first alternative to the retropubic tapes, the transobturator tape (TOT) was born. By avoiding the retropubic space, the major complications associated with retropubic passage of trocars were theoretically avoided. Another potential advantage of the transobturator method was the potential elimination of intraoperative cystoscopy. This point is still debated today.[177] Delorme’s original description of the TOT required passage of the trocar from “outside-in”. In 2003, de Leval aimed to further reduce the chance of bladder and urethral injury and described placing the trocar of the vaginal tape from “inside-out”. [69] These two methods remain the major division of transobturator slings and are both still widely used today.

Further efforts have been recently made to modify the inside-out method. In an attempt to minimise post-surgical leg pain, the length of mesh used has been shortened and surgeons have tried to minimise the number of punctures to the obturator membrane [172, 178] Initial results have shown improvement in leg pain in the immediate post-operative
period, without sacrificing efficacy (at 1 year). Further confirmatory studies are needed to strengthen these findings.

b) Initial prospective cohort trials

The original TOT procedure was performed in 40 women, 16 of whom had isolated SUI. The authors reported 15/16 were "totally continent" and the remaining patients improved with short term follow up (3-12 months). [68] There were no intraoperative complications. Post-operatively, the only complication was 1 episode of sepsis. Following this study, Delorme et al. published a series of 32 patients treated with the transobturator tape with at least one year follow-up (UraTape® Mentor-Porge's, a non-woven, non-knitted thermally-bonded polypropylene) [179, 180]. With a mean follow-up of 17 months, and a rigorous definition of cure (defined by patients reporting no protection and no SUI, along with a negative cough test with a full bladder) 22/29 patients (90.6%) were cured and 3/32 (9.4%) were improved. Preoperatively, 43.7% (14 patients) had pure SUI, and 56.3% (18 patients) had mixed incontinence. Of note, 4 patients had prior anti-incontinence procedures (3 TVT, 1 Burch and 1 with multiple procedures) and 5/32 had preoperative urethral closure pressures of <20cm H2O. Again, no intraoperative complications were recorded. There was one patient who required self-catheterisation but retention resolved in this patient by 4 weeks. There were 5 patients with voiding disorders suggestive of bladder outflow obstruction. Two patients developed de novo urgency incontinence and one had worsening of her preoperative urgency.

Short term safety and efficacy data are also available from a prospective multicentre cohort study. [176] In this study, 183 women received the UraTape (outside-in TOT) and follow up data were obtained at a mean of 7 months (1-21 months). All women had SUI associated with hypermobility, 26 had mixed incontinence and 26 had concomitant (POP) surgery performed at the time of their TOT. Intraoperatively, there was a complication rate of 2.2% including 1 bladder perforation, 2 urethral perforations and 1 lateral vaginal sulcus perforation. Seventeen patients were not cured of stress incontinence including 5 patients that had the sling removed for vaginal extrusion (3) and urethral erosion (2). 4 patients reported post-operative de novo urgency, 2 of which also complained of urinary leakage. At 6 months 83% (of 130 patients) were cured and 5.4% were improved.

Based on data from the prospective series from Costa et al. and other case reports, extrusions and infections were linked to the silicon part of the UraTape and the tape was modified to the Obtape®. [176, 181, 182] This modification was introduced in 2003. This newer tape was made of monofilament strands of nonwoven polypropylene fibre with interlacing monofilaments forming pores of 50 mcg (smaller than the 75 mcg needed to allow for the migration of macrophages and leukocytes). The materials used for transobturator slings have continued to be modified to decrease risk of erosion, extrusion and infection. Today, all commercially available synthetic transobturator slings (as well as retropubic slings) are made of Amid type I polypropylene mesh and have an extrusion and erosion rate well below 5%. This is much lower when compared to the transobturator Obtape® with vaginal erosion rates as high as 13%. [183] [184]

The first description of the "inside-out" modification by de Leval also included feasibility/safety data from 107 patients. [69] Of these, 74 suffered from isolated SUI, and the remaining 33 women had POP, 15 had associated SUI, and the remaining 18 had prophylactic slings for occult SUI. There were no intraoperative complications or perioperative complications reported. At one month, one patient had a minor vaginal erosion and 2.8% of patients had urinary retention (2 of the 3 had concomitant prolapse surgery). 15.9% of patients complained that they had moderate pain or discomfort in the thigh fold. All pain had resolved by one month.

After the original inside-out cohort was described, patients from the same institution were then offered participation in a prospective observational study (TVT-obturator or TVT-O, Ethicon, Somerville NJ, USA). [185] 102 patients out of 253 consecutive patients fulfilled the inclusion criteria and agreed to participate in the trial. 4.9% (5/102) of this group did not complain of SUI but had occult SUI. There were no urethral or bladder perforations and one patient had a vaginal sulcus laceration noted intra-operatively. No patients presented with vaginal or urethral erosion at follow-up. After catheter removal, 2 patients had an "important PVR" of >400ml. This voiding dysfunction resolved (after CIC in one and SPT What's SPT in the other) by the last reported follow-up. There were 99 women with at least 12 month follow-up (mean follow-up of 14.9 months) and the complete cure rate was 91% while SUI symptoms improved in 5% of patients. Worsening or de novo urgency symptoms or urgency urinary incontinence (UUI) were reported by less than 10% of the patients. Approximately 75% of those with preoperative urgency and/or UUI experienced disappearance or improvement of these symptoms postoperatively. Voiding difficulties developed in 7% of the patients.

This same group of 102 women, who underwent a transobturator inside-out sling, were followed for a minimum of 3 years (median 40 months) and complete data were available for 91 (89.2%). [185] Issues of erosion or persistent pain were not found with this medium term follow-up. Four patients required tape release or tape incision, all within the first year. Disappearance and im-
progression of SUI were observed in 88.4% and 9.3% of the patients respectively. These cure rates were similar to those obtained 1 year after the operation.\[185\] Cure of SUI was defined as the disappearance of subjective SUI, as assessed by a SUI symptom scale score equal to zero. One patient developed a vesicovaginal fistula 2 years after sling placement. The authors did not believe that this was secondary to the TVT-obturator, but rather was due to a prior history of pelvic radiation. An additional 2 patients developed symptomatic POP between the first and second year and each went on to have an uncomplicated laparoscopic repair.

There are several large, multicentre European studies that examined the safety of the original TVT.\[67, 186, 187\] Similarly, a study was performed to address the safety of the inside-out transobturator approach.\[188\] This study compiled a registry of 984 women from 86 centers in France. There was an overall perioperative complication rate of 2.2%, with vaginal wall perforation (1.3%) and hematoma (0.7%) being the most common. The post-operative complication rate was 5.2%, with residual leg pain being the most common complication (2.7%). Reintervention, urinary retention, vaginal erosion, and paravesicle hematoma were all reported with percentages of less than 1 (0.9%, 0.8%, 0.6% and 0.1% respectively). Although the design of this study was aimed at safety, the paper does report efficacy at 4–12 weeks. Surgeons assessed 90% of patients as completely cured and 8.7% as improved, with only 1.2% of patients being similar to their preoperative status. Of those 303 patients with preoperative overactive bladder (OAB), cure was reported in 54.5%, improvement in 40.25%, and 5.3% noting no change. Other large single institutional studies have also looked at safety of the inside-out transobturator sling.\[189\]

c) Transobturator Outside-In versus Inside-out

It was suggested by Delorme et al. that there is a greater risk of nerve injury (dorsal nerve of the clitoris) with the inside-out passage of the trocar.\[180\] A cadaveric study suggested that the inside-out technique required the trocar to pass closer to the obturator canal and was more likely to injure the obturator nerve (or vessels) that travel in this space.\[190\]

The association between inside-out obturator slings and an increased risk of complications compared to outside-in obturator slings has not been supported in clinical studies. Latthe et al. used a meta-analysis with direct and indirect comparisons of randomised trials to assess the effectiveness and complications for the inside-out (TVT-O) and outside-in (TOT) transobturator slings.\[191\] The conclusion was that there was equivalent short-term effectiveness between the two methods. By indirect comparison, fewer bladder injuries and voiding difficulties were seen in the inside-out tapes.

In 2009, a Cochrane Review of minimally invasive synthetic sub-urethral sling operations for SUI contained an analysis of the inside-out outside-in approaches (comparison #5) and concluded that there were no statistically significant differences in any of the outcomes measured.\[40\] However, the review acknowledged that the four trials randomised trials that this conclusion was based on were all small in size.\[192-195\]

Houwert et al. presented medium term follow up from their prospective comparative randomised trial.\[196\] They did not find any statistical significant difference, but it is not clear that the study was powered appropriately to show a difference. Abdel-fattah et al. published a study that was powered to show a 10% difference in success rates between the two methods of obturator sling placements.\[197\] They enrolled 107 inside-out and 171 outside-in patients. This prospective single blinded study did not show any differences in objective cure rates (87.6% inside-out vs. 83.2% outside-in, \( p = 0.2 \)) or patient reported success rates as reported by Patient Global Impression of Improvement (83% inside-out vs. 77% outside-in, respectively, \( p = 0.138 \)) at 6 months follow-up.\[197\] There were statistically more vaginal angle perforations with the outside-in approach compared the inside-out method (17 vs. 3, respectively, \( p = 0.001 \)). Women in the inside-out group more commonly reported severe post-operative thigh pain, but this was not statistically significant (6.7% vs. 3.5%, \( p = 0.19 \)).

d) Comparator Trials: Transobturator versus Retropubic MUS in the Index Patient

Once cohort studies had confirmed the feasibility of transobturator mid-urethral slings, a number of small RCTs and quasi-RCTs were performed comparing transobturator to the then gold standard, retropubic mid-urethral sling. A Cochrane review\[40\] and two recently updated meta-analyses\[48, 191\] use the pooled data of these RCTs to compare the outcomes of retropubic and transobturator MUS.

In a Cochrane Review, Ogah et al. found 24 trials comparing outcomes between retropubic and transobturator MUS.\[40\] Subjective cure or improvement rates were reported in 10 of these trials and meta-analysis revealed no statistically significant difference between approaches (83% subjective cure in each group, RR 1.00, 95% CI: 0.96-1.05). Objective cure was measured by urodynamic evaluation, cough-stress test, one hour pad test of ≤ 2 g, one hour pad test of ≤ 1 g, or 24 hour pad test of ≤ 5 g various means in 17 studies. The transobturator route was found to have a significantly lower cure rate than the retropubic route (84% vs. 88%, RR 0.96, 95% CI 0.93-0.99). The clinical significance of this 4% difference in objective cure versus no difference in subjective cure has been questioned.
In a recent systematic review and meta-analysis, Latthe et al. found 12 RCTs that compared TOT with TVT, and 15 that compared TVT-O with TVT.\[191]\ When compared at 1–44 months, the subjective (OR: 1.16; 95% CI: 0.83–1.6) and objective (OR: 0.94; 95% CI: 0.66–1.32) cure of TOT was similar to TVT. For TVT-O, the subjective (OR: 1.06, 95% CI: 0.85–1.33) and objective cure (OR: 1.03, 95% CI: 0.77–1.39) was also similar to TVT.

Novara et al examined 11 RCTs comparing TVT with inside-out TOT and 9 RCTs comparing TVT with outside-in TOT.\[48]\ Meta analysis revealed that continence rate according to any definition of cure (OR: 1.02; 95% CI: 0.78–1.33; \(p = 0.90\)) and subjective continence rates (OR: 0.97; 95% CI: 0.75–1.24; \(p = 0.80\)) were similar between the two procedures. Overall, retropubic tapes had significantly higher objective continence rates when compared to the transobturator tape group (OR: 0.80; 95% CI: 0.65–0.99; \(p = 0.04\)). Interesting, a statistically significant difference in favour of TVT was shown when comparing objective continence rates between TVT and inside-out TOT (OR: 0.71; 95% CI: 0.52–0.96; \(p = 0.03\)) but no difference was found comparing TVT to outside-in TOT (OR: 0.90; 95% CI: 0.66–1.22; \(p = 0.51\)). However, when studies of lower methodological quality were excluded only a non-statistically significant trend in favour of TVT was found. (OR: 0.74; 95% CI: 0.54–1.01; \(p = 0.05\)).

The majority of RCTs used in the aforementioned Cochrane review and meta-analyses were small, had short- to medium term follow-up and were designed only to detect superiority. This has precluded robust conclusions regarding long-term success and equivalence efficacy with this data.

Angioli et al. provide long-term data regarding the success rates of TVT and TVT-O in a multicentre RCT.\ [198]\ At 5 years follow-up, objective cure, defined as a negative cough stress test, was similar between TVT and TVT-O (71.4% vs. 72.9%; \(p = 1\)). After 5 years, patients in this trial were asked to describe their overall satisfaction. 60% and 62% of women reported that they were satisfied or very satisfied with the results of their TVT and TVT-O respectively (\(p = 1\)).

TOMUS (Trial of Mid-Urethral Slings) is a large multicentre, equivalence RCT designed to compare the efficacy and safety of retropubic and transobturator mid-urethral slings.\ [170]\ The 12-month outcomes of 565 women were recently reported. The criteria required for objective treatment success were a negative provocative stress test, a negative 24-hour pad test, and no retreatment (behavioural, pharmacological, or surgical) for SUI. The unadjusted rates of objective treatment success met the predefined criteria for equivalence, less than a 12 percentage-point difference. (80.8% in the retropubic sling group and 77.7% in the transobturator sling group; 3.0 percentage-point difference; 95% CI: 3.5 to 9.6). The subjective treatment success criteria were the absence of self-reported SUI symptoms as assessed with the use of the Medical, Epidemiological and Social Aspects of Aging questionnaire, no leakage recorded in a 3-day voiding diary, and no retreatment for SUI. The unadjusted rates of subjective treatment success did not significantly differ between groups but the predetermined criteria for equivalence was not met (62.2% in the retropubic sling group and 55.8% in the transobturator group, 6.4 percentage point difference; 95% CI, −1.6 to 14.3).

e) Comparator Trials: Transobturator versus Retropubic MUS in patients with Intrinsic Sphincter Deficiency (ISD)

The diagnosis of ISD in the literature has traditionally been based on the urodynamic finding of a Valsalva leak-point pressure (VLPP) < 60 cmH20 or a mean urethral closure pressure (MUCP) < 20 cm H20. A retrospective study of 300 women with SUI and ISD found an overall cure rate for TVT to be significantly higher than TOT (78.3% vs. 52.5%; \(p < 0.0001\)).\ [111]\ Jeon et al. retrospectively compared 253 patients with ISD and found that after 2 years cure rates were 86.94% and 34.89% for TVT and TOT respectively (\(p < 0.0001\)).\ [156]\ Schieltz et al.\ [87] randomised 184 women with urodynamic evidence of SUI and ISD to receive TVT or TOT. At 6 months, urodynamic SUI was present in 21% in the TVT group compared to 45% in the TOT group.\ [87]\ Similarly, in a large RCT, a VLPP < 60 cmH20 was a predictor of poor outcome in the transobturator sling group but not in the retropubic sling group.\ [88]\ In these studies ISD was defined by a low VLPP or MUCP, but there is no mention of urethral mobility. Contradictory to these findings, Rapp et al. retrospectively reviewed their results and found no significant differences in continence rates across different preoperative VLPPs.\ [113]\ In a large observational study, women with SUI were stratified according to preoperative MUCP and VLPP and followed for 5 years after TOT. The objective overall cure rates were similar across all strata indicating that MUCP and VLPP may not be predictive of outcome in TOT.\ [199]\ In the TOMUS trial, there was no material change in the rates of treatment success according to objective or subjective criteria when the analyses were adjusted for VLPP and MUCP.\ [170]\

The data comparing retropubic and transobturator MUSS outcomes in patients with ISD appears equivocal. Recent studies suggest that evaluation of urethral mobility in ISD patients can be more informative. A cohort of 107 women with SUI had their urethral mobility measured prior TOT and at 10 months subjective cure was assessed. Women with preoperative urethral mobility < 45 degrees were at least 4 times more likely to report postoperative incontinence compared to women with preoperative urethral mobility > or = 45 degrees (29.4% vs 6.9%, RR 4.29, 95% CI 1.59–11.60, \(p = 0.005\)).\ [200]\ Halilolu et al. divided 65 women with SUI into three groups prior to receiving TOT: 1) patients with ISD with a VLPP < or = 60 cm
H2O and a Q-tip test > 30 degrees (ISD and hyper-mobile urethra), II) patients with ISD who have VLPP < or = 60 cm H2O and Q-tip test < or = 30 degrees (ISD without hypermobile urethra), and III) patients without ISD who had VLPP > 60 cm H2O and Q-tip test > 30 degrees (hypermobile urethra without ISD). [201] All cure and improvement rates were statistically lower in group II at 6, 12, and 24 months leading authors to conclude that lack of urethral hypermobility may be an important risk factor for TOT failure in patients with ISD.

f) Complications of Obturator Slings

Complications of MUS are categorised as intraoperative complications (bladder, urethral, visceral and vessel injury), immediate postoperative complications (voiding dysfunction, groin pain, infection) and chronic problems (de novo urgency, sling erosion/ extrusion). Placement through the obturator foramen avoids the space of Retzius, decreasing more serious intraoperative trocar complications. In 2008 Novara et al. conducted a systematic review and meta-analysis of complication rates in mid-urethral slings. [202] When comparing retropubic vs. transobturator approach, bladder perforations (OR 2.33; 95% CI: 1.26–4.32; p = 0.007), pelvic hematoma (OR 4.83; 95% CI: 1.22–19.15; p = 0.03) and storage lower urinary tract symptoms (OR 1.81; 95% CI: 1.13–2.91; p = 0.01) were less frequent in women who had undergone a transobturator sling. Rates of vaginal erosions, urinary tract infections and reoperation rates were similar amongst groups. The 2009 Cochrane review by Ogah et al. on mid-urethral slings found that the transobturator approach was associated with a shorter operating time, less blood loss, less postoperative voiding dysfunction, and fewer bladder perforations, but more groin pain (12% vs. 1.7%, RR 6, 95% CI: 3–11) than the retropubic route. [40] In 2010 Latthe et al. updated their systematic review which assessed the effectiveness and complications of transobturator slings. [191] Adverse events such as bladder injuries (TOT, OR 0.11, 95% CI 0.05–0.25; TVTO, OR 0.15, 95% CI 0.06–0.35) and hematomas (OR 0.06, 95% CI 0.01–0.30) were less in the TOT than TVT. Voiding difficulties (TOT, OR 0.61, 95% CI 0.35–1.07); TVTO, OR 0.81, 95% CI 0.48–1.31) were slightly lower in TOT but this was not statistically significant. Groin/thigh pain (TVT-O, OR 8.05, 95% CI 3.78–17.16) and vaginal injuries (TOT, OR 5.82, 95% CI 1.85–18.3; TVTO, OR 1.69, 95% CI 0.73–3.91) were more common in the transobturator tapes. Mesh erosion in TVT-O (OR 0.77, 95% CI 0.22–2.72) and TOT (OR 1.11, 95% CI 0.54–2.28) was similar to TVT.

A recent publication by Brubaker et al. reported on 2 year adverse events in patients enrolled in the TOMP trial who were undergoing retropubic or transobturator midurethral slings. [203] UTIs were the most common adverse events in both groups with a higher incidence in the retropubic group (16.7% vs. 9.1%, p = .02). Patients in the retropubic group had higher rates of bladder perforation (5% vs. 0%, p < .0001), voiding dysfunction requiring surgery or catheter use (3% vs. 0%, p = .002) and postoperative bleeding (2% vs. 0%, p = .02). Neurological symptoms, defined as new paresthesias or alterations in motor function in the first 6 weeks after surgery, were more frequent in the transobturator group than in the retropubic group (9.7% vs. 5.4%, p = .04). Mesh complications were reported in 3-5% of women and these rates were similar in both groups.

But and Fagenelj randomised 120 patients to Monarc (inside-out transobturator sling) or to TVT-O (outside-in). [193] There was a higher incidence of vaginal wall perforations and lacerations in the Monarc (0% vs. 15%), and the TVT-O was more painful than the Monarc (p = .00015). Liapis et al. evaluated 114 patients randomised to TVT-O and Monarc, finding no statistically significant differences between the two procedures. [195] In patients that have undergone the Obtape, there have been reports of higher rates of vaginal erosion, ischiorectal abscesses, adductor myositis with symptoms of leg pain, difficulty ambulating and cellulitis. The newer polypropylene slings have been associated with a lower incidence of complications. However, the true incidence of major complications is probably limited by the heterogeneity of the outcome measures and the short-term follow-up of most of the studies. Future studies with validated outcomes and long-term follow-up are needed.

g) Transobturator Slings in Special Populations

1. Mixed Urinary Incontinence

Mixed urinary incontinence (MUI) is defined as the complaint of involuntary leakage from the urethra, associated with urgency, and also with exertion, effort, sneezing or coughing. How mid-urethral slings affect patients with MUI is less apparent. Many studies have demonstrated an improvement or cure in OAB symptoms and UUI in those patients undergoing sling procedures for the stress component of MUI with cure rates ranging from 50-74%. [204] Other studies have reported a decrease in subjective and objective cure rates but still quality of life improvement after treatment in women with MUI [53, 205]. Two studies by Paick et al reported on patients with MUI. [53, 205] The first, which reported on 73/274 with MUI who underwent TVT with more than six months follow-up, showed that the mixed UI group had the same cure rate for stress urinary incontinence (SUI) as the SUI-only group. They also found that 16.4% of the mixed UI group had persistent UUI, so that the overall UI cure rate was lower for the mixed UI than the SUI group, but still quite favourable (78.1% vs. 95.5%). In their second study, they evaluated 144 women with mixed UI who had undergone TVT, Sparc or TOT slings. There were no significant differences in the three groups in terms of the cure rate for SUI (SUI; TVT, 95.8%; SPARC, 90.0%; TOT, 94.0%; p = 0.625) and for total cure (TVT, 81.9%; SPARC, 86.4%; TOT, 82.0%; p = 0.965). There were no risk factors for cure of SUI, except detru-
sor overactivity (DO) on urodynamic studies. There was one difference between groups preoperatively; the TOT patients had less severe UUI than those patients who underwent the SPARC or TVT.

In 2008 Gamble et al. evaluated 305 women with MUI and found 31.5% of women had postoperative resolution of detrusor overactivity (DO). [204] Sling type was strongly related to persistence of DO with a 53% persistence of DO in the transobturator tape group, followed by retropubic (64% after TVT, 66% after SPARC), and 86% after bladder neck slings ($p < .001$). Botros et al. evaluated 276 patients with MUI who underwent retropubic slings (TVT, N = 99; SPARC, N = 52) or transobturator slings (Monarc, N = 125). [206] Patients who underwent transobturator sling placement (8%) had significantly less de novo subjective UUI compared to the patients who had TVT (33%) and SPARC (17%) ($p = 0.04$). In patients with preoperative UUI, 14-16% who underwent TVT or SPARC had worsening of their UUI symptoms while only 6% of the transobturator sling group did ($p = 0.02$). There was no difference in rates of resolution of DO or de novo DO among the three groups. Ballert et al. evaluated 83 women who underwent TVT [203] and TOT-O ? TVT-O? [87] using pre- and post-operative AUASI (American Urologic Association Symptom Index) scores to evaluate lower urinary tract symptoms. [207] Patients with SUI had lower postoperative AUASI scores than patients with MUI. There were no differences between patients who underwent TVT or TVT-O in any category. In 2011 Lee et al. performed an observational cohort study evaluating risk factors for persistence of urgency or UUI after midurethral slings. [208] Out of 1112 women who completed the questionnaire, 754 patients had preoperative urgency or urgency urinary incontinence. 955 patients underwent retropubic slings and 270 patients underwent transobturator slings. The overall subjective rate for persistent urgency and UUI was 40.3% and 32.3% respectively. Age (OR 1.03, 95% CI: 1.02-1.04), baseline symptoms severity (OR 1.41, 95% CI: 1.10-1.78) and coexistent DO (OR 2.04, 95% CI: 1.39-3.01), were risk factors for persistent urgency while concomitant prolapse surgery (OR 0.54, 95% CI: 0.38-0.75) and transobturator sling surgery (OR 0.61, 95% CI: 0.39-0.94) decreased the risk. There was no difference in type of sling surgery and persistence of UUI. These studies are consistent with results published by Novara et al. who performed a meta-analysis of randomised controlled trials comparing transobturator vs. retropubic MUSS. [33] Results showed a higher prevalence of storage lower urinary tract symptoms in patients randomized to retropubic slings than in patients randomized to transobturator slings (OR 1.35; 95% CI OR: 1.05-1.72; $p = 0.02$).

In conclusion, women with mixed urinary incontinence benefit from sling surgery. It appears that placement of a transobturator sling provides the greatest improvement in OAB and UUI symptoms and seems to have the lowest rates of de novo urgency and UUI; it also appears to have the greatest resolution of DO. However, women with mixed urinary incontinence should be carefully counseled preoperatively as persistence or worsening of symptoms may have a negative impact on quality of life and may lead to poor overall satisfaction after surgery.

2. Recurrent SUI

There have been multiple studies reporting on outcomes after repeat anti-incontinence surgery, however the appropriate choice of a secondary continence procedure for women with recurrent SUI is poorly studied and the available studies are limited by their small numbers. Two studies of repeated mid-urethral slings report cure rates of 74–76% at 18 months, which is lower than cure rates for primary surgery. [209, 210] Lee et al. performed a retrospective study on repeat midurethral slings. [209] 13 patients underwent retropubic and 16 patients underwent transobturator slings. Overall cure was 75.9% and overall improvement was 6.9%. Cure rates were 92.3% for the retropubic approach and 62.5% for the transobturator approach, however this was not statistically significant ($p = 0.089$). Stav et al. evaluated 1,225 women with SUI, among these 77 patients had repeat mid-urethral slings. [211] The subjective stress incontinence rate was 62% in the repeat group compared to 86% in the primary group ($p < 0.001$). A repeat retropubic approach was significantly more successful than a repeat transobturator approach (71% vs. 48%, $p = 0.04$). These results could be due to a higher incidence of intrinsic sphincter deficiency or lack of urethral mobility in patients undergoing a repeat mid-urethral sling (31% vs. 13%, $p < 0.001$).

A recently published study by Abdel-Fattah et al. reported on outcomes on a total of 46 women with recurrent SUI after previous failed continence surgery. [212] 18 patients underwent “outside-in” and 28 underwent “inside-out” procedure. Overall subjective and objective success rates in this group were 70% and 77% but it should be noted that these numbers included 10 women with failed colposuspension. Higher success rates were seen in women who underwent the inside-out TVT-O compared to the “outside-in” TOT but this study was not adequately powered to make this comparison. Biggs et al. evaluated 27 patients who underwent TVT-O after a previous anti-incontinence procedure. [213] There was an 80% success rate assessed by PGI-I (“very much better” or “much better”) at a mean follow-up of 25.7 months.

A repeat synthetic mid-urethral sling procedure has significantly lower cure rates than a primary sling procedure. Although the data are limited, it seems that in patients who failed a primary anti-incontinence surgery, a repeat retropubic approach has a higher success rate than the repeat transobturator approach especially in cases with intrinsic sphincter deficiency.

3. Elderly

Thirty-seven million people are aged > 65 years (12% of the total US population) and 5.3 million of these are aged > 85 years. With the national life span
increasing, it is estimated that by 2030, 1 in 5 people in the United States will be aged > 65 years, and 1 in 4 elderly individuals will be aged > 85 years. Advanced age is related to increased prevalence of urinary incontinence and there is evidence of a higher rate of DO and ISD in the elderly population. Surgical intervention is considered the most efficient and durable approach to treat SUI and mid urethral slings have become the treatment of choice in the majority of patients. The effect of age on outcomes of mid urethral slings is still scarce and the definition of elderly varies across studies. There are some studies that evaluate the efficacy of retropubic slings in the older population but there are limited data assessing safety and efficacy of the transobturator slings in elderly vs. younger patients. Sevestre et al. analysed a series of 76 patients with a mean age of 76 years who underwent TVT.[214] There were no major postoperative complications, however, 13.7% of the patients had postoperative persistent SUI and 18.4% had urgency incontinence. De novo urgency without incontinence was detected in 21% of the patients. In another study, pre- and postoperative quality of life parameters were compared in a small series of 21 elderly and 46 younger stress-incontinent patients that underwent TVT.[215] At postoperative follow-up of 3-24 months, SUI was improved in 91% of the younger and 80% of the elderly patients and all quality of life parameters were significantly improved in all age groups. Perioperative morbidity and complications are also a consideration in older patients. In the study of Gordon et al. the incidence of early postoperative morbidity was similar in both age groups who underwent TVTs. [216] However, several cases of significant age-related morbidity were noted among elderly patients: two cases of pulmonary embolism, two cases of cardiac arrhythmia, one case of severe pneumonia, and one case of deep vein thrombosis. All major complications occurred in elderly patients who were undergoing concomitant prolapse surgery. The risk of de novo urgency was 18% at one year in older vs. 4% in the younger patients. Barber et al. identified predictors of recurrent urinary incontinence one year after treatment with retropubic and transobturator slings. [85] They found that increasing age was the only identified variable that was independently associated with recurrent SUI (adjusted OR 1.7; 95% CI: 1.1-2.6 per decade). Chen et al. found that surgical failure after inside-out transobturator sling was significantly greater in women aged 60 years old or older, compared with those younger than 60 years (adjusted OR 11.7, 95% CI: 1.8-76) in a small series of 54 women. [217] Groutz et al. evaluated patients aged 70 or older (n=97) and compared them to patients younger than 70 (n=256) who underwent TVT-O.[218] The mean follow up was 30 months ± 17 months. The incidence of persistent, urodynamically confirmed, SUI was similar in both age groups (5%). However, asymptomatic urodynamic SUI was significantly more common among elderly patients (19% vs. 3.7%, p <0.05). The incidence of persistent OAB was similar in elderly and younger patients (68% and 62%, respectively), while de novo OAB was significantly more common in elderly patients (11.9% vs. 4.7%, p <0.05). Postoperative morbidity was similar in both groups except the elderly group had a higher incidence of recurrent UTI’s (13.7% vs. 6.2). Even though there are limited data and further studies are needed, it appears that transobturator slings are both safe and efficient in elderly patients and women should not be excluded from mid-urethral slings based on their age.

### 4. Concomitant Prolapse Surgery

Approximately 40% of women with pelvic organ prolapse (POP) also report SUI.[219] Asymptomatic women who undergo prolapse surgery have a 11-20% risk of developing de novo stress incontinence. [220] Patients who leak during preoperative testing after reduction of their prolapse have a risk of up to 80% of developing de novo SUI.[221] The role of concomitant slings in patients undergoing POP repair has been debated, with some studies showing differences in cure rates or complications and others finding no differences. In a prospective observational study, Liang et al. evaluated 49 patients with stage 3 or 4 prolapse and occult stress incontinence.[222] In 32 (65.3%) patients a concomitant TVT procedure was performed and the remaining 17 (34.7%) patients had a prolapse repair only. The rate of postoperative SUI was significantly lower in those who had a TVT placed (9% vs. 65%) and the rate of detrusor overactivity was lower in patients who had prolapse repair alone after surgery (6% vs. 16%). Casiano et al. compared outcomes after retropubic mid-urethral slings with and without concomitant prolapse repair. [223] After 2.7 years survival free of “any” incontinence (Incontinence Severity Index score, >0) was similar in both groups (adjusted hazard ratio, 1.07; p=0.77). Women with concomitant repair for advanced prolapse tended to be more bothered by frequent urination (adjusted OR 1.78; p=0.08) and more likely to require urethropessy (OR 6.11; p=0.04) than those without prolapse repair. There is only one study that reports on transobturator slings and prolapse surgery. Wang et al evaluated 140 women who underwent TVT (n = 70) and TOT (n = 70) with SUI with or without POP.[224] In the TVT group 30 patients and in the TOT group 22 patients had concomitant prolapse surgery. Surgical results were similar in both groups and concomitant pelvic reconstructive procedures had no effect on surgical results. At 1-year follow-up, the objective cure rates for patients with isolated SUI were 95% in the TVT group and 93.75% in the TOT group. For patients with concomitant POP, the cure rates were 90% in the TVT group and 86.36% in the TOT group. There are no randomised trials in patients undergoing pelvic organ prolapse surgery and obturator slings but with the currently available literature, it would appear that it is beneficial to treat concomitant SUI and prolapse. There are no current studies on the role of transobturator slings in occult SUI.
5. Obesity

Obesity is gradually increasing worldwide and epidemiological studies have found a link between obesity and urinary incontinence with odds ratio for the presence of urinary incontinence as high as 1.6 to 5 with each unit increase in body mass index (BMI). [225, 226] The role of mid-urethral slings in obese women has been debated due to concerns for higher failures and a potential increase in intraoperative and postoperative complications. Numerous studies have been carried out evaluating obesity as an independent predictor in patients that have undergone TVTs. [227, 228] [229] [230] [231-234]

Hellberg et al. reported a decrease in cure of 52.1% in patients with a BMI higher than 35 compared to 81.2% in those with a BMI less than 25. Six other studies have shown overall cure rates that approach 90% with no difference in the obese vs. the non-obese patient.[231] However Greer et al. in their meta-analysis included these seven studies and did find a significant difference in cure rates between the two groups with cure rates being 81% and 85%, respectively (p = 0.001; OR 0.576, 95% CI: 0.426–0.779).[227] There are very limited data evaluating outcomes for transobturator slings in obese women. Liu et al did a retrospective review evaluating the TVT-O procedure in overweight and obese women. [235] They retrospectively evaluated 129 patients who had undergone TVT-O and they were stratified according to their BMI, normal weight (n=29), overweight (n = 58), and obese (n = 32) groups. The median follow up was 24 months and there were no statistically significant differences in between groups comparing objective or subjective surgical outcomes, in the incidence of de novo DO, in quality of life scores or postoperative complications. Another study undertaken by Rechberger et al. found no significant association between BMI and surgical outcome at 18 months of follow-up among normal weight (n = 43), overweight (n = 81), and obese (n = 73) women who underwent transobturator slings.[88] However, they did notice a trend towards worse outcomes in overweight patients. Haverkorn et al. conducted a retrospective study evaluating patients that had undergone a transobturator sling (Monarc) in women with a BMI higher than 30 (n = 117) and BMI less than 30 (n = 161) with a minimum follow up of 12 months. [236] The percentage of women achieving global cure and SUI cure was significantly higher in non-obese women (83.9% and 91.9%) than in obese women (70.9% and 81.2%) (p < 0.001). Obese women achieved improvement in quality of life similar to those of non-obese women. Although the results from these studies are conflicting, it seems that regardless of BMI, transobturator slings may be an acceptable method of treatment for SUI in obese patients. Follow up in these studies is limited and larger studies are needed to confirm these findings and to evaluate the long term effects of the procedure.

4. SINGLE INCISION MINI SLINGS (SIS) (TABLE 3)

The single incision mini slings have been developed in an attempt to further reduce the morbidity associated with continence surgery and to provide an outpatient or office procedure to treat stress urinary incontinence. The blind passage of needles, during TVT and TOT procedures, through the retropubic space or the obturator foramen respectively is associated with a small risk of vascular, nerve or visceral injury [202]. The shorter SIMS will theoretically minimise this risk.

The concept of the single incision sling is not novel. Smith presented a small series of SIMS in 1987[237], however this was a porcine dermis sling which in vivo probably degrades and hence long term cure rates were poor.

The first commercially available mid-urethral incision sling , TVT-Secur (Gynaecare), was launched in 2006 with no published human trial data. The last 6 years have seen a increase in the number of commercially available single incision slings. There are currently 9 different products available. All are made of type I polypropylene mesh however the length & anchoring mechanisms are variable. (Figure 1)

The method of insertion is either U shaped, inserted in the same manner as the TVT or the H “hammock” insertion of the TOT. There is currently very little good quality RCT data to support the use of these slings.

Ten trials have been published including 1072 women. 6 of the RCTs published compared TVT- Secur to MUS, 2 compared MiniArc to MUS, 1 compared TVT-Secur to MiniArc and to MUS, and one compared Contasure to TVT-O. The numbers in each trial are relatively small (60-194).

Five of the seven trials of TVT-secur found it to be inferior to TVT or TVT-O. Several different outcome measures were report in these 7 trials , making it difficult to compare the trials directly. Two of these trials were stopped prematurely following an interim analysis which demonstrated TVT-secur results to be significantly less effective than the comparator MUS. Hamer et al [245] also reported concerns about the morbidity associated with TVT-secur. They reported three significant complications in 67 cases, one hemorrhage 1000ml, one urethral perforation and one perforation of the bladder.

Three trials compared MiniArc to MUS , two found no significant difference between MiniArc and obturator tapes however the third trial by Basu et al[240] reported a considerably worse outcome for MiniArc compared to TVT, 9 out of the 37 patients who underwent the MiniArc subsequently had a TVT. Table 3 summarises the data currently available.

h) Conclusion and recommendation

Sufficient Level I /II evidence exists which evaluate mid-urethral tapes (retropubic). Current series include retrospective cohort studies and high level RCTs . There is a need for further prospective randomised assessment of this intervention – especially from the durability standpoint. Quality of evidence is A / B.
In 2011 Abdel-Fattah et al[247] published a meta-analysis of RCT comparing SIMS to standard MUS, the review included both full text publications and conference abstracts. A total of 758 women in nine RCTs with a mean follow-up of 9.5 months were included. SIMS were associated with significantly lower patient-reported and objective cure rates compared with MUS (risk ratio [RR]: 0.83; 95% confidence interval [CI]: 0.74–0.97, respectively).

One of the reasons for the development of SIMS is to reduce the morbidity of continence surgery. Hence trial design should include an assessment of morbidity, including perforation, hemorrhage, chronic pain and voiding difficulty. The meta-analysis demonstrated that there was no significant difference in the perforation rate between SIMS and MUS, the confidence intervals (CI) for these parameters were however extremely wide. There was also a trend toward more voiding difficulties following SIS but again the CI were very wide.

Proponents of SIMS have speculated that the initial poor results reflect an incorrect insertion technique used in early trials. SIMS were initially inserted in the tension free manner by which TVT are inserted, however SIMS insertion has evolved and the current insertion technique is in closer proximity to the urethra and with greater tension than TVT.

In 2011 Abdel-Fattah et al[247] published the protocol Cochrane review of SIMS which will enable ongoing assessment of data.

Due to the considerable variation in the anchoring mechanism of each type of SIMS, data from one device cannot be extrapolated to another. There is a need for further RCT. Currently the recommendation is that SIMS should only be performed in the context of research.

All reports are Level I - III in terms of evidence and there continues to be a lack of durable outcomes reporting for this technique. Current series suggest that some efficacy may be inherent to these interventions, however, comparable efficacy to either retropubic or mid-urethral tapes has yet to be proven. Grade of recommendation is –B/ C.

5. TRADITIONAL SLING PROCEDURES

As in the previous ICI4 review, the term ‘traditional’ sling procedure is used here, in line with the terminology used in the latest Cochrane review. [249] This is done mainly to distinguish open sling procedures typically placed at the region of the bladder neck from the newer, minimally-invasive mid-urethral sling (MUS) procedures.

Sling procedures came into prominence in the beginning of the twentieth century. In 1907, Giordano transplanted gracilis muscle and wrapped it around the urethra. [250] Soon thereafter, other autologous tissues were transplanted under the urethra to provide additional support: pyramidalis [251], levator ani [252], rectus fascia [253], gracili [254], and bulbocavernosus muscle and fat [255]. While it was
hypothesised that the transplanted muscle would retain its contractility and act as a neo-sphincter to prevent SUI, these procedures compressed the urethra and created a partial obstruction. Complications such as recurrent cystitis, urethral sloughing, and fistula formation were common.

The modern autologous bladder neck sling exists mainly due to the work of Aldridge in the 1940’s and McGuire and Blaivas in the latter part of the twentieth century. [256-258] The majority of sling procedures have involved a combined abdomino-vaginal approach, although procedures performed entirely through an abdominal approach have been described. Suspended, or ‘sling on a string,’ methods have been developed in order to reduce the invasiveness of the procedure and to shorten the length of sling material. These shorter slings can also vary in length, from a “mid-length” sling (7-10 cm) to a “patch” sling (2-4 cm). As with needle suspension procedures, bone anchoring has been used as an alternative form of sling suspension, although the benefit of this additional step has not been adequately studied.

Sling materials may vary widely and individual materials may have only a modest effect on initial sling efficacy. However, these materials may considerably affect the long-term outcomes of sling procedures and the associated morbidity. Materials may be synthetic or biological. The latter include autografts (rectus fascia, fascia lata, round ligament, dermis, vaginal skin, and gracilis, levator, and rectus muscles), cadaveric allografts (fascia, dermis, and dura mater) and xenografts (porcine dermis and small intestinal submucosa, bovine dermis and pericardium). Case series of autologous rectus fascial (ARF) sling were reviewed within the systematic review underlying the NICE guidance on urinary incontinence. [259] Ten series including a total of 1280 women were considered. Studies had a mean or median duration of follow-up between 2 and 6 years, while in three studies, maximum follow-up of 15–18 years was reported. Subjective cure rates ranged from 26% to 97% (median 81%); and cure rates that included subjective and objective elements ranged from 73% to 95%. Satisfaction rates of 86% and 92% were reported in two studies.

Synthetic sling materials have included nylon, polyethylene, polytetrafluoroethylene (PTFE), and polypropylene. On occasion, these polymers have been ‘enhanced’ with synthetic or biologic coatings in an attempt to improve their biocompatibility profiles. Many additional variations in the technique have been described, although it is unclear which of these materially influence the outcome. Several case series have published outcomes for polyethylene and PTFE slings with short-term cure rates typically in the 80-90% range, depending on the definition [EL=3]. Vaginal extrusion, erosion, and sinus formation have been common with these materials. Since the last ICI review, there have been no additional studies published and the number of these procedures performed appears to have waned significantly in favour of polypropylene midurethral slings.

Both biological and synthetic sling materials are analysed together in the Cochrane review [Rehman et al., 2011], although these were considered separately in the systematic review underlying the NICE guidance on urinary incontinence. [249, 259] NICE has also published a non-systematic review of biological sling procedures under its Interventional Procedures Programme. [260] The most recent Cochrane review included 26 RCTs (or quasi-randomised trials) describing a total of 2284 women of whom 1287 were treated with suburethral traditional slings. Sample sizes ranged from 20 to 655 participants. Several of these trials are available only in abstract form and remain unpublished as full peer-reviewed papers. Owing to the significant number of recent meeting abstracts about surgical procedures for SUI, only full publications have been included in this section. Additional studies have been included, but the majority of these are case-control studies and have a relatively low level of evidence.

There have been no trials identified that compared traditional suburethral sling operation vs. no treatment, sham operation, conservative management (e.g. pelvic floor muscle training, electrical stimulation, cones, biofeedback), anterior repair, laparoscopic retropubic suspension, or artificial urinary sphincter [Rehman et al., 2011]. [249] One trial studied patients with MUI treated with oxybutynin or surgery [Osman, 2003]. [261] The type of surgery was selected according to Valsalva leak point pressure (VLPP): those women with VLPP ? 90 cm H2O underwent an ARF sling and those with VLPP ? 90cm H2O underwent Burch colposuspension. The results for the total surgically managed group were similar to those for the subgroup having slings. The study suggested that slings are significantly better for treating MUI than oxybutynin. Results were analysed in terms of patient reported incontinence within one year (RR 0.18; 95% CI 0.08 to 0.43). Fewer women had persistent UIU after the sling surgery (RR 0.29; 95% CI 0.09 to 0.94).

a) Traditional sling vs. bulking agent (table 4E)

One RCT compared ARF sling with periurethral silicone cone injection in women with SUI secondary to ISD in whom conservative treatment had failed [Maher et al., 2005]. [165] At 6 months, no significant differences were seen between groups in subjective cure (1-hour pad test) or satisfaction, QOL (UDI-6, IIQ). Significantly more women undergoing sling surgery were objectively cured on the basis of urodynamic assessment (81% vs. 9%; p=0.0001), but duration

Key: RP MUS=retropubic midurethral sling; F/U=follow-up (months); LE=level of evidence; TVT=tension-free vaginal tape; o=objective; s=subjective; N/A=not available; OC=open colposuspension; LC=laparoscopic colposuspension; ITT=intention to treat
of the procedure, catheterisation, inpatient stay, and
time to return to normal activities were significantly
longer in the sling group. A survey of two-thirds of
the women at 5 years found no statistically signifi-
cant differences between groups in urinary symp-
toms or in satisfaction with surgery, although fewer
women in the silicone bulking group were satisfied
(29% vs. 69%) (n=45). [EL=2]

Open continence surgery (a suspension procedure
in 46% and ARF sling in 54%) was compared with
periurethral collagen in women with SUI or MUI in
an additional RCT [Corcos et al., 2005]. [164] As
in the previous study, there were no significant dif-
fferences in patient satisfaction or QOL (SF-36, IIQ)
between groups at 1 year. Using ITT analysis, there
was no significant difference in continence rates at 1
year (52% collagen, 55% surgery). If only the 89%
of women who underwent the randomised interven-
tion were considered, the continence rate with surgery
was 72% vs. 55% (n=45). [EL=2]

b) Traditional sling vs. colposuspension (Table 4A)

Nine randomised or quasi-randomised trials were
identified from the literature. Six of the trials com-
pared suburethral slings with open abdominal
retropubic suspension [Henriksson & Ulmsten,
1978, Enzelsberger et al., 1996, Sand ef al., 2000,
Demirci & Yucel, 2001, Bai et al., 2005, Albo et al.,
2007] while one trial reported the long-term out-
comes [Culligan et al., 2003] and another reported
the complications [Chai et al., 2009] of aforemen-
tioned trials. [38, 119, 121-126] One additional
trial compared sub urethral slings with the Stamey
transvaginal needle suspension [Hilton, 1989].
[120] The Cochrane review systematically evaluat-
ed the six trials comparing suburethral slings with
open retropubic suspension and an additional trial
that was only published in abstract form [Rehman
et al., 2011]. [249]

One RCT compared dura mater sling with open
colposuspension in 72 women with recurrent SUI after
hysterectomy [Enzelsberger et al., 1996]. [121] At
a minimum follow-up of 32 months, the combined
objective and subjective cure rates were 92% after
dura mater sling compared with 86% after colpo-
suspension. While both were common, significantly
more women in the sling group had postopera-
тиве voiding difficulty or urinary retention. More
women in the colposuspension group developed a
postoperative rectocele. Bladder perforation and
de novo urgency were common in both groups. The
time to spontaneous voiding was significantly longer
in the sling group (n = 72). [EL=1/2]

Three trials compared ARF sling with open colpo-
suspension. In a small trial alternating 17 women
each to ARF and colposuspension, ARF was su-
perior to colposuspension at 12 months follow up
by objective measures (94% vs. 88%) [Demirci &
Yucel, 2001]. [124] In a second trial randomising
women to ARF, colposuspension, and TVT, ARF
was significantly superior to colposuspension at 12
months (92.8% vs. 87.8%) using a subjective and
objective definition of cure [Bai et al., 2005]. [38]
The significant difference in the two procedures
was not evident at 6 months follow-up (92.8% vs.
90.9%). Finally, a large RCT performed by the Urin-
ary Incontinence Treatment Network revealed that
ARF was significantly superior to colposuspension
both in its cure of SUI (47% vs. 38%) and overall
incontinence cure (66% vs. 49%) at 24 months [Albo
et al., 2007]. [125] Fifty percent of the women un-
derwent concomitant surgery for pelvic organ pro-
lapse (POP) and 79% (265:255) were available for
the 24-month outcome assessment. Women under-
going ARF sling had a higher percentage of postop-
erative UTIs within the first six weeks of follow-up,
voiding and storage urinary symptoms [Chai et al.,
2009]. [126][EL=1]

Two small RCTs evaluated an expanded polytetra-
fluoroethylene patch sling (PTFE; Gore-Tex®) and
open colposuspension, with the second trial provid-
ing long-term subjective and objective outcomes
[Sand et al., 2000; Culligan et al., 2003]. [122] [123]
Although the groups were different at baseline in
terms of the proportion with detrusor overactivity
(DO) (95% colposuspension vs. 41% sling), cure
rates with PTFE were not significantly different from
open colposuspension at 3 months (objective 100%
vs. 90%) and 2.5 years (objective 100% vs. 85%;
subjective 84% vs. 93%) (n = 36). No significant
differences were found between groups in hospital
stay or time to catheter removal. [EL=2]

In the Cochrane review, trials comparing rectus
fascia with other materials heavily weighted the
comparison of different types of sling [Rehman
et al., 2011]. [249] Furthermore, the results of the
most recent, and by far the largest and most rigor-
ous RCT of colposuspension and ARF sling heav-
ily weighted the results of the analysis [Albo et al.,
2007]. [125]This trial randomised 655 women of
whom 520 were assessed at 24 months, while the
next largest trial randomised 72 women [Enzels-
berger et al., 1996]. [121] The summary statistic,
combining urodynamic and symptom only diagno-
sis, showed a lower incontinence rate with sling
procedures (RR 0.75; 95% CI 0.62 to 0.90). The
data from the trials where women all had urody-
namic SUI showed no significant difference in uri-
inary incontinence after one year (RR 0.72, 95%
CI 0.31 to 1.67). Data beyond five years were
provided by only one trial [Sand et al., 2000], and
there was no statistically significant difference be-
tween the groups, but with very wide confidence
intervals (RR 2.31; 95% CI 0.24 to 22.62). [122]
Adverse events in general (47% vs.63% (p<0.001)
and voiding difficulty in particular (14% vs. 2%, p<0.001) were more common in sling group [Chai et al., 2009]. [126][EL=1].

Only one small trial is available to allow comparison between sling (porcine dermis) and needle suspension (Stamey) in a group of women unsuitable for abdominal colposuspension because of vaginal narrowing secondary to either previous interventions or atrophic change [Hilton, 1989]. [120]. Although there were no differences in objective cure rates or atrophic change [Hilton, 1989]. [120]. Al though there were no differences in objective cure rates at 3 or 24 months, perioperative complications (RR 4.50; 95% CI 1.28 to 15.81) and length of hospital stay (RR 13.00; 95% CI 5.00 to 21.00) favored the needle suspension procedure (n=20). [EL=2]

c) Traditional sling vs. traditional sling (Table 4B)

Our review identified 3 RCTs and 2 quasi-RCT comparing one type of traditional sling with another [Barbalias et al., 1997; Lucas et al, 2000; Viseshsindh et al., 2003; Choe et al., 2000; Kuo, 2001], with an additional RCT providing long-term outcomes of one of the aforementioned studies [Guerrero et al., 2007]. [128, 132-135, 139] The remainder were cohort and case control studies.

ARF and vaginal wall slings were compared in one RCT and two non-randomised retrospective studies [Viseshsindh et al., 2003; Kaplan et al., 1996; Rodrigues et al., 2004]. [127, 139, 141] All of these trials were considered to be of poor quality. The RCT reported high subjective cure, and satisfaction rates (80–100%) for both procedures, with median follow-up of 7 months and minimum follow-up of only 3 months (n = 26) [Viseshsindh et al., 2003] [139][EL=2]. The non-randomised studies reported similar ‘success’ rates with both interventions, ranging from 80% to 97%, with follow-up of 21 months, and 70 months versus 45 months (n = 232, n = 79) [Kaplan et al., 1996; Rodrigues et al., 2004]. [EL=2/3]. Other than the proportions of patients requiring intermittent catheterisation after surgery (2% in the ARF group and 0% in the vaginal wall group), no additional differences were noted in rates of other postoperative complications (e.g. voiding and storage dysfunction, wound infection and seroma formation, and bladder or urethral injury).

One RCT compared two techniques of fascial sling in 168 women with urodynamic SUI 89% of whom had had prior continence surgery [Lucas et al., 2000]. [133] Women underwent a standard fascial sling procedure or a ‘sling on a string’ (a shorter sling mounted on each end with a nylon thread). At 1 year, subjective cure rates were 84% using both techniques. Satisfaction and changes in IIQ scores were also similar in both groups, whereas improvements in UDI scores were greater with the standard approach (adjusted for differences in baseline UDI data). A further evaluation of women in this study was reported at 5 to 7 years of follow-up [Guerrero et al., 2007]. [134] There were no significant differences in symptoms of SUI or UUI between groups, with 40%-53% vs. 36%-51% reporting SUI in sensitivity analysis. [EL=1]

Eight non-randomised studies compared the outcomes of autologous and allograft slings in a total of 859 women with SUI [Wright et al., 1998, Brown & Govier, 2000, Soergel et al., 2001, Flynn & Yap, 2002, O’Reilly & Govier, 2002, Almeida et al., 2004, McBride et al., 2005, Onur et al., 2008], while one additional study also compared both interventions with a xenograft material (porcine dermis) [Simison et al., 2005]. [129-131, 137, 138, 140, 142, 143, 146] All were retrospective reviews, each with differences in duration of follow-up for the interventions evaluated (between 1 month and 3 years), with dropout rates of 4% to 34%. Additionally, between 16% and 82% in different studies underwent other concomitant surgeries, and all of these studies were considered to be of poor quality. [EL=3]

Four of these studies compared autologous with allograft (cadaveric) fascia lata. Three reported similar results for all outcomes (subjective cure, satisfaction, and UDI-6, IIQ-7 and SEAPI scores) [Wright et al., 1998, Brown & Govier, 2000, McBride et al., 2005], while the fourth study reported significantly higher cure rates in the autologous group [Almeida et al., 2004]. [129, 130, 140, 142] [EL=3] In three studies that compared autologous rectus fascia or fascia lata with allograft fascia lata, two found a significantly higher cure rate in the autologous group [Soergel et al., 2001, Simison et al., 2005]; [137, 143] the other found no significant differences in cure rate, although satisfaction rates were higher in the autologous group after 2 years follow-up [Flynn & Yap, 2002]. [36] In the study with a xenograft arm, cure rates were significantly higher with autograft material [Simison et al., 2005]. [143] The study comparing ARF to cadaveric dermis found no significant difference in subjective cure rates at a mean follow-up of 18 months and 13 months, respectively [Onur et al., 2008]. [146] [EL=3].

One RCT compared the porcine dermis sling vs. ARF and tension-free vaginal tape (TVT), a retropubic MUS [Guerrero et al., 2010]. [160] It should be noted that the ARF and porcine dermis slings were placed at the midurethra rather than the bladder neck, but suspended above the rectus fascia like traditional slings. The primary outcome was patient-reported improvement rates at 6 months and 1 year. At 6 months, the porcine dermis arm had significantly poorer improvement rates (73%) than TVT (92%) and ARF (95%), and, at 1 year, only 61% of the porcine dermis slings remained as improved, vs. 93% and 90% of the TVT and ARF arms, respectively. At 1 year, women undergoing porcine dermis slings had significantly lower dry rates (22%) as compared to TVT (55%) and ARF.
slings (48%), respectively. Subsequently, the porcine dermis arm was suspended following interim analysis. There was no difference in success rates between the TVT and ARF arms. [EL=1/2].

One non-randomised trial compared porcine dermis sling vs. ARF [Giri et al., 2006], a second compared porcine dermis sling vs. both ARF and TVT [Morgan et al., 2007], and a third trial mentioned earlier compared porcine dermis vs. both ARF and allograft slings [Simsiman et al., 2005]. [143-145] At a follow-up of 36 months, the subjective success rate (cure and improved) after ARF sling was significantly higher than porcine dermis sling (80.4% vs. 54%) [Giri et al., 2006]. [144] Women undergoing porcine dermis slings were found to have significantly higher postoperative symptom severity than women undergoing either ARF sling or TVT [Morgan et al., 2007]. [145] Objective cure rates after ARF were significantly higher (87%) than either porcine dermis sling (54%) or cadaveric fascia lata (64%) [Simsiman et al., 2005]. [143][EL=2/3]

A quasi-RCT compared an ARF sling with a self-fashioned polypropylene mesh sling placed at the bladder neck [Kuo, 2001]. [135, 148] At a median follow-up of approximately 24 months, cure and satisfaction rates were similar but operating time and hospital stay were significantly shorter in the prolene sling group. Delayed voiding occurred in more women in the ARF sling group. No other significant differences were seen between groups in complications (e.g. haematoma, dysuria, de novo urgency or UUI) (n=50). [EL=2] A second, retrospective, non-randomised trial found no significant difference in subjective cure rate (81% vs. 88.9%) in women undergoing ARF and polypropylene mesh (Marlex) slings [Winckler et al., 2010]. [45] It should be noted that both slings in this study were placed at the midurethral but tied without tension above the rectus fascia as in the traditional bladder neck sling. Interestingly, vaginal extrusion rates and rates of surgical intervention for extrusion were not significantly different between ARF and Marlex slings. [EL=3]

One RCT compared ARF and PTFE slings in women with SUI, 92% of whom had had previous continence surgery [Barbalias et al., 1997]. [128] Combined objective and subjective cure rates at 6 months follow-up were 81% and 88%, respectively. No complications were reported in the ARF sling group; however, urethral erosion, recurrent UTI and de novo DO were very common with PTFE (n = 48). [EL = 1] A quasi-randomised comparison of MycroMesh patch sling (PTFE mesh impregnated with silver diacetate and chlorhexidine) with vaginal wall sling gave no statistical analysis, but found combined subjective and objective cure in 95% vs. 75% at mean follow-up of 22 months [Choe et al., 2000]. [132][EL=2] Again, the need for sling removal was common, reported in up to 31% (median 8%) in a review of case series within the systematic review underlying the NICE guidance on UI [National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence]. [259][EL=3].

A retrospective cohort study compared an ARF sling with one reinforced with polyglactin mesh in women with urodynamic SUI, one-third of whom also had UUI (n=51) [Maher et al., 2001]. [136] Follow-up differed between groups and, overall, no clear difference was seen between groups in success rates. As with most studies, results depended on the definition of success used. No significant differences were noted between groups in terms of complications (e.g. wound infection, incisional hernia, voiding dysfunction, and de novo DO). [EL=3]

A small, non-randomised trial compared ARF to bovine dermis sling (n=85) [Wilson et al., 2008]. [147] Patients were allocated to material by institution and all had ISD, advanced age, and/or recurrent SUI after previous anti-incontinence surgery. At 12 months follow-up, the SUI-specific cure rates (consisting of subjective stress SEAPI domain and negative cough stress test) and global cure rates (consisting of SEAPI composite score and visual analog score) were not significantly different between the two slings. QOL indices (UDI-6, IIQ-7) were significantly improved in both groups. There were significant differences in several preoperative demographic variables between the groups.

The Cochrane review included 4 published trials in their statistical comparison [Barbalias et al., 1997; Lucas et al., 2000; Viseshsindh et al., 2003; Guerrero et al., 2008], as well as 2 trials in abstract form [Rehman et al., 2011]. [249] A total of 379 women studied after 12 months showed no statistically significant difference in incontinence rates (RR 0.89; 95% CI 0.72 to 1.10). However, results reported improvement after one year in favour of the traditional ARF sling (RR 0.33; 95% CI 0.17 to 0.64). The incontinence rate after five years was reported in only one trial [Lucas et al., 2000] and showed no statistically significant difference between different lengths of the autologous material used (RR 1.17; 95% CI 0.86 to 1.59). There was significant heterogeneity in the incidence of perioperative complications between groups in two trials, which was attributed more to complications with the use of Gore-Tex in one trial (RR 0.05; 95% CI 0.00 to 0.80, Barbalias et al., 1997). In the other trial, there was no statistically significant difference between two biological slings (RR1.14, 95% CI 0.78 to 1.66, Lucas et al., 2000). No statistically significant difference was found in assessment of the following adverse events, reported in only one trial [Lucas et al., 2000]: bladder perforation (RR 0.69; 95% CI 0.12 to 4.03), UTI (RR 1.73; 95% CI 0.66 to 4.54), de novo DO or urge symptoms (RR 3.11; 95% CI 0.65 to 14.97), and voiding dysfunction (RR 1.16; 95% CI 0.65 to 2.07).
d) Traditional sling vs. midurethral sling (Table 4C and D)

Our review identified 17 trials that addressed the comparison between traditional sling operations and MUS operations. Eight RCTs compared traditional slings placed at the bladder neck with the retropubic MUS [Arunkalaivanan & Barrington, 2003; Lucas et al., 2004; Bai et al., 2005; Wadie et al., 2005; Kondo et al., 2006; Basok et al., 2008; Shariﬁghad & Mortazavi, 2008; Amaro et al., 2009;] and 3 additional RCTs provided long-term outcomes of aforementioned studies [Abdel-Fattah et al., 2004; Guerrero et al., 2010; Wadie et al., 2010]. [38, 149, 150, 152, 154, 155, 158, 160, 161, 162] One of the trials [Lucas et al., 2004] was only available as an abstract and 3 studies were non-randomised case control or cohort studies (Hung et al., 2004; Morgan et al., 2007; Trabuco et al., 2009). [145, 151, 153][159] Two RCTs compared a traditional ARF sling to a transobturator (TO) MUS (Safyre-t) (Silva-Filho et al., 2006; Tcherniakovsky et al., 2009). [162, 163] Finally, a non-randomised trial compared pubovaginal slings (material not stated) with TVT and TOT (Jeon et al., 2008). [156]

Five RCTs compared ARF sling with TVT and reported on a total of 403 patients (Lucas et al., 2004; Bai et al., 2005; Wadie et al., 2005; Shariﬁghad & Mortazavi, 2008; Amaro et al., 2009). [38, 152, 158, 161, 162] Two of the studies were recently updated at a longer-term follow-up (Guerrero et al., 2010; Wadie et al., 2010). [153, 160] Cure rates at 12-36 months (subjective +/- objective) varied widely depending on definition and were 55%-95% for both ARF and TVT. Although a statistical difference was not observed at 6 months, one trial (Bai et al., 2005) showed a significant difference in subjective + objective cure rate at 12 months favoring TVT (92.8% vs. 87%). [38] This trial also had a colposuspension arm, which had a 12 month cure rate of 88%. Another trial had a porcine dermis sling arm with a cure rate of only 53% (Lucas et al., 2004; Guerrero et al., 2010). [160, 161] The remainder of the RCTs did not reveal a statistical difference in cure rates between ARF and TVT. [EL=1/2]. One RCT found no statistical difference in objective and subjective cure rates at 12 months after cadaveric fascia lata slings and the intravaginal slingplasty (IVS), a multifilament, polypropylene MUS (Basok et al., 2008). [155]

One non-randomized trial that also included a porcine dermis arm found no statistical difference between ARF slings and TVT (Morgan et al., 2007). [145] Symptom severity, as assessed by validated questionnaire, was not significantly different between the ARF sling and TVT groups. As mentioned in the previous section, symptom severity was significantly higher in the porcine dermis group than in the other 2 groups. [EL=2/3] A second retrospective study compared traditional sling (material not stated), TVT, and the transobturator tape (TOT) (Jeon et al., 2008). [156] Overall complication rates were not significantly different between the sling groups. At 2 years postoperatively, the cumulative cure rates of the traditional sling, TVT, and TOT groups were significantly different (87.3% vs. 86.7% vs. 34.9%, respectively; p<0.0001). The risk of treatment failure in women who received TOT was 4.6 times higher than in women who underwent traditional sling. The 7-year cumulative cure rates of traditional sling and TVT groups were 59.1% and 55.1%, respectively. [EL=2/3] One trial each found no statistical difference in outcomes between traditional polypropylene sling and TVT (Hung et al., 2004) and ARF sling and Uretex, a monofilament polypropylene sling (Trabuco et al., 2009). [151, 159][EL=2/3]

One RCT comparing porcine dermis sling with TVT found no significant differences operating time, hospital stay, complication rates, or subjective cure at 1 year (85% vs. 89%) (Arunkalaivanan & Barrington, 2003), nor in cure (88% vs. 82%) or satisfaction at 3 years, assessed by mailed questionnaire (77% vs. 80%) (Abdel-Fattah et al., 2004). [48, 55] [EL=1]. It is not clear why this study found comparable results between porcine dermis and TVT, whereas the 3-arm trial cited above found such significantly poorer results after porcine dermis to require the premature curtailment of recruitment (Lucas et al., 2004; Guerrero et al., 2010). [160, 161]

Two small RCTs compared ARF sling to Safyre-t transobturator MUS (Silva-Filho et al., 2006; Tcherniakovsky et al., 2009). [59, 60] At a follow-up of 12 months, subjective + objective cure rates were not statistically different (95% vs. 90.5%) in one trial (Tcherniakovsky et al., 2009), while higher pad weight at 6 months was observed for the ARF group in another trial (39g vs. 8.4g) (Silva-Filho et al., 2006). [162, 163] [EL=2]

The Cochrane database identified 12 trials that addressed the comparison between traditional sling procedures and minimally invasive, MUS operations. [249] Ten of these studies have been summarised in our assessment and 2 studies were only in abstract form. [38, 149, 152, 154-156, 158, 160, 163, 262] Data on incontinence after the first year were available from four RCTs (Arunkalaivanan & Barrington, 2003; Bai et al., 2005; Kondo et al., 2006; Guerrero et al., 2010). [38, 149, 154, 160] Incontinence was reported by 31.6% of those women in the traditional sling and 25.3% of those in the MUS groups. This was not statistically significant (RR 1.23; 95% CI 0.91 to 1.66). This translates to 311 per 1000 women being incontinent after a traditional sling compared with 253 per 1000 after a MUS. Improvement after a year was addressed by two trials (Arunkalaivanan & Barrington, 2003; Guerrero et al., 2010) and there was no statistically significant difference between the two types of sling (RR 1.30; 95% CI 0.57 to 2.94). [149, 160]
Pooled data from 3 trials (Arunkalaivanan & Barrington, 2003; Kondo et al., 2006; Tcherniakovsky et al., 2009) showed a statistically significant higher risk of perioperative complications after traditional sling operations (RR 1.59; 95% CI 1.03 to 2.44). [149, 154, 163] Seven RCTs (Arunkalaivanan & Barrington, 2003; Bai et al., 2005; Kondo et al., 2006; Sharifiaghdas & Mortazavi, 2008; Song et al., 2004 (abstract only); Tcherniakovsky et al., 2009; Wadie et al., 2005) reported bladder perforation. [38, 149, 152, 154, 163, 262] There were more perforations after MUS procedures, but this did not reach statistical significance (RR 0.62; 95% CI 0.34 to 1.11) and the confidence interval was wide. The combined results from 3 trials showed less de novo urgency symptoms after MUS (RR 3.13; 95% CI 0.96 to 10.24) but this did not reach statistical significance and the confidence interval was wide. However, 3 trials showed that development of de novo DO was significantly less after MUS operations (RR 3.21; 95% CI 1.29 to 8.03). This was principally due to the higher weighting given to the largest trial (Basok et al., 2008). [155] The combined results from 5 trials showed that more women had postoperative voiding dysfunction after traditional slings than after MUS (RR 1.60; 95% CI 0.94 to 2.71) but this did not quite reach statistical significance and the confidence interval was wide. More women in the traditional sling group required release of sling (9% versus 2%), reported in two trials (RR 3.67; 95% CI 0.95 to 14.22) but again this was not statistically significant. There was no statistically significant difference in urinary retention up to 6 weeks (RR 5.51; 95% CI 0.68 to 44.63) from one trial and vaginal erosion (RR 0.35; 95% CI 0.02 to 8.10) based on one trial.

e) CONCLUSIONS / RECOMMENDATIONS

The conclusion of the Cochrane review was that data on traditional sling operations remain too few to adequately address the effects of this type of surgical treatment. They highlight the fact that many studies fail to address appropriate outcome measures to address the broader effects of the surgery, such as general health status and health economics. They also emphasise that reliable evidence on which to judge whether or not traditional slings are better or worse than other surgical or conservative management is currently not available.

From the available evidence, ARF sling is the most widely evaluated biological sling and is an effective and durable treatment for SUI. [EL=1] Limited data suggest that pubovaginal sling using porcine dermis is also effective, [EL=1] although data relating to other biological slings are few, and generally of poor quality. The inclusion of the large trial on traditional slings (Albo et al., 2007) strengthened the trend towards a better performance of the traditional slings in terms of patient reported incontinence rates, but higher early post-operative voiding dysfunction rates compared to open colposuspension. [EL=1] The limited data available suggest that the overall rates of late surgical complications are similar after sling and colposuspension; however, the pattern of complications may vary.

Meta-analysis showed a significantly greater patient-reported improvement of symptoms, using autologous materials, both within and after 1 year. There is no high level evidence of a difference in efficacy between biological and synthetic sling materials, although adverse events may be more common following the use of synthetic materials for ‘traditional’ sling procedures [EL=3]. Some synthetic slings, such as Gore-Tex, may have a higher incidence of erosion, infections and urgency symptoms. There is no high level evidence of a difference in efficacy between different biological sling materials, although those studies that find a difference all favour autologous materials [EL=2]. However trials were few in number, with short follow-up and small populations. More evidence is needed to compare slings made of autologous materials with synthetic or exogenous biological materials.

Minimally invasive MUS operations appeared to be as effective as traditional suburethral slings in the short term (RR 0.97; 95% CI 0.78 to 1.20), although the confidence interval was compatible with minimally invasive slings being 20% better or 12% worse. [EL=1] The operating time and length of stay were also significantly shorter with minimally invasive synthetic MUS operations, and women had less perioperative complications and DO. The main perioperative complication of minimally invasive sling procedures is bladder puncture, although this does not appear to have longer term implications.

Autologous fascial sling is recommended as an effective treatment for stress urinary incontinence, which has longevity. [Grade A] Further high quality research is required to clarify the place of ‘traditional’ sling procedures in relation to other procedures, and to establish the optimum sling materials. [Grade D]

6. LAPAROSCOPIC COLPOSUSPENSION (TABLE 5)

a) Laparoscopic versus open colposuspension

The Cochrane review of laparoscopic colposuspension includes details of 22 RCTs that include laparoscopic colposuspension [263], 14 more than their initial review [264]. Of these 22 trials, ten compared laparoscopic colposuspension with open colposuspension [265-274].

Eight of the ten studies comparing laparoscopic colposuspension with open colposuspension were included along with eight retrospective cohort studies in a recently published meta-analysis [275].

We identified two further RCTs on laparoscopic colposuspension [276, 277]; in addition one study

Notes: patient numbers are given as – total no. followed up or analysed /total no. recruited (no. in index group: no. in comparator group)
SS = sample size; ITT = intention to treat
previously only in abstract form has recently been published [267], and two have further publications with longer-term follow-up [278] or cost-effectiveness data [279].

Studies included in the Cochrane review had different lengths of follow-up, although eight studies had follow-up in the region 6 to 18 months. In comparison with open colposuspension they found subjective cure rates to range from 58% to 96% in the open and 62% to 100% in the laparoscopic group within the 18 months follow up, with a non-significant 5% lower relative subjective cure rate for laparoscopic colposuspension (RR 0.95, 95% CI 0.90 to 1.00) [263] [EL=1]. The two studies with follow-up at five years or beyond unfortunately remain unpublished and available in abstract form only. Both these studies were relatively small, and their results are inconsistent, one finding better subjective outcome from the laparoscopic procedure [273], and one favouring the open procedure [272]; the methodology of this latter study in particular has been questioned [EL=2].

Overall, the objective cure rate as judged by cough stress testing or pad test within 18 months was statistically significantly lower following laparoscopic colposuspension (RR 0.91, 95% CI 0.86 to 0.96) [EL=1]. Between 18 months and five years there was no significant difference (RR 1.01, 95% CI 0.88 to 1.16); again however, there was heterogeneity with one small trial greatly favouring open procedure [272] and the other favouring laparoscopic [273] [EL=2]. When objective cure was judged by urodynamic investigations there was a significantly higher success rate following open colposuspension (RR 0.91, 95% CI 0.85 to 0.99).

b) Laparoscopic colposuspension versus other techniques

Eight trials have compared laparoscopic colposuspension with minimally invasive mid-urethral slings [166, 280-284].

In comparison with minimally invasive mid-urethral slings there was no statistically significant difference in subjective cure rates within 18 months (RR 0.91, 95% CI 0.80 to 1.02) [EL=1]. The definition of objective cure varied widely between studies, although overall the objective cure rate was higher for minimally invasive mid-urethral slings than laparoscopic colposuspension (RR 0.92, 95% CI 0.85 to 0.99) [EL=1].

Although laparoscopic colposuspension is regarded as a less invasive operation than the open colposuspension the mid-urethra tape procedures had significantly shorter operating time (<0.001), hospital stay (<0.001) and time for resuming normal activity (<0.01 -0.001) than the laparoscopic colposuspension.

c) Different techniques of laparoscopic colposuspension

Different aspects of the laparoscopic technique (one vs. two sutures [285], sutures vs. Mesh [266, 286, 287] and transperitoneal vs. extraperitoneal approach to laparoscopy [288].

Two sutures either side of the bladder neck resulted in higher subjective (RR 1.37, 95% CI 1.14 to 1.64) and objective (RR 1.42, 95% CI 1.14 to 1.77) cure rate than one [285] [EL=2].

When comparing sutures and mesh to secure para-urethral support, sutures resulted in higher subjective (RR 1.28, 95% CI 1.11 to 1.47) and objective (RR 1.20, 95% CI 1.07 to 1.35) cure rate than mesh [266, 276, 286, 287] [EL=1].

The transperitoneal versus extraperitoneal study reported above employed different techniques (sutures vs mesh) and therefore gives little insight into the value of either approach given the superior results obtained with sutures.

The use of glue or fibrin sealants has not been reported outside small case series.

d) Cost effectiveness of laparoscopic colposuspension

Cost effectiveness was assessed in only one trial [270, 289]. This study showed that whilst laparoscopic surgery produced greater quality adjusted life years (QALYs), there was an additional cost when compared to open surgery. The differential mean cost was GB £372 (95% credibility interval [CrI]: 274–471), and at 6 months QALYs were slightly higher in the laparoscopic arm relative to the open arm (0.005; 95% CrI: –0.012 to 0.023). The cost of each additional QALY in the laparoscopic group or incremental cost-effectiveness ratio (ICER) was £74,400 at 6 months, but reduced to £9,300 by 24 months, in view of a further increase in QALYs, but no additional costs (assumed) [289] [EL=1].

Earlier studies have shown TVT™ to be dominant in cost effectiveness terms over both open [290] and laparoscopic colposuspension (albeit using a mesh technique) [279] [EL=1].

e) Complications of laparoscopic colposuspension

Bladder, ureteric and vascular injuries are recognised complications of colposuspension. The Cochrane review reported 21 bladder injuries among 521 laparoscopic procedures (compared with 10 among 507 open procedures) and two studies reported obturator vein lacerations. However, when compared with the traditional open colposuspension, the laparoscopic group was found to have significantly fewer postoperative complications (RR 0.74, 95% CI 0.58–0.96) with lower estimated blood losses and shorter duration of catheterisation.
Longer operating times are a significant disadvantage of the laparoscopic approach; however, women have reported significantly less pain, (Carey et al 2000, Burton 1999)[272, 291] shorter hospital admissions, faster recoveries and quicker return to normal activities. (Cheon et al 2003, Fatthyl et al 2001, Kitchener et al 2006 and Su et al 1997)[292-295].

f) Longevity of laparoscopic colposuspension
A long-term review of women who had undergone laparoscopic colposuspension more than 10 years previously (Barr et al 2009)[296] compared the results with a group of women who had open colposuspension. Subjective cure rates deteriorated over time from 71% and 67% at 6 months to 52% and 36% at 10 years for the laparoscopic and open procedures, respectively.

The conclusion from the Cochrane review was that the available evidence suggests that laparoscopic colposuspension may be as effective as open colposuspension two years postoperatively [263]. The systematic review specific to laparoscopic colposuspension and TVT™ concluded that the evidence so far appears to favour the latter as the minimal-access technique of choice for UI [297]. In both cases however the authors indicated that the place of laparoscopic colposuspension in clinical practice could not be clearly defined without further long-term results.

It should also be noted that much of the published research in this area is from individuals with enthusiasm and skill in laparoscopic surgery; their results should not necessarily be seen as being generalisable to the urogynecological/urological community at large. The NICE guidance includes amongst its recommendations that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI in women, but that the procedure should be performed only by an experienced laparoscopic surgeon working in a multidisciplinary team with expertise in the assessment and treatment of UI [298, 299]; this same point is emphasised in the meta-analysis from Tan and colleagues [275] [EL=4].

g) Summary:
Laparoscopic colposuspension shows comparable subjective and objective outcome to open colposuspension in the short to medium term; longer term outcomes are unknown [EL=2].

Limited evidence suggests that whilst the subjective outcome from laparoscopic colposuspension is similar to the TVT™ the objective outcome is poorer. (EL=2)

Laparoscopic colposuspension may not be good value for money when compared with open colposuspension in the short term (i.e. first 6 months following surgery), but it could be a cost-effective alternative over 24 months [EL=1]; other comparisons however suggest that minimally invasive mid-urethral tape procedures may be dominant in health economic terms.

h) Recommendations:
Laparoscopic colposuspension can only be recommended for the surgical treatment of SUI in women by surgeons with appropriate training and expertise. (Grade D)

Women should be advised about the limited evidence available about the longevity of laparoscopic colposuspension. (Grade D)

Laparoscopic colposuspension might be considered for the treatment of SUI in women who also require concurrent laparoscopic surgery for other reasons. [Grade D]

II. STRESS INCONTINENCE AND PELVIC ORGAN PROLAPSE

Women who present with urinary incontinence as their primary symptom may often have symptomatic or asymptomatic pelvic organ prolapse (POP). In a patient with POP, SUI may be evident and overt or POP may be protective of, or mask, obvious urinary incontinence via urethral kinking. This is termed “occult” SUI and is elicited only during maneuvers to reduce the POP. SUI and POP are intimately related. Coexistent symptoms of SUI may be present in over 60% of women with POP, [38] and occult SUI may occur in up to 80% of clinically continent women with severe POP. [303-306] Postmenopausal women may have up to twice the risk of developing occult SUI. Furthermore, women with both SUI and POP have more lower urinary tract symptoms and more functional impairment than women with POP only. [307]

There is some evidence from Medicare claims data that addressing POP at the time of SUI surgery may avoid an early repeat operation for either POP or SUI; however, the rates of postoperative outlet obstruction are higher. [308] As such, the decision to treat POP surgically at the same operation as the SUI should be determined by the symptoms and bothers the POP produces to the patient and the influence that the POP surgery may have on the outcome of the surgery for SUI. In instances where the prolapse is symptomatic, it will be a matter of subjective opinion whether the incontinence or the prolapse is more significant and bothersome (rather than a pathological diagnosis). If the treatment selection is based on subjective assessment, it follows that the outcome from treatment must also be based on subjective rather than objective measures. As with most issues in pelvic floor reconstruction, the decision to perform an anti-incontinence procedure
and the choice of the procedure itself is a source of great debate. The literature evaluating the following clinical scenarios will be evaluated: (a) overt SUI with POP; (b) occult SUI with POP reduction; (c) high grade POP in the absence of occult or overt SUI; and, (d) the status of preoperative urgency urinary incontinence (UUI) and overactive bladder symptoms (OAB) after POP repair.

1. OVERT SUI WITH POP

Women who present with SUI commonly have deficient support of the anterior vaginal wall. Significant POP is generally defined anatomically as the presenting part of the prolapse reaching to within a centimetre of the hymenal remnant. The presenting part of the prolapse reaching to within a centimetre of the hymenal remnant. The presence of preoperative POP may have an impact on the efficacy of anti-incontinence surgery, and the outcomes of any surgery to correct SUI should be evaluated along with the incidence of de novo or worsened postoperative obstructive and storage urinary symptoms.

Milani et al noted that the presence of preoperative POP led to a lower cure rate of SUI after either the Burch colposuspension or the MMK procedure, with greater degrees of POP associated with lower SUI cure rates. [309] (Level 3) Additionally, Colombo et al performed a RCT to compare Burch colposuspension with anterior colporrhaphy in women with SUI and Grade 2-3 anterior vaginal wall prolapse. [310] Level 1/2 The authors found that the Burch colposuspension was better in controlling SUI but that cystocele recurred in 34% of patients. The cure rate for cystocele with anterior colporrhaphy was high (97%) but cure rate of SUI was very low. The authors concluded that neither operation was recommended for combined SUI and advanced cystocele.

In a recent RCT, Costantini et al revealed that Burch colposuspension does not provide a significant cure of SUI in incontinent women undergoing sacrocolpopexy. [10] (Level 1/2) Out of 47 women with POP and SUI, 24 underwent sacrocolpopexy and Burch and 23 underwent sacrocolpopexy alone. The primary outcome measures were anatomical outcome and changes in incontinence status as indicated by a bladder diary, daily pad use, and CST, while secondary end points were changes in subjective symptoms and quality of life as measured by the UDI and IIQ. In the Burch group, 13 of 24 patients (54.2%) were still incontinent after surgery compared with 9 of 23 (39.1%) in the non-Burch group. Two women in the Burch group (8.3%) and one in the non-Burch group (4.3%) complained of de novo urinary storage symptoms. There was no significant intergroup difference (p=0.459). No significant intergroup difference emerged in anatomical outcome and UDI and IIQ scores improved in both groups (p = 0.0001) and the intergroup difference was not significant in either questionnaire (p = 0.769 and p = 0.327, respectively).

Moon et al compared the Burch colposuspension (n=49) and TOT (n=60) in consecutive women undergoing sacrocolpopexy for POP ≥ Grade III and SUI. [311] (Level 2) Mean hospital stay was longer in the Burch group (11.3 days vs. 7.8 days, p<0.001), as were the rates of postoperative urinary retention (53.1% vs. 11.7%, p<0.001), de novo urgency (18.4% vs. 3.3%, p=0.01), and recurrent SUI (18.4% vs. 1.7%, p=0.003). The SUI cure rate was significantly higher in the TOT group than in the Burch group (98.3% vs. 69.7%, p <0.001).

Gordon et al prospectively followed 30 patients short-term who underwent TVT at the same time as surgery for severe POP. [312] (Level III) No patients had postoperative symptoms of SUI despite three patients (10%) having positive postoperative stress tests. De novo detrusor overactivity occurred in 13% of subjects. Yip and Pang recruited 302 patients, 250 (82.8%) of when completed 1-year follow-up. [313] (Level II/III) There were 157 (62.8%) patients who had a TVT alone, and 93 (37.2%) had TVT and concomitant POP surgery. All patients had urodynamic studies before and one year following surgery. The objective cure rate for SUI was 87.3% for patients with TVT alone and 80.6% for TVT with concomitant procedures (p>0.05). The subjective SUI cure rates for TVT alone and TVT plus concomitant procedures were 89.2% and 86.0% at 4 months, and 93.0% and 94.6% at 1 year, respectively (p>0.05). The most common complications were postoperative urinary retention (15.2%), de novo detrusor overactivity at one year (10%), and intraoperative bladder puncture (8%). In an additional prospective cohort study and a case series, the TVT combined with vaginal reconstruction resulted in 85% to 95% cure rates for urodynamic SUI. [314, 315] (Level III) The rates of postoperative urinary urgency and voiding dysfunction were 10% and 11%, respectively. Voiding difficulties and post void residuals of > 100 mL were treated with urethral dilatation and the authors did not report any cases of long-term urinary retention.

Transobturator midurethral slings may also be effective in the setting of overt SUI and POP. The addition of TVT-O to anterior colporrhaphy in 50 women with SUI and high grade anterior POP resulted in 1-year objective cure rates for SUI and POP of 92% and 91%, respectively. [316] (Level 3) Overall early postoperative complication rate was 16%, although all were minor. At 12-month follow-up, tape extrusion requiring surgical removal developed in only one patient. The ICIQ-UI SF questionnaire scores were 13.4 +/- 6.8 and 3.5 +/- 3.2 (p <0.01) between preoperative and 12-month follow-up, respectively.

In data from the National Hospital Discharge Survey, the addition of an anti-incontinence procedure did not significantly increase the immediate morbidity in women who underwent POP surgery. [317] Of the 1931 women who underwent POP procedures, concomitant anti-incontinence procedures
were performed in 26.6% and complications were reported in 14.9%. Complications were associated with medical comorbidity (OR 11.2) and concomitant hysterectomy (OR 1.5), while concomitant procedure for SUI was not.

2. OCCULT SUI WITH POP

Overall, the level of evidence supporting a specific anti-incontinence procedure in women with POP and occult SUI is low. Chaikin et al discovered occult SUI after reduction of prolapse with a pessary in 14 of 24 women (58%). [304] (Level III) Ten women with no urodynamic evidence of sphincteric incontinence underwent anterior colporrhaphy and no additional anti-incontinence procedure was performed. Mean follow-up was 44 months (range 12 to 96). None had postoperative SUI but one (10%) had a recurrent grade 2 cystocele. The 14 remaining women with urodynamic stress incontinence after POP reduction underwent anterior colporrhaphy with a bladder neck pubovaginal sling procedure. Mean follow-up in these cases was 47 months (range 12 to 108). In two patients (14%) SUI developed postoperatively and one (7%) had a recurrent grade 3 cystocele. The incidence of UUI did not appear to be significantly influenced by either surgical intervention. Overall 12 patients had preoperative UUI, of whom 9 (75%) had persistent UUI postoperatively. De novo UUI developed in another woman. The authors’ findings suggest that patients without occult SUI may be effectively treated with POP repair alone, while women with occult SUI on urodynamics should be offered anti-incontinence surgery.

Barnes et al reported on 34 women with grade 3-4 POP and occult SUI who underwent a bladder neck pubovaginal sling as the anti-incontinence procedure. [318] (Level III) Sling materials included autologous rectus fascia, cadaveric fascia lata, or a free vaginal wall graft. Mean follow-up was 15 months (range 6 to 39). The mean time required before spontaneous voiding resumed without the need for catheterisation was 11.8 days (range 2 to 46) and no patient developed permanent urinary retention. Two (9.5%) of 21 women without preoperative UUI developed de novo UUI; however, preexisting UUI resolved in 45%. SUI occurred in two women (7%) at four and 19 months postoperatively, while clinically significant uterine prolapse developed in one woman two years after surgery.

Groutz et al reported on 100 women with occult SUI undergoing concomitant transvaginal POP surgery and TVT.[319] (Level 3) The mean follow-up period was 27 months (range: 12-52 months). Two patients had postoperative urinary retention necessitating catheterisation for more than seven days, but neither required any surgical intervention. Vaginal extrusion was diagnosed in three patients, all of whom were successfully treated by partial TVT excision. Two (2%) patients developed urodynamically-confirmed SUI within one year postoperatively; however, postoperative urodynamics revealed asymptomatic urodynamic stress incontinence in 15% of other patients. Thirteen (72%) of 18 patients with preoperative UUI had postoperative persistent UUI, while de novo UUI developed postoperatively in 8 (8%) of patients.

A RCT compared concomitant endopelvic fascia plication at the urethrovesical junction vs. TVT in 50 women with severe POP and occult SUI. [320] (Level 1/2). The addition of a TVT resulted in a higher 2-year objective continence rate than endopelvic fascia plication (92% vs. 56%, respectively; p<0.01). The subjective cure rates were 96% for TVT compared to 64% for plication (p=0.01). Time for resumption of spontaneous voiding, rates of urinary retention, de novo UUI, and perioperative complications did not differ between the groups. Despite negative cystometrograms, de novo UUI symptoms were reported in 12% of the TVT group compared to 4% of the suburethral plication group (p=0.66).

Karateke et al reported on the outcomes of TOT in the treatment of women with occult SUI and POP. [321] (Level 3) Urodynamic evaluation revealed occult SUI in 25 of 79 patients with POP. Post-operative OAB, SUI, and MUI were found in three (12%), two (8%), and one (4%) patients in the occult SUI group, respectively. The corresponding numbers were six (11%), five (9%), and three (6%) in the preoperatively continent group. No significant difference was found between the groups in terms of post-operative OAB symptoms, SUI, and MUI. Groutz et al also reported on the outcomes of TVT-O in the management of occult SUI in women with significant POP. [322] (Level 3) Of the 117 patients, 6 (5.1%) had immediate postoperative voiding difficulties necessitating catheterisation for more than two days. Late postoperative morbidity was assessed in 110 patients with >3 months of follow-up (mean 27.2 ± 17.7). Of these 110 patients, 7 (6.4%) had protracted postoperative thigh pain with spontaneous resolution within 1-3 months and 7 (6.4%) had developed recurrent UTIs. There were no cases of vaginal extrusion. The functional outcome analysis was restricted to 92 patients with >12 months follow-up. Of these, 13 (14%) were found to have urodynamic stress incontinence; however, only two patients (2.2%) were symptomatic, amounting to a subjective and objective cure rate of 97.8% and 86%, respectively. Of the 34 patients who had had urinary storage symptoms preoperatively, 22 (64.7%) had persistent symptoms postoperatively. An additional four patients (6.9%) had developed de novo urinary storage symptoms, and one patient developed bladder outlet obstruction.

3. NO OVERT OR OCCULT SUI AND POP

There has been a tremendous amount of debate on how to treat women with significant POP who have no complaints of SUI and occult SUI cannot be demonstrated on either cough-stress test or urodynamic evaluation after prolapse reduction. The case for a concomitant anti-incontinence procedure is to
potentially prevent a second surgical intervention in a cohort at high risk for developing SUI. The case against performing anti-incontinence surgery in the same time hinges on the potential for developing de novo or worsened urinary storage and voiding symptoms in a population with minimal to no preoperative symptoms. The literature appears divided on the topic. As mentioned previously, Chaikin et al found that the majority of women with significant POP who do not have overt or occult SUI will not develop overt SUI after transvaginal POP repair alone. [304] (Level III)

The decision to perform a concomitant colposuspension at the time of sacrocolpopexy has been passionately debated. In a well-publicised study by Brubaker et al as part of the Colpopexy and Urinary Reduction Efforts (CARE) trial, stresscontinent women undergoing sacrocolpopexy were randomised to receive or not to receive a concomitant Burch colposuspension. [323] (Level I)

At two years, 302 of 322 randomised participants were available for analysis. Two years after surgery, 32.0% and 45.2% of women in the Burch and control groups, respectively, met the SUI endpoint. [324] (RR 1.39, 95% CI 0.53 to 3.70). The authors also concluded that occult SUI detection rates varied widely based on the method of prolapse reduction. Interestingly enough, while only 23% of the 1134 members of the American Urogynecological Society (AUGS) responded to a survey about their practice patterns regarding high-grade POP, 57% of the respondents stated that they would not perform a prophylactic Burch colposuspension at the time of sacrocolpopexy in a woman without symptoms of SUI. [325] Conversely, Costantini et al found that the Burch procedure did not confer a significant benefit in terms of SUI cure to women undergoing surgical prolapse repair. [326] (Level I/II) A total of 66 continent women with POP were randomly assigned to abdominal sacrocolpopexy and concomitant Burch in 34 (group 1) or sacrocolpopexy alone in 32 (group 2). Median follow-up was 97 months (range 72 to 134). Nine of 31 group 1 patients (29%) were incontinent compared with 5 of 31 (16%) in group 2 (p=0.553). In group 1, all except one patient were successfully treated for voiding dysfunction. Storage symptoms had disappeared in one patient and de novo storage symptoms had developed in two since the previous follow-up. De novo incontinence developed in two group 2 patients after midterm outcomes were reported. Median UDI-6 and IIQ-7 scores were improved in all groups at last follow-up (p<0.0001).

Ballert et al suggested a protocol to determine if MUS should be placed at the time of transvaginal POP repair. [327] (Level 3) A total of 50 women reported clinical (symptomatic) SUI preoperatively, while 55 did not. Regardless of clinical presentation, patients with urodynamic or occult SUI underwent simultaneous MUS, while those without urodynamic or occult SUI did not. The risk of intervention due to obstruction after receiving MUS was 8.5%, while the risk of intervention for de novo SUI in patients with no clinical, urodynamic, or occult SUI who did not undergo MUS was 8.3%. The risk of intervention for SUI in patients with clinical SUI but no urodynamic or occult SUI and no MUI was 30%. These data suggest that a prophylactic sling in women without clinical, urodynamic, or occult SUI may be as likely to cause postoperative urinary retention requiring reoperation as it is to prevent postoperative de novo SUI requiring surgery. The evidence also suggests that MUS should be considered for women with clinical SUI (regardless of the presence or absence of urodynamic or occult SUI), as there is a much higher possibility for further intervention for SUI in this population. While this report lacks a control group, the findings of this study underscore the importance of a detailed informed consent discussion between the patient and surgeon.

A study by Liang et al further supported the suggestion that urodynamic evidence be used to guide possible treatment of SUI during POP surgery. [222] (Level III) Among the 79 patients evaluated for severe POP without symptoms of SUI, 32 patients had a positive pessary test and underwent vaginal hysterectomy, anterior and posterior colporrhaphy, and TVT (Group 1). In group 2, 47 patients (17 of whom had positive pessary tests and 30 of whom had negative pessary tests) underwent vaginal hysterectomy and anterior and posterior colporrhaphy alone. Eleven (64.7%) of 17 patients with positive pessary tests who did not undergo TVT had urine leakage after their hysterectomies. Conversely, none of the 30 patients who had negative pessary tests developed symptomatic SUI after vaginal hysterectomy. Among the 32 patients with positive pessary tests who had TVT with their hysterectomies, three developed urine leakage later for a cure rate of 90.6%. Had all patients with high-grade POP undergone TVT, 35% would have undergone an unnecessary anti-incontinence procedure. This study supports the notion that women without symptoms of overt or occult SUI are not likely to leak after undergoing POP surgery alone. Additionally, the Cochrane database recently evaluated the value of anti-incontinence surgery at the time of prolapse repair in continent women and concluded that this practice did not reduce the rate of postoperative SUI (RR 1.39, 95% CI 0.53 to 3.70). [328]
Thus, the value of adding an anti-incontinence procedure to a POP repair in women who are dry before operation remains to be adequately assessed; however, available evidence suggests that the majority of women without occult or overt SUI may remain continent after POP repair alone. While the addition of a Burch colposuspension to a sacrocolpopexy may not add a significant amount of additional morbidity, it may not confer a benefit in terms of preventing the development of overt SUI. Furthermore, the potential benefit of Burch colposuspension cannot necessarily be extrapolated to other prophylactic anti-incontinence procedures. An urodynamic approach to decision making appears to be a prudent one. Adequately powered RCTs are urgently needed to answer these questions and high level evidence may be on the horizon. The details of multicentre, prospective RCTs comparing POP and anti-incontinence surgery in women with overt SUI and those with occult SUI (CUPIDO) have recently been described and recruitment is under way. [329] A second, multicentre RCT is in preparation to determine whether the prevalence of postoperative urinary incontinence differs between stress continent women receiving vaginal prolapse repair with concomitant TVT and those with only sham incisions at 3 months after surgery. [330] A second objective of the OPUS trial is to determine whether it is more cost-effective to place a TVT prophylactically than to treat the SUI symptoms postoperatively as they occur over a 12-month period after the index surgery.

4. UII AND POP

Symptoms of OAB such as urinary urgency, frequency, and UII are often seen in women with POP and community-based, hospital-based, and cross-sectional studies have shown that the prevalence of OAB is higher in women with POP vs. those without POP. [331, 332] The prevalence of any OAB symptom approached 50% and increases with advancing age. [332] Symptoms of POP may be an independent risk factor for symptomatic OAB.[332] As such, the impact of POP repair on OAB symptoms and UII is of great value in preoperative counseling of women with high-grade POP.

The impact of anterior vaginal wall prolapse repair on bladder function has been much debated. Digesu et al reported on a 12-month prospective cohort study of 93 women who had a standard anterior colporrhaphy for cystocele. [333] (Level 3) Post-operatively, urinary frequency resolved in 60%, urgency resolved in 70%, and UII resolved in 82%, illustrating that anterior repair may lead to resolution of the majority of OAB symptoms. Similar findings were reported in a prospective cohort study of prolapse repair in elderly women by Foster et al. [334] (Level 3) The authors also noted that vaginal reconstructive or obliterator surgery produced a similar improvement in urinary symptoms at 12 months after surgery. Nguyen and Bhatia noted that UII resolved in 24 of 38 women (63%) and persisted in 14 (37%) after surgical repair of uterine and/or vaginal vault POP. [335] (Level 3) The authors included both transvaginal and transabdominal POP repairs in their analysis. Uninhibited bladder contractions < 25 cm H₂O during cystometry (p=0.01) and bladder trabeculation (p=0.03) were each an independent predictor of UII resolution after POP repair. In a review of MEDLINE and Embase literature, de Boer et al found no evidence for a distinct relationship between the compartment or stage of the POP and the presence of OAB symptoms. [331] The authors also concluded that all treatments for POP, including surgery and pessary management, resulted in an improvement of OAB symptoms. There is no consensus regarding the predictors for OAB symptom resolution and individual OAB symptoms had different predictors. [331] When there is concomitant DO and POP, DO resolves in a proportion of the patients and bladder outlet obstruction appears to be the primary mechanism by which POP induces OAB symptoms and urodynamics DO.

5. CONCLUSIONS

There is Level II/III evidence to support a concomitant anti-incontinence procedure at the same time as repair of POP in a woman with overt SUI. There is Level II/III evidence supporting pubovaginal sling, retropubic MUS, and transobturator MUS as effective anti-incontinence options in a woman with overt SUI and POP. Anterior colporrhaphy alone and pubocervical fascia plication are not effective options for overt SUI in women undergoing POP repair. (Level I/II) Burch colposuspension may not be more effective than no additional surgery in curing overt SUI in women undergoing sacrocolpopexy. (Level I/II) There is Level III evidence that bladder neck pubovaginal sling, retropubic MUS, and transobturator MUS are effective in resolving occult SUI during POP repair. There is controversy whether prophylactic Burch colposuspension is effective in improving the chances of developing overt SUI after sacrocolpopexy. (Level I) There is Level 3 evidence to support not performing a concomitant anti-incontinence procedure in a continent woman at time of POP repair. There is Level III evidence that treatment of prolapse by reconstructive or obliterator surgery improves overactive bladder symptoms.

### III. NEUROMODULATION

1. SACRAL NEUROMODULATION
   a) Recent Cochrane review

A recent Cochrane review [336] examined, systematically the evidence of the effects of implantable stimulation devices in the treatment of urgency urinary incontinence, urgency or frequency, and urinary retention.

Eight RCTs were considered eligible and were included in the analysis.
At 6 months follow up SNM was found to be superior to no treatment for all indications as there were highly significant changes in all the outcomes measured (leakage episodes, number of voids, rating of urgency, having no leakages, reduction in number of voids, pad usage, volume at first contraction, and bladder capacity). Both the SF-36 mental and physical scales favoured the immediate implant group but the results were not statistically significantly different between the treatment and no treatment groups.

The quality of the studies included was rated poor. There were no studies comparing SNM with other treatment methods.

The review concluded that SNM can be of benefit in selected patients with overactive bladder symptoms, retention without organic obstruction, and in those for whom other methods of treatment have failed.

b) Long term results

1. Refractory UUI

The long term results of SNM have been addressed by several case studies. There are 4 studies reporting median or mean follow up of >5 years. Two of the studies are presented in the last ICI report and these are the largest ones. Most of the long-term studies do not report the complete continence rates.

2. Long Term Results – Efficacy Over Time

De Groen et al [337] evaluated the long-term results of neuromodulation in 60 patients with refractory idiopathic urgency urinary incontinence. All subjects recruited from a single institution and were assessed prospectively at regular intervals for at least 5 years after implantation. The success rate gradually decreased from 52 patients (87%) at 1 month to 37 (62%) at 5 years. Complete continence persisted in 15% of patients. The analysis was extended to the 41 patients who passed the 10-year follow-up. At least 25 of these women (61%) were still on active SNS. The 10-year success rates did not appear to be different from the 5-year results suggesting that a deterioration of the results is observed during the first 5 years which stabilised thereafter. A total of 57 adverse events occurred in 32 (53%) patients the majority of those being related to hardware failure and pain or discomfort at various sites. Pain was managed conservatively. A total of 23 reoperations, including the 2 explantations, were done in 15 patients (25%). (Level 3 evidence)

3. Urgency And Frequency

There are no new studies examining the long term results of SNM in patients with urgency frequency. The largest study so far (van Kerrebloech) has been presented in the last ICI report.

A more recent small case series [338] examined the long term efficacy of sacral neuromodulation in patients with IC/PBS not responding to medical treatment. Overall 22 patients had a permanent generator implantation. Success with the device was defined as greater than 50% improvement in the chief complaint of urinary pain, urgency and frequency or urgency incontinence. For an average follow up of 59.9 months 17 of 22 patients (77%) reported long-term cure or more than 50% improvement in those symptoms. However 50% of patients underwent explantation due to technical reasons, infection, battery depletion, or pain at the implantation site (Level 3 evidence).

Zabihi et al [339] evaluated the efficacy of bilateral caudal epidural sacral neuromodulation for the treatment of refractory chronic pelvic pain (CPP), painful bladder syndrome, and interstitial cystitis (IC). Thirty consecutive patients (21 female, 9 male) with severe refractory symptoms underwent bilateral S2–S4 sacral neuromodulation for CPP/IC. Patients were evaluated with the O’Leary IC symptom and problem index (ICSI, ICPI), the short form of the Urogenital Distress Inventory (UDI-6), and the RAND 36-item health survey (SF-36) preoperatively and 6 months postoperatively. The mean and minimum follow-up were 15 and 6 months, respectively. Of the 30 patients, 23 (77%) had a successful trial stimulation and were permanently implanted. Among these patients, the ICSI and ICPI scores improved by 35 (\(p = 0.005\)) and 38\(\%\) (\(p = 0.007\)), respectively. The pain score improved by 40\(\%\) (\(p = 0.04\)) and the UDI-6 score by 26\(\%\) (\(p = 0.05\)). On average, patients reported a 42\% improvement in their symptoms. SF-36 scores did not improve significantly. (Level 3 evidence)

4. Non Obstructive Urinary Retention (Table 6)

The effectiveness of SNM in women with urinary retention has been confirmed by previous RCT (Jonas 2001) and has been presented in the last ICI report.

The long term efficacy of SNM for women with urinary retention particularly those with urethral hyperactivity (Fowler’s syndrome) has been presented by Datta et al [340].

Thirty (50\%) had a one stage and the rest a two stage procedure. Overall, 43 of 60 (72\%) women were voiding spontaneously, with a mean postvoid residual volume of 100 mL; 30 (50\%) no longer needed to use CISC. The efficacy of the 2 stage compared to the one stage procedure was similar (73\% vs 70\%). Women with a normal urethral sphincter electromyogram had worse outcomes than women with an abnormal test (43\% vs 76\%). There were 99 adverse events (AEs) and 63 surgical revisions for the women during a total of 2878
months of SNS experience. In all, 73% of the women had an AE during their treatment with SNS (Level 3 evidence).

A recent retrospective single centre study [341] examined the long-term efficacy and durability of sacral nerve stimulation (SNS) for the treatment of refractory, non-obstructive urinary retention. Forty patients were included (29 with complete retention requiring CISC) and 11 with incomplete retention (high post-micturition residuals). Of the 40 patients 28 (70%) responded successfully to the test stimulation and underwent a placement of an IPG. At a mean follow-up of 40.03 +/- 19.61 months, 24 (85.7%) of 28 patients demonstrated sustained improvement of greater than 50% with significantly reduced number and volumes of catheterisations/day and improvement of post-micturition residuals. The Interstim device was removed in 4 patients (14.3%) and required revision in further 6 (21.4%) (Level 3 evidence).

5. Effect Of SNM On Sexual Function

The effect of SNM on the female sexual function was investigated by a small pilot prospective single centre study [342]. Overall 36 women with severe frequency, urgency, retention, and chronic pelvic pain refractory to medical and other treatments were enrolled and were assessed by the Female Sexual Function Index (FSFI) questionnaire preoperatively and 6 months postoperatively. Twenty-one patients had some form of pelvic pain component to their symptoms, and 15 had voiding dysfunction without pain. The overall score on the FSFI improved by 52% (p = 0.05). Results were better in patients who underwent the treatment for voiding dysfunction (n = 15) compared to those who had pain as their primary complaint. In this group, the overall score improved by 157% (p = 0.004). Those who underwent the procedure for the indication of IC/CPP (n = 21) did not show a statistically significant change in their scores.

Another small study [342] showed that in sexually active women who had a permanent sacral neuromodulator implanted there was no difference in the sexual function before and 6 months after implantation as assessed by the FSFI.

6. Patient Satisfaction

Long-term clinical efficacy of SNM has been assessed and confirmed by many studies. However it is quite unclear how this can be translated to patient satisfaction and improvement of quality of life bearing in mind that there are technical problems and adverse effects needing constant medical attention in a significant proportion of these patients.

The long term QOL data were assessed in 2 previous reports. [343] [344]

Leong et al [345] examined the long-term satisfaction of patients with an implanted SNM for various medical indications such as overactive bladder syndrome, non-obstructive urinary retention, combined overactive bladder and retention, and pelvic pain. Overall 275 patients received a postal questionnaire regarding satisfaction and experiences with the system, such as side effects, complications, burden, impact on sexuality and defecation changes. The response rate was 75% (207 patients) with a median post-implantation period 77 months (range 12 to 214). The patient satisfaction rate was high at 90% and significantly related to the perceived clinical effect and 85% if all explanted cases (13 patients) were considered as failures. Satisfaction had no direct relationship with patient age, gender, duration of therapy or type of complaint for which SNM was offered, but was significantly lower in patients with more than 1 pelvic floor comorbidity. The patient’s attitude towards

Table 6: Summarises the follow-up data for patients with non obstructive urinary retention who were treated with SNS (from 1. Bosch JL. An update on sacral neuromodulation: Where do we stand with this in the management of lower urinary tract dysfunction in 2010? BJU Int 2010, Nov;106(10):1432-42.)

yearly follow-up and the ability to use the patients programmer was positively related to the degree of satisfaction. Overall 40% reported having some limitations or concerns with SNM such as exclusion from MRI and passing through metal detectors after an INS was implanted, possible changes in future reimbursement. Most patients perceived regular pain (56%) and discomfort (40%) at the INS site. (Level 3 evidence)

7. **Neurogenic Lower Urinary Tract Dysfunction (LUTD)**

The efficacy and safety of the use of SNM for the treatment of neurogenic lower urinary tract dysfunction was examined in a recent meta-analysis [346]. This included overall 357 patients from 26 independent studies (prospective and retrospective cohort studies and case reports) with level of evidence ranging from 2b to 4. There was no RCT available for analysis. The pooled success rate was 68% and 92% for the testing and the permanent phase of SNM respectively for a mean follow up of 26 months. With regards to adverse events the pooled rate was 0% during the first stage to 24% for the chronic phase of the treatment. The most frequent adverse events were lead migration and pain at the site of permanent neuromodulator further surgery was performed in 45 of 224 patients. The available evidence from this meta-analysis suggest that SNM may be effective and safe for the treatment of patients with neurogenic LUTD (level of evidence 2) but further well designed adequately powered studies are needed before SNM is routinely recommended for the treatment of neurogenic LUTD.

The use of SNM in patients with neurogenic LUTD is limited by the fact that quite often they need to be investigated by magnetic resonance imaging studies.

The progressive nature of the neurologic disease in some patients could be a limiting factor in the effectiveness of the SNM.

8. **Selection Of Patients**

• **Testing procedure**

The application of the two-stage procedure using the permanent tined lead appears to be superior to the percutaneous PNE technique

A study by Bannowsky et al.[347], in a retrospective case control study examined urodynamic and clinical outcomes of the two different testing techniques and found that permanent quadripolar electrodes led to significant differences in the overall response rate (81.8% versus 47.6%) and urodynamic parameters (max detrusor pressure, bladder capacity) compared to the PNE.

This has to be balanced against the cost implications: the permanent electrodes are several times the cost of the cheaper PNE wires.

In a recent study [348] 41 of 76 (54%) who failed to respond to PNE were subsequently tested with tined lead procedure permanent stimulators. Of those 18(44%) were implanted with a neuro-stimulator after a successful response suggesting that the tined lead procedure is more sensitive screening tool. At 53-month follow-up 12 of these patients (67%) had a successful outcome, which was not statistically different from the success rate in patients with a positive response to an initial PNE or TLP test.

The response rate to PNE as compared to the 1st stage tined-lead placement test (FSTLP) were directly compared in a prospective single centre study[349].

One hundred patients with refractory idiopathic overactive bladder syndrome (OAB) or non-obstructive urinary retention, screened with both PNE and FSTLP. The positive response rate on PNE was 47%. FSTLP showed a 69% positive response rate, which was negatively related to age. The 22% gain in positive response was statistically significant (p < 0.001) and positively associated with female gender and younger age. This study also suggests that the FSTLP may be a more sensitive screening method than PNE. (Level of evidence 2)

• **Unilateral versus Bilateral lead placement at screening phase**

A retrospective study by Pham et al. [350] compared the success of the bilateral to unilateral neuromodulator lead placement in 124 patients undergoing screening for permanent placement of sacral neuromodulation. Fifty-five (44%) patients underwent unilateral stage I lead placement and 69 (56%) received bilateral S3 leads. Successful stage I trials were reported in 32/55 (58%) and 53/69 (76%) of unilateral and bilateral cohorts, respectively (P = 0.03). There was no difference in wound infection or other complications. (Level of evidence 3)

• **Pre-treatment psychological problems**

Psychiatric comorbidity has previously been proposed as a negative predictor by some authors.

In a recent single centre prospective study the relationship between psychiatric history and the outcome of chronic SNM treatment was assessed. Fifty four patients with symptoms of OAB or chronic non-obstructive problems completed the Amsterdam Biographic Questionnaire (ABQ), which measures the personality traits of the patient, and the Symptom Check-List-90-Revised (SCL-90-R), which is a screening instrument for...
neuroticism, and for current level of complaints. Of those 15(28%) reported a history of psychiatric disorder in their medical history. The authors found that a history of psychiatric disease was not related to the outcome of test stimulation, but was shown to be a positive predictor for the occurrence of AEs with permanent SNM treatment. (Level of evidence 4)

- Urodynamics

A recent study [351] examined urodynamic diagnosis as a predictor of outcome. 111 patients undergoing permanent SNM after a successful PNE test were divided into those with DO (67) on urodynamics and those without DO (44). Both groups showed a statistically significant improvement in bladder volumes at first sensation of filling (FSF) and at maximum fill volume (MFV) before voiding for both UI subgroups, compared with baseline. Resolution of DO post treatment occurred in 51% of patients, however the success in those patients was not significantly different from those with persistent DO. Interestingly patients with UI and no DO had a higher rate of clinical success (73%) than those with UI and DO (61%) although this did not reach to statistical significance. (Level of evidence 3)

- Comparison to the botulinum toxin-A (BTX-A)

The efficacy rates reported for both SNM and BTX-A in patients with refractory OAB appear to be similar.

The use of BTX-A has recently been approved by the FDA for use in patients with OAB due to neurological conditions such as spinal cord injury and multiple sclerosis. SNM is more invasive but offers long term efficacy whereas treatment with BTX-A injections is less invasive but needs to be repeated on a less-than a year basis in order to provide sustained efficacy. In addition it has been reported that 20% of patients treated with BTX-A injections need to enhance treatment efficacy with anticholinergics and a small proportion report reversible voiding difficulties and need to self catheterisation.

At present there is no RCT published to compare the efficacy and safety of the two methods.

However there are published studies examining the cost-effectiveness of these 2 methods.

Siddiqui et al [352] suggested that BTX-A would be a cost-effective therapeutic option for refractory urgency incontinence in the first 2 years of therapy. Costs were analysed from the societal perspective and in relation to effectiveness. All direct costs related to the treatment modalities as well as the costs of incontinence were calculated but not the indirect costs (lost productivity secondary to incontinence) due to the limited data available. Two years is a short duration for a chronic condition. The prolonged effect of SNS and the cost and time needed for repeat BTX-A injections might change significantly the comparison of cost effectiveness for a longer duration of treatment.

In another study Leong et al [353] by comparing the costs and effects value of the two methods in patients with refractory OAB concluded that starting with SNM, treatment is cost-effective after 5 years compared to BTX. However, when different scenarios were examined, such as the use of local anaesthesia for BTX treatment and SNM peripheral nerve evaluation or bilateral test, SNM was not cost-effective.

It is also acknowledged that the costs for surgery and for the devices may vary significantly between countries and even between hospitals within one country.

c) Conclusion and Recommendations

Sufficient Level II / III evidence exists evaluating implantable neuromodulation. Current series include retrospective cohort studies and no high level RCTs. There is a need for further prospective randomised assessment of this intervention – especially from the durability standpoint. Grade of recommendation is A / B

2. PERCUTANEOUS TIBIAL NERVE STIMULATION (PTNS)

a) Efficacy

Several case series have shown a reduction of frequency, urgency, urgency urinary incontinence in 60-80% of patients with no serious adverse events. Recent research provides level I evidence that PTNS is efficacious in the treatment of refractory OAB.

b) PTNS vs Placebo (sham device)

A multicentre, double-blind, RCT (SUmiT) [354] compared the efficacy of PTNS to sham through 12 weeks of therapy. A total of 220 adults with overactive bladder symptoms were randomised 1:1 to 12 weeks of treatment with weekly percutaneous tibial nerve stimulation or sham therapy. In the sham group a Streitberger placebo needle was used to simulate the location and sensation of PTNS needle electrode insertion without actually puncturing the skin. In addition two active TENS surface electrodes were placed, one under the little toe and one on the top of the foot. Sham stimulation parameters were determined based on subject first sensory level of localised stimulation through a TENS unit.

Patients were evaluated by overactive bladder and quality of life questionnaires as well as 3-day voiding diaries before treatment and at week 13.
At 13 weeks follow-up there was moderate or marked improvement in overall bladder symptoms in 54.5% (60/110) and 20.9% (23/110) of subjects respectively (p<0.001). All individual symptoms such as frequency, nighttime voids, voids with moderate to severe urgency and urgency urinary incontinence episodes demonstrated statistically significant improvement from baseline to 13 weeks for the PTNS group compared to the sham group (Table 7). This was also confirmed on voiding diaries.

There were no serious adverse effects with 4% (5/110) reporting bleeding and discomfort at the needle site and one case of ankle bruising and a further one with leg tingling.

In a further RCT[355], 35 patients not responding to anticholinergics were randomised to PTNS or control group. The control group (17 patients) received an original placebo treatment using a 34 gauge needle placed in the medial part of the gastrocnemius muscle. Patients were considered to be responders if they had a reduction in urgency incontinence episodes greater than 50%. After 12 weeks of weekly treatments 71% (12/17) in the PTNS group and 0% (0/12) in the placebo group were considered responders (p < 0.001). (Level of evidence I - II)

All reports are Level III in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature and there is a need for prospective randomised assessment of management of these patients. Functional assessment across all domains of pelvic floor activity (pain, continence, urinary storage, and sexual function) are critical to the complete assessment of response to this intervention

c) PTNS vs tolterodine ER

Another multicentre RCT showed comparable efficacy of PTNS to medical treatment (OrBIT trial)[356].

A total of 100 adults with urinary frequency (> 8 times/day) were randomised 1:1 to 12 weeks of treatment with weekly PTNS or to 4 mg daily extended-release tolterodine. Voiding diaries and overactive bladder questionnaire were completed at baseline and at the end of therapy. Global response assessments were completed by subjects and investigators after 12 weeks of therapy. The two groups were comparable for baseline characteristics and OAB symptoms.

At 12 weeks 79.5% (35/44) of the PTNS and 54.8% (23/42) of the tolterodine patients considered themselves to be cured or improved (p = 0.01).

Urinary frequency, urgency urinary incontinence episodes, urgency severity and nighttime voids, voided volume and QoL improved significantly in both groups but there was no difference between the PTNS and the tolterodine patients. (Level of evidence I)

d) Long term data

A long-term follow-up of the OrBIT Trial evaluated the durability of PTNS benefits[357].

Patients who were randomised to weekly PTNS in the OrBIT trial were offered an additional 9 months of treatment with assessments at 6 and 12 months from baseline. Outcome measures included voiding diary data, overactive bladder questionnaires, global response assessments and safety assessments. A total of 33 percutaneous tibial nerve stimulation responders continued therapy with 32 and 25 subjects completing 6 and 12 months of therapy, respectively. Subjects received a mean of 12.1 treatments at various intervals during an average of 263 days, with a mean of 21 days (median 17) between treatments.

Sustained improvement was shown with 94% (30/32) of patients continuing periodic treatment considering themselves to be cured or improved at 6 months and 96% (24/25) at 12 months follow-up. Overactive bladder questionnaire symptom severity was significantly improved from 12 weeks to 12 months (p<0.01) as well as from 6 to 12 months (p<0.01). No serious adverse events were reported.

Table 7: PTNS: Improvement of global response assessment at 13 weeks compared to baseline (Level of evidence I)
e) Mode of action

The exact mechanism of PTNS on bladder function is unclear but it is thought that this is mediated through the retrograde stimulation of the sacral nerve plexus. The posterior tibial nerve is a peripheral nerve with mixed sensory and motor fibres. It originates from spinal roots L4 through S3, which also contribute directly to sensory and motor control of the urinary bladder and pelvic floor. A recent study suggests that a plastic reorganisation of cortical network triggered by peripheral neuromodulation could be a mechanism of action of PTNS[358].

f) Neurogenic DO

The efficacy and safety of PTNS was evaluated by a prospective multicentre study in 16 women with MS and LUTS unresponsive to anticholinergics,[359] Patients were offered 12 sessions of PTNS. Assessment of LUTS was by validated, self-administered chart and questionnaires, testing the subjective and objective relevance of LUTS for patients and their impact on QoL before and after treatment. There was a significant reduction in daytime frequency, nocturia and the mean post-micturition residual and there was an increase of the mean voided volume. Eighty-nine percent of patients reported treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King’s Health Questionnaire. No adverse events were reported. (Level of evidence III)

Kabay et al.[360] suggested that PTNS can be acutely effective to suppress detrusor overactivity in patients with neurogenic detrusor overactivity due to Multiple Sclerosis. The researchers performed urodynamics before and during PTNS treatment and found that there was a significant improvement of mean volume of first involuntary detrusor contraction from 145.2 ml, to 244.7 ml and of the maximum cystometric capacity from 204.8 ml, to 301.2 ml during the stimulation period. The results have been criticised as the PTNS was applied after a 2nd filling of the bladder and this repeat cystometry during the stimulation could have affected the urodynamic parameters. (Level of evidence III)

In a further study [361] the same group of researcher found similar results of an acute effect of PTNS on detrusor contraction in patients with neurogenic DO due to Parkinson’s Disease. (Level of evidence III)

g) CONCLUSION AND RECOMMENDATIONS

Reports are Level I - III in terms of evidence and there are few comparative reports assessing different techniques. Most current series are retrospective in nature however recent prospective randomised (against sham) assessment of management of these patients has improved the overall quality of reporting. Current recommendations range from A – C.

IV. ENTEROCYSTOPLASTY

Vesical enlargement, or augmentation cystoplasty (AC), has been used for many years with varying degrees of success for refractory detrusor overactivity (DO) and related incontinence. Other than idiopathic detrusor overactivity (IDO), indications for enterocystoplasty include small capacity bladders due to fibrosis, tuberculosis, radiation, or chronic infection, neurogenic detrusor overactivity (NDO), poor bladder compliance, as well as others [362-365] AC typically involves a segment of the bowel that is removed from continuity with the fecal stream, detubularised, and patched into the bisected bladder. This method increases bladder capacity and decreases bladder pressure caused by uninhibited detrusor contractions. Additionally, incorporation of bowel into the bladder results in decreased bladder contractility and an increased interval in the volume to first involuntary bladder contraction during cystometric evaluation.

Virtually any portion of the GI tract can be utilised for enterocystoplasty, and each segment has its own unique favourable properties as well as inherent complications [365, 366] There is no ideal segment for all cases. Technically, the surgeon must be aware that the selected bowel segment should contain a suitable length of mesentery to reach into the deep pelvis for a tension free anastomosis between bowel and bladder. There has been no general agreement on whether it is more favourable to bivale the bladder sagittally or transversely during enterocystoplasty; however, it is considered ideal to create the broadest possible opening in the bladder and thereby create the widest possible anastomosis between bladder and bowel resulting in the most spherical configuration possible. The bowel is divided and detubularised on its antimesenteric side prior to anastomosis to maximally reduce peristaltic contractions. Again, the goal of enterocystoplasty is to create a high capacity, low-pressure reservoir during the filling/storage phase of the micturition cycle. When successful, and properly combined with other concomitant reconstructive procedures (i.e. ureteroneocystostomy, slings, artificial urinary sphincters, continent catheterisable channels, etc.), enterocystoplasty can protect the upper urinary tract from pressure-related injury, infection, and vesicoureteric reflux while ideally providing complete urinary continence.

Apart from the inherent risks of open abdominal surgery associated with bowel and bladder anastomoses, AC carries several distinct long-term risks. The risks of this surgery include kidney or bladder infections, new-onset recurrent UTIs, metabolic derangements, mucus production, and,
in rare cases, bladder tumours. As a segment of bowel is used for AC, the available absorptive surface area of the bowel is reduced, and the incorporation of bowel segments into the urinary tract may have metabolic consequences [367]. Hyperchloraemic metabolic acidosis can occur if ileal and/or colon segments are used, as well as malabsorption of vitamin B12 and bile acid after the use of ileal segments. Blackburn et al demonstrated a reduction in serum B12 level with time following ileocystoplasty in 44% of their patients at 7-year follow-up and recommended that these patients should have their B12 levels measured in the long term [368].

There has been concern about the incidence of secondary malignancies that may develop as a long-term consequence of bladder augmentation. Using colonic segments, tumours are most likely to occur at the ureteral implantation site. To prevent metabolic complications, careful patient selection and meticulous and lifelong follow up, as well as prophylactic treatment, are mandatory. Endoscopy for early detection has been recommended, starting 10 years postoperatively for patients who underwent surgery for a benign condition. Of interest, Higuchi et al retrospectively review their registry of 153 patients with an ileal/colonic AC and a matched control population and found that AC does not appear to increase the risk of bladder malignancy over the inherent cancer risk associated with the patient’s underlying congenital abnormality [369]. Immunosuppression irrespective of bladder treatment was an independent risk factor for malignancy in their patient population.

**Conclusion and Recommendations**

**Level I Evidence:**

There have been no randomised controlled trials, double blind or sham-controlled trials or cohort studies which have examined the effects of enterocystoplasty for the treatment of NDO or directly compared it to another therapy for the same indication, (Recommendation grade C). Also the role of enterocystoplasty is not defined in subjects with idiopathic detrusor overactivity. (Recommendation grade D)

**Other Evidence:**

The conclusions of several recent reviews on the role of AC indicate that the overwhelming predominance of literature is dedicated to AC in patients with a neurogenic bladder [370, 371]. By some estimates, approximately 10% of reports in the literature have examined the results of AC in adults with IDO. These include only case series (LOE=4). Since the publication of the 4th International Consultation on Incontinence, there have been few additions to the AC literature for IDO (See Table). The studies differ in several ways. Most include both males and females, and some include a varying number of patients with NDO. Additionally, length of follow-up differs widely and the criteria for success may be considerably different and inconsistently reported [372]. Outcome measures have included mostly non-validated questionnaires and subjective patient assessments. Furthermore, continence rates must also be considered with caution, as many AC procedures are combined with bladder outlet procedures [364]. Overall, there does not appear to be a consensus whether patients with IDO or NDO achieve better outcomes [364, 373, 374] The reasons for the inconsistencies in patient satisfaction in neuropathic patients and non-neuropathic patients remain unclear.

Several variations on the standard AC have been recently described. Novel bowel options include urothelium lined seromuscular colocystoplasty and an appendicular-based caecal flap [375-377]. The recent incorporation of robotic-assisted laparoscopic surgery (RALS) and laparoendoscopic single site (LESS) procedures has further added to the surgical options for AC [34-40]. While the initial results are encouraging, long-term outcomes are uniformly absent. Overall, due to its invasive nature and potential for long-term adverse effects, AC is considered to be one of the last choices of treatment in refractory IDO cases [378].

**V. AUTO AUGMENTATION**

Initially described by Cartwright and Snow, auto augmentation of the bladder was described as an alternative option to AC, especially in children with neuropathic bladder [379, 380]. Auto augmentation may be performed by incision (detrusor myotomy) or excision (detrusor myectomy) of a portion of the detrusor muscle. Either technique aims to create an iatrogenic bladder mucosal “bulge” or pseudodiverticulum and an increase in the storage capacity of the bladder with a concomitant decrease in storage pressures. The reported advantages of detrusor auto augmentation over enterocystoplasty is the avoidance of complications related to the use of bowel in the urinary tract including malignancy, mucous formation, stones, surgical morbidity related to opening and reanastomosis of the GI tract, and metabolic acidosis [364, 381, 382].

**Level I Evidence:**

There have been no randomised controlled trials, double blind trials or cohort studies which have examined the effects of auto-augmentation as a treatment for non-neurogenic detrusor overactivity incontinence. (Recommendation grade D)

**Other evidence:**

There are few studies on auto-augmentation in the adult non-neurogenic population and there
have been no additions to the literature since the publication of the 4th International Consultation on Incontinence (See Table 8). One small study of 5 patients with urgency incontinence showed promising results in all patients at the initial postoperative visit, but clinical deterioration and failure occurred in 4 of the 5 patients at three months follow-up [383]. (LOE=4) Mean bladder capacity increased but mean volume to first involuntary bladder contraction decreased. Four of the 5 patients continued to have involuntary bladder contractions on cystometry. One additional retrospective study including 61 patients with NDO and IDO compared detrusor myectomy to AC [384]. Comparable clinical success was reported for the two procedures; however, there was a 22% incidence of serious complications in the 27 patients undergoing AC, compared to only 3% of the 33 patients undergoing detrusor myectomy.

Long term follow-up of auto augmentation in children with neurogenic bladder have for the most part demonstrated disappointing results, which have been attributed to eventual fibrosis of the pseudodiverticulum [382, 385, 386]. Recently, Chrzan et al reported promising results on 49 detrusorectomy performed for neuropathic bladder at a mean follow-up approaching 10 years [387]. Bladder behaviour was assessed as good, fair or poor depending on the volume and intravesical pressure. In 24 patients, good bladder compliance and capacity were seen before detrusorectomy. Good and fair outcomes were observed in 35 (71%) patients at 1 year and in 39 (79%) patients 6 years after detrusorectomy. In 30 (60%) patients, there was hardly any difference between the first and second follow-up. In 9 (18%) patients, formal AC was necessary. Seven patients improved during follow-up, 5 of them after resuming oxybutynin. In 11 patients, oxybutynin could be stopped, and in 2 the dosage could be reduced to once daily.

In an attempt to improve long-term outcomes with this procedure and create a biological “backing” and blood supply for the pseudodiverticulum, a number of variations of this procedure have been described. These variations have included the use of demucosised bowel segments, stomach, peritoneum and rectus abdominis muscle [382, 388-392]. Additionally, the use of an inflatable balloon placed in the bladder for 2 weeks after auto-augmentation improved long-term capacity and compliance [393]. Long-term follow-up demonstrating favourable clinical results with these variations is lacking. This technique is no longer considered as an option for surgical management of detrusor overactivity. (Recommendation grade F).

VI. URETHRAL DIVERTICULUM

1. PREOPERATIVE STAGING

Since the last consultation, relatively insignificant data have emerged on the treatment and surgical management urethral diverticula. No new data have been published regarding classification systems and many are now characterised on the basis of MRI, presentation and size. A variety of imaging techniques need to be investigated for urethral diverticula. The MRI is widely used for evaluation. Dwarkasing, et al., in 2011 [408] reported a study of 60 women undergoing evaluation of urethral diverticula. They emphasized the importance of T2-weighted sequences and the use of endoluminal coil placement in the vagina to produce best overall results. Using a combination of techniques, they had 100% sensitivity and specificity for diagnostic tests. Some groups, however, have found MRI to be nonconsistent with findings at surgery. Chung, et al., [409] [2010] assessed a case series of 76 women who underwent diverticulectomy (41 actually ? had pre-operative MRI scanning. In ten of those patients the discrepancy between MRI imaging and surgical findings was noted. MRI mis-diagnosed one diverticulum as a Bartholin’s cyst. In another case a sterile abscess was diagnosed as urethral diverticulum. In two cases MRI was not sensitive enough to determine a malignancy within the diverticulum. Porten et al., [2011] [410] assessed MRI evaluation and other imaging modalities including VCUG and CT scan. MRI was felt by these authors to be a useful adjunct for determining the extent of surgical dissection and any other complicating factors related to the diverticulum size or presentation. Han, et al., [411] [2007] analysed 30 women undergoing diverticulectomy with pre-operative MRI. They found the MRI useful for surgical planning especially in cases of large, complicated or circumferential diverticula.

Foster et al., [412] [2007]) also identified the utility of MRI imaging in diagnosis and surgical planning in women. In a study of 27 women, 15% of the patients had altered surgical management based upon pre-operative staging with MRI scanning.

Additional staging studies continue to be utilised including VCUG. Double blend retrograde urethrography is not considered of historic interest only. Recent data regarding transvaginal ultrasonographic evaluation also demonstrated the utility of this technique Wu, et al., [413] (2009) reported the utility of transvaginal ultrasound for determination of size, content and location of the diverticulum and had good correlation with operative findings.

2. TREATMENT

Since the last report, various management options have been reported. Ljungqvist, et al., [414]

Key: Dx: diagnosis; N: neurogenic; I: idiopathic; O: other; C+I: cured and improved.
(2007) reported a long follow-up series of 68 women who underwent standard urethral diverticulectomy. They noticed over a 26 year follow-up, that 11 of the 68 women experienced diverticula recurrence and urinary incontinence of varying degrees. Dyspareunia was also noted in these patients with recurrence. Despite this, 92% of the patients would recommend surgery, in their study. One small fistula was also identified over long-term follow-up in their patients. Recent analysis of surgical procedures performed in the United States of America over a twenty year period, (Burrows, et al, 2005) [415] assessed frequency of interventions for diverticulectomy in the United States at 6.7 per 1 million women per year. Rates of intervention were three-fold higher for African American as opposed to Caucasian women. Overall frequency of surgical intervention for diverticula has decreased over time.

Several authors have described standard resection techniques and these appear to be the most commonly and now currently reported (open diverticulectomy, transvaginal resection with periurethral dissection and layered closure being the most common technique). This technique now is the most commonly performed, (Rovner, et al, 2007) [416]. Lee et al (2009) [417] reported the use of SIS graft and noted good response in a single patient where this was utilized. Additionally, bovine pericardium has also been used for this purpose (Tolosa Eizaguirre, et al, 2012) [418]. Native tissue appears to be best for this purpose. Additionally, pericardium has recently been described as another type of interpositional graft with good results in a single case study (Gunasekaran et al, 2011) [419] Recent urologic guidelines, Dmochowski et al., [420] stressed the importance of not placing synthetic materials over a fresh urethrotomy at the time of diverticular repair due to concerns regarding erosion. Recently, increased reports of diverticula formation related to midurethral tape formation have been identified. The first report in the English literature occurred in 2007 (Hammad) [421], since then Mahdy, et al, 2008, [422] and Athanasopoulos, 2008 [423] have both described diverticula occurring after implantation of transvaginal tape presumably due to excess tension placed on the midurethral tape.

The importance of differential diagnosis continues to be critical as women with chronic pelvic pain are sometimes found to have a urethral diverticulum (Fletcher, et al 2009) [424]. Foley et al,2011, [425] identified the importance of critical evaluation in differential diagnosis and accurate assessment of these individuals. Another important aspect in consideration of surgical management of urethral diverticula is potential risk of malignant change within these. Thomas et al. 2008 [426], Ninety women going through diverticulectomy at a single institution. Neoplastic changes were identified in five patients of whom all were glandular carcinomas. The potential for metaplasia occurring in these lesions is needs to be stressed. Reoperation for diverticulum has recently been assessed. (Ockrim, et al 2009)[427] evaluated a group of women who had undergone previous intervention for diverticulum requiring repeat resection. The resection was secondary either to incomplete resection and/or recurrence of the diverticulum. The authors found that a standard approach utilising a sling or Martius fat pad labial graft interposition provided the best results in their complicated series.

3. RECOMMENDATIONS

All reports are Level III in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature there is a need for prospective randomised assessment of management of these patients. Functional assessment across all domains of pelvic floor activity (pain, continence, urinary storage, and sexual function) are critical to the complete assessment of urethral diverticulae. (Grade of recommendation B/C)

VII. ARTIFICIAL URINARY SPHINCTER IN WOMEN

The artificial urinary sphincter continues to be used as a surgical option for sphincter dysfunction in women solely a salvage procedure (after multiple failed previous procedures or special circumstances). There is limited but now some long term experience with the sphincter as a primary intervention.

Since the last publication, there have been several longer term follow-up studies which will be referenced below. The device may be placed either transvaginally, trans-abdominally or recently described as being placed laparoscopically. Success (cure or improvement of stress incontinence) rates overall range between 76 and 89 per cent.

More recent results have been reported in small groups (Hoda, et al) [428] reported experience with two women who underwent open implantation of a sphincter(endooscopic extraperitoneal approach, laparoscopic). The overall operating time for these cases was 120 minutes. Both women were reported as being continent after the device implantation A slightly larger experience with laparoscopic insertion of artificial urinary sphincter reported has been reported by Roupret et al [429]. Twelve women underwent laparoscopic insertion of a sphincter over a two year period, eleven of whom had undergone previous procedures. After a variable period of activation ranging from four to fourteen weeks, with a mean follow-up of 12.1 month (range 5.2 to 27) incontinence was cured in 88% of the women. Com-
Complications included the need for open conversion in two patients, two bladder injuries, two vaginal injuries with an overall complication rate of 25%.

Mandron, et al, [430] contemporaneously reported their experience with 25 patients undergoing laparoscopic AUS implantation over a four year timeframe. No cases required open conversion and the authors reported only an intraoperative complication, Of vaginal perforation. Five of the patients developed urinary retention which required re-catheterisation for a short period (no longer than four weeks). At a mean follow-up of 26.1 months, two patients failed due to vaginal erosion and required removal of the AUS; however, 23 patients reported continence, either total [19] or social (minimal pad use) [4].

Longer term follow-up has been reported by several groups recently. Chung et al [431] reported twenty-five year single institution experience with sphincter implantation in 47 consecutive women, of whom 35 had failed previous anti-incontinence surgery. Two wound infections were identified after insertion. Of the 47 patients 83% still retained a functional sphincter at follow-up. Eight (17%) required removal due to erosion or infection. Additionally 20 revisions were required; the majority due to mechanical complications. Kaplan–Meier analysis revealed slightly over 80% of devices still working after 100 months. Continence rate (no pad use) at the time of follow-up was 59%.

Vayleux, et al., [432] reported an analysis of 215 women undergoing sphincter implantation over a 22 year period. 88% of women had undergone previous treatment for incontinence, 73.5% of the patients were considered continent (0 to 1 pad use) at follow-up. 170 (or 79%) were satisfied. The revision rate in this group was 15.3% after a mean interval of 8.47 years. 15 explantations (7% of total) were performed. The major risk factor for intraoperative complications was a history of smoking (10.7%). Multivariate analysis revealed age to be the major risk factor for failure (odds ratio 2.46), which occurred in 23.7% of the subjects. In addition, pelvic radiotherapy was also associated with failure (4.37 odds ratio). The longest term analysis was recently published by Costa, et al., [433]. Over a 20 year period, 376 devices were implanted in 344 women. At mean follow-up of 9.6 years, 85.6% of patients were fully continent (no incontinence), 8.8 were socially incontinent (occasional incontinence episode) and 5.6% were incontinent (defined as one pad or more incontinence). Three, five and ten year device survival rates by Kaplan-Meier analysis were 92%, 88.6% and 69.2%. Mean mechanical survival time was 176 months (14.7 years). The authors identified three factors for AUS survival including number of previous incontinent procedures, presence of associated neurogenic disease, and simultaneous augmentation procedure. Recent Cochrane Database Review (Lipp, et al), [434] failed to identify any subsequent new data regarding the experience of artificial urinary sphincters.

Two trials have also assessed role of the sphincter in women as a salvage procedure. Chung et al., [435] reviewed 29 patients in whom AUS was implanted after failed anti-incontinence procedures. 5 (17%) of those patients required explanation of the device either due to erosion or infection. In addition, 13 revisions were performed with device malfunction accounting for 95% of those cases. Overall survival analysis revealed 90% malfunction of the device at less than 100 months from the time of implant. There was a significant decrease in pad use noted in the trials and overall continence rates (no pad use) were 70% in this study.

Other additional device modifications have included the use of a larger implanted cuff (greater than 8cm). Revaux, et al., [436] reported 50 women who underwent implantation with a large cuff device over a 23 year period, of whom 86% had undergone previous incontinence procedures.

At a mean follow-up of eight years, 34 women had complete resolution of their incontinence (68%). Factors that were associated with device survivability included less than two pregnancies, urethral closure pressure higher than 19cm of H2O and a cuff size equivalent to 8 cm.

Several consensus statements regarding use of the artificial urinary sphincter have recently been published. Chartier-Kastler, et al., [437] noted a higher risk of erosion and revision rates in women after multiple previous procedures. The authors concluded that the AUS should be implanted at high volume specialist centres with appropriate knowledge and experience in the management of complex cases of incontinence.

Richard, et al., [438] reported the recommendations of the committee in Women’s Urology and pelvic urology of the French Association of Urology. This guideline recommended avoidance of patients who had not had multiple prior procedures and where a well standardised technique performed by surgeons with regular experience and sufficiently long deactivation after implantation, long term monitoring as key aspects for device success.

Lovatis et al., [439] summarised the guidelines for the evaluation of treatment of urinary incontinence for the Society of Obstetricians and Gynaecologists of Canada. The authors concluded that the AUS was an option in patients with significantly decreased dexterity and mobility (recommendation of III-C).

Modifications of the sphincter have been reported and evolution of the device types continues.
Garcia-Montes, et al., [440] reported a new type of sphincter known as the FlowSecure device. Feasibility of implantation was assessed and noted to be reasonable. The authors concluded that further research and development of the device should continue.

**Conclusion and Recommendations**

All reports are **Level III/IV** in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature and there is a need for prospective randomised assessment of management of these patients. **(Evidence Level III/IV).** Evidence is available to support the use of the artificial sphincter for the indications of recurrent and primary incontinence **(Grade of recommendation is B/C).**

**VIII. CONFOUNDING VARIABLES**

### 1. INTRODUCTION

Surgery remains the main stay in the management of women with stress urinary incontinence and there are many different operations and procedures reported. Success rates are often found to vary significantly; this may be due to many confounding factors some of which may be modifiable and some which are not.

The purpose of this review is to update the previous report on confounding variables published in the 4th consensus with the more recently reported evidence. A Medline search was performed from 2008 onwards and, for convenience; the confounding variables are subdivided as in the previous report. For the purposes of this update only new studies will be included.

### 2. AGE

There have been several recent papers investigating the effect of age on continence surgery since the last report and a large Australian epidemiological study has demonstrated that the number of procedures, particularly in the elderly is increasing. [441] Data from Medicare Australia from 1994 -2009 were analysed and showed that there was almost a doubling of procedures for stress urinary incontinence over a three year period following the introduction of mid-urethral tapes. Over the 15 year period there was an 87% increase in women over 55 years old as compared to a 1% increase in younger women. Mid urethral slings were the most commonly performed procedure and accounted for 85.5% of all operations for stress urinary incontinence performed in 2009 (14 mid urethral slings for every one colposuspension).

Although now less commonly performed both colposuspension and pubovaginal sling remain efficacious procedures for stress urinary incontinence. The Stress Incontinence Surgical Treatment Efficacy Trial investigated the effect of age on both perioperative and postoperative outcome with both procedures in 659 women. [442] The older group (mean age 69.7 years) were compared with a younger group (mean age 49.4 years). Overall older women had slightly longer return to normal activities (50 days vs 42 days; \( p=0.05 \)) although there were no differences in the return to normal voiding (14 days vs 11 days; \( p=0.42 \)). In addition older women were more likely to have a positive stress test at follow up (OR 3.7; 95%CI: 1.70-7.97; \( p=0.001 \)), less subjective improvement in both stress and urgency symptoms and were also more likely to require redo surgery (OR 3.9; 95%CI: 1.30-11.48).

The safety and efficacy of mid urethral sling surgery has been investigated in a large Australian series of 1225 women (955 retropubic and 270 transobturator) which compared outcomes in the elderly (96 women ≥ 80 years) to those in younger women (1016 women < 80 years). [443] Overall there was no significant difference in subjective cure between the two groups (elderly 81% vs younger 85%; \( p=0.32 \)). Whilst there were no differences in bladder perforation rates the hospital stay was longer in the elderly group (1.6 ± 1.7 days vs 0.7 ± 1.1 days; \( p<0.001 \)). In addition there was a higher incidence of short term voiding difficulties in the elderly with 37% failing their initial trial of void as compared to 9% in the younger group (\( p<0.001 \)). However there were no differences in long term voiding problems (elderly 8% vs younger 6%; \( p=0.21 \)) and de novo urge symptoms occurred in 7% of both groups.

These findings are supported by a further study investigating the safety and efficacy of TVT-O in a consecutive series of 97 older women aged over 70 years (mean 75 years) and 256 younger women (mean 55 years). [218] Mean follow up was 30 ±17 months and post operative morbidity was similar in both groups although there were significantly more recurrent urinary tract infections in the elderly (13.7% vs 6.2%). Post operative asymptomatic urodynamic stress incontinence (USI) was found more commonly in the elderly group (19% vs 3.7%; \( p<0.05 \)) although the rate of overt USI was 5% in both. Whilst the incidence of persistent overactive bladder (OAB) was similar in both elderly and younger women (68% and 62% respectively) de novo OAB was higher in the elderly group (11.9% vs 4.7%; \( p<0.05 \)).

A smaller prospective questionnaire survey of 100 women undergoing tension Free Vaginal Tape (TVT) has also investigated the effect of age on outcome of surgery. Those women with more severe symptoms preoperatively were found to have a greater improvement in the symptom of stress incontinence and Quality of Life (QoL) and age did not appear to have an effect on outcome [444] although these findings are contradicted by a larger study of 537 women undergoing a retropubic or transobturator mid urethral
slightly decreased the likelihood for symptom recurrence. [450]

Patient reported outcomes have become increasingly important in the evaluation of women following surgery and a small retrospective cohort study has been reported in 122 younger women (<65 years) and 70 older women (≥65 years) who had combined surgery for SUI and urogenital prolapse. [446] At mean follow up of 10 ± 2 months both groups reported significant subjective improvement in symptoms and QoL although the older group had an increased risk of SUI treatment failure (OR 1.10; 95% CI: 1.05-2.5) but not prolapse treatment failure (OR 0.90; 95%CI: 0.29-2.8). A further study investigating preoperative and postoperative factors which correlated with surgical satisfaction in 371 women following fascial or mid urethral sling surgery. [447]

Overall increasing age (OR 0.8; p=0.002), body mass index (BMI) (OR 0.8; p=0.003) and autologous fascial sling (OR 0.5; p=0.003) were associated with decreased odds of satisfaction.

3. RACE

There have been four papers evaluating the effect of race on the outcome of continence surgery since the last report. A large epidemiological study examining 129 778 women who underwent continent surgery in the United States in 2003 found the overall rate of 12 surgical procedures per 10 000 women. This figure was 10 per 10 000 (95% CI: 7-12) in white women and dropped to 3 per 10 000 (95% CI: 0-9) and 6 per 10 000 (95% CI: 0-13) in women of other ethnicity. [448] This is further supported by Medicare data from the United States which showed higher operation rates for SUI in white and Hispanic women when compared to black or Asian women (p<0.01). [449]

A further analysis of the Stress Incontinence Surgical Treatment Efficacy Trial examined the effect of racial group in 654 women (11% Hispanic, 73% non-Hispanic white, 6.7% non-Hispanic black and 8.9% were of other ethnicity) following colposuspension or pubovaginal sling. Overall there were no differences seen between groups in any of the urinary incontinence measures investigated. [450]

The function of the continence mechanism has also been compared in a cross sectional population based study of 335 black and white women aged 35-64 years classified as continent (n=137), stress incontinent (n=102) and urge incontinent (n=96). [451] When comparing black women to white women the maximum urethral closure pressure (MUCP) was 22% higher (68.0 vs 55.8 cmH2O; p=0.0001). In addition white and black women complaining of stress incontinence were found to have an MUCP 19% and 23% respectively lower than controls. The MUCP in white women with urgency incontinence was as low as those white women with stress incontinence although black women with urgency incontinence had normal urethral function.

4. OBESITY

Whilst there are now considerable data linking severity of incontinence with obesity the evidence regarding the effect on continence surgery is less robust. Evidence from a large series of mid urethral tape procedures has shown no effect of BMI in terms of outcome. [445] This is supported by a further study of 195 women who were followed up for one year following TVT which showed no difference in outcome in different BMI cohorts. [452] The risk of perioperative morbidity however is higher with an increased risk of pain following transobturator sling placement (OR 2.51; 95% CI: 1.01-6.22) and of hip and thigh pain (OR 1.99; 95%: 0.79-4.99) in obese women. [453] This however is contradicted by a retrospective review of 129 women with BMI < 30 kg/m2 and 69 with BMI ≥ 30 kg/m2. Overall the bladder injury rate was significantly higher in those patients with lower BMI (14.0% vs 4.3%; p=0.04). After controlling for confounding factors BMI < 30 kg/m2 remained a risk factor for bladder injury (OR 4.63; 95% CI: 1.20 -17.86) as did previous continence surgery (OR 3.55; 95% CI: 1.01-12.50). [454]

5. PSYCHIATRIC ILLNESS

There have been no new relevant publications since the last report.

6. ACTIVITY

There have been no new relevant publications since the last report.

7. PREVIOUS CONTINENCE SURGERY

Surgical success rates often tend to be lower in those women having redo continence surgery and there have been several studies examining this since the last consensus statement. The efficacy of redo colposuspension has been reported in a case series of 52 women from one centre with an objective cure rate of 78% and a subjective cure rate of 80%. [455] The role of redo laparoscopic colposuspension following a failed mid urethral tape has also been assessed in a smaller retrospective case series of 16 women. At a median follow up of 24.5 months objective and subjective cure rates were 54.5% and 92.9% respectively. [456]

There is now also a considerable amount of data examining the efficacy of mid-urethral tape procedures following failed previous surgery. The efficacy of TVT following failed previous continence surgery has been reported in a prospective follow up study of 130 women in Finland. Of these 60 women had recurrent and 70 primary incontinence. Overall there were no differences between the groups in terms of transient voiding difficulties and complications. At three year follow up satisfaction rates were 86% and 91% in the recurrent and primary groups respectively and the subjective cure rate was 93%
in both. At follow up 20% of those having recurrent surgery complained of de novo urge symptoms as compared to 5.7% in the primary group. A small series of 24 women with recurrent urinary incontinence and intrinsic sphincter deficiency following Burch colposuspension has also reported an objective success rate of 70.8% following TVT.

In addition to studies investigating the use of the retropubic approach there are also several studies investigating the efficacy of the transobturator approach in recurrent stress incontinence. A secondary analysis in a large Scottish study comparing inside-out TOT with outside-in TOT in 341 women assessed outcome in a subgroup of 46 women with recurrent incontinence at one year. Overall the subjective and objective success rates were 69.9% and 76.5% respectively and there were no differences between the two routes. Once again in this study a low MUCP (<30 cmH2O) was the only independent risk factor for failure (OR: 4.52; 95%CI: 1.51-56.1; p=0.016). A smaller series of 29 women with recurrent stress incontinence following a previous colposuspension has also been reported in 29 women who had a TVT or TOT with cure rates of 62.1% after one previous procedure and 57.1% after two.

There is now also increasing evidence to support the use of a redo mid-urethral sling in those women who have previously had a failed mid-urethral sling. In a large series of 1 225 women reported from Australia 1 112 were a primary procedure and 77 were secondary procedures. All redo slings were placed without removal of the first. Those women having a redo procedure were more likely to have intrinsic sphincter deficiency (31% vs 13%; p<0.001) and cure rates were 86% and 62% in the primary and secondary procedures respectively. A repeat retropubic approach was significantly more successful than a repeat transobturator approach (71% vs 48%; p=0.04). Whilst complications were similar in both groups de novo urgency (30% vs 14%; p<0.001) and urgency incontinence (22% vs 5%; p<0.001) were more common with redo surgery. A further study has reported on 31 patients who had a TVT after a failed mid urethral tape with an 18 month follow up. Overall objective cure assessed using a pad test was 74% with a 6% improvement rate and 19.5% failure rate whilst objective cure assessed with urodynamics was 77.4%. The subjective cure rate was 71%. (also, see section on mid-urethral slings).

8. CONCOMITANT HYSTERECTOMY

There have been no new relevant publications since the last report.

9. SEVERITY AND DURATION OF SYMPTOMS

There have been no new relevant publications since the last report.

10. DETRUSOR OVERACTIVITY AND STRESS INCONTINENCE

There have been four papers assessing the effect of detrusor overactivity as a confounding variable in stress incontinence surgery since the last report.

A large Australian cohort study has reported on 754 consecutive women with stress urinary incontinence and urgency (SUI) and 514 women with stress urinary incontinence and urgency urinary incontinence (UUI) who had a mid urethral sling and were followed up for a mean of 50 months. Overall persistent urgency was commonly reported in both groups (SUI 40% and UUI 32%). In the SUI group coexistent detrusor overactivity (OR 2.04; 95%CI: 1.39-3.01), baseline symptom severity (OR 1.41; 95% CI: 1.10-1.78) and age (OR 1.03; 95%CI: 1.02-1.04) increased the risk of persistent urgency. Conversely transobturator sling (OR 0.61; 95%CI: 0.39-0.94) and concomitant prolapse surgery (OR 0.54; 95% CI: 0.38-0.75) decreased the risk. In the UUI group coexistent detrusor overactivity (OR 1.86; 95% CI: 1.18-2.93) baseline symptom severity (OR 1.88; 95% CI: 1.38-2.56), previous continence surgery (OR 2.18; 95% CI: 1.28-3.70) increased the risk of persistent urgency whilst apical prolapse surgery (OR 0.33; 95% CI: 0.15-0.70) decreased the risk.

A further study of 121 women has investigated the risk factors affecting outcome after TVT and TOT. Multivariate analysis revealed that preoperative detrusor overactivity was an independent risk factor affecting cure after TVT (OR 113.1; 95%CI: 1.84-6592.77; p=0.02) or TOT (OR 23.7; 95%CI: 1.63-344.53; p=0.02) and MUCP <40 cmH2O (OR 8.34; 95%CI: 1.52-45.65; p=0.01) was a risk factor in the TOT group.

A case control study in 34 women with mixed incontinence matched for age and type of procedure has shown a significantly higher rate of failure in the TOT group (29.4%) compared to the TVT group (0%). In addition women were significantly more likely to require repeat surgery following TOT (OR 10.1; 95% CI: 2.6-38.2).

11. URETHRAL OCCLUSIVE FORCES

Since the last report there have been several papers investigating the role of the urethra on outcome following continence surgery.

The role of urethral mobility and intrinsic deficiency on outcome following mid urethral tape has been assessed in two studies. The first of these investigated 134 women following transobturator tape insertion. Overall 86% reported subjective cure and 14% complained of persistent symptoms. Median preoperative urethral mobility was significantly lower amongst treatment failures compared to those women who were cured (40 (10-60) degrees vs 50 (10-90) degrees; p=0.0049). In addition women with
preoperative mobility <45 degrees were at least four time more likely to report incontinence when compared to those with ≥45 degrees mobility (29.4% vs 6.9%; RR 4.29; 95% CI: 1.59-11.60; p=0.005). [200]

A prospective 2 year study of 65 women has also found that intrinsic sphincter deficiency with a fixed urethra is associated with a poorer objective outcome at 24 months following TOT when compared to intrinsic sphincter deficiency and urethral hypermobility and hypermobility alone (66.7% vs 87.5% and 96.6% respectively). [201]

Two studies have also examined the role of urethral retro-resistance pressure (URP) and surgical outcome. The first of these reported on 100 women and found no relationship between URP and severity of incontinence assessed by a 24 hour pad test. In addition there was no correlation between URP and incontinence severity. Following mid urethral tape insertion the objective cure rate was 84.9% although there were no significant differences in pre and post operative URP values (62.7±19.4 cm H2O vs 61.2 ± 20.4 cm H2O; p=0.57). [461] A further study of 69 women has shown that URP is not predictive of outcome following TVT. [462]

12. SURGEON’S EXPERIENCE

All surgical procedures and surgeons are subjected to the effect of a ‘learning curve’ and this has recently been assessed in two studies evaluating the outcome of mid urethral tapes. The learning curves of TVT and TOT have been compared in a study of 83 women and overall found TVT procedures were longer (p=0.025) although the duration was reduced after the surgeon had performed 15 procedures. [463] The effect on outcome was not assessed.

The impact of surgical experience and the effect of the learning curve has also been investigated in the use of Single Incision Mini Slings (SIMS) in a prospective study of 131 patients who had TVT Secur. Overall the study clearly demonstrated improved surgical outcome in those patients who had their procedures performed by more experienced surgeons. In addition whilst surgical time and intra-operative complications were not associated with surgical experience, the length of postoperative catheter use and hospital stay decreased with increasing experience. [464]

13. ADJUVANT OESTROGEN THERAPY

The role of oestrogens and lower urinary tract dysfunction remains controversial although there is evidence to suggest that vaginal oestrogen therapy may be useful in women with symptoms suggestive of OAB. Since the last report two studies have investigated the role of adjuvant oestrogen therapy in women having continent surgery.

The role of adjuvant vaginal oestrogen therapy has been assessed in a prospective study of 59 post-menopausal women having a TVT procedure. [465] Patients were randomised to surgery with and without vaginal oestrogen therapy and followed up over 6 months. Overall the incidence of OAB symptoms at baseline was 7% and this rose to 32% at 6 months. Urinary urgency was significantly higher in those women not receiving vaginal oestrogen therapy (28% vs 4%; p=0.01) although decreases in frequency and nocturia were not significantly different.

More recently the role of adjuvant vaginal oestradiol (Vagifem, Novo Nordisk) 25mcg has been assessed in a prospective randomised study of 190 post-menopausal women who had a TVTO procedure with 6 month follow-up. Overall there was no statistically significant difference between those women who received oestradiol and those who did not in terms of peri operative complications and hospital stay. However in the post-operative period those women treated with vaginal oestradiol showed a statistically significant decrease in the symptoms of urgency and frequency although not nocturia and urgency incontinence. Equally there were no difference in efficacy rates between the two groups. [466]
en enrolled in a clinical trial who were planning to undergo SUI surgery. While all women were reported to have pure or predominant SUI for study inclusion, the range of women with mixed incontinence was 8.3% to 93.3% depending on what definition was used. If such variations exist in the defining of subjects enrolled in SUI trials from the onset, it is natural to expect wide variations in how outcomes are reported postoperatively. [468] Rapp reported such wide variations when looking at different definitions of success after SUI surgery. In the same cohort of women, successful outcomes ranged from 33% to 87% depending on the definition used for success. [469]

Outcome assessments can be broken down into objective and subjective measures. [470] Objective parameters typically include: physical exam, pad tests, voiding diaries, urodynamic studies. Subjective assessments typically include patient reported measures such as validated instruments that measure symptoms, patient bother, satisfaction and HRQOL. However, these outcome tools are usually limited to a specific area and improvement in one area may not mean improvement in other areas or could even be at the detriment of another area. In addition, the degree of improvement experienced by one patient might be considered a “success” in that patient however the same improvement may be perceived differently by another patient. Furthermore, outcome measures limited to specific domains may not take other symptomology into account. For example, resolution of SUI might be considered a success by itself however if it were to occur in conjunction with urinary retention or worsening irritative voiding symptoms and urgency incontinence, the patient might not agree. Indeed, the majority of SUI outcome assessments rarely take complications into account. It is clear that focusing on a single measure is often inadequate and necessitates the need for measuring multiple outcomes which imposes greater burden on patients. [471] (SUNG). Lastly, no single instrument is universally accepted by all investigators although significant headway has been seen in the adoption of instruments advocated by professional organisations such as the International Continence Society and the International Consultation on Incontinence.

In response to the shortcomings seen with traditional SUI research outcomes, investigators have increasingly relied on greater use of composite outcomes as well as patient reported outcomes that especially assess global response. The use of composite outcomes have increased especially with the advent of clinical trial networks. While providing more comprehensive assessments, composite outcome often create a stricter definition of success especially if all of the components of the composite must be satisfied. Many of the large scale trials often include multiple outcomes measures as primary or secondary outcomes which allows them to be more comprehensive. However, a vast number of outcome measures have been utilised in the field of SUI research. While more comprehensive listings of SUI clinical trials can be found in the respective sections of this chapter, examples of trials utilising different outcome parameters that have been published since the last ICI report are listed in the following tables. Table 9 provides a sampling of composite outcomes used in SUI trials. Table 10 provides a sampling of patient reported outcomes measures used in SUI trials.

While many of the self-reported measures can be considered “patient reported”, the concept of true Patient Reported Outcomes (PRO) is one that is more complex and encompasses a more global assessment. The use of PRO’s has gained acceptance as noted by the fact that most research funding sponsors, industry and regulatory agencies now require inclusion of outcome measures that include the patient’s perspective. The NIH recently established the Patient Reported Outcomes Measurement Information System (PRoMIS) for women with urinary incontinence [471] (Sung). True PRO’s measure patient impressions in a more global context by encompassing 4 domains: 1) Symptoms, 2) Functioning, 3) General Health Perception and 4) HRQOL. The International Consultation on Incontinence has adopted the use of PRO’s and established the ICI Modular Questionnaire (ICIQ) Project that includes the assessment of a wide spectrum of urinary, bowel and vaginal symptoms along with their impact on HRQOL (Coyne)[477].

Another outcome measure that has recently gained popularity is the patient global impression of severity (PGIS) and the patient global impression of improvement (PGII). Initially validated by Yalcin, use of such global assessment instruments provides a single response which is easier for the patient and clinician to understand [478] (Yalcin). Furthermore, the measurement is all encompassing since the subject takes success and complications into account when responding. Indeed, the UITN recently adopted the use of the PGIS and PGII for use as a major eligibility criterion and as the primary outcome in the VALUE trial which will look at the impact of urodynamic studies on SUI Surgery outcomes. [479]

I. INTRODUCTION

Pelvic organ prolapse (POP) is a common problem affecting up to 50% of parous women and 6.3% of women will have undergone a surgical correction for pelvic organ prolapse by the age of 80. Prolapse surgery is an increasingly important aspect of gynaecological practice due to our ageing population, the decreasing rate of hysterectomy due to alternative treatments of menorrhagia and finally decreasing rates of cervical interventions for cervical dysplasia following introduction of vaccinations for Human Papilloma Virus. Already prolapse surgery is performed at least as frequently as continence surgery and, the operating and admission times are at least three times greater than for continence surgery. Given the increasing time and resources that will be required for POP surgery in the future it is paramount that we perform effective, durable, cost effective interventions with minimal morbidity. This chapter serves to outline and summarise the information relating to POP surgery reported in the English-language scientific literature after searching PubMed, Medline, Cochrane library and Cochrane database of systematic reviews, published up to January 2012, with Level 1 evidence. Level 2 or 3 evidence have been included if Level 1 data were lacking.

II. PREVALENCE AND INCIDENCE OF POP

There is a lack of epidemiological studies of the natural history, incidence and prevalence of POP.

It is widely accepted that 50 percent of women will develop prolapse but only 10 to 20 percent of those seek evaluation for their condition [Phillips 2006]. In the current literature, the overall prevalence of POP varies significantly depending upon the definition utilised, ranging from 3-50 percent (Table 1). Where POP is defined and graded on symptoms the prevalence is 3-6 percent as compared to 41-50 percent when based on examination, because mild prolapse on examination is common and frequently asymptomatic (Phillips 2006, Samuellson 1999, Nygaard 2004, Swift 2003). On examination anterior compartment prolapse is the most frequently reported site of prolapse and is detected twice as often as posterior compartment defects and three times more commonly than apical prolapse [Hendrix 2002, Handa 2004]. Following hysterectomy 6 to 12 percent of women will develop vaginal vault prolapse [Marchionni 1999, Aigmueller 2009] and in two-thirds of these cases multi-compartment prolapse is present [Morley 1988].

There is little knowledge about the natural history of POP. The reported incidence for cystocele is around 9 per 100 women-years, 6 per 100 women-years for rectocele and 1.5 per 100 women-years for uterine prolapse [Handa 2004]. Some data show that there is a 1-year incidence of POP of 26 percent and a 3-years incidence of 40 percent with regression rates of 21 percent and 19 percent, respectively. In general, older parous women are more likely to develop new or progressive POP than to show regression. Over a three year period 11 per cent of the women aged over 65 had prolapse progression of more than 2 cm whilst only 2.7 percent had a regression by the same amount [Bradley 2007].

Luber has shown in a large demographic study that the peak incidence of symptoms attributed to prolapse is between ages of 70 to 79 whilst POP symptoms are still relatively common in women of younger age (Figure 1) [Luber 2001].

Demographic changes including an ageing population have significant implications for the future planning of women’s health services. Wu et al [Wu 2009] have predicted that by 2050 the number of women suffering from symptomatic POP in the United States will increase at minimum by 46 percent (from 3.3 up to 4.9 million women and in a “worst-case scenario” up to 200 percent or 9.2 million women with POP. These figures were based upon population growth statistics in the United States however models that evaluate the impact of decreasing parity and increasing elective caesarean section rates are required to more accurately predict future rates of POP.

Incidence and Prevalence of Prolapse Surgery

Both incidence and prevalence for prolapse surgery increase with age. Women older than 80 years are currently the fastest growing segment of the population. The estimated lifetime risk of an American woman undergoing at least one surgical intervention by the age of 80 is 6.3 percent with 30% requiring subsequent surgery [Olsen 1997]. However, a more recent, prospective study showed a significantly lower reoperation rate of only 13 percent which may be explained by improved surgical procedures [Clark 2003]. The longevity and durability of POP surgery are important variables for planning and require ongoing evaluation.

The annual incidence for POP surgery is stated to be between 1.5 [Boyles 2003] and 1.8 [Shah 2007] cases per 1000 women-years with the incidence peaking in women between 60-69 years. Shah et al also demonstrated a peak incidence in 70 year old women however surprisingly high numbers of younger women were also undergoing surgical treatments reflecting a similarity in the prolapse symptoms reported in younger women by Luber 2001 (Figure 2) [Shah 2007]. In a more recent study Smith et al [Smith et al 2010] reported a lifetime risk of undergoing prolapse surgery as high as 19% in Western Australia. This figure is three times higher than the 6.3% lifetime risk for POP surgery reported by Olsen and requires further evaluation of local factors and definitions that may have contributed.

In the US, POP is thought to be the leading cause for more than 300,000 surgical procedures per year [22.7 per 10,000 women] with 25% undergoing reoperations at a total annual cost of more than 1 billion dollars [Brown 2002, Boyles 2003, Silva 2006, Shah 2007]. Also of note during a nine year period [1996 – 2005] the ambulatory costs related to pelvic floor disorder increased by 40% and if these figures are extrapolated to POP surgery the total annual cost would be over 1.4 billion dollars.

The incidence of prolapse which required surgical correction following a hysterectomy is 3.6 per 1000 women-years according to Mant et al from his large cohort study in the UK. The cumulative risk rises to 5 percent 15 years after hysterectomy [Mant 1997].

Further more detailed modelling of factors that will impact on future rates of POP in the community are required so that services can be provided to match the future demands of POP surgical interventions.

III. OUTCOME ASSESSMENT

Pelvic organ prolapse, like all pelvic floor disorders, is a multidimensional phenomenon and “success” of treatment is often difficult to define. Historically most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life [Barber 2009], yet until recently these areas have largely been ignored. Fortunately, over the last 15 years, measures to evaluate POP have

Figure 2. Shows the surgical treatment for POP/ rate per 10000 women (2003)
improved; there is now an internationally-accepted and reliable assessment of the anatomic support of the uterus and vagina [POPQ] and a number of valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments.[Bump 1996; Barber 2001; Barber 2005; Digesu 2005; Price 2006; Baessler 2010]. A recent joint report from the International Continence Society [ICS] and International Urogynaecological Association [IUGA] recommended that the following outcomes be reported in studies of POP surgery: Objective (e.g. POPQ). Patient reported outcomes (particularly the presence or absence of vaginal bulge symptoms), Satisfaction, Quality of Life, and Perioperative data (e.g. operative time, hospital stay, etc) (Toozs-Hobson, 2012). A careful report of short- and long-term complications are also essential to properly weigh the risk-benefit ratio of each procedure.

1. OUTCOME ASSESSMENT: ANATOMY

The Pelvic Organ Prolapse Quantification system (POPQ), introduced in 1996, is the international standard for describing female pelvic organ support. [Bump 1996] The POPQ allows a reproducible and reliable description of the support of the anterior, posterior and apical vaginal segments using precise measurements to a fixed reference point, the hymen, and established criteria for “staging” the various levels of pelvic organ support from good support [POPQ stage 0 or I] to almost complete lack of support [POPQ stage IV].[Bump, 1996] The POPQ system has proved a valuable measurement tool that over the last 15 years has improved our understanding of POP and allowed a reliable assessment of the anatomical success of POP surgeries. However, there remain several critical challenges in the anatomical assessment of POP surgery.

First, it is difficult to establish dichotomous anatomical outcome criteria for success and failure, especially in the absence of symptoms. Traditionally researchers have defined surgical success using the NIH satisfactory anatomic outcome [POPQ stage 0 -1] and defined surgical failure as POPQ stage 2 or greater. More recently it is suggested that these anatomical definitions are too strict as over 75% of women presenting for annual gynaecological examinations without symptoms of pelvic organ prolapse would not meet the definition of “optimal anatomic outcome” and almost 40% would not meet the definition of “satisfactory anatomic outcome.”[Samuelsson 1999; Swift 2005] Thus, a substantial number of women considered “surgical failures” by these definitions would be within the normal distribution of vaginal support for parous women. The hymen maybe a more clinically relevant anatomic threshold for surgical success and some researchers have begun defining anatomic failure after surgery as POP that extends beyond the hymen.[Culligan 2005; Barber 2009; Zyczynski 2010; Chmielewski 2011; Sayer 2011].

Second, the five-level staging system of the current POP-Q (Stages 0-IV) may be insufficient to discriminate among clinically important groups of women with POP, placing virtually all such women into Stage II or III. While the staging may facilitate comparisons, it may not describe sufficient detail as the individual POP-Q measurements provide. A third area of uncertainty is whether or not apical prolapse should be considered by the same anatomic standards as prolapse of the anterior or posterior vaginal wall.

Controversy also surrounds the impact that the observer recording the anatomical outcomes has upon reported success rates. Traditionally in the retrospective assessment of anterior compartment trials the reported success rates ranged from 80-100%[Macer 1978; Stanton 1982; Walter 1982; Porges RF 1994]. However, prospective assessment of similar surgical interventions utilising similar definitions of success under the auspices of randomised controlled trials report significantly lower success rate ranging from 37-64%[Sand 2001; Weber 2001]. Further variation is also reported in prospective evaluations of prolapse staging depending upon whether the assessor is blinded to the surgical intervention. Antosh et al[Antosh 2011] demonstrated that the recurrence rate in a RCT comparing native tissue and transvaginal mesh repairs was significantly higher when performed by a blinded versus unblinded assessor at the 3 months (68 versus 53%) and at 1 year (57 versus 43%). Finally, there is an increasingly common trend for authors with financial conflict of interest related to the commercial products being evaluated reporting the outcomes of surgical interventions, which further increases the risk of reporting bias.

2. OUTCOME ASSESSMENT: SYMPTOMS

Women seeking care for POP often have concurrent pelvic symptoms. Ellermann et al found that in 237 women evaluated for POP 73% reported urinary incontinence, 86% reported urinary urgency and/or frequency, 34-62% reported voiding dysfunction and 31% complained of faecal incontinence.[Ellermann 2001] The evaluation of a patient with vaginal prolapse requires a comprehensive review of the full spectrum of pelvic floor symptoms and an assessment of how these symptoms affect their quality of life. The most valid way of measuring the presence, severity, and impact of pelvic floor symptoms on a patient’s activities and well-being is through the use of psychometrically robust self-administered questionnaires [Bump 1996; Barber 2001; Barber 2005; Digesu 2005; Price 2006; Baessler 2010]. We have gained an improved understanding of the relationship between pelvic organ support and the development of symptoms. Most symptoms often attributed to POP have at best weak to moderate correlations with worsening pelvic organ support, however, the one symptom that is almost consis-
tently acknowledged by patients with advanced POP is the presence of a vaginal bulge that can be seen or felt.[Ellerkmann 2001; Swift 2003; Barber 2005; Bradley 2005; Tan 2005] The absence of vaginal bulge symptoms postoperatively has a significant relationship with a patient's assessment of overall improvement and improvement in quality of life after surgery, while anatomic success alone does not.[Barber 2009] The hymen seems to be an important "cut off point" for symptom development. Women with prolapse beyond the hymen have more pelvic floor symptoms and are more likely to report a vaginal bulge than women with prolapse at or above the hymen.[Ellerkmann 2001; Swift 2003; Barber 2005; Bradley 2005; Swift 2005; Tan 2005]

3. OUTCOME EVALUATION: QUALITY OF LIFE

Health-related quality of life [HRQOL] refers to a person's total sense of well-being and considers multiple dimensions including (but not limited to) their social, physical, and emotional health. Measures of HRQOL can be classified into two types: generic and condition-specific. Generic HQOL instruments are used to assess quality of life in a broad range of illness or populations while condition-specific measures are designed to measure the impact of a specific disease on HRQOL. Women with advanced POP (stage 3-4) have decreased generic and condition-specific HRQOL compared to women with normal vaginal support.[Jelovsek 2006] It is recommended that investigators describe the impact of POP surgical treatment on HRQOL. Most studies that have assessed condition-specific HRQOL after POP surgery have demonstrated a significant improvement postoperatively. Improvements in generic HRQOL after POP surgery have been seen in some studies but not others. Maher et al reported significant improvements in condition-specific and generic QOL after SSLF, similar to that after abdominal sacrocolpopexy.[Maher 2004] The CARE trial reported significant improvements in condition-specific quality of life following sacrocolpopexy at three months and two years. [Brubaker 2006; Brubaker 2008] Barber et al demonstrated significant improvements in generic and condition-specific HRQOL in a prospective cohort of elderly women receiving vaginal surgery for POP and demonstrated similar improvements in women undergoing reconstructive surgery and those receiving colpocleisis.[Barber 2007] While some of these condition specific HRQOL incorporate assessment of sexual function [Baessler 2010] specific validated questionnaires on sexual function are available and provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire [PISQ][Rogers 2001] and the Female Sexual Function Index[FSFI][Rosen 2000] are two questionnaires frequently used. The joint ICS/IUGA paper on reporting outcomes after prolapse surgery has also recommended authors report the sexual function status of all individual participants pre and post intervention as seen in Figure 3 (Toozs-Hobson, 2012).

4. OUTCOME ASSESSMENT: REOPERATION

Reoperation after POP surgery for recurrence is an important measure of procedure efficacy. It is important to realise that reoperation rates are likely to represent the "tip of the iceberg" in terms of unsuccessful surgical outcomes as many women with recurrence of symptomatic prolapse may not elect another operation, nonetheless the repeat surgery for recurrent POP is an undesirable outcome that should, in most cases, be considered a surgical failure. The rates of reoperation after POP surgery vary widely in the literature, in large part because of varying definitions and timeframes. Olsen et al using administrative data from a large U.S. healthcare system reported a lifetime reoperation rate of 29.2%.[Olsen 1997] Importantly, this study included both POP and stress incontinence surgery and did not distinguish between reoperation for incontinence or POP in their report. Moreover, the authors did not distinguish between reoperation for POP in the same compartments originally operated versus the development of new POP in a new segment of the vagina ["de novo POP"]. More recently several investigators have looked specifically at the issue of site-specific recurrence with re-operation rates ranging from 3.4%-9.7%. [Miedel 2008; Kapoor 2010] In a meta-analysis of 258 studies evaluating reoperation rates after apical prolapse repairs, Diwadkar et al, reported a reoperation rate of 3.9% [95%CI 3.5-4.4%] for traditional vaginal vault suspensions (sacrospinous ligament suspension and uterosacral vault suspensions) after a mean of 32 months, 2.3% (95% CI 1.9-2.7%) for sacrocolpopexy with a mean follow-up of 26 months and 1.3% (95% CI 1.0-1.7%) after transvaginal mesh procedures at a mean follow-up of 17 months.[Diwadkar 2009] Notably, the total reoperation rate if one includes reoperations for recurrent POP and for complications was highest in the transvaginal mesh group (8.5%).[Diwadkar 2009]

In order to provide some clarity for future studies reporting reoperation rates after POP surgery, the joint ICS/IUGA report on reporting outcomes after prolapse surgery has proposed the following standardised terminology for POP surgery studies[Toozs-Hobson 2012]:

**Primary surgery** for POP is the first procedure required for the treatment of POP in any compartment

**Further surgery** This gives a global figure for the number of subsequent procedures the patient undergoes directly or indirectly relating to the primary surgery. This is subdivided into:

- **a. Primary prolapse surgery/different site.** A prolapse procedure in a new site compartment following previous surgery in a different compartment (e.g. anterior repair following previous posterior repair).
b. Repeat surgery: is a repeat operation for prolapse arising from the same site. Where combinations of procedures arise, e.g., new anterior repair plus further posterior repair these should be reported separately i.e., repeat posterior repair and primary anterior repair.

c. Surgery for Complications: e.g., mesh exposure or extrusion or pain or patient compromise e.g., haemorrhage (see complications section)

d. Surgery for non-prolapse related conditions: e.g., subsequent surgery for stress urinary incontinence or fecal incontinence.

5. DEFINING TREATMENT SUCCESS

The definition of success substantially affects treatment success rates following POP surgery.[Barber 2009] Since the publication of the NIH Workshop recommendations, considerable variability in defining treatment success still persists in studies evaluating surgery for prolapse. A number of trials define success as POPQ stage 0 or 1 consistent with the Workshop’s “satisfactory anatomic outcome” definition with one reporting success rates as low as 30% using standard surgical techniques.[Weber 2001; Brubaker 2005] Some have used the Baden-Walker prolapse grading system rather than the POPQ system.[Maher 2004] Other studies have used a combination of anatomic criteria and the presence or absence of symptoms to define treatment success. [Paraiso 1996; Barber 2000; Brubaker 2005] Such variability makes it difficult to compare study results. Moreover, there are many unknowns, including clinical relevance of these definitions or how different outcome definitions might affect the comparison between treatment arms within a study.

A recent secondary analysis of the CARE trial described POP surgical success rates after sacrocolpopexy using 18 different definitions of treatment success with differing requirements for anatomic, symptomatic and/or retreatment outcomes.[Barber 2009] Treatment success varied widely depending upon definition used (19.2% to 97.2%). 71.4% considered their surgery “very successful” and 85.2% considered themselves “much better” than before surgery. Definitions of success requiring all anatomic support to be proximal to the hymen had the lowest treatment success (19.2% to 57.6%). 94.3% achieved surgical success when it was defined as the absence of prolapse beyond the hymen. Subjective cure (absence of bulge symptoms) occurred in 92.1% while absence of retreatment occurred in 97.2% of subjects. Subjective cure was associated with significant improvements in the patient’s assessment of both treatment success and overall improvement, more so than any other definition considered [p = .0002 and <.0001 respectively]. Similarly, the greatest difference in symptom burden and HRQOL between treatment successes and failures was noted when success was defined as subjective cure (absence of vaginal bulge symptoms; p<.0001). These authors concluded that the absence of vaginal bulge symptoms postoperatively has a significant relationship with a patient’s assessment of overall improvement, while anatomic success alone does not. Based on this analysis along with the currently available literature on the distribution of pelvic support loss in the general population and on data on the relationship between pelvic organ support loss and symptom development, authors from the NIH Pelvic Floor Disorders Network have recommended that: 1) any definition of success after POP surgery should include the absence of bulge symptoms in addition to anatomic criteria and the absence of re-treatment and 2) using the hymen as a threshold for anatomic success seems a reasonable and defensible approach.[Barber 2009].
Conclusion

The committee concludes that authors when reporting outcomes on the surgical management of prolapse should include a variety of standardised anatomical and functional outcomes. It is expected such measures will improve the reporting of surgical outcomes and aid in meaningful meta-analysis of pelvic organ prolapse outcome data in the future.

- Anatomical outcomes reported should include all POP-Q points and staging utilising traditional definition of success and also with the hymen as the threshold for success. Assessment should be prospective and assessors blinded as to the surgical intervention performed if possible and without any conflict of interest related to the assessment undertaken. (Grade C)

- Subjective success postoperatively should be defined as absence of vaginal bulge (Grade C).

- Functional outcomes are best reported using valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments (Grade C).

- Sexual function is best reported utilising validated condition specific HRQOL that assess sexual function or validated sexual function questionnaires such as the Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ) or the Female Sexual Function Index (FSFI). The sexual activity status of all study participants should be reported pre and post-operatively under the following categories: sexually active without pain, sexually active with pain or not sexually active (Grade C).

- Prolapse surgery should be defined as primary surgery, and repeat surgery sub-classified as primary surgery different site, repeat surgery, complications related to surgery and surgery for non-prolapse related conditions. (Grade C)

IV. ANTERIOR COMPARTMENT SURGERY

Ahlfelt stated in 1909 that the only remaining problem in plastic gynaecology was the permanent cure of cystocele and now more than a century later this problem persists [White GR 1909]. Following high reported objective failure rates and reoperation rates after native tissue repairs and the success of mesh tapes in continence surgery and mesh utilised abdominally at sacral colpopexy the last decade has seen an unprecedented introduction of biological and permanent meshes in the management of anterior compartment prolapse.

1. NATIVE TISSUE REPAIRS

Historically anterior colporrhaphy was the standard procedure in the management of anterior compartment prolapse with objective success rates ranging from 80-100% in retrospective series [Macer 1978; Stanton 1982; Walter 1982; Porges RF 1994]. White [White GR 1912] as early as 1912 demonstrated the importance of paravaginal defects in anterior compartment prolapse. Richardson [Richardson AC 1976] in 1976 described a series of defects in the pubocervical fascia explaining why no single repair should be applied indiscriminately to all with anterior compartment defects. He also advocated the abdominal paravaginal repair which has a 75-97% success rate for cystoceles reported in case series (Table 2) [Richardson AC 1976; Richardson 1981; Shull 1989; Scotti 1998; Bruce 1999]. The surgical technique of the laparoscopic paravaginal repair is well described however little information is available on the efficacy of this approach. Shull [Shull 1994] also reported on the safety and efficacy of the vaginal paravaginal repair in 1994. Although the success rates of the vaginal paravaginal repair for cystoceles in case series vary from 67 –100% [White GR 1912; Shull 1994; Grody. M 1995; Elkins. T 2000; Mallipeddi 2001; Young 2001] significant complications have been reported recently. Mallipeddi [Mallipeddi 2001] reported on complications in a series of 45 including: 1 bilateral ureteric obstruction, 1 retro-pubic hematoma requiring surgery, 2 vaginal abscesses; 2 transfusions. In a series of 100 women Young [Young 2001] reported a 21 major complications and a 16% transfusion rate.

No randomised control studies have evaluated the abdominal or vaginal paravaginal repair in isolation. Benson et al [Benson 1996] and Maher et al [ Maher 2004] have reported RCT’s on upper vaginal prolapse comparing abdominal sacral colpopexy and vaginal sacrospinous colpopexy. Abdominal paravaginal repair was performed in the abdominal group if required and an anterior colporrhaphy without or without vaginal paravaginal laterally. Both authors reported the abdominal group to have a statistically lower rate of postoperative anterior vaginal prolapse than the vaginal group.

Goldberg et al [Goldberg 2001] reported results from a case control study of women with cystocele and stress urinary incontinence. He suggested that the addition of the pubovaginal sling to the anterior colporrhaphy significantly reduced the recurrence rate of cystocele from 42% in the control group to 19% in the anterior colporrhaphy and sling group [P<0.05].
In line with our surgical colleagues there has been a move towards the use of prosthesis to augment native tissue repair in reconstructive Gynecology. This movement took much of its impetus from two early papers. Firstly, Olsen et al [Olsen 1997] reported a reoperation of 29% following prolapse and or continence surgery and Weber [Weber 2001] reported a 70% failure rate of native tissue anterior compartment repair. Recent re-evaluation of the Olsen’s same demographic 10 years later revealed a significantly lower re-operation rate of 17% [Denman M 2008] and the reader should be cautious in making conclusions even from this data as the surgical interventions performed in 1995 are not representative of interventions performed today. More importantly, Weber et al [Weber 2001] and Sand et al [Sand 2001] in randomised control trials reported the anterior col-

5% of subjects developing symptomatic recurrence beyond the hymen, 5% of subjects developing symptomatic recurrence and re-operations less than 1% at 23 months follow-up [Chmielewski 2011].

During the decade between these initial and subsequent publications surgeons have introduced a plethora of biological and mesh grafts to improve the outcomes of anterior compartment prolapse surgery.

2. SYNTHETIC GRAFTS IN ANTERIOR COMPARTMENT SURGERY

As seen in Table 3 as early as 1996 Julian et al [Julian 1996] demonstrated in a prospective case control study that in women who had undergone at least 2 previous vaginal repairs, the overlaying of a Marlex (Bard) mesh to the anterior colporrhaphy reduced the recurrence rate of cystocele from 33% to 0%. The Marlex mesh was associated with a mesh erosion rate of 25%. Flood et al [Flood 1998] in a retrospective review of 142 women with Marlex mesh augmentation of anterior colporrhaphy demonstrated a 100% success rate for cystoceles at 3.2 years and a mesh erosion rate of only 2%.

Absorbable meshes are an attractive option as an augmenting material as they offered the increased strength during the early healing phase without the long-term complications of permanent mesh and have been evaluated in 2 randomised controlled trials. Weber et al [Weber 2001] in a randomized control trial compared the anterior colporrhaphy [33], ultra-wide anterior colporrhaphy [24] or anterior colporrhaphy with absorbable polyglactin (Vicryl) 910 mesh [26] in the management of cystocele. The study size was too small to detect small differences in efficacy or adverse events. However, at a mean follow-up of nearly 2 years the groups had similar proportions of women experiencing satisfactory or optimal anatomic results, 30%, 46% and 42% respectively.

Sand et al [Sand 2001] in a larger RCT allocated cystoceles to anterior colporrhaphy alone [n=70] and to anterior colporrhaphy plus polyglactin mesh underlay [n=73]. At 1 year the success rate in the mesh group was 75% and significantly greater than the 57% success rate in the anterior repair group alone [P=0.02]. Concurrent paravaginal defect were present in 11 women and concomitant paravaginal repair was significantly associated with a lower recurrence of cystocele overall [P=0.02].

A variety of permanent polypropylene mesh overlays have been evaluated in case series for the management of anterior wall prolapse. The anatomical success rate varies from 76 to 100% [Cervigni ; Julian 1996; Salvatore S 2002; O’Reilly BA 2003]. Salvatore et al reported worrying functional outcomes after a prolene mesh overlay including a mesh erosion rate of 13%, overactive bladder increasing from 28 to 56% and dyspareunia increasing from 18 to 38% postoperatively [Salvatore S 2002]. More recently, three year follow-up after the polypropylene mesh

overlay in the anterior compartment has been reported. Cervigni reported on 218 women and found a 76% objective success rate at three years. Mesh erosions were identified in 12.3% and vaginal stenosis in 7.7% [Cervigni 2007]. De Tayrac reported on 55 women at 3-year review with a 89% success rate, 9.1% mesh erosions, 5.5% mesh shrinkage and 16.7% dyspareunia [de Tayrac 2006]. He concluded that lower weight and coated meshes were required to limit the rate of complications and duly reported on 132 women, 12 months following low weight coated polypropylene mesh with a 92% success rate [de Tayrac 2007]. Unfortunately local problems remained in 6.3% and de novo dyspareunia in 12.8%. Rane et al provided a 5 year review of 376 consecutive women with grade 3 anterior compartment prolapse after Perigee (AMS) and reported a 94% success rate, 11.1% mesh extrusion rate and deteriorating sexual function in 4% [Rane 2011].

Carey et al [Carey 2009] performed an RCT comparing anterior and posterior fascial plication and repair with self styled anterior and posterior polypropylene Gynemesh (Ethicon) overlay and reported no significant advantage to adding a mesh overlay at one year. The morbidity in the mesh group was lower than that reported above with a mesh erosion rate of 6.5% and no difference in dyspareunia and denovo dyspareunia rates between the groups.

Five randomised control trials have been published comparing armed or trans-obturator polypropylene mesh and traditional anterior colporrhaphy (Table 3). Nieminen et al [Nieminen 2010] compared 104 women undergoing anterior compartment prolapse repair with self-styled 6x11cm low weight monofilament 4 armed polypropylene mesh (Parietene light, Sofradim Co, Trevoux, France) with 97 undergoing traditional anterior colporrhaphy. Concomitant hysterectomy and posterior compartment prolapse surgery was allowed. At 3 years the objective success (stage 0 or 1 Aa and Ba) rate was 87% in the mesh group and 59% in no mesh group [P<.001]. Awareness of bulge was seen in 18% in the repair group as compared to 10% [p=0.07] in the mesh group. The mesh exposure rate was 19% with 66% requiring surgical correction. The reoperation rate for prolapse was 10% in the native tissue group with all but one of the recurrences in anterior compartment. In the mesh group the prolapse reoperation was 6% with all six recurrences occurring in the posterior or apical compartments.

Sivaslioglu et al reported on 43 undergoing low weight self styled polypropylene mesh as compared to 42 undergoing site-specific vicryl repair and at 12 months found the objective success rate was significantly higher at 91% in the mesh group as compared to 72% in the non-mesh group[Sivaslioglu 2007]. The mesh erosion rate was 6.9% and de novo dyspareunia was reported in 4.6% in the mesh group. Quality of life assessment demonstrated no difference in outcomes between the groups and no patient in either group underwent further surgery for anterior compartment prolapse.

Nguyen compared anterior polypropylene [Perigee, AMS] mesh [n=37] with anterior colporrhaphy [38]. At 1 year the objective success rate was higher in the mesh group (89% vs. 55%). Functional outcomes including quality of life, sexual activity and dyspareunia were similar in both groups with a 5% mesh erosion and 2% unilateral leg pain that settled at 8 weeks following the mesh surgery [Nguyen 2008].

Altman and colleagues reported on behalf of the Nordic transvaginal mesh group a multicentre study (funded by Karalinska Institute and Ethicon unrestricted grants) comparing anterior colporrhaphy [n=182] to anterior transvaginal trocar mesh kit
(Prolift) [n=186] in women with symptomatic stage II or greater cystocele [Altman 2011]. Although the need for concomitant prolapse and continence surgery were exclusions an undetermined number of women with posterior and apical compartment prolapse well beyond the introitus were included. Reviewers were unblinded, surgeons were reviewers and conflict of interest statements are not available for authors or members of Nordic transvaginal mesh group. At one year, the success rate [composite Point Ba <-1 and absence of vaginal bulging] was significantly greater after the mesh repair 61% as compared to colporrhaphy group 35%. The subjective success rate was also significantly greater after the mesh repair (75% versus 62% p=0.008) as compared to the native tissue repair while no difference was detected on validated pelvic floor questionnaires (Urinary Distress Inventory) between the groups. The Prolift mesh procedure was associated with greater morbidity with a longer operating time, greater blood loss, higher rate of intra-operative cystotomy (3.5 versus 0.5%) , post-operative denovo stress urinary incontinence [ 12.3 versus 6.0%], and combined reoperation rate for USI, prolapse and mesh exposure (6% versus 0.5%). Denovo dyspareunia was seen in 7.3% after the mesh surgery as compared to 2% after anterior colporrhaphy [p=0.07] however no difference was detected between the groups utilising the Pelvic organ Prolapse Urinary Incontinence questionnaire [PIQ-12]. The mesh exposure rate was 11.5% [21/183].

Lastly, Vollebregt and colleagues reported a multicentre randomised control trial from the Netherlands with blinded reviewers comparing anterior colporrhaphy [n=58] with polypropylene trans-obturator mesh kit Avaulta [n=56] [Bard] for stage 2 primary anterior compartment prolapse [Vollebregt 2011]. Concomitant hysterectomy and posterior compartment surgery was allowed with hysterectomies being excluded. At one year the objective success rate was significantly greater in the mesh group as compared to anterior colporrhaphy group (91% versus 41%). Reoperation for anterior compartment prolapse was performed in 5% after the native tissue repair and in no patients in the mesh group [p=0.05]. No difference in awareness of prolapse or outcomes using validated questionnaires (Urogenital Distress Inventory and Incontinence Impact Questionnaire) were identified between the groups. The authors attributed the low mesh exposure rate of 4% to not performing hysterectomy and or collagen coating on the polypropylene mesh. Resolution of preoperative dyspareunia occurred in 80% in the repair group as compared to 20% in the mesh group. Denovo dyspareunia was reported in 15% following mesh and 9% after native tissue repair and denovo rectocele in 23% versus 10% respectively. The authors concluded that despite the significantly improved anatomical outcome in the mesh arm when using a functional outcome as a definition of success that there was not enough evidence to support the trans-obturator mesh in primary anterior compartment prolapse surgery.

The 2012 Cochrane meta-analysis of these RCT found that transobturator meshes had a lower rate of recurrence on examination [59/424, 14%] as compared to anterior colporrhaphy alone [200/410, 49%] RR 3.50, 95% CI 2.71 to 4.52. This finding was consistent for both the self styled (Niemenen 2010; Sivaslioglu 2008) [RR 3.41, 95% CI 2.04 to 5.67] and commercial transobturator polypropylene mesh kits [Altman 2011; Nguyen 2008; Vollebregt 2011] [RR 3.53, 95% CI 2.62 to 4.74]. Three trials demonstrated that anterior colporrhaphy [ 94/333, 28%] also had a higher subjective failure rate than the anterior transvaginal mesh repair [60/344, 17%] [RR1.62, 95% CI 1.22, 2.14] [Altman 2011; Nieminen, Vollebregt 2008]. Further prolapse surgery was not significantly more common after anterior colporrhaphy 14/459 (3%) as compared to 6/470 (1.3%) after trans-obturator polypropylene mesh [RR 2.18 95% CI 0.93 to 5.10]. No difference was detected in individual studies in validated prolapse specific questions and meta-analysis was not possible due to variations in questionnaires utilised. The operating time and blood loss were significantly greater in the mesh group and there was a tendency towards lower cystotomy rate [0.4% versus 2.7%, RR.0.19 95%CI 0.03,1.07] Altman 2011;Nieminen 2010], denovo dyspareunia [4% versus 8%, RR 0.51 95% CI 0.21 to 1.23] and denovo stress urinary incontinence [7.3% versus 11.4% RR, 0.65 95% CI 0.4 to 1.07,] [Altman 2011, Sivaslioglu 2008; Nieminen 2010] after anterior colporrhaphy. Further continence surgery was performed in 15/368 women following anterior colporrhaphy and 12/380 after polypropylene mesh procedure [RR 1.29, 95% CI 0.63 to 2.63]. This data need to be interpreted with caution as variations in concomitant surgeries existed. Mesh erosions were reported in 10.4% [41/393] of women who had an anterior compartment polypropylene mesh and surgical intervention to correct mesh erosion occurred in 6.3% [34/540].

Withagen in an observational study of 150 women undergoing Polypropylene mesh kit (Prolift) found that after an isolated anterior polypropylene repair there was a 46% incidence of stage 2 prolapse in the untreated compartment [Withagen 2010]. Altman et al, performed no concomitant surgery in the study and no difference in posterior compartment prolapse was identified between the groups or post-operative within the mesh group when evaluating median Point Bp. However, meta-analysis of those studies [Niemenen 2010; Vollebregt 2011] that reported denovo prolapse in the apical or posterior compartment following anterior compartment mesh repair found at a lower rate after the anterior colporrhaphy [14/147, 9.5%] as compared to trans-obturator mesh [26/148 17.7%] [RR 0.49 95% CI 0.24 to 0.97] Both study protocols allowed concomitant posterior compartment surgery.
dependent reviewers are required for all mesh kits. Although the reoperation rates for prolapse was similar in Nieminen et al between the 2 groups all the reoperations in AC group were anterior compartment failures and all in trans-obturator mesh group were in the posterior or apical compartment [Nieminen 2010]. This outcome is not surprising as we have seen previously when the vaginal axis is significantly altered compensatory prolapse can develop in other compartments. Compensatory prolapse is described in the posterior compartment after colposuspension [Ward 2008] or in the anterior compartment after sacrospinous colpopexy [Paraiso 1996; Maher 2001].

In the 8 trials that evaluated 553 patients that underwent some form of transvaginal mesh in the management of anterior compartment prolapse no patient underwent surgical intervention for vaginal pain or dyspareunia. This is in contrast to the Food and Drug Administration (FDA) transvaginal mesh alert were vaginal pain and dyspareunia accounted for 39% of adverse events and was marginally more frequent than mesh erosions at 38% of adverse events reports. While mesh exposures and their management remain well described vaginal pain and dyspareunia associated with anterior transobturator polypropylene mesh remain poorly characterised and will be fully evaluated in the complications and sexual function section of this chapter.

Given the relatively robust anatomic outcomes associated with transobturator mesh many clinicians were surprised that many mesh kit manufactures recently elected to introduce trocarless mesh kits and the majority have little or no data supporting their claims of superiority. Most recently, Moore et al [Moore 2012] described single incision anterior elevate [American Medical Systems, Minnetonka, MN, USA] using a lightweight polypropylene graft (24g/m2) and reported 92% objective success rate at 13 months in 60 patients with anterior and or apical prolapse. No mesh exposures were reported and the authors who reviewed the patients reported a financial relationship with the company manufacturing the product being evaluated.

Another new system involves polypropylene mesh [Prosima, Ethicon] overlay with arms extending but not secured to deeper structures. Patients use a Vaginal Support Device that is removed in the outpatient setting 3-4 weeks postoperatively, to splint the mesh while it is being incorporated into the paravaginal tissues. On prospective evaluation performed by surgeons all of whom have declared financial agreements with the manufacturing company, they reported a 77% objective success rate [ <stage 2 POP-Q] at 1 year [Zyczynski 2010] and 69% at 2 years [Sayer 2011] with a mesh exposure rate of 9% in women with Stage 2 anterior and/ or posterior compartment prolapse. Significant further prospective comparative trials with blinded independent reviewers are required for all mesh kits.

3. BIOLOGIC GRAFTS ANTERIOR COMPARTMENT SURGERY

Alternatively to synthetic prosthetic grafts autologous material may have a lower risk of host rejection or infection. Cosson [Cosson 2001] described an autologous 6-8cm long and 4 cm wide vaginal patch suspended from the tendinous arches of the pelvic fascia and tucked under the anterior repair. The success rate [<grade 1 POP] was 93% at a mean follow-up of 16 months.

Allografts from post-mortem tissue banks have been used for many years in orthopaedic surgery and decrease the risk associated with harvesting autologous rectus sheath or fascia lata. Cadaveric fascia lata with or without pubovaginal sling has been utilised to correct anterior compartment prolapse with a success rate varying from 81-100% with acceptable complication rates[Groutz 2001; Kobashi 2002; Powell 2004; Frederick 2005]. Gandhi et al have reported preliminary results of a randomised control trial comparing anterior colporrhaphy alone and augmented with fascia lata graft for cystoceles [Gandhi 2005]. At 1 year they were not able to demonstrate that the addition of the fascial lata graft improved outcomes with the success rate after anterior colporrhaphy alone being 71% as compared to 82% in those augmented with the fascia lata graft [P=0.07]. No complications were reported. Cadaveric dermis has been employed as a graft material in the anterior compartment with success rates varying from 42-84% at 2 years [Chung 2002; Clemons 2003; Behnia-Willison 2007; Ward 2007]. Concerns regarding prion transmission causing infectious diseases [Simonds RJ 1992] or residual antigenicity [Hathaway 2002] that may cause host graft reactions have encouraged the use of porcine or bovine xenografts as detailed in Table 4.

Leboeuf et al retrospectively reviewed 24 women with native tissue four corner defect repair (FDR) and 19 FDR with porcine dermis [Leboeuf L 2004]. At 15 months the success rate was 100% in the FDR group and reduced to 84% if porcine dermis overlay was utilised. Wheeler et al reported on 36 women who all underwent high uterosacral vault suspension with anterior repair augmented with porcine dermis and at 17 months found a 50% recurrence rate [Wheeler 2006]. The authors highlighted that despite the high objective failure rate greater that 90% of the women were satisfied or somewhat satisfied with the repair and 83% would undergo the surgery again. Handel et al retrospectively compared anterior colporrhaphy [n=18], porcine dermis [n=56] and polypropylene graft [n=24] in those with cystocele [Handel 2007]. The success rate at 13 months was 94%, 64% and 96% respectively with a 21% rate of vaginal extrusion of the porcine dermis graft. Alternatively to these relatively disappointing
results, a number of groups have reported satisfactory objective results utilising porcine dermis. [Gomelsky 2004] [Simsiman 2006].

Meschia et al in a multicentre randomised clinical trial compared the anterior colporrhaphy [n=103] and anterior colporrhaphy-augmented with 4x7cm piece of porcine dermis [Meschia 2007]. The success rate at 1 year was 93% in the anterior colporrhaphy with porcine graft overlay group as compared to 81% in anterior colporrhaphy alone group [P<0.001] with a 1% rate of graft erosion.

Hviid et al reported a smaller randomised controlled trial comparing polyglactin plication anterior colporrhaphy and porcine dermis 4x7cm graft at one year [Hviid 2010]. The objective failure rate [defined as point Ba ≥-1] was 2/28 in the porcine dermis group as compared to 4/26 in the anterior colporrhaphy and was not significant. Guerette et al compared the anterior colporrhaphy group [n=17]and anterior colporrhaphy with bovine pericardium collagen [n=27] matrix graft reinforcement and reported no difference on objective examination with success rate of 63% after the AC and 77% in the bovine pericardium collagen repair at 2 years(Guerette 2009). The reoperation rate for prolapse was 37% in AC group and 23% in the bovine pericardium group. Denovo dyspareunia occurred in 5% follow-

Variable definitions of success used.
Dallinger AC only. There was no difference in quality of life outcomes between the groups utilizing Urinary Distress Inventory and Pelvic organ prolapse and Incontinence sexual questionnaire.

Feldner et al compared anterior colporrhaphy with 7x10cm small intestine submucosa (SIS) graft in a randomised control trial and demonstrated reduced operating time in AC group (30 min versus 46) as compared to SIS [p=0.02][Feldner 2010]. The objective failure rate of 33% [9/27] was significantly higher after the AC versus 14% [4/29] in the SIS group. The dyspareunia rate was similar in both groups [AC 4/27 versus 5/20 SIS] and no reoperations were reported. Prolapse quality of life assessment [F-QOL] improved postoperatively in both groups with no significant difference between the groups. In another RCT, Natale et al compared polypropylene mesh (Gynemesh) with porcine dermis (Pelvicol). At two years, significantly fewer women had anterior vaginal wall recurrence in the mesh group 28% [27/96] versus to 44% [41/94] of the porcine graft group [RR 0.64, 95% CI 0.43 to 0.96]. Mesh erosion was seen in 6.3% following mesh surgery. Although similar numbers of women reported dyspareunia [10 versus 12], the authors reported superior sexuality outcomes in the porcine graft group as compared to polypropylene mesh [p = 0.03][Natale 2009].

Finally, Menefee et al in a randomised control trial compared three operations, anterior colporrhaphy, vaginal paravaginal repair using porcine dermis graft and vaginal paravaginal with self-styled polypropylene mesh and also reported a higher objective success rate after the polypropylene mesh 86% [25/29] as compared to 52% [12/23] in the porcine dermis arm [Menefee 2011] and 53% [10/19] in the AC arm. The subjective failure rate was not significantly different and was 3.4%,12% and 13% respectively. The graft erosion rate was 1/23 [4.3%] in the porcine dermis group and 4/29 [13.8%] in the mesh group.

The 2012 Cochrane meta-analysis concluded that when anterior colporrhaphy was compared to any biological graft the objective failure rate in anterior compartment was significantly higher in the anterior colporrhaphy group 56/222 [25%] as compared to the biological graft group 31/218 [14%]. Results from 3 trials [Gandhi 2005; Meschia 2007,Guerette 2009] demonstrated no difference in prolapse symptoms when native tissue repair was compared to biological graft repair [RR 1.03 0.61 to 1.75]. Differences in the methodology and the nature of the different biological grafts utilised in five trials [Feldner 2010, Gandhi 2005, Guerette 2009, Hviid 2010, Meschia 2007, Menefee 2011] were considered to be too dissimilar to combine with any other results in a meta-analysis except to highlight that 2 RCT’s [Feldner 2010, Menefee 2011] demonstrated superior objective outcomes following polypropylene mesh as compared to Porcine graft overlay.

While many clinicians believe the primary role of polypropylene mesh may be in complex or high risk prolapse such as recurrent prolapse there is little evidence to support these proposals. Fayyad et al prospectively evaluated 36 women with recurrent anterior compartment prolapse and reported an objective success rate (less than stage 2 anterior compartment prolapse) of 47% with a mesh exposure rate of 19%[Fayyad 2011].

In a prospective multicentre Dutch RCT trial women who had undergone prior prolapse surgery were randomised between native tissue repairs and tension free Vaginal polypropylene mesh [Withagen 2011]. Allocation concealment was not confirmed and neither patient, surgeon or assessor were blinded. Surgeons performed the reviews and all authors declared a financial relationship with the company manufacturing the commercial mesh product. Unfortunately preoperatively the two groups were significantly different pointing to a systematic failure in the randomization process which discredits the remaining findings of the manuscript.

The reported failure rate in the native tissue group using an unorthodox outcome definition (no prolapse in the treated compartment or reoperation) was 45% AC versus 9% mesh group at 1 year. Utilising the definition any grade 2 prolapse or subsequent prolapse surgery the failure rate was 66% in the conventional surgery group as compared to 49% [p=0.03] in the mesh group. The mesh exposure rate was 16.7% with 6% undergoing surgical intervention. Utilising Patients global Impression of Improvement [PGII] and Urogenital Distress Inventory both groups had similar outcomes.

**Conclusion for anterior vaginal compartment repairs:**

The following conclusion can be made regarding surgical interventions for anterior vaginal compartment repairs:

- absorbable mesh augmentation of native tissue repair improves the anatomical outcome as compared to native tissue repair alone with no increased complication rate in meta-analysis of 2 RCTS (Grade B)
- Biological grafts in meta-analysis have improved anatomical outcomes with no change in subjective outcomes as compared to native tissue repairs (Grade B). Conflicting level one evidence supports porcine dermis graft (Meschia, Hviid, Menefee) and single RCT supports small intestine submucosa as graft agent in anterior compartment prolapse surgery (Feldner) (Grade B).
- Consistent level one data supports a superior anatomical outcome for Polypropylene mesh as compared to biological graft (Pelvicol) in the anterior compartment (Feldner, Menefee). Mesh exposure rate was significantly higher in the polypropylene mesh group. (Grade A)
V. UTERINE PRESERVATION DURING POP SURGERY

Traditionally, surgical correction of uterovaginal prolapse includes a hysterectomy despite the fact that the uterus is believed to be a passive structure in the disease process. More recently, women have opted for uterine preservation for a variety of reasons including: desire to maintain future fertility, belief that the uterus affects sexual function or sense of identity, and concern about risks of hysterectomy. While the overall number of hysterectomy studies have increased, most are retrospective or lack a control group. Comparisons between the different hysterectomy procedures are challenging due to the limited numbers of prospective controlled trials measuring a variety of outcomes.

1. PATIENT SELECTION

Careful patient selection is critical prior to considering uterine preserving prolapse surgery. Table 5 list contraindications to uterine preservation. Most studies exclude subjects with menstrual disorders and abnormal uterine or cervical pathology such as large fibroids, endometrial hyperplasia, and cervical dysplasia. A recent study by Frick illustrates the need for hysterectomy in woman with post-menopausal bleeding even with a negative workup because of the high risk [13%] of unanticipated endometrial cancer or hyperplasia [Frick 2010]. Postmenopausal women without bleeding and premenopausal women with regular menses without abnormal uterine bleeding and a negative workup are at low risk for unanticipated pathology.

2. VAGINAL HYSTEROPEXY

The vaginal route can be divided into repairs with and without mesh. The non-mesh repairs include Manchester repair and sacrospinous hysteropexy.

a) The Manchester procedure

The Manchester procedure is one of the oldest prolapse repairs that involves amputation of the cervix and reattachment to the cardinal ligaments. Modified Manchester procedures include plication of the uterosacral ligaments posteriorly and cardinal ligaments anteriorly for improved apical support. Nevertheless, this is primarily a procedure for cervical elongation in premenopausal women that wish to maintain fertility or older women with medical comorbidity. There are high rates of cervical stenosis and menstrual disorders [7-35%] associated with cervical amputation and the use of Sturmdorf sutures [Williams 1966; Tipton 1970; Thomas 1995; Ayhan 2006]. All studies using this technique are retrospective and show relatively good anatomic and symptomatic improvement. One retrospective cohort comparing modified Manchester to total vaginal hysterectomy and uterosacral ligament suspension showed 100% cure of the apical compartment but a 40% success rate based on overall stage in the Manchester group. [DeBoer 2009] Three other retrospective cohorts comparing Manchester to vaginal hysterectomy showed no difference in anatomic or symptomatic outcomes with decreased operating time and blood loss in the Manchester group [Thys ; Thomas 1995; Kalogirou 1996]. Despite good success rates, Kalogirou concluded, “that the Manchester procedure has a limited place in modern gynecology…” Better surgical options exist for pre-menopausal women that wish to preserve fertility including sacrospinous hysteropexy, laparoscopic uterosacral hysteropexy or laparoscopic sacral hysteropexy. For post-menopausal women with medical comorbidity that require a minimally invasive approach, sacrospinous hysteropexy or LeFort colpocleisis would be preferable depending on their desire to preserve vaginal function.

b) Sacrospinous Hysteropexy

At sacrospinous hysteropexy the cervix or uterosacral ligaments are transfixed to the sacrospinous ligament using permanent or delayed absorbable suture. In a recent RCT comparing sacrospinous hysteropexy [n=37] to vaginal hysterectomy with uterosacral ligament suspension [n=34], Dietz et al reported a higher rate of apical recurrences in the hysteropexy group 21% versus 3% hysterectomy group p=0.03.[Dietz 2010] Three women had stage 4 uterine prolapse preoperatively that underwent hysteropexy and all developed recurrent uterine prolapse within one year. Subjective outcomes improved for both groups. Hysteropexy was associated with shorter hospitalisation, quicker recovery with more rapid return to work and the total vaginal length was longer 8.8cm versus 7.3cm in hysterectomy group [p<0.01]. Both groups had high rates of postoperative anterior vaginal wall prolapse [51% vs. 64%]. Another RCT unfortunately failed to report objective or subjective outcomes and revealed no difference in sexual function between sacrospinous hysteropexy and vaginal hysterectomy [Jeng 2005]. Sexual function domains of the Female Sexual Function Index-7 remained relatively unchanged in the majority of subjects with low rates of dyspareunia [5%]. Transient buttock pain occurred in 15% of subjects, similar to sacrospinous ligament fixation. Among the other studies in our review, buttock pain was present in up to 18% of patients and was usually self-limited [Hefni 2003; Jeng 2005; Hefni 2006; Dietz 2007; Dietz 2008].

Three cohort studies comparing sacrospinous hysteropexy to vaginal hysterectomy with or without sacrospinous fixation showed no difference in anatomical or symptomatic improvement with the exception of a three-fold increase in overactive bladder and urge incontinence symptoms in the vaginal hysterectomy group [Maher 2001; Hefni 2003; van Brummen 2003]. The sacrospinous hysteropexy group had shorter operating time, less blood loss, faster recovery, and fewer complications with similar recurrence and reoperation rates.

Lin and colleagues performed an interesting and unique prospective two-part study [Lin 2005]. The first phase identified cervical elongation [relative risk 10.9] and severe prolapse as risk factors for recurrent prolapse after sacrospinous hysteropexy. Among the first 33 patients, cure of uterine prolapse was 93% for those without risk factors compared to 71% for those with at least one risk factor. Next, they excluded patients with severe prolapse and performed a partial trachelectomy for those with cervical elongation resulting in a 96-100% cure rate with no recurrences in the 7 women undergoing partial trachelectomy.

The majority of studies have revealed relatively high success rates for the apical compartment with low complication rates for sacrospinous hysteropexy. Evaluation of available data from Table 6 re-

Table 6. Compares outcomes sacrospinous hysteropexy and vaginal hysterectomy.

SSHP = sacrospinous hysteropexy; TVH = total vaginal hysterectomy; DVT = deep venous thrombosis
*variation in surgical techniques and definition success exist

1394
veals no difference in the mean objective success rate of 87% [373/428] sacrospinous hysteropexy versus 93% [244/262] in the hysterectomy group. While the data on efficacy of sacrospinous hysteropexy are conflicting sacrospinous hysteropexy remains an alternative to vaginal hysterectomy in women who desire future fertility or uterine conservation. However, women with severe advanced prolapse desiring uterine conservation are at high risk of recurrence and should consider alternative approaches for hysteropexy [Lin 2005; Dietz 2010]. Those with cervical elongation should consider partial trachelectomy, which may affect future pregnancy outcomes.

c) Vaginal Mesh Hysteropexy

Several sacrospinous hysteropexy studies show high rates [11-51%] of recurrent anterior vaginal wall prolapse despite performance of a concomitant cystocele repair [Paraiso 1996; Maher 2001; Hefni 2003; Dietz 2007; Dietz 2008; Dietz 2010] and probably secondary to the posterior deflection of the vaginal axis with sacrospinous fixation. Level 1 evidence demonstrates improved anterior vaginal wall anatomical support with the addition of vaginally placed mesh. [Maher 2010] Intuitively, hysteropexy with anterior mesh placement seems ideal to improve anterior vaginal wall support and decrease recurrences in women desiring uterine conservation. Studies involving vaginal mesh repair with uterine conservation frequently include post-hysterectomy subjects and those undergoing concomitant hysterectomy making it difficult to identify outcomes specific to hysteropexy [Feiner 2010]. For the purposes of this section, we excluded anterior vaginal mesh repairs for uterovaginal prolapse that did not require an apical support procedure that would qualify as a hysteropexy.

Collinet et al reported 5-fold increased odds of mesh exposure with concomitant hysterectomy and 6-fold increased odds with an inverted T colpotomy incision [Collinet 2006]. Uterine preservation and minimizing the size of the colpotomy were protective. These data support the role of hysteropexy for women with uterovaginal prolapse planning a vaginal mesh repair. However, there are no RCTs or prospective cohort studies comparing vaginal mesh hysteropexy to hysterectomy with prolapse repair. There are 3 retrospective cohort studies confirming the efficacy of vaginal mesh hysteropexy. McDermott et al reported similar high anatomic success, symptomatic improvement and perioperative outcomes with total Prolift hysteropexy and total Prolift colpocexy [McDermott 2011]. The mesh erosion rate was 13% in the hysteropexy group. Chu et al discovered excellent support and high satisfaction when hysteropexy and vaginal hysterectomy were performed in conjunction with Perigee and Apogee, apical arms placed through the sacrospinous ligaments (Chu). The hysteropexy group had shorter operating time, less blood loss, and lower rates of mesh erosions [4% vs. 13%, NS]. Neuman et al reported similar high success and satisfaction for posterior intravaginal slingplasty with hysteropexy and hysterectomy [Neuman 2007]. There was only 1 case of recurrent uterine prolapse despite the fact that cervical amputation was performed in 17% of hysteropexy subjects. Tape erosion rates were similar [11% vs. 14%, NS] and hospitalisation was shorter [1.5 vs. 4.2 days] in the hysteropexy group.

A prospective series of 100 anterior Prolift, sacrospinous hysteropexy and posterior colporrhaphy procedures revealed 75% objective success, 12% uterine recurrences and 11% mesh erosions [Feiner 2010]. Satisfaction was high [94%] because 84% had no prolapse symptoms and all recurrent uterine prolapse were mild, stage 2. Other retrospective and prospective hysteropexy series demonstrate higher cure rates with similar or lower mesh risk [Huang ; Nicita 2005; Inoue 2009]. Fatton et al demonstrated a high number of mesh related complications in a multicentre retrospective series of 110 Prolift procedures [Fatton 2007]. There was 1 bladder injury, 5 mesh exposures, 3 granulomas without mesh exposure, 18 cases of mesh shrinkage, and 1 vaginal synechia. Meta-analysis of the limited available data in Table 7 demonstrates no difference in anatomic success rate of 86% [273/316] in the mesh hysteropexy versus 98% [81/83] in the mesh hysterectomy group [p=0.21]. Nor was there a significant reduction in the mesh exposure rate when mesh repairs were performed with hysteropexy 8.8% versus 13% with hysterectomy [p=0.22]. Newer trocarless kits using lower volume light weight mesh are being promoted for uterine conservation surgery without any supporting data in the peer reviewed literature to date.

3. ABDOMINAL HYSTEROPEXY

Abdominal hysteropexy has been performed for over a century. Early procedures transfixed the uterus to the anterior abdominal wall [Swain 1897; Giles 1930]. Other small series have successfully utilised ventral fixation to the pectineal ligaments with or without a graft [Nesbitt 1989; Joshi 1993]. However, abdominal sacral hysteropexy is generally the procedure of choice when performed through an open abdominal incision. Similar procedures can be performed laparoscopically or robotically including sacral hysteropexy and uterosacral ligament suspension. Other laparoscopic options have been described including round ligament suspension [O’Brien 1994] and anterior abdominal wall fixation [Chen 2010]. We present the data for the most common abdominal and laparoscopic techniques.
a) Abdominal Sacral Hysteropexy

Early studies performed in the 1950’s either directly sutured the uterus to the anterior longitudinal ligament or used a thin strip of external abdominal oblique fascia tunneled retroperitoneally from the sacral promontory to the posterior cervix for support [Stoesser 1955; Arthure 1957]. More recently, a variety of grafts and techniques have been described. Frequently polypropylene mesh is secured posteriorly to the cervix/vagina or a second graft is passed through windows made in the broad ligament and secured to the anterior cervix/vagina. Addison and Van Lindert published a series of abdominal sacral colpopexy in 1993 containing subsets of women [11 total] undergoing successful abdominal sacral hysteropexy with synthetic mesh [Addison 1993; van Lindert 1993]. Over the past 15 years, there have been multiple small studies evaluating abdominal sacral hysteropexy [Costantini; Banu 1997; Costantini 1998; Leron 2001; Roovers 2002; Barranger 2003; Roovers 2004; Bai 2005; Costantini 2005; Demirici 2006; Jeon 2008] as listed in Table 8.

Roovers and colleagues performed the only RCT comparing abdominal sacral hysteropexy [n=41] and Burch to vaginal hysterectomy, uterosacral ligament suspension, and needle suspension [n=41] [Roovers 2004]. Anatomic outcomes were similar with high success rates for the apical [95%] and posterior [85-95%] compartments. Anterior recurrences occurred in 61 and 64% of women. Urogenital distress inventory scores improved for all domains with the greatest improvement in prolapse symptoms. There were more doctor visits and reoperations performed or planned in the abdominal hysteropexy group. No differences existed for operating time, blood loss, length of hospitalisation, and number of complications. Constantini et al reported results of a prospective cohort study comparing abdominal sacral hysteropexy to total abdominal hysterectomy and sacral colpopexy [Costantini 2005]. There were no differences in anatomic success [91% vs. 92%], symptomatic improvement or satisfaction. Three women required vaginal revision due to mesh erosions [8%] in the hysterectomy group. Hysteropexy was associated with shorter operating time, less blood loss, and shorter hospitalisation.

There are 2 retrospective cohort studies that each included 3 arms. Jeon et al compared abdominal sacral hysteropexy to abdominal hysterectomy with sacral colpopexy or uterosacral suspension [Jeon 2008]. There were no recurrences in the hysteropexy group. Recurrences were 6.2 times more likely to occur in the uterosacral suspension group compared to the sacral colpopexy group when hysterectomy was performed. Bai et al compared smaller numbers of abdominal sacral hysteropexy to sacral colpopexy with or without hysterectomy [Bai 2005; Jeon 2008]. Success rates were high for all groups [95-100%]. There were 3[16%] mesh erosions in the hysterectomy group that did not require reoperation and no erosions in the other groups. Hysteropexy had shorter operating time and length of hospitalisation. All of the prospective observational trials and retrospective series revealed satisfactory anatomic success [87-100%] and symptomatic improvement [92-100%] [Costantini ; Banu 1997; Costantini 1998; Leron 2001; Barranger 2003; Demirici 2006]. In 2 studies, cervical amputation was performed without subsequent problems for 7 women with cervical elongation.

b) Laparoscopic sacral hysteropexy

Laparoscopic sacral hysteropexy techniques are similar to those described with the abdominal sacral hysteropexy with an anatomic success rate

*variety surgical techniques and definitions of success
of 88-100% with equally high symptomatic improvement and satisfaction. Several of the studies include different combinations of patients including post hysterectomy prolapse undergoing laparoscopic sacral colpopexy, uterine prolapse undergoing both abdominal and vaginal hysterectomy or laparoscopic sacral hysteropexy making it difficult to determine specific results associated with laparoscopic sacral hysteropexy. Table 8 describes the anatomic outcomes of sacral hysteropexy performed laparoscopically or open compared to hysterectomy and sacral colpopexy and demonstrates similar success rates in the two groups 91% [310/339] and 92% [84/91] respectively [p=.17]. The sacral hysteropexy was quicker to perform and also had a lower mesh exposure rate of 1.5% [5/339] versus 8.5% [11/129] versus sacral colpopexy with hysterectomy [p<0.05%].

c) Laparoscopic Uterosacral Hysteropexy

At surgery the plicated uterosacral ligaments are secured to the distal cervix or by plicating the ligaments in the midline with a McCall’s technique. Some add a Moschcowitz culdoplasty at the time of uterosacral suspension. Rosen et al compared laparoscopic uterosacral hysteropexy to total laparoscopic hysterectomy with uterosacral suspension, both groups did reasonably well without noticeable differences in outcomes [Rosen 2008]. When laparoscopic uterosacral hysteropexy was compared to vaginal hysterectomy and colpopexy in 25 age matched pairs, anatomic and symptomatic improvement was slightly better for the laparoscopic group with less blood loss and shorter length of hospitalisation [Diwan 2006]. Other series show similar anatomic and symptomatic success [80-100%] with few complications in women undergoing laparoscopic uterosacral or McCall’s hysteropexy. [Maher 2001; Krause 2006; Medina 2006]. Evaluation of available trials in Table 9 demonstrates a mean objective success rate of 83% [148/176] after laparoscopic uterosacral hysteropexy as compared to 78% [21/27] after laparoscopic hysterectomy and 88% [22/25] after vaginal hysterectomy and uterosacral ligament suspension.

Laparoscopic round ligament suspension was not as successful with all women having a rapid re-

</table>
currance of prolapse [O’Brien 1994]. Laparoscopic attachment to the anterior wall with mesh was highly successful in a group of 28 women [Chen 2010]. This technique could potentially increase the risk of posterior compartment recurrences due to vaginal axis deflection anteriorly, similar to a retropubic urethropexy.

**d) Hysterectomy at time of sacral colpopexy**

The evidence supporting sacral colpopexy is largely based on post-hysterectomy vault prolapse and it is not clear from the literature whether the excellent outcomes reported in the post-hysterectomy group will be reproduced in the uterine prolapse group. When considering sacral colpopexy for women with uterovaginal prolapse, the literature is relatively sparse. The choice of hysterectomy includes supracervical, abdominal, laparoscopic assisted vaginal and vaginal. Additionally, the mesh can be attached vaginally or laparoscopically following a vaginal hysterectomy. Placement of synthetic mesh over a healing sutured incision plus exposure to vaginal microbes theoretically increases the risk of graft erosion when hysterectomy is performed at the time of sacral colpopexy. While the evidence in the literature is conflicting meta-analysis of all available comparative studies in Table 10 demonstrate that the risk of mesh erosion is approximately 4 times greater if a hysterectomy is performed at the time of sacral colpopexy 8.6% [51/592] as compared to 2.2% [25/1125] without a hysterectomy and 1.7% [1/58] if subtotal hysterectomy is performed. Introducing synthetic mesh transvaginally or laparoscopically after vaginal hysterectomy or through a posterior vaginal excision appears to significantly increase the risk of mesh erosion after sacrocolpopexy[Visco 2001; Tan-Kim 2011].

Therefore, based on the current literature, hysterectomy at time of sacral colpopexy should be selected with caution and patients should be counseled regarding increased risk of mesh exposure. For this reason supracervical hysterectomy and sacral hysteropexy and supracervical hysterectomy should also consider the significant surgical challenge of removing a retained cervix or uterus that is encompassed in mesh.

### 4. PREGNANCY AND HYSTEROPEXY

For women with uterovaginal prolapse who have not completed their family, conservative management with a pessary should be offered as a first line treatment before surgical hysteropexy. Most believe that definitive surgical management should be deferred until childbearing is completed due to the potential impact of future pregnancy and delivery on pelvic support and surgical repair. In situations where a pessary cannot be fitted properly or for younger patients that refuse conservative therapy for a prolonged period of time, hysteropexy is a reasonable option. There are no documented pregnancies after laparoscopic sacral hysteropexy or vaginal mesh hysteropexy. There were 12 pregnancies after a Manchester procedure with mostly full term vaginal deliveries and only 1 documented recurrence of prolapse. There were 17 pregnan-

1398
cies after sacrospinous hysteropexy with half vaginal and half cesarean deliveries at term followed by 2 recurrences. There were a few pregnancies after laparoscopic uterosacral hysteropexy that had mixed routes of delivery at term with 1 recurrence. Giles reported the majority of documented pregnancies that occurred after abdominal wall suture hysteropexy [Giles 1930]. There were 139 pregnancies and 110 full term deliveries that were mostly vaginal [75%] with only 1 recurrence. Ot, other abdominal hysteropexy studies revealed 9 pregnancies with mostly vaginal deliveries and no recurrences.[Stoesser 1955; Joshi 1993; Banu 1997; Barranger 2003]

Despite relatively good outcomes, limited information exists to aid in counseling patients that desire hysteropexy and plan to become pregnant in the future. Unfortunately, we do not know which type of hysteropexy is better for women that desire future pregnancy with respect to fertility, pregnancy and delivery, and postpartum support and durability? We also do not know the true impact of a future pregnancy on long-term success rates and whether a cesarean delivery prevents recurrent prolapse compared to vaginal delivery. Since relatively few women undergo hysteropexy and subsequent pregnancy, it would be difficult to design a feasible study to answer these questions.

Summary

In summary a wide variety of surgical options remain for women presenting with uterine prolapse.

- Uterine preservation is a suitable option in women with uterine prolapse without contraindications to uterine preservation. However longterm data is limited and the need for subsequent hysterectomy unknown (Grade C).

- Sacrospinous hysteropexy is as effective as vaginal hysterectomy and repair in retrospective comparative studies and in a meta-analysis with reduced operating time, blood loss and recovery time. However in a single RCT there was a higher recurrence rate associated with sacrospinous hysteropexy as compared to vaginal hysterectomy (Grade D). Severe prolapse increases the risk of recurrent prolapse after sacrospinous hysteropexy.

- In consistent level 2 evidence sacrospinous hysteropexy with mesh augmentation of the anterior compartment was as effective as hysterectomy and mesh augmentation with no significant difference in the rate of mesh exposure between the groups. (Grade B)

- Level one evidence from a single RCT suggests vaginal hysterectomy and uterosacral suspension was superior to sacral hysteropexy based on reoperation rates despite similar anatomic and symptomatic improvement. (Grade C).

PP=polypropylene, Lap=Laparoscopic, MD=missing data
Consistent level two and three evidence suggest sacral hysteropexy (open or laparoscopic) was as effective as sacral colpopexy and hysterectomy in anatomical outcomes however the sacral colpopexy and hysterectomy was associated with a five times higher rate of mesh exposure as compared to sacral hysteropexy (Grade B).

At meta-analysis of hysterectomy at the time of sacral colpopexy as compared to sacral colpopexy without hysterectomy was associated with a four times higher risk of mesh exposure (Grade B).

Abdominal sacral hysteropexy and hysterectomy with sacral colpopexy have better anatomic outcomes compared to abdominal hysterectomy with uterosacral suspension in a single retrospective comparison (Grade C).

VI. APICAL SUPPORT PROCEDURES

While anterior vaginal prolapse is most common, loss of apical support is usually present in women with prolapse that extends beyond the hymen [Swift 2000; Delancey 2002]. There is growing recognition that adequate support for the vaginal apex is an essential component of a durable surgical repair for women with advanced prolapse [Tooze-Hobson 1998; Shull 1999]. Because of the significant contribution of the apex to anterior vaginal support, the best surgical correction of the anterior and posterior walls may fail unless the apex is adequately supported [Rooney 2006; Hsu 2008]. While recognition of apical defects is one of the biggest challenges in the preoperative evaluation of pelvic support defects, surgical correction of the apex has several good options with relatively high success rates. Apical suspension procedures can broadly be separated into those performed transvaginally and those performed abdominally. Abdominal procedures can be performed via laparotomy or using conventional laparoscopic or robotically assisted-laparoscopic techniques. Although precise estimates are not available, most studies suggest that the vaginal approach is most common with 80-90% of procedures being performed through this route [Olsen 1997; Brown 2002; Boyles 2003; Brubaker 2005]. The individual woman’s surgical history and goals, as well as her individual risks for surgical complications, prolapse recurrence and de novo symptoms affect surgical planning and choice of procedure for apical POP.

1. SACROSPINOUS LIGAMENT SUSPENSION (SSLS)

One of the most popular and widely reported transvaginal procedures for correcting apical prolapse is the SSLS. First described in 1958 [Sederl 1958], this procedure suspends the vaginal apex to the sacrospinous ligament either unilaterally or bilaterally, typically using an extraperitoneal approach. Observational series and clinical trials suggest that while apical recurrence after SSLS is uncommon [2.4% to 19%], recurrence of anterior vaginal prolapse is more problematic [6% to 28.5%] (Table 11). A meta-analysis by Morgan et al found an overall failure rate at any site of 28.8% [95% CI 18.4%-36.3%] with failure of the anterior segment seen in 21.3% [17-3-25.3%], apical segment of 7.2% [95% CI 4.0 – 10.4%] and posterior segment of 6.3% [95% CI 4.2-8.4%]. Whether the relatively high rate of anterior vaginal prolapse recurrence seen with SSLS is due to the posterior deflection of the vaginal axis, as many authors suggest,[Shull 1992; Benson 1996; Paraiso 1996; Colombo 1998] or simply represents a general predilection of anterior support to fail after pelvic reconstructive surgery remains unknown [Weber 2005]. Reoperation rates after SSLS range from 1.3% to 37%, with all but two series reporting rates less than 9% (Table 11).

Information on the functional or QOL outcomes of SSLS is limited. Maher et al demonstrated significant improvements in condition-specific and generic QOL after SSLS, similar to that after abdominal sacral colpopexy [Maher 2004]. A meta-analysis of randomised and observational studies found a pooled average for failure to provide relief of prolapse symptoms after SSLS of 10.3% [95% CI 4.4-16.2%] [Morgan 2007]. The pooled average for failure to provide patient satisfaction after SSLS in this analysis was 13% [95% CI 7.4%-18.6%] [Morgan 2007]. Although infrequent, serious complications associated with SSLS include buttock pain and sacral/pudendal neurovascular injury. In a review of 22 studies that included 1229 SSLS procedures, 3 patients [0.2%] had life-threatening hemorrhage from sacral or pudendal vascular injury and the overall transfusion rate was 2% [Sze 1997]. Buttok pain occurred in 3% of subjects, the vast majority of which resolved by 6 weeks postoperatively [Sze 1997].

2. UTEROSACRAL LIGAMENT SUSPENSION (USLS)

The USLS was first described by Miller [Miller 1927] in 1927 and later popularised by Shull in the late 1990s. The USLS suspends the vaginal apex to the proximal remnants of the uterosacral ligaments using an intraperitoneal surgical approach. This procedure restores the vagina to its normal axis, avoiding the retroflexion associated with SSLS. The current evidence supporting the use of USLS is limited primarily to uncontrolled retrospective case-series and evaluation of these data confirm a mean objective success rate of 85% [range 48-96%] and mean reoperation rate for prolapse of 5.8% [range 0-12%] (Table 12). A meta-analysis performed by Margulies et al found

* Prospective and Retrospective cohorts with n >50 published since 1985 and SSLS arms of 3 RCTs comparing SSLS to Abdominal sacrocolpopexy (ASC); **POP staging systems, if used, are indicated as ‘grade’ for Baden-walker(Baden 1972) or ‘stage’ for POPQ(Bump 1996); # optimal and satisfactory outcomes combined
pooled rates of anatomic success [POPQ Stage 0-1] of 81.2% [95% CI 67.5-94.5%] for the anterior segment, 98.3% [95% CI 95.7 -100%] for the apical segment and 87.4% (95% CI, 67.5%-94.5%) for the posterior segment [Margulies 2010]. Postoperative prolapse symptoms were reported in 5 of 11 studies in this review and were relieved in 82-100% of patients. These promising results are balanced by ureteral kinking/injury rate of 1%-11% with this procedure [Margulies 2010]. A review of 700 consecutive vaginal prolapse surgeries found intraoperative ureteral kinking/injury of 5.9% directly attributable to USLS. However, 87% were identified at cystoscopy before the completion of the index surgery and relieved by removing suspension sutures intraoperatively with no long-term consequence to the patient [Gustilo-Ashby 2006]. Only 3 of 355 ULS [0.9%] performed in this series required additional procedures to relieve or correct ureteral obstruction or injury. Margulies et al identified 10 studies including a total of 820 women that reported on perioperative complications of ULS [Margulies 2010]. The ureteral reimplantation rate in this series was only 0.6%. Blood transfusions were reported in 1.3%, cystotomy in 0.1%, and bowel injury in 0.2%. To date, no clinical trials comparing the ULS to sacrocolpopexy or to SSLS have been published. The Pelvic Floor Disorders Network has an ongoing RCT comparing USLS to SSLS that includes 440 subjects who will be followed for 2 years; results from this trial are expected in 2013. [Barber 2009]

While the USLS is traditionally performed using an intraperitoneal approach, Dwyer and Fatton have described an extraperitoneal variant of the USLS. [Dwyer 2008; Fatton 2009] In their series of 123 consecutive women undergoing an extraperitoneal ULS,

3. MAYO/MCCALL’S CULDOPLASTY

Like the USLS, the Mayo/McCall’s culdoplasty uses the proximal uterosacral ligaments to suspend the vaginal apex. The major difference is that with the Mayo/McCall procedure the uterosacral ligaments are plicated in the mid-line to obliterate the posterior cul-de-sac. While commonly performed, data describing the outcomes for this procedure are limited. **Table 13** Colombo and Milani retrospectively compared the outcomes of a modified-McCall’s culdoplasty to the SSLS [n = 62 in each group] [Colombo 1998]. Recurrence after the McCall’s culdoplasty to the SSLS [n = 62 in each group] [Colombo 1998] was 15% 4 to 9 years after surgery and not significantly different from the SSLS group. Recurrent anterior vaginal prolapse occurred less frequently in the McCall’s group than the SSLS group (6% vs. 21%, p = .04; OR 4.1 [95% CI 1.3 to 14.2] [Colombo 1998]. A large retrospective series of 693 women from the Mayo clinic described an 82% satisfaction rate on subjective follow-up with few complications [Webb 1998]. The rate of subsequent prolapse repair in this population was 5.2%. A retrospective case series of 411 women undergoing Mayo culdoplasty found that a more dorsal “deep” placement of sutures through the uterosacral ligaments reduced the incidence of ureteral obstruction compared to other published series [Aronson 2005].

### 5. Ilioococygeus Fascia Fixation

There are no randomised trials that support the use of this procedure. Several case series have provided

* excludes SSLS group; ** excludes Inmon group
some information. Shull reported that apical support was optimal in 39/42 [83%] of patients, but eight others had apical or other defects. [Shull 1993] Meeks and colleagues reported a 96% objective cure in 110 women followed up to 13 years.[Meeks 1994] In a retrospective case-control study, Maher and colleagues reported similar subjective [91% v 94%] and objective [53% vs. 67%] cure rates with illococcygeus fixation [n=50] compared to sacrospinous fixation [n=78].[Maher 2001].

6. TRANSGINGIVAL MESH APICAL PROLAPSE

Two randomised control trials are available that evaluated transvaginal polypropylene meshes in apical prolapse. Sokol et al reported a multicentre double blinded RCT comparing uterosacral colpopexy and native tissue repair [n=33] and monofilament polypropylene mesh kit [Prolift n=32] for stage 2 or greater uterovaginal prolapse or vaginal prolapse [Sokol 2011].

At one year the conventional surgery group had no subsequent surgical interventions as compared to 15.6% in the mesh group [p=0.017] including 3 for prolapse surgery (2x sacral colpopexy and 1 illococcygeus fixation) and 2 interventions for mesh exposure. The objective failure rate (any stage 2 or greater prolapse) was 70% in the conventional surgery group versus 63% in the mesh group [P>0.05]. The subjective failure rate was also similar in both groups, 9.1% in native tissue repairs versus 3.8% in the mesh group. One patient was transfused and 2 inadvertent cystotomies occurred in the mesh group with no perioperative complications reported in the native tissue group. No differences were seen between the groups utilising a wide variety of validated outcome tools.

Unfortunately, due to reaching an ethics committee imposed stopping criterion of 15.6% mesh exposure rate the study did not recruit the appropriate sample size and is underpowered to detect a significant difference between the groups if they exist.

Maher et al recently reported results from a randomised trial comparing LSC [n=53] to a total vaginal mesh kit [TVM] [Prolift, Ethicon Women's Health and Urology] [n=55] [Maher 2011]. LSC was associated with longer operating time (mean difference +52 min [95% CI 41.5-62.6], decreased hospital stay [mean difference -0.5 days [95% CI -.93 to -.10] and quicker return to normal activities (mean difference -5.3 days [95% CI -8.4 to -2.3]. Two years after surgery, objective success [Overall POPQ Stage 0 or 1] was seen in 77% of the LSC group compared with only 43% of the TVM group, p <.001 [Maher 2011]. Also, reoperations were significantly higher in the TVM group [22%] than in the group that received LSC [5%, p =.006].

As seen in Table 14 the success rate of transvaginal meshes for apical prolapse in level 3 evidence

is significantly higher and ranges from 87-100% for monofilament polypropylene meshes with mesh erosion rates varying from 0-15%.

7. SACRAL COLPOPEXY

Since its introduction by Lane in 1962 [Lane 1962], sacrocolpopexy has proven to be an effective and durable technique for correcting apical prolapse. In 2010, approximately 34,000 sacrocolpexies were performed in the U.S. representing 11% of all prolapse surgeries performed during that time period. Traditionally, sacrocolpopexy has been performed via a laparotomy (i.e. abdominal sacral colpopexy) but the use of laparoscopic and robotic approaches is increasing.

a) Abdominal Sacral Colpopexy (ASC)

Observational studies and clinical trials suggest that ASC is a highly effective procedure for apical prolapse. The success rate of ASC, when defined as lack of apical prolapse, ranges from 78-100% (Table 15). When success is defined as no recurrent prolapse in any segment the published success rates are 56% - 100%. A systematic review of ASC performed by Nygaard et al reported a median reoperation rate for recurrent prolapse of 4.4% [range 0 -18.2%] and for postoperative stress incontinence of 4.9% [range 1.2% to 30.9%] [Nygaard 2004]. Clinical trials demonstrate significant improvements in prolapse symptoms, urinary function and quality of life after ASC [Maher 2004; Maher 2004; Brubaker 2008]. There is level 1 evidence that ASC has superior anatomic outcomes when compared to SSLS but this is balanced by longer operating time, longer recovery and higher cost [Maher 2010]. There are no randomised trials comparing ASC to ULS or to transvaginal mesh procedures. Given the prolonged recovery and unique complications associated with laparotomy, many surgeons reserve sacrocolpopexy for patients with apical prolapse thought to be of high risk of failure from a vaginal approach, often considering such factors as age, comorbidities, history of previous prolapse surgery, and vaginal length. [Toozs-Hobson 1998; Shull 1999; Maher 2004; Brubaker 2005; Weber 2005] Unfortunately, there is little published data to allow an evidence-based decision about which patient with POP will be best served by an ASC relative to other techniques.

Some surgeons have attempted to decrease mesh complications of ASC by using biological materials instead of synthetic mesh. However, the current evidence suggests that biologic materials whether allograft or xenograft have inferior anatomic outcomes compared with polypropylene mesh with similar rates of graft-related complications [Quiroz 2008; Deprest 2009; Claerhout 2010].

Beyond mesh erosion, reported complications of ASC are generally consistent with other major open pelvic surgeries. The systematic review by Nygaard et al reported that wound complications occurred in 4.6% [range 0.4% to 19.8%], hemorrhage or transfusion in 4.4% [2% to 16.9%], cystotomy in 3.1% [0.4% to 15.8%], ureteral injury in 1.0% [0.8% to 1.9%] and bowel injury in 1.6% [0.4% to 2.5%] [Nygaard 2004]. One in 20 women in the CARE trial experienced significant gastrointestinal morbidity after sacrocolpopexy. Of 322 women in the study, 19 had symptoms of possible ileus or small bowel obstruction; of these, 4 had reoperation for small bowel obstruction, 11 were readmitted for medical management, and 4 had a prolonged initial hospitalisation for gastrointestinal symptoms [Whitehead 2007].

b) Abdominal sacral colpopexy (ASC) versus sacrospinous ligament suspension (SSLS)

To date, there are three RCTs that directly compare ASC to SSLS.[Benson 1996; Lo 1998; Maher 2004] The Cochrane review on the surgical management of POP by Maher et al summarises these studies and concludes that these trials provide level 1 evidence that there were no statistically significant differences in objective failure at any site [any pelvic organ prolapse RR 0.77, 95% CI 0.39 to 1.53], subjective failure [RR 0.53, 95% CI 0.25 to 1.09], reoperation for POP [RR 1.46, 95% CI 0.19 to 1.11] or patient satisfaction [RR 0.82, 95% CI 0.32 to 2.06] [Maher 2010]. However, ASC was superior to SSLS for the following outcomes: Prolapse < Stage 2 [RR 0.29, 95% CI 0.09 to 0.97], recurrent vault prolapse [RR 0.23, 95% CI 0.07 to 0.77] post-operative stress urinary incontinence [RR 0.55, 95% CI 0.32 to 0.95] and less post-operative dyspareunia RR 0.39, 95% CI 0.18 to 0.86. In contrast, ASC was associated with a longer operating time (Weighted Mean Difference [WMD] 21 minutes, 95% CI 12 to 30), longer time to recover [WMD 8.3 days, 95% CI 3.9 to 12.7] and was more expensive [WMD US $1334, 95% CI 1027 to 1641] than SSLS [Maher 2010].

c) Laparoscopic Sacral Colpopexy (LSC)

The laparoscopic approach of sacral colpopexy has been adopted by many surgeons over the last decade as an alternative to ASC with the hopes of...

*Prospective and Retrospective cohorts with n > 50 published since 1985, ASC arms of 3 RCTs comparing ASC to sacrospinous ligament suspension. POP staging systems, if used, are indicated as 'grade' for Baden-walker{ or 'stage' for POPQ

NS = not stated; SUI = stress urinary incontinence; RPU = retropubic urethropexy; RCT=randomised clinical trial

***Question 5 on the Pelvic Floor Distress Inventory – “Do you usually have a bulge or something falling out that you can see or feel in the vaginal area?”}
reproducing the high success rate of the ASC while decreasing the morbidity and delayed recovery associated with laparotomy. Multiple prospective and retrospective case series demonstrate good short to mid-term success rates with mean objective success rate of 90.5% [range 60 -100%], subjective success rates of 79-98%[Higgs 2005; Rivoire 2007; Sarlos 2008] and mean reoperation rate of 5.9% (Table 16). Recently, several prospective studies have been published that demonstrate significant improvements in pelvic symptoms and quality of life after LSC [Sergent ; Maher 2011; Paraiso 2010]. To date, no randomised trials have compared LSC to ASC, however three retrospective comparisons have been published [Paraiso 2005; Hsiao 2007; Klauschue 2009]. While results vary somewhat between studies, in general, LSC is associated with shorter hospital stay, less blood loss with conflicting data on operating time. Objective outcomes appear to be similar between the groups. Well designed high quality clinical trials are necessary to establish independently the effectiveness and safety of the LSC relative to ASC.

There is Level 1 evidence that LSC provides superior outcomes to total vaginal mesh procedure for women with symptomatic Stage 2-4 vaginal vault prolapse as described above. There are currently no comparative studies, randomised or not, evaluating the relative safety and efficacy of LSC and native tissue [non-mesh] vaginal POP repair.

A recent retrospective study assessed the complications rates in 402 LSC cases.[Stepanian 2008] This study compared patients who received concurrent laparoscopically-assisted vaginal hysterectomy with those that had previous hysterectomy. They showed no differences in intra- or perioperative complications and similar rates of mesh erosion between the two groups.[Stepanian 2008] Overall the complication rates for this cohort were 0.75% for hematoma, 2.2% for ileus or small bowel obstruction, 1.5% for bladder injury, 0.75% for bowel injury and 0.25% ureteric injury. At 1 year, the overall mesh erosion rate was 1.2%. In contrast, Tan-Kim et al reported on a retrospective series of 188 minimally invasive sacrocolpopexy and found a significantly higher mesh exposure rate in those who received concurrent total vaginal hysterectomy [TVH] [23%] compared with those who were post-hysterectomy (5%) or received a supracervical hysterectomy [5%].[Tan-Kim 2011] TVH was found to be an independent risk factor for mesh erosion on multivariable regression analysis in this study [OR 5.67; 95% CI 2.88-17.10].

Despite the clinical advantages of a laparoscopic approach, adoption of LSC has been relatively limited probably because of the steep learning curve associated with attaining laparoscopic suturing and knot tying skills that are required to attach the mesh to the vagina and sacrum. Claerhout et al evaluated their learning curve in the first 206 cases performed by a single surgeon. [Claerhout 2009] Operating times declined rapidly during the first 30 procedures in this series and reached steady state (175 minutes) after 90 cases. Using a cumulative sum (CUSUM) approach to evaluate operative time and failures (laparotomy, complication or anatomic failures) they found that adequate learning occurred after 60 cases. [Claerhout 2009] Complication rates remained unchanged throughout this series. Akladios et al found that there was a steady decrease in LSC operative time in a series of the first 48 cases after 60 cases. [Akladios 2010] Complication rates (18-24 cases) they found that adequate learning occurred after 90 cases (mean 175 minutes) after 90 cases. Using a cumulative sum (CUSUM) approach to evaluate operative time and failures (laparotomy, complication or anatomic failures) they found that adequate learning occurred after 60 cases. [Claerhout 2009] Complication rates remained unchanged throughout this series. Akladios et al found that there was a steady decrease in LSC operative time in a series of the first 48 cases after 60 cases. [Akladios 2010] Complication rates remained unchanged throughout this series. Akladios et al found that there was a steady decrease in LSC operative time in a series of the first 48 cases after 60 cases. [Akladios 2010] Complication rates remained unchanged throughout this series. Akladios et al found that there was a steady decrease in LSC operative time in a series of the first 48 cases after 60 cases. [Akladios 2010] Complication rates remained unchanged throughout this series.

d) Robotic Sacral Colpopexy (RSC)

Because of the relatively long learning curve required for LSC, many surgeons have turned to robotic-assisted surgery in order to offer patients a minimally invasive approach to sacrocolpopexy. Robotic surgical systems have been developed with the goal of facilitating technically difficult procedures by improving the surgeon’s vision, dexterity and ergonomics. No data has been published on the learning curve for RSC however expert opinion suggests that the learning curve is shorter for RSC compared to the laparoscopic approach.

The currently available data for RSC are relatively limited and consist primarily of uncontrolled cases series, but meta-analysis suggests anatomic outcomes similar to that of ASC and LSC with objective success rates reported at 60-100% [mean 93%], subjective success of 91-94% and mean mesh erosion rate 5%.

</table>
published studies that provide comparative data for the RSC. Geller et al retrospectively compared 73 patients who received RSC to 105 who received ASC [Geller 2008]. RSC was associated with less blood loss, longer operative time, shorter length of stay and a higher incidence of fever [4.1% vs. 0%] Anatomic outcomes 6 weeks after surgery were similar between groups [Geller 2008].

In the only randomised comparison of RSC to date, Paraiso et al recently published a clinical trial that provides level 1 evidence that RSC results in longer operating time and increased pain and cost compared with LSC.[Paraiso 2011] This single-centre, blinded randomised trial compared RSC [n = 40] to LSC [n=38] in women with stage 2-4 post-hysterectomy vaginal prolapse. Total operative time was chosen as the primary outcome for this study serving as a proxy measure for surgical efficiency. Total operative time was significantly longer in the robotic group compared with the laparoscopic group (+67-minute difference; 95% confidence interval [CI] 43-89; P<.001).[Paraiso 2011] Anesthesia time, total time in the operating room, total sacral colpopexy time, and total suturing time were all significantly longer in the robotic group. Participants in the robotic group also had significantly higher pain at rest and with activity during weeks 3 through 5 after surgery and required longer use of nonsteroidal anti-inflammatory drugs (median, 20 compared with 11 days, P<.005). The robotic group incurred greater cost than the laparoscopic group (mean difference +$1,936; 95% CI $417-$3,454; P=.008).[Paraiso 2011] Both groups demonstrated significant improvement in vaginal support and functional outcomes 1 year after surgery with no differences between groups. It is worth noting that the surgeons in this study had considerable experience with LSC.

A meta-analysis of observational studies on robotic gynaecological surgery, found that the currently available evidence shows that for most gynaecological procedures studied robotic surgery achieved a shorter hospital stay and less blood loss than open surgery.[Reza 2010] However, no clinically significant improvements were noted when robotic surgery is compared with conventional laparoscopic surgery in benign gynaecological procedures.[Reza 2010] The current evidence, while limited, suggests that these conclusions are also applicable for RSC (Table 18). RSC probably has a shorter learning curve than LSC and thus may be more generalisable however published evidence for this is currently lacking. In surgeons with advanced laparoscopic skills, RSC offers no clinical benefit when compared to LSC and results in longer operating times, greater cost and greater postoperative pain.

8. OBLITERATIVE PROCEDURES: LEFORT COLPOCLEISIS

Obliterative surgery, such as total colpocleisis (also called colpectomy/colpocleisis) or the LeFort partial colpocleisis, corrects POP by closing off the vaginal canal either in part or whole.[FitzGerald 2006] Obliterative procedures are less commonly performed in the Europe, Asia, and Australia compared to the United States, and are usually reserved for women who are elderly, medically compromised, and no longer sexually active.[Jelovsek 2007] The purported advantages of obliteratorve surgery in this population are decreased operative time, decreased perioperative morbidity, and an extremely low prolapse recurrence risk. The obvious disadvantage is the elimination of the potential for vaginal intercourse. Preoperative counseling is essential when choos-

MD, missing data #Randomised trial, all other studies are retrospective comparisons; *indicates statistically significant result that is superior to the comparator.
ing between the obliteratorive and reconstructive options. A systematic review of colpocleisis published in 2006 noted colpocleisis appears to be nearly 100% effective for correcting pelvic organ prolapse, however until recently little was known about postoperative functional or quality of life outcomes.[FitzGerald 2006] In the last few years a number of reports evaluating symptom improvement and changes in quality of life after colpocleisis have been reported.[Barber 2007; Hullfish 2007; Fitzgerald 2008; Gutman 2009] Overall, these series have found high rates of patient satisfaction and significant functional improvement with low rates of regret for loss of sexual function. [Barber 2007; Hullfish 2007; Fitzgerald 2008] Barber et al reported results from a multicentre study of obliteratorive surgery using a prospective cohort design with a concurrent control group of age-matched women undergoing vaginal reconstructive surgery.[Barber 2007] Despite permanent alterations in sexual function, significant improvements in bladder, bowel and prolapse symptoms as well as body image were noted after surgery with no differences between those who received colpocleisis and those who underwent reconstructive surgery. Additionally, significant and clinically important improvements were noted in bodily pain, vitality, social functioning, role-emotional, and mental health summary scales of the SF-36.[Barber 2007] Similarly, a retrospective cohort of women over age 65 by Murphy et al comparing women who underwent colpocleisis [n=45] and similar group women who underwent reconstructive surgery with transvaginal mesh (Prolift, Ethicon Women’s Health and Urology) found that improvements in condition-specific quality of life and postoperative patient satisfaction were comparable between the two treatment groups.[Murphy 2008].

The Pelvic Floor Disorders Network has reported on a large series of women undergoing colpocleisis [n=153] with one year follow-up.[Fitzgerald 2008]. All pelvic symptom scores and related bother significantly improved at 3 and 12 months, and 125 [95%] patients said they were either ‘very satisfied’ or ‘satisfied’ with the outcome of their surgery.[Fitzgerald 2008] Bothersome stress and urge incontinence were present before surgery in 54% and 41% of subjects respectively. Forty percent of subjects received a concurrent midurethral sling at the time of their colpocleisis and the rates of bothersome stress and urge incontinence one year after surgery was 14% and 15% respectively. Similarly, bothersome bowel symptoms were present in 77% of subjects at baseline. One year after surgery, the majority of bothersome bowel symptoms resolved, particularly obstructive and incontinence symptoms, and development of new bowel symptoms was uncommon [0-14%].[Gutman 2009]. While obliteratorive procedures are predominantly performed in elderly, frail women who often have multiple co-morbidities, the rate of serious adverse events after this procedure appears to be low. In general, major complications due to performance of surgery on the elderly (e.g., cardiac, pulmonary and cerebrovascular complications) occur at a rate of approximately 2%. [FitzGerald 2006] Major complications due to the surgery itself (e.g. pyelonephritis, blood transfusion) occur at a rate of approximately 4%. [FitzGerald 2006] A systematic review of published series of colpocleisis from 1966 to 2004 reported a surgical mortality rate of approximately 1 in 400 cases.[FitzGerald 2006] One complication that appears to be uniquely associated with obliteratorive surgery is development de novo rectal prolapse after surgery.[von Pechmann 2003; Collins 2007] Collins et al in a retrospective cohort of 916 women undergoing vaginal POP surgery at one institution and found that the incidence of postoperative full-thickness rectal prolapse in women who were > or = 65 years old who underwent obliteratorive surgery was 3 of 74 [4.1%; 95% CI, 1.4-11], with an estimated odds ratio of 22 [95% CI, 2.3-196; P < .002] compared with women who were > or = 65 years old who underwent reconstructive surgery.[Collins 2007].

Conclusions Apical prolapse

• Level 1 evidence suggest ASC has a higher success rate as compared to sacrospinous colpopexy with less SUI and post-operative dyspareunia. ASC had greater morbidity including operating time, inpatient stay, slower return to activities of daily living and higher cost. (Grade A)

• ASC has the lowest inpatient cost as compared to LSC and RSC. LSC has lower inpatient cost than RSC (Grade B)

• In single RCT’s the RSC had longer operating time than both ASC and LSC (Grade B). In small trials objective outcomes appear similar although postoperative pain was greater in RSC.

• LSC as effective as ASC with reduced blood loss and admission time. (Grade C). The data relating to operating time are conflicting

• ASC performed with polypropylene mesh has superior outcomes to fascia lata (Level I) and pericardium and small intestine submucosa (Level 3) (Grade B)

• In a single RCT, LSC had a superior objective and subjective success rate and lower reoperation rate compared to polypropylene transvaginal mesh for vault prolapse (Grade B).

• Level three evidence suggest vaginal uterosacral ligament suspension, McCaulli culdoplasty, lliococcygeus fixation and colpocleisis are relatively safe and effective interventions (Grade C)
The prevalence of rectoceles in women ranges from 12.9-18.6% and the average annual incidence is estimated to be 5.7 cases per 100 women years [Hendrix 2002; Handa 2004]. Approximately 225,000 operations are performed every year in the United States for pelvic organ prolapse and repair of posterior vaginal wall is performed in between 40-85% [Olsen 1997; Boyles 2003; Whiteside 2004].

Terms used to describe the supportive tissue utilised for posterior wall prolapse repair date back to a publication by Jeffcote in 1961 [Francis WJA 1961]. The concept of site-specific repair stems from observations by Richardson who felt that discrete defects in what he termed rectovaginal fascia should be addressed by a directed repair of the defect thus producing a more anatomical repair in his opinion [Richardson 1993]. In recent years there has been a clearer understanding of the anatomy of the posterior vaginal wall and its support however surgical studies in this area continue to utilise terms that are not anatomically based. The goal of this review will be to provide a brief overview regarding current understanding of the anatomy of the support of the posterior vaginal wall, discuss various anatomic defects that can clearly contribute to posterior vaginal wall prolapse, and finally update the previous ICI report by citing the various studies that have reported outcomes for the surgical correction of posterior vaginal wall prolapse.

1. ANATOMY OF THE POSTERIOR VAGINAL WALL

Historically pelvic organ support as it relates to the anterior and posterior vaginal wall compartments has been described in relation to supportive tissues termed endopelvic fascia. In the anterior segment this has been called pubocervicovesical fascia and in the posterior segment this has been called rectovaginal fascia. Histological studies have noted that what has previously been termed fascia is actually vaginal muscularis in both the anterior and posterior segments.[Farrell 2001] With respect to the rectovaginal fascia it is now well appreciated that there is no such layer between the posterior vaginal wall and the anterior wall of the rectum. At the level of the mid vagina histological assessment of the posterior vaginal wall from the lumen of the vagina to the lumen of the rectum notes the following layers: vaginal epithelium, the lamina propria of the vagina, fibro muscular wall of the vagina (smooth muscle cells, elastin, and type II collagen) adventitia, outer muscular wall of the rectum, inner muscular wall of the rectum, lamina propria of the rectum, and rectal mucosa.

Delancey et al performed cross-sections on nulliparous and multiparous cadavers and noted that the support of the posterior compartment was maintained by a complex interaction of connective tissue and levator ani muscle [DeLancey 1999]. He went on to note that the support of the posterior vaginal wall was best divided into 3 separate and distinct levels of support. Level III support being the most distal portion of the vagina is provided by the perineal membrane and the rectovaginal septum. This level of support has strong attachments to the levator ani complex and is thus less susceptible to pelvic pressure transmission that may cause prolapse. Level II or the mid vagina is supported by its attachments of the vaginal muscularis laterally to the fascia of the levator ani muscles. Level I support or the upper vagina is supported by the cardinal-uterosacral ligament complex.

This same group of investigator’s recently discussed posterior vaginal wall anatomy in a review article and likened it to an open container. The front wall of the container would be formed by the posterior vaginal wall while the bottom of the container is made up of the perineal body and anal sphincters. The levator ani muscles form the lateral sides of the container and the levator plate where the muscles decussate behind the rectum to create the iliococcygeal raphe form the back wall of the container. The uppermost portion of the container would be that created by the attachment of the posterior vaginal wall to the uterosacral ligament which extend below the peritoneum. All of these boundaries are subject to defects that can give rise to different structural failures.[Lewicky-Gaupp 2009]

2. ANATOMIC DEFECTS THAT MAY CONTRIBUTE TO PROLAPSE OF THE POSTERIOR VAGINAL WALL

The patient who presents with prolapse of the posterior vaginal wall either in isolation or in conjunction with prolapse of other segments of the pelvic floor could potentially have a posterior enterocele, a rectocele, or a sigmoidocele.[Fenner 1996] These 3 conditions can occur in isolation or in conjunction with each other and will commonly be accompanied by a perineal defect and or a widened genital hiatus. While it is beyond the scope of this article to discuss clinical and radiographic mechanisms that can be used to differentiate these various defects suffice it to say that they can all result in descent of the posterior vaginal wall in various degrees.

The published literature continues to classify posterior vaginal repairs into what has been termed a “traditional technique” which implies that the repair has been supplemented with a levator ani muscle plication in the midline or a “site specific technique” which implies that discreet defects in the rectovaginal fascia are identified and repaired and no levator plication is performed. To date we are unaware of any studies that have addressed how often a posterior enterocele or sigmoidocele coexist with a rectocele and how the presence of these defects impacts on ultimate surgical out-
comes. Based on our current understanding of the anatomy of the posterior vaginal wall and perineum it is clear that the defect specific repairs involve plication of the fibromuscular layer of the posterior vaginal wall and based on the initial level of dissection this tissue may be found on the anterior wall of the rectum or may have to be mobilised off the vaginal epithelium to allow an appropriate tension free plication. In patients with advanced prolapse and a widened genital hiatus the only way to address the gaping vagina is to routinely perform a distal levatorplasty. In the authors opinion future surgical studies assessing outcomes of prolapse repair involving the posterior vaginal wall should take into consideration these points, and realise that these procedures are not mutually exclusive and a combination of the techniques, especially in cases of advanced prolapse is commonly required. Other type of repairs that have been reported include transanal repairs, transperineal mesh (biologic or synthetic) augmented repairs, and abdominal sacral colpopexy in which the mesh attachment is extended down to the distal portion of the posterior vaginal wall and or perineum. The authors have also observed that aggressive reattachment of the uppermost portion of the full thickness of the posterior vaginal wall (level III support) to the uterosacral ligament provides significant support to the posterior vaginal wall in patients with high rectoceles or rectoceles in conjunction with a posterior enterocele.

3. MIDLINE PLICATION OR TRADITIONAL POSTERIOR COLPORRHAPHY

The mean reported anatomic success rates with this type of repair is 83% (range 76-96%) with mean post-operative dyspareunia rate of 18% (range 5-45%) and 26% using vaginal digitation to defecate. (Table 19)

4. SITE SPECIFIC DEFECT REPAIR

This technique is similar to traditional post repair in terms of dissection. The aim of the repair is for the surgeon to indentify and individually correct breaks in the rectovaginal septum. Tradition levatoroplasty is avoided. The mean anatomic success rate is 83% (range 56-100%) with 18% postoperatively needing vaginal digitation to defecate and 18% experiencing post-operative dyspareunia (Table 20).

Abramov et al retrospectively compared the midline fascial plication and discrete site specific repair for rectoceles [Abramov 2005]. They noted a significantly higher recurrence rate of rectoceles following the discrete site-specific repair (32%) as compared to 13% following the midline fascial plication [P=0.015]. The correction of the rectovaginal fascia defect that allows entrapment of feces on straining in significant rectoceles maybe too large to be repaired with the discrete approach [Kenton 1999] and appears to be corrected by the more robust midline fascial plication.

In a randomised control trial Paraiso et al compared three techniques for rectocele repair in a prospective randomized trial [Paraiso 2006]. Patients were randomized to receive either a traditional repair [N=37], a site specific repair [N=37] or a site-specific repair augmented with porcine small intestine mucosa [N=32]. All patients preoperatively had Stage II or greater posterior vaginal wall prolapse. The objective anatomic failure rate was highest in the graft augmented group [12 to 26] at 1 year which was statistically significantly worse than results in the site specific group [6 of 27] and traditional repair [4 of 28]. There was no significant difference in subjective symptoms (worsening prolapse or colorectal symptoms) or dyspareunia between the three groups.

Recently Sung et al reported on a double blind multicentre randomised control trial comparing native tissue repair [70] or native tissue porcine submucosal (SIS) graft [67] for symptomatic grade 2 rectocele [Sung 2012]. The native tissue repair involved either a midline plication or site specific repair with majority undergoing site-specific repair. In the graft group this repair was augmented with porcine SIS overlay. At one year there was no difference between the groups in objective and subjective success rates or in resolution of defecatory symptoms. Post operative dyspareunia rates were not significantly different at 7% in the native tissue group and 12.5% graft group.

In a single trial Vijaya (Abstract #52, ISC 2011 Glasgow) reported at 6 months follow up superior support of the posterior vaginal wall was attained after the fascial plication as compared to levator ani repair. Block randomisation was performed with 26 women randomised to each operation. Allocation concealment, power analysis, and status of reviewers was not reported. Anatomic outcomes were reported via POP-Q point AP and a variety of quality of life assessments were performed without reporting the data.

5. TRANSANAL REPAIR OF RECTOCELE

Three trials have evaluated transanal vs transvaginal repairs of rectoceles [Kahn MA 1999; Nieminen 2004; Farid 2010]. Each trial had slightly different inclusion criteria. Kahn included women who had symptoms of prolapse or impaired rectal evacuation with incomplete emptying on isotope defaecography and normal compliance on anorectal manometry [Kahn MA 1999]. Nieminen’s included women with symptomatic rectoceles not responding to conservative therapy. Importantly women with compromised anal sphincter function and other symptomatic genital prolapse were excluded. In both trials the vaginal repair was performed by gynaecologists and the transanal repair by colorectal surgeons. In Kahn’s trial the posterior vaginal wall repair was performed using levator plication and in Nieminen’s trial the rectovaginal fascia was plicated. Farid’s inclusion criteria required women to have a rectocele...
larger than 2 cm on defaecography with symptoms including digitation, incomplete evacuation, excessive straining and dyspareunia. Women with a compromised anal sphincter complex or recurrent prolapse, rectal prolapse, intussusception, or anal incontinence were excluded. The surgery was performed within the surgery department and blinded examiners utilised defecography, anal manometry, and a modified obstructed defaecation syndrome patient questionnaire to report outcomes.

Based on these three trials we can conclude that the results for transvaginal repair of rectocele are superior to transanal repair of rectocele, in terms of subjective and objective outcomes. In women with rectocele alone recurrent rectocele occurred in 2 out of 39 women in the vaginal group and 7 out of 48 following the transanal repair, a difference that did not reach statistical significance. Post-operative enterocoele was however significantly less common following vaginal surgery as compared to the transanal group.

Farid [Farid 2010] reported on outcomes of three types of rectocele repair comparing transperineal repair to levatorplasty to transanal repair and noted conclusions similar to the two previously discussed trials. The size of the rectocele on defecography was significantly smaller in the transperineal group (with or without levatorplasty) as compared to the transanal repair. Also functional outcome based on a modified obstruction defecation syndrome patient questionnaire was better after transperineal repair compared to transanal repair.

Puigdollers et al reported results from a prospective cohort of women with rectocele and constipation who underwent surgery via either endorectal or a transperineal approach based on surgeon preference [Puigdollers 2007]. At the end of one year the overall subjective improvement in constipation was reported in 43% [p<0.001] and the need to splint decreased in 52% [p=0.001].

Thornton et al [Thornton 2005] reported in a single non-randomised study outcomes for a cohort of women with symptomatic rectocele who were treated laparoscopically [N=40] vs transanally [N=40]. Level 2B evidence from this study supports the superiority of the transanal approach for symptom relief (55% vs 28%, p<0.02) but lower post-operative dyspareunia rates (22% vs 36%) with the laparoscopic approach.

van Dam et al [van Dam 2000] performed a combined transvaginal and transanal repair in 89 women who were evaluated at a follow up of 52 months. The anatomic success rate was 71% (defined as no persistent or recurrent rectocele on defaecography at 6 months). However de novo dyspareunia was reported in 41% of women and there was a deterioration of fecal maintenance in 7 patients.

6. GRAFT AUGMENTED RECTOCELE

Sand et al [Sand 2001] compared posterior repair with and without mesh and noted rectocele recurrence appeared equal with and without polyglactin (vicryl) mesh augmentation [7 out of 67 vs 6 out of 65]. Neither Paraiso et al or Sung et al noted any benefit to augmenting a native tissue repair with a porcine submucosal graft overlay [Paraiso 2006; Sung 2012]. Mesh exposure was not reported in these trials. Altman et al reported on a prospective evaluation of insertion of a 7x4cm porcine dermis graft at three years and found a 40% recurrence rate on examination and while there was a significant decrease in rectal emptying difficulties as compared to preoperatively less than 50% reported cure of rectal emptying issues [Altman 2006]. There was no change in the rate of anal incontinence or dyspareunia post-intervention.

7. MODIFIED SACROCOLPOPEXY

The abdominal route has been employed in the correction of posterior vaginal wall prolapse when a co-existing apical defect requires surgery. The technique is a modification of sacrocolpopexy with extension of the posterior mesh down to the distal posterior vaginal wall and or the perineal body. The procedure has been reported completely abdominally or as a combined abdominal and vaginal approach. Table 21 summarises a series of studies that have reported on extended posterior fixation of sacrocolpopexy mesh.

Summary

- Transvaginal Repair of Posterior Vaginal Wall prolapse continues to be reported as either a traditional repair with levatorplasty, midline fascial plication without levatorplasty or site-specific repair. Level one and two evidence suggest midline plication posterior repair without levatorplasty has superior objective outcomes as compared to site-specific posterior repair. (Grade B)
- Higher dyspareunia rate reported when levatorplasty is employed. (Grade C)
- Transvaginal approach is superior to the transanal approach for repair of posterior wall prolapse (Level 1 Grade A)
- To date no study has shown any benefit to mesh overlay or augmentation of a suture repair for posterior vaginal wall prolapse. (Grade B)
- While modified abdominal sacrocolpopexy results have been reported, data on how these results would compare to traditional transvaginal repair of posterior vaginal wall prolapse is lacking.
In women with stage II POP about 55% have concurrent stress urinary incontinence (SUI). This prevalence decreases with increasing POP stages to 33% in women with stage IV POP [Slieker-ten Hove 2009]. However, if the prolapse is reduced digitally or with the help of a pessary, sponge holder or speculum, SUI might be demonstrated in a further 10% to 80%. [Haessler 2005; Reena 2007; Sinha 2007; Ellstrom Engh 2010] This type of SUI is termed occult, masked or latent SUI and is present when stress urinary incontinence is only demonstrable with the prolapse reduced in otherwise continent women. The importance of this finding remains ambiguous [Visco 2008]; the test itself is not optimal [Visco 2008] as it does not necessarily mimic prolapse surgery and may obstruct or put undue tension on the urethra. Although different techniques to reduce the prolapse have been described, a gold-standard has not been established. [Visco 2008; Ellstrom Engh 2010] Neither the speculum nor the pessary test to reduce the prolapse had acceptable positive predictive values to identify women in need of a concomitant continence procedure. The negative predictive values however were 92.5% [95%CI 90.3–1.00] and 91.1% [95%CI 88.5–99.7], respectively. Therefore, women with negative tests for occult SUI preoperatively are at low risk of developing SUI postoperatively. [Ellstrom Engh 2010; Chuhtai 2011] Women with occult SUI are at risk of developing SUI after POP repair. Reducing the prolapse may also restore normal voiding function during urodynamics. [Romanzi 1999] These findings demonstrate the importance of testing bladder function in continent women with and without the prolapse reduced.

The Cochrane review on surgical management of POP found that new or denovo SUI symptoms were reported by 187 of 1280 women (15%) after prolapse surgery. [Maher 2010] The term de novo stress urinary incontinence is used to describe stress incontinence that develops following surgical correction of the prolapse, amongst women who were continent prior to surgery. De novo SUI might develop because POP surgery has uninked the previously obstructed urethra. [Kenton 2005; Mueller 2007] De novo stress urinary incontinence is clearly disappointing to women and this outcome measure is considered in this review.

A third of women with stage II or more POP experience difficulties emptying the bladder. [Slieker-ten Hove 2009] Voiding difficulties might disappear postoperatively because the obstruction caused by the prolapse has been corrected. [Romanzi 1999] In contrast, they might develop because of kinking of the urethra due the surgical technique.

This section of the chapter assesses the effect of POP surgery on bladder function including stress urinary incontinence, overactive bladder and voiding dysfunction. In order to optimally evaluate pre and postoperative bladder symptoms, only studies with standardised or validated pre and postoperative outcome measures, more than 20 operated women and a follow up time of at least 12 months are included and summarised in Table 22. The follow up time of 12 months does not apply to studies assessing voiding dysfunction. We will evaluate the evidence surrounding common clinical scenarios.

### 1. CONTINENT WOMEN UNDERGOING POP SURGERY. WHAT IS THE RISK OF DE NOVO SUI AND IS CONTINENCE SURGERY REQUIRED?

For symptomatically and clinically dry women an anterior native tissue repair yields lower rates of de novo SUI than transobturator anterior mesh procedures. The overall cumulative de novo SUI rate after anterior repairs is 9% [44/481]. In five RCT’s [Hiltunen 2007; Sivaslioglu 2008; Altman 2011; Sokol 2011; Withagen 2011] de novo SUI was found in 31/377 (8%) women and in 13/104 (12%) women in two prospective studies [Hung 2004; Ellstrom Engh 2010]. After armed-mesh repairs the overall cumulative rate is significantly higher at 14% [134/951; p=0.017, chi-square] with a rate of 17% [101/584] in six RCT [Hiltunen 2007; Sivaslioglu 2008; Halaska 2010; Altman 2011; Sokol 2011; Withagen 2011] and 9% [33/367] in eight prospective trials [Sentilhes 2007; Ek 2010; Fayyad 2010; Feiner 2010; Sergent 2010; Takahashi 2011; Kuribayashi 2011; Liang 2011].

Five RCT’s directly compared anterior colporrhaphy and transobturator mesh procedures [mesh kits or self-fashioned] and reported 12-months results [Hiltunen 2007; Sivaslioglu 2008; Altman 2011; Sokol 2011; Withagen 2011]. Anterior native tissue repair significantly reduced the risk of de novo SUI (RR

0.64 95%CI 0.42, 0.97; Figure 4). Although all these trials employed quality of life and symptom questionnaires, different instruments were used and meta-analysis was not able to be performed.

In a longer term follow up of Hiltunen ’s trial [Hiltunen 2007], subsequently more women developed new SUI after anterior repair resulting in similar SUI rates after three years of 17% after both anterior repair [15/86] and transobturator mesh procedure [15/84]. [Niemin0n 2010].

Similar rates of de novo SUI occurred if the anterior compartment prolapse was repaired using a polypropylene transobturator mesh 2% [2/96] or a porcine dermis graft 1% [1/94],[Natale 2009] In a single RCT de novo SUI was significantly more common after sacrospinous fixation and vaginal repairs compared with abdominal sacral colpopexy 8/24, 33% versus 2/22, 9% in a single RCT][Maher 2004], however, these data need to be reviewed cautiously as in the sacral colpopexy group continent women pre-operatively received paravaginal repairs which may be effective in limiting de novo SUI postoperatively.

In the large multicentre randomised controlled CARE trial (Colpopexy and urinary reduction efforts), preoperatively continent women were randomly allocated to undergo sacral colpopexy with [n=157] or without colposuspension [n=165]. Brubaker et al. demonstrated at 2 years that Burch colposuspension, performed concomitantly with an abdominal sacrocolpopexy significantly reduced the risk of de novo SUI. Subjective SUI was reported by 38/147 (26%) after additional Burch colposuspension and by 63/155 women (41%) after sacrocolpopexy alone. However, objective testing yielded similar findings in the two groups: 11/116 (9%) and 9/134 women (7%), respectively, demonstrated SUI. The study was terminated prematurely because of the high postoperative SUI rate in women who did not receive concomitant Burch colposuspension and as a result of early termination was underpowered. Unfortunately, irregularities in study design create uncertainty for the reader regarding the study findings. Firstly, different and complicated definitions were used to categorise stress continence prior to and after the interventions that made it more difficult to be classified as stress continent post intervention than prior to the intervention. Thirty-nine percent of women classified as stress continent prior to surgery would have been classified as stress incontinent using the post-intervention definition! Secondly, while surgery was standardised for colposuspension neither the paravaginal repair nor sacral colpopexy was standardised with significant variations in use of suture type and graft materials: in 17% biological grafts, in 43% Mersilene, in 39% polypropylene and in 6% Gore-tex utilised.[Brubaker 2006; Brubaker 2008] which may have impacted on the continent results.

After a follow up of 8 years, Costantini et al. in another smaller RCT reported contrary results with 9/31 women (29%) developing SUI after additional Burch colposuspension compared to 5/31 (16%) after sacrocolpopexy alone.[Costantini 2007; Costantini 2010]. Figure 5 summarises these two RCT’s in a meta-analysis.[Brubaker 2008; Costantini 2010] Because of contrary outcomes resulting in significant heterogeneity, a random-effects model was used. According to this model, women do not benefit from Burch colposuspension in addition to abdominal sacral colpopexy. This is true for subjective de novo SUI [RR 0.96 95%CI 0.35, 2.62] and objective rates of de novo SUI [RR 1.56 95%CI 0.82, 2.95].

2. POP SURGERY AND STRESS URINARY INCONTINENT WOMEN

In women with SUI undergoing prolapse surgery, what kind of prolapse procedure and which continence surgery is required concomitantly in order to reduce postoperative SUI rates? The cumulative success rate for SUI after anterior colporrhaphy in two randomised trial arms was 48% [19/40][Colombo 2000; Hvid 2010]. Colombo et al.[Colombo 2000] compared to Burch colposuspension and anterior repair for the treatment of women with anterior vaginal wall prolapse and SUI. While women benefited more from Burch colposuspension with regards to SUI [cure of SUI 30/35, 86% versus 17/33, 52%], anterior repair better corrected the anterior prolapse [cure of cystocele 23/35 versus 32/33].[Colombo 2000].

Prospective POP surgery studies employing transobturator mesh without additional continence surgery show a cumulative SUI success rate of 61% [81/132]

Figure 4. De novo SUI: Forrest plot of five RCT’s comparing anterior repair and transobturator mesh repairs.
Success rates improve considerably if a suburethral tape is performed concomitantly [cumulative rate 235/237, 99%]. [Hung 2004; Fayyad 2010; Feiner 2010; Takahashi 2010] Persisting or worsening SUI was described in 9/15 (60%) by Fayyad et al. [Fayyad 2010] who prospectively evaluated the role of transobturator polypropylene mesh without any concomitant surgery in the management of recurrent prolapse.

Whether a suburethral tape (TVT) is inserted concomitantly or after three months did not result in significantly different success rates based on an “on-treatment” analysis of Borstad et al. [83/87, 95% versus 47/53, 89% three months later]. [Borstad 2010] Twenty-seven/94 (29%) women were cured of SUI after prolapse surgery alone and did not receive a TVT three months later. [Borstad 2010].

Costantini et al. 2008 compared abdominal sacrocolpopexy or sacrohysteropexy with and without concomitant Burch colposuspension in women with POP and SUI. [Costantini 2008] Similarly to their randomised trial in continent women, Burch colposuspension increased the postoperative SUI rate: 13/24 (54%) versus 9/23 (39%) were incontinent. [Costantini 2008].

3. SHOULD WOMEN UNDERGOING POP SURGERY WITH OCCULT SUI IDENTIFIED PREOPERATIVELY UNDERGO CONTINENCE SURGERY AT TIME OF POP SURGERY?

Three randomised trials addressed this issue [Meschia 2004; Schierlitz 2007; Wei 2011] and found that after the addition of TVT to vaginal prolapse repairs (mainly anterior and posterior colporrhaphy) significantly fewer women complained of SUI [21/116, 18% versus 64/125, 51%]. The meta-analysis of these three trials calculated that a concomitant TVT reduced the risk of postoperative SUI significantly [RR 0.54, 95% CI 0.41, 0.72; Figure 6]. In two trials, including women who tested positive for SUI after the POP was reduced (occult SUI) [Meschia 2004; Schierlitz 2007], whereas in Wei et al. study (OPUS trial) only 34% demonstrated occult incontinence. [Wei 2011] However, they reported data separately for women with a positive stress test after reduction of the prolapse: 41/57 women without and 16/54 with an additional TVT were stress incontinent at three months follow up (Figure 6).

In a retrospective trial of 60 women who tested negative for occult SUI on preoperative urodynamic studies, 15 (25%) developed SUI after vaginal mesh surgery. [Kasturi 2011] However, 12% [7/60] had preoperative symptomatic SUI.

4. OVERACTIVE BLADDER (OAB) SYMPTOMS

OAB symptoms may be associated with POP. [Sliker-ten Hove 2009] Therefore, prolapse surgery may cure or improve OAB but it may also result in new OAB symptoms. The current Cochrane review on the surgical management of POP [Maher 2010; Maher 2011] calculated that new overactive bladder symptoms developed in 103/854 [12%] women in nine trials with various prolapse surgery. [Bump 1996; Colombo 1996; Colombo 1997; Maher 2004; Meschia 2004; Brubaker 2006; de Tayrac 2008; Natale 2008; Natale 2009] Whether women have been treated with anticholinergics e.g. postoperatively is not at all clear and numbers might in fact be higher. The cumulative rate of de novo OAB in women who underwent transobturator anterior mesh procedure...
is 7% [39/557]. [Sentilhes 2007; Moore 2009; Faddy 2010; Feiner 2010; Halaska 2010; Liang 2011] whereas it is 10% [7/71] in the few studies reporting data after anterior repair with or without suburethral tape.[Meschia 2004; Foster 2007] This difference is not statistically significant [p=0.4].

In a new RCT, Halaska et al. reported de novo overactive bladder in 7/97 (7%) after anterior Prolift, in 7/34 (21%) after anterior Prolift and sacrospinous fixation, in 8/84 (9%) after total Polypropylene mesh repair and in 1/98 (1%) after posterior Prolift only. [Halaska 2010] In another RCT, after vaginal sacrospinous fixation 6/29 women complained of OAB whereas after sacrocolpopexy 11/33 developed symptoms.[Maher 2004]. Sacrocolpopexy with or without Burch colposuspension resulted in similar rates of de novo OAB [3/34 versus 2/32].[Costantini 2007]. Similarly, after vaginal POP surgery with or without TVT OAB rates were not different [3/25 versus 1/25].[Meschia 2004].

In 22/48 (46%) of women with several different prolapse operations urgency incontinence resolved, whereas it persisted in 26/48 (54%) and developed de novo in 3 (12%).[Foster 2007].

5. VOIDING PROBLEMS

The Cochrane review noted new voiding dysfunction in 56/476 (12%) women in six randomised trials with various prolapse surgeries with or without continence procedures [Bump 1996; Colombo 1996; Colombo 1997; Maher 2004; Natale 2007; de Tayrac 2008]. However, variation in defining and reporting voiding problems makes meta-analysis is unfeasible.

After anterior repair, voiding dysfunction ranges from 0% to 37%.[Colombo 2000; Meschia 2004; Gandhi 2005; Meschia 2007; Stekking 2011; Withagen 2011]

In their RCT Withagen et al. described significantly different temporary urinary retention rates in 5/97 (5%) compared with 15/93 (16%) after transobturator mesh repair [p=0.008]. Normal micturition was restored in all women within 14 days. [Withagen 2011] Anterior repair with or without concomitant vaginal POP surgery resulted in postvoid residuals exceeding 150 ml in 27/126 (21%) in an RCT comparing transurethral and suprapubic catheterisation.[Stekker 2011]

After anterior mesh repair, voiding difficulties occur between 5% and 42%.[Maher 2004; Feiner 2010; Steinberg 2010; Withagen 2010; Feiner 2011; Maher 2011; Withagen 2011] One study looked at postoperative urinary retention defined as the need to discharge the patient with an indwelling catheter because of a failed trial of void.[Steinberg 2010] Voiding dysfunction ranged from 34% [10/29] after isolated anterior mesh repair to 42% [30/71] cases after combined anterior and posterior repairs. After isolated posterior repair 8/42 (19%) developed urinary retention. At the 3-months follow up, there were no more voiding complaints.[Steinberg 2010]

If there are postoperative voiding problems with residuals exceeding 150 ml, clean intermittent catheterisation is superior to an indwelling catheter for three days with regards to bacteriuria, urinary tract infection and length of required catheterisation according to one RCT [Hakvoort 2011] and intermittent transurethral catheterisation is equivalent to a suprapubic catheter regimen.[Stekker 2011] Insertion of a suprapubic catheter however resulted in more related complications including dislodgment or blockage of the catheter and haematuria.[Stekker 2011].

Another RCT [Huang 2010] reported on the duration of postoperative urethral catheterisation between two and four days after anterior repair and found no differences in voiding dysfunction. This was confirmed by an RCT comparing two and five days of routine postoperative indwelling catheter placement. Longer hospital stay and more urinary tract infections were associated with the five days protocol.[Weemhoff 2011] Patients do not seem to benefit from postoperative urethral catheterisation beyond two days.[Huang 2010; Weemhoff 2011].

Summary

Assessed trials were considerably heterogeneous regarding inclusion and exclusion criteria, clinical testing for stress urinary incontinence and operations performed. Also, the lack of separate reports of bladder symptoms account for a difficult interpretation of outcomes.

Continent women undergoing anterior compartment POP surgery have a lower rate of de novo SUI after anterior repair than armed mesh procedures. (Grade A)

Data are conflicting on whether colposuspension should be performed prophylactically in continent women undergoing sacral colpopexy. (Grade C)

In continent women undergoing POP surgery with occult SUI the addition of continence surgery reduces the rate of postoperative SUI (Grade A).

In women with POP and SUI prolapse procedures alone (transobturator mesh and anterior repair) are associated with low success rates for SUI. Concomitant continence procedures reduce the risk of postoperative SUI.

No clear conclusion can be made regarding the management of continent women undergoing POP surgery without occult SUI.

Preoperative bladder overactivity may resolve in 40% undergoing POP surgery and denovo bladder overactivity occurs 12%.

No valid conclusions regarding voiding dysfunction following POP surgery can be drawn from the available data.

Level 1 evidence demonstrates there is no need to leave an indwelling catheter beyond two days and a suprapubic catheter yields similar outcomes to clean intermittent self catheterisation however is associated with more complications.

IX. COMPLICATIONS AND METHODS OF PREVENTION

Pelvic reconstructive surgery for genital prolapse, with or without mesh, results in improved prolapse related symptoms and quality of life improvement in most of the cases [Jia 2008; Iglesia 2010; Maher 2010] (Level 1). While the use of non-absorbable synthetic mesh in the anterior compartment subjectively and objectively decreases the rate of anterior vaginal wall prolapse recurrence in comparison to native tissue repair Cochrane 2012 (Level 1) however, short term improvement of quality of life or reduced reoperation rates have yet to be demonstrated [Jia 2008; Iglesia 2010; Maher 2010; Altman 2011]. Furthermore, the use of non-absorbable synthetic mesh exposes patient to moderate to severe specific complications.

The first objective of this section is to report non specific and specific complications related to pelvic reconstructive surgery for genital prolapse with mesh, in comparison to surgery with no mesh. The second objective is to describe the recognised methods of prevention of these complications.

1. CLASSIFICATION OF COMPLICATIONS

Recently, the IUGA (International Urogynaecological Association) and the ICS (International Continence Society) have published a specific classification of complications related to pelvic reconstructive surgery [Haylen 2011]. That classification has been developed to be sensitive to all possible physical complications involving the use of a prosthesis or graft in a female pelvic floor surgical procedure. Both insertion complications (e.g. trocar related) and healing abnormalities are covered. Whilst this creates a large number of possible complication scenarios, appropriate organisation has still been possible by category (C), time (T) and site (S). A key advantage of a standardised classification is that all parties involved in female pelvic floor surgery will be referring to the same clinical issue. It is anticipated that in time this classification will significantly add to clarity in reporting mesh related complications.

2. REOPERATION AFTER VAGINAL MESH SURGERY

Table 23 shows the reoperation rates after vaginal mesh surgery for both non specific (linked to surgical dissection) and specific (linked to the mesh) complications. Only randomised trials have been used for analysis. Although meta-analysis shows a decreased rate of anatomical recurrences after mesh surgery, the total reoperation rate is increased after transvaginal mesh surgery (8.5%) as compared to surgical procedures using native controls.

### Table 23. Reoperation rates after Polypropylene and porcine dermis vaginal surgery from randomised control trials

* Different mesh weight, ** Different porcin dermis graft, *** Comparative studies anterior colporrhaphy vs mesh, or biologic graft vs synthetic mesh (procedures for de novo SUI were excluded), **** Procedures for vaginal exposition, infection or painful contraction† Comparative studies between two synthetic meshes or vaginal vs abdominal mesh

Abreviations: SUT, sub urethral tape; SBM, sub bladder mesh; PD, porcin dermis; CF, cadaver fascia; MD, missing data; GT, goretex; PE, polyester; PP, monofilament polypropylene; PPM, polypropylene multifilament; PPPE, polypropylene + polyester; PPS, monofilament polypropylene-dimethyl siloxane (silicone); PTFE, polytetrafluoroethylene.
3. REOPERATION AFTER ABDOMINAL SURGERY

Mean rates of reoperation for prolapse recurrence and for de novo stress urinary incontinence after open abdominal sacral colpopexy are 4% and 5%, respectively [Nygaard 2004; Culligan 2005; Elneil 2005; Handa 2007; Meschia 2007; Jeon 2009].

Table 16 demonstrates the total reoperation rate for laparoscopic sacrocolpopexy is 5.9%, with 2.9% representing complications and 1.7% representing reoperations for prolapse. [Agarwala 2007; Maher 2007; Sarlos 2008; Stepanian 2008; Deprest 2009; Granese 2009; Sabbagh 2010; Price 2011; Sergent 2011].

The rate of reoperation for recurrences after laparoscopic sacrocolpopexy is significantly higher with the use of porcine dermis grafts in comparison to polypropylene mesh [Deprest 2009] (Level 3).

Tijdink et al [Tijdink 2011] reported on the surgical management of 60 mesh complications following mesh prolapse surgery. Twelve followed sacral colpopexy and 48 vaginal mesh surgeries. Most women reported more than one complication however the principle presentation requiring surgical intervention was pain in 77% (vaginal pain, dyspareunia or other chronic pain buttock, abdomen or thighs). They detected a distinct difference in symptoms related to mesh complications following transvaginal mesh and ASC. Vaginal pain and dyspareunia were the most commonly reported symptoms necessitating surgical intervention following transvaginal mesh and vaginal discharge and bleeding following ASC. Previous mesh excision procedures had been performed in 29% and complete mesh excision was required in 37% of cases. Perioperative complications occurred more frequently in those requiring complete excision of mesh. Furthermore perioperative complications were more common in those who had undergone ASC as compared to vaginal mesh surgery (23% versus 1% p=0.001). Finally, recurrence of prolapse was significantly more likely if complete excision of the mesh was required and occurred in 29% as compared to 5% after partial excision of mesh. Resolution of preoperative symptoms was reported in 92% who underwent surgical management of mesh complications.

4. VAGINAL MESH EXPOSURE

It is difficult to know the exact rate of vaginal mesh exposure, as the definition of exposure is variable between studies and meshes used are different. Table 24 shows the rate of exposures after vaginal mesh surgeries in the current available randomised controlled trials. In these trials, the mean rate of exposure was 13.1% [Meschia 2007; Nguyen 2008; Sivaslioglu 2008; Natale 2009; Hvid 2010; Iglesia 2010; Lopes 2010; Nieminen 2010; Altman 2011; Maher 2011; Vollebregt 2011; Withagen 2011](Level 1).

Abreviations : RCT, randomised controlled trial; L, Level; SBM, sub bladder mesh; PD, porcine dermis; CF, cadaver fascia; MD, missing data; GT, goretex; PE, polyester; PP, monofilament polypropylene; PPM, polypropylene multilament; PPPE, polypropylene + polyester; PPS, monofilament polypropylene-dimethyl siloxane (silicone); PTFE, polytetrafluoroethylene.

95% CI for 13.1% [10.4-15.8] for PP and 0.9% [0-2.1] for PD

The mean rate of vaginal mesh exposure after open sacrocolpopexy was 3% [Nygaard 2004; Culligan 2005; Elneil 2005; Wu 2006; Handa 2007; Jeon 2009]. Table 16 shows the rate of exposures after laparoscopic sacrocolpopexy is 2.5% [Cosson 2002; Antiphon 2004; Gadonneix 2004; Maher 2004; Paraiso 2005; Ross 2005; Rozet 2005; Agarwala 2007; Rivoire 2007; Stepanian 2008; Sabbagh 2010; Price 2011; Sergent 2011] Paraiso(Level 2).
Maher et al, have shown a non significant increased rates of vaginal mesh exposure and reoperation for vaginal mesh exposure after vaginal mesh surgery in comparison to laparoscopic sacrocolpopexy (13% vs 2%, p=0.07 and 9% vs 2%, p=0.11, respectively) [Maher 2004] (Level 2). However, that was not the primary endpoint of the study, and that study was underpowered for this parameter.

5. VISCERAL (BLADDER, RECTUM) MESH EXPOSURE

There was no visceral mesh exposure reported in the randomised controlled trials after vaginal mesh surgeries, but follow-up were short [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Iglesia 2010; Nieminen 2010; Altman 2011]. Late bladder or ureteric and rectal exposure were reported after both sacrocolpopexy [Nicolson 2009; Paine 2010] and vaginal surgery [Huffaker 2009; Karateke 2010]. The rate of late visceral exposure after laparoscopic sacral colpopexy is between 0.5 and 1% [Sabagh 2010] (Level 4).

6. INFECTION, ABSCESS, CELLULITIS, SPONDYLODISCITIS

There is no clear definition of bacterial colonisation around a mesh or mesh infection. Consequently, the rate of infection is currently unknown [Jia 2010]. Some studies have reported up to 80% bacterial mesh colonisation [Boulanger 2008; Vollebregt 2009]. However, the rate of relevant clinical infection (abscess, cellulitis, spondylodiscitis) does not seem to be more than 1%, after both sacrocolpopexy (Level 4) [Akl 2009; Donnez 2009; Walid 2009; de Tayrac 2011], or vaginal mesh surgery (Level 4) [Chen 2009; Lewicky-Gaupp 2009].

In a cohort of 684 polypropylene mesh implanted vaginally (TVM procedure), the rates of pelvic abscess and cellulitis have been reported to occur in only 0.29% and 0.15%, respectively [Caquant 2008] (Level 4).

7. PAINFUL MESH CONTRACTION

Feiner et al defined mesh contraction as an adverse outcome following armed polypropylene mesh repair in which patients experience vaginal pain with movement and dyspareunia and on examination have localised areas of prominent, tense and tender mesh under the vaginal epithelium [Feiner 2010]. They reported a case series of 17 painful meshes and in that series, 90% of the patients have been improved by a reoperation for partial mesh removal, however in three patients a second reoperation with wider excision of the mesh was required. The rate of polypropylene mesh-related pain reported ranged between 4 and 11% according to the definition used (Level 3) [Caquant 2008; Nguyen 2008; Sivaslioglu 2008; Lunardelli 2009; Feiner 2010; Iglesia 2010; Lopes 2010; Moore 2010; Nieminen 2010; Withagen 2011].

Maher et al have reported a rate of reoperation for mesh contraction significantly greater after vaginal mesh surgery than after laparoscopic sacrocolpopexy (7% vs 0%, p=0.05) [Maher 2004] (Level 2). Ridgeway et al [Ridgeway 2008] reported a cases series of 19 polypropylene mesh complications that underwent a variety of vaginal and abdominal procedures to partially remove mesh. Six underwent excision for severe pain and one had residual pain following partial excision.

In the 2011 American FDA report regarding transvaginal mesh, vaginal pain and dyspareunia

were the most common adverse event reported and vaginal pain and dyspareunia were also the most common indications for reoperation following transvaginal mesh in the report by Tijdink et al. [Tijdink 2011] These reports contrast with the common perception in the literature that mesh exposure is the commonest complication associated with transvaginal meshes and requires ongoing evaluation.

8. OTHER COMPLICATIONS

Other rare but severe complications have been described after mesh surgery, such as massive haemorrhage after a trans-obturator mesh procedure, major vessel injury during sacrocolpopexy, trocar hernia, bowel obstruction, ureteric complications, thrombo-embolism.

9. METHODS OF PREVENTION

a) Influence of non specific factors on mesh-related complications (obesity, smoking, age, sexual activity)

Concerning vaginal mesh surgery, obesity (BMI>30 kg/m², OR=10.1) and smoking (OR=3.7) are independent risk factors for mesh exposure [Araco 2009] (Level 3). With regard to sacrocolpopexy, smoking (OR=5.2 ; IC95% 1.7-16) is also an independent risk factor for vaginal mesh exposure [Cundiff 2008] (Level 3). Although there is no specific study in prolapse surgery, to demonstrate the cessation of smoking prior to surgery will decrease the post-operative complication rate (healing problems) in many other surgical specialties these data exist (Level 2).

Current data on the impact of aging on mesh complications are conflicting and no conclusion can be drawn. [de Tairac 2006; Cundiff 2008; Araco 2009; Ganj 2009; Nosti 2009; Kaufman 2011].

Sexual activity has been reported to be a risk factor for vaginal mesh exposure after vaginal mesh surgery [Letouzey 2010; Kaufman 2011] (Level 3) however this could simply reflect that those who are sexually active are more likely to identify a mesh exposure than those who are not.

No study has shown that the following are significantly associated with mesh exposure: diabetes mellitus, corticosteroid use, immunosuppressive therapy, previous pelvic irradiation, history of previous mesh exposure, vaginal atrophy. However, many studies have shown in other surgical specialties that poorly controlled diabetes mellitus is a risk factor for post-operative infection.

b) Oestrogen therapy

Although some authors report routine use of local oestrogen therapy for the pre and post-operative course of prolapse surgery in post-menopausal women [Altman 2011], others did not give any details on such prescription, and there is no comparative study. In multivariate analysis, local oestrogen therapy has no protective effect of vaginal erosion, after vaginal mesh surgery [Guillibellet 2009] (Level 3), or after sacrocolpopexy [Kohli 1998] (Level 4).

c) Antibiotic prophylaxis

There is not specific study on the use of antibiotic prophylaxis at the time of mesh reconstructive surgery for prolapse. However, most of studies report their use during surgery [Withagen 2011] [Hiltunen 2007; Carey 2009].

There are no data on the need to identify a urinary tract infection in the preoperative course, nor to perform a vaginal bacteriological test or to use antisepctic or antibiotic meshes.

Prolonged post-operative bladder catheterisation increases the risk of lower urinary tract infection. [Liang 2009].

d) Mesh implantation and visceral injury

Although there is no comparative study, most of authors would consider the use of mesh after a rectal injury during dissection as a contraindication to mesh insertion, due to a perceived higher risk of mesh infection and subsequent recto-vaginal fistula [Jacquetin 2010] (Level 4).

In the anterior compartment, a small series of five cases of recognised intra-operative bladder injury (out of 704 Trans-Vaginal Mesh procedures) has shown that mesh surgery was feasible without subsequent complications after appropriate bladder repair [Popovic 2007] (Level 4). These data are limited and further evaluation is required.

e) Surgeon training

Regarding sacral colpopexy, a learning curve has been shown, with a reduction of operative time and laparoverconversion over the first 80 procedures [Claeirhout 2009] (Level 3). However, the incidence of severe complications does not seem to be related to the learning curve [Claerhout 2009] [Akladios 2010].

The data regarding the impact of the learning curve for transvaginal meshes on the incidence of post-operative complications is conflicting. Some authors have reported that learning has a significant effect on the complication rate [Dwyer 2004] while others did not [Fatton 2007] [Sentilhes 2007] (Level 3).

10. VAGINAL MESH SURGERY

a) Choose the right mesh for vaginal surgery

For vaginal mesh surgery, the use of non-absorbable synthetic meshes was associated with a reduced rate of short-term recurrences in comparison to the use of absorbable biological or synthetic meshes, for both primary and recurrent cases [Jia 2008] [Iglesia 2010] [Maher 2010] [Altman 2011] [Withagen 2011] [Nieminen 2010] [Natale 2009] (Level 1). Contrarily, the use of
absorbable biological or synthetic meshes is associated with a lower risk of vaginal mesh exposure and re-operation in comparison to non-absorbable synthetic meshes [Jia 2008] [Natale 2009] (Level 1).

Concerning the type of non-absorbable synthetic mesh, the use of polyester is associated with an increased risk of vaginal exposure in comparison to polypropylene [33.3% vs 8.8%, p<0.03] [Sentilhes 2008] (Level 4). Furthermore, the use of multifilament polypropylene is associated with an increased risk of vaginal exposure than monofilament polypropylene [Sentilhes 2008] [Deffieux 2009] (Level 4), and the use of microporous monofilament polypropylene is associated with an increased risk of vaginal exposure than macroporous monofilament polypropylene [Baessler 2005] [Guillibert 2009] (Level 4). Composite polypropylene/polyglactin meshes do not seem to reduce the vaginal exposure rate [7.2% vs 6.9%, p=0.4] [Achtari 2005] (Level 4). Finally, lower-weight meshes, titanium or collagen-coated meshed have currently shown a significant reduction rate of vaginal mesh exposure rates [de Tayrac 2007; Deffieux 2007; Milani 2008; Cervigni 2011] [Sergent 2011] (Level 4). However, comparative studies would be necessary to compared new ultra-light-weight or composite to existing meshes.

b) Interest in mesh kits

The rate of intra-operative complications does not seem to be reduced by the use of a mesh kit rather than a self-prepared mesh [Caquant 2008] (Level 4). However, the rate of vaginal mesh exposure was shown to be reduced by the use of the same mesh in a kit format (4.5% versus 11%, p=0.048), in a retrospective study where the same surgeons had the experience of the technique with the self-prepared mesh before to use the kit [Caquant 2008] (Level 4).

Only one small randomised controlled trial has compared commercial transvaginal mesh kits to self styled mesh, however the techniques used where different (the kit only was trans-obturator) [Finamore 2010] (Level 2).

c) Concomitant hysterectomy

Several studies have shown an increased rate or vaginal mesh exposure with concomitant vaginal hysterectomy [Ganj 2009] [Guillibert 2009] [de Tayrac 2007] [Cervigni 2011] [Collinet 2006] [Lowman 2008], while others did not find any differences [Deffieux 2007] [Sentilhes 2008] [Achtari 2005] Table 25. Meta-analysis demonstrates demonstrates that the addition of hysterectomy to a transvaginal mesh surgery significantly (p<0.001) increases the risk of mesh exposure from 7.3% (98% CI 4.1 to 9.6) without hysterectomy as compared to 19.2% [98% CI 15.8 to 22.7] with hysterectomy.

d) Surgical incision

Although some authors recommend avoiding sagittal or inverted T colpotomy and trimming of excessive vaginal epithelium in order to reduce the rate of vaginal mesh exposure [Fatton 2007], this has not been evaluated by other authors.

11. ABDOMINAL SACROCLOPOPEXY

a) Choice of surgical route for sacrocolpopexy

Laparoscopic sacrocolpopexy is as efficient as open abdominal sacrocolpopexy, with a reduced rate of intra-operative bleeding, hospitalisation and wound complications [Paraiso 2005] [Klauschie 2009] [Hsiao 2007] (Level 3).

The risk of vaginal mesh exposure is higher if the mesh is sutured vaginally during sacrocolpopexy [Higgs 2005] [Visco 2001; Tan-Kim 2011] (Level 4).

Although the feasibility of robotic-assisted and single-port sacrocolpopexy have been demonstrated there is currently not enough evidence to determine if these interventions will have an impact on complication rates.[Xylinas 2010; Paraiso 2011].

b) Choose the right mesh for abdominal surgery

In a retrospective comparative study of open abdominal sacrocolpopexy, Quiroz et al have shown that the short-term mesh-related complication rate was significantly higher with polypropylene than with porcine dermis [24/102 vs 12/134, p=0.003] [Quiroz 2008] (Level 3), however the prolapse recurrence rate using porcine dermis was higher [7/93 vs 0/105, p = 0.004]. Another study comparing fascia lata and polypropylene meshes with 5-year review, has shown a long-term increased recurrence rate, but

</table>
with no differences in the rate of complication (Tate) (Level 2). Concerning laparoscopic sacrocolpopexy, in a prospective comparative non randomised study, Deprest et al have shown that recurrences at the level of anterior and apical compartment occur significantly more often when using a biograft, in comparison to polypropylene [21% vs 3%, p<0.01 and 36% vs 19%, p <0.05, respectively] [Deprest 2009] [Level 3]. Partially absorbable composite meshes (polyglactin + polypropylene) also seems to increase the risk of short-term recurrences [Granese 2009] (Level 4).

The risk of vaginal mesh exposure seems to be higher with the use of polytetrafluoroethylene than with polypropylene meshes at ASC If you are going to abbreviate you must do it throughout or not at all [15% vs 0%, p=0.03] [Jeon 2009] (Level 4) and 19% vs 5% [Cundiff 2008] (Level 2). Similar results were observed with the use of silicon-coated polyester (19% vs 0%, p<0.05) [Govier 2005] (Level 4).

d) Choose the right fixation to the promontory, vaginal wall and levator ani

Most of authors perform a direct fixation to the vaginal wall using absorbable or non-absorbable sutures, and to the promontory using non-absorbable sutures [Agarwala 2007] [Rozet 2005] [Ross 2005] [Gadonneix 2004] [Antiphon 2004]. Fewer authors use staples for the mesh fixation, both to the vaginal wall and to the levator ani muscle [Cheret 2001] [Claerhout 2009], or tackers to the promontory [Maher 2004], with no specific reported complications. Several cases of spondylodiscitis were reported after the use of tackers to the promontory [Cosson 2001] however this complication also occurs if sutures are utilised. [Sergent 2011] [Rivoire 2007] [Ross 2005] [Antiphon 2004]. Whatever the fixation material use for the vaginal wall, the main method to prevent the occurrence of vaginal mesh exposure seems to avoid breaching the vaginal epithelium. [Paraiso 2005] [Cheret 2001] (Level 4).

d) Concomitant hysterectomy

The risk of vaginal mesh exposure is significantly increased in cases of sacrocolpopexy associated with concomitant total hysterectomy (8.6%), in comparison to 2.2% in those with previous hysterectomy [Wu 2006] [Stepanian 2008] [Cundiff 2008] [Nosti 2009] [Quiroz 2008] (Level 4), 1.5% at sacral hysteropexy and 1.7% subtotal hysterectomy [Jeon 2009] [Costantini 2005] [Bensinger 2005] (Level 4) (Table 8 and10 ).

12. PERITONEAL CLOSURE

Most of authors close the peritoneum after a sacrocolpopexy, both after open [Culligan 2005] [Wu 2006] [Stepanian 2008] [Maher 2004; Brubaker 2006] or laparoscopic approach [Maher 2011] [Rivoire 2007] [Rozet 2005] [Antiphon 2004].

13. TREATMENT OF VAGINAL MESH EXPOSURE

Vaginal mesh exposure, both after vaginal mesh surgery or sacrocolpopexy is usually associated with vaginal discharge, and sometimes pain, dyspareunia, vaginal infection, and rarely abscess or cellulitis [Deffieux 2007] [Costantini 2011] (Level 3).

The choice of treatment has to take into account the type of mesh implanted (need to obtain previous surgical records), clinical symptoms, location and size of exposure.

All cases with abscess or cellulitis need an immediate reoperation to withdraw the maximum (if possible) of the foreign material. In cases of mesh exposure after vaginal mesh surgery, if there is no abscess or cellulitis, medical treatment is usually undertaken using local oestrogens and/or local antiseptic. However, medical treatment efficacy is low at 23.5% as seen Table 26. [Withagen 2011] [Feiner 2010] [Moore 2010] [Achtari 2005] [Cervigni 2011] [Collinet 2006] After failure of medical treatment, a reoperation under local or general anesthesia is generally performed, in order to remove the exposed portion of the mesh and to close the vaginal epithelium.

In cases of mesh exposure after sacrocolpopexy, most of authors report a reoperation by the vaginal approach as first line [Wu 2006] [Stepanian 2008] [Claerhout 2009] [Kohli 1998] [Bensinger 2005] [Begley 2005], because of the risk of spondylodiscitis and of the very low success rate of medical treatment (<15%) [Price 2011] [Stepanian 2008] [Cundiff

Abbreviation: PP, polypropylene
When recurrence occurs after vaginal mesh excision, or in case of associated pelvic infection, total mesh removal by laparoscopy or laparotomy has been described [Quiroz 2008] (Level 4).

**Conclusion**

The use of mesh for pelvic reconstructive surgery is associated with a risk of specific complications, whatever the surgical approach and whatever type of mesh (Level 1).

Preoperatively, patients must be informed of these risks and give their consent for the use of a mesh. Patients must also be informed of conservative and alternative surgical techniques.

**PROPOSED RECOMMENDATIONS TO REDUCE THE RATE OF COMPLICATIONS**

**Grade A**

Transvaginal mesh have a higher re-operation rate than native tissue vaginal repairs. (grade A)

**Grade B**

*Concerning Vaginal Surgery:*

- If a synthetic mesh is placed by the vaginal route, it is recommended that a macroporous polypropylene monofilament mesh should be used.
- Polyester mesh is not recommended.

*Concerning Sacral Colpopexy:*

- It is recommended that the mesh should not be introduced or sutured by vaginal route when a sacral colpopexy is performed.
- The use of silicone-coated polyester, porcine dermis, fascia lata, and polytetrafluoroethylene meshes is not recommended.
- It is recommended to avoid total hysterectomy

**Grade C**

*Whatever the Surgical Route:*

- There is no evidence to recommend routine local or systemic oestrogen therapy before or after prolapse surgery using mesh.
- The first cases should be undertaken with the guidance of an experienced surgeon in the relevant technique.

*Concerning Sacrocolpopexy:*

- Laparoscopic approach is recommended for sacral colpopexy
- The use of polyester (without silicone coating) or polypropylene meshes is recommended.

**X. PELVIC ORGAN PROLAPSE AND SEXUAL FUNCTION**

Sexual health is an essential component of a woman's well-being. Female sexual dysfunction is defined as a sexual desire, sexual arousal, orgasm and/or sexual pain disorder which causes personal distress [Basson 2000]. Up to 64% of sexually active women attending a Urogynecology clinic suffer from female sexual dysfunction [Pauls 2006]. The data on sexual function after prolapse surgery are conflicting although in most cases sexual function will improve or remain the same.

Apart from anatomical outcome, clinicians increasingly understand the importance of functional data after POP surgery. To measure sexual function, validated questionnaires on sexual function...
are necessary. Some validated quality of life and symptom questionnaires are inclusive of sexual function [Baessler 2010] or there are dedicated questionnaires specific to sexual function that provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ)[Rogers 2001] and the Female Sexual Function Index (FSFI) [Rosen 2000] are two questionnaires frequently used.

**1. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITHOUT MESH**

Overall, sexual function improves after prolapse surgery without mesh [Ghielmetti 2006; Rogers 2006; Komesu 2007]. In two randomized controlled trials, sexual function was measured after sacrospinous hysteropexy and vaginal hysterectomy. No differences were found between the two groups [Jeng 2005; Dietz 2010]. No validated questionnaires were used.

**2. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITH MESH**

Increasing data on sexual function after mesh repair are becoming available. Excellent randomised controlled trials on efficacy of mesh prolapse surgery have been published and while most have not utilised validated questionnaires regarding sexual function most do include data on dyspareunia. Data from level 1 studies comparing transvaginal mesh and native tissue repairs are summarised in Table 27. When comparing sexual function in the anterior compartment with or without mesh, no differences in de novo dyspareunia, post-operative dyspareunia or PISQ scores were found [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Nieminen 2010; Altman 2011; Milani 2011; Vollebregt 2011]. Most women improved or remained the same. In one study by Vollebregt [Vollebregt 2011], baseline dyspareunia disappeared more often after anterior colporrhaphy than after mesh implant [80% vs 20%, p=0.018]. Natale et al showed that the use of Porcine dermis graft (Pelvicol), compared to polypropylene mesh (Gynemesh) in the anterior compartment, was associated with an improvement in the PISQ scores [Natale 2009]. Possibly, porcine dermis allows more flexibility to the anterior wall resulting is less pain, however this requires further evaluation.

In the posterior compartment, fewer RCT’s have been performed comparing native tissue repairs to mesh repairs. Paraiso et al compared three techniques (posterior colporrhaphy, site-specific repair and use of porcine small intestine sub mucosa) [Paraiso 2006]. No differences in sexual outcome were found between the groups and PISQ scores improved after surgery in all three groups. Trials which analysed anterior and posterior mesh together also reported no differences in sexual outcome between native tissue and mesh repairs [Iglesia 2010; Milani 2011; Withagen 2011]. Overall, after mesh surgery in the anterior and/or posterior compartment, de novo dyspareunia ranged from 5-28% of women [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Vollebregt 2011; Withagen 2011]. Data on the apical compartment using mesh showed less dyspareunia after abdominal sacral colpopexy as compared to vaginal sacrospinous colpopexy [Benson 1996; Maher 2004; Maher 2010].

Meta-analyses from all RCT comparing transvaginal mesh and native tissue repairs shown in Table 25 demonstrated no difference in the rate of de novo dyspareunia (mesh 10.6% versus 11.8% native tissue),

</table>
post-operative dyspareunia (14.4% versus 12.5%), and PISQ scores (WMD 0.09 95% CI -0.17 to 0.36).

Although data from RCT’s is valuable, sexual function was a secondary outcome measurement and most studies are underpowered to detect differences in sexual function. Therefore, reports from Level 3 cohort studies on the use of mesh were evaluated. The rate of de novo dyspareunia after anterior and/or posterior mesh in these cohort studies was comparable to the RCT’s mentioned before and varied between 21-43% (Table 28) [Fayyad 2011; Milani 2011]. Milani et al stated that mesh should be abandoned because of high scores on dyspareunia [20% more dyspareunia after anterior mesh and 63% more dyspareunia after posterior mesh] (Milani 2005). However, when measuring sexual function with questionnaires, the impact of transvaginal meshes was variable with some demonstrating poorer sexual outcomes [Altman 2009; Su 2009; Wetta 2009] [lower PISQ scores] and some improved outcomes or no change following surgery. [Moore; Sentilhes; Milani 2011; Sayer 2011]. Altman et al showed lower scores on sexual function one year after mesh surgery (anterior repair and posterior repair), however this was related to behavioral-emotional function and partner related items, not to physical function [Altman 2009].

Pain and dyspareunia before surgery with mesh was a risk factor for pain and dyspareunia after mesh surgery [Withagen 2011]. There is some evidence that light meshes, partly absorbable meshed or non anchored meshes have less negative side effects on sexual function, however comparative studies or RCT’s on this subject have not been performed [de Tayrac 2007; Zyczynski 2010; Milani 2011].

**Recommendations**

**Grade B**

With regard to the anterior compartment, the use of mesh is neither associated with a worsening in sexual function nor with an increase of de novo dyspareunia compared to traditional anterior colporrhaphy.

**Grade D**

There is insufficient information to provide evidence based recommendation on sexual function after vaginal mesh in the posterior compartment.

There is insufficient information to provide evidence based recommendation on sexual function after new light of partially absorbable vaginal meshes.

It is essential to use validated questionnaires measuring sexual function in women before and after prolapse surgery. We also recommend reporting sexual activity and dyspareunia rates pre and post intervention in all patients.

---

XI. ECONOMIC EVALUATION

Vaginal prolapse is an increasingly common problem affecting approximately 3-6% [Bradley 2008; Lawrence 2008] of community dwelling American women and the lifetime risk of surgery for pelvic organ prolapse varies between 6-19%. [Olsen 1997; Smith 2010] The need for pelvic organ prolapse surgery increases with age and it has been conservatively estimated that the surgical workload related to pelvic organ prolapse will increase by 46% over the next 4 decades as our population ages [Wu 2009]. Despite the high prevalence and frequency of surgery for POP, there is little information on costs of medical care for this condition. A study in the United States (US) estimated that the direct costs of POP surgery were substantial accounting for $1012 million (95% confidence interval $775, 1251 million) for a total of 226,000 in patient surgical procedures during 1997[Subak 2001].

A European study showed that the number (rate) of admissions for POP surgery was 36,854/1000 women in Germany, 36,679/1000 women in France, and 28,959/1000 women in England during the year 2005[Subramanian 2009]. The total costs were €144,236,557, €83,067,825, and €81,030,907 in Germany, France and England respectively which are also considered to be substantial and required more attention in order to decrease the burden on the countries studied.

Traditionally a Gynaecologists have based their decisions on surgical interventions upon the success rate, patient satisfaction, peri-operative morbidity and complications. With rising health care cost and in a setting of finite resources it is now imperative that clinicians include the financial costs of surgical interventions as a vital part of our decision making process. Despite considerable consumable costs there is a scarcity of cost effectiveness data on pelvic organ prolapse surgery.

Hullfish designed a study to compare the relative cost effectiveness of treatment decision alternatives for post-hysterectomy POP[Hullfish 2011]. The authors used a Markov decision analysis model to assess and compare the relative cost effectiveness of expectant management, use of a ring pessary, and Vaginal Reconstructive Surgery (VRS) and open or robotic sacral colpopexy for obtaining months of quality adjusted life over 1 year. Laparoscopy for prolapse and vaginal mesh kits were excluded as the authors do not utilise those two procedures at their institution and colpoplesis was excluded as the baseline case desired preservation of coital function. Only two decision alternatives were found to be cost-effective: pessary use and VRS. Pessary use achieved 10.4 quality-adjusted months at a cost of $10,000 per patient. This cost includes all events for patients initially assigned to pessary use including costs for those patients who eventually underwent to surgery within the 12-month time frame. The VRS alternative obtained 11.4 quality-adjusted months, at $15,000 per patient. Each of the other alternatives achieved fewer quality-adjusted months at greater cost.

Abdominal sacral colpopexy (ASC), in rudimentary analysis of inpatient cost has been shown to be more expensive than vaginal sacrospinous colpopexy for vault prolapse mainly reflecting the longer operating time and inpatient stay for the ASC. Two cost-minimisation studies have evaluated the relative inpatient cost of robotic sacral colpopexy (RSC), laparoscopic sacral colpopexy (LSC) and ASC [Patel 2009; Judd 2010] with both finding the ASC was the least costly inpatient option. Patel reviewed 15 cases, 5 each of ASC, LSC and RSC performed in Connecticut USA in 2008 [Patel 2009]. Results showed that ASC was the least expensive at $13,149, LSC $19.308 and RSC most expensive at $24,161. Importantly in this model there were no differences in length of stay and all procedures had long operating time with the robotic procedure being over 2 hours quicker than the laparoscopic procedures which does not reflect common practice in the literature.

Judd et al, using a decision model, estimated the hospital cost of ASC at $5792, LSC at $7353 and RSC at $8508 (excluding the cost of the robotic system)[Judd 2010]. In this model, RSC and LSC became cost equivalent only when robotic operating times was reduced to 149 minutes, robotic disposables were reduced to $2132 or laparoscopic disposables were increased to $3413. Both models of analysis only included inpatient care and may not reflect other benefits of minimally invasive approach such as quicker recovery and possibly faster return to work.

As already reported in the apical prolapse section of this document Parasio et al [Parasio 2011] performed a RCT comparing RSC [38] and LSC [40] for vault prolapse and reported cost analysis alongside the clinical outcomes which the authors of this document would prefer to see as the standard reporting requirements. The robotic group incurred significantly greater cost than the laparoscopic group [mean difference $1,936; 95% CI $417-$3,454; P=.008]. Importantly in this study the authors were experienced laparoscopic surgeons who had also completed the learning phase of the RSC.

Over the last decade both clinical efficacy and cost efficiency of the suburethral tapes in continence surgery has been demonstrated. Transvaginal mesh kits have been introduced to prolapse surgery in an attempt to replicate this benefit for the community. Unfortunately a paucity of cost analysis data is available for review. A study on the analysis of the cost-effectiveness of tradition-
al anterior colporrhaphy (AC), non kit mesh and commercial mesh kit for anterior vaginal prolapse repair showed that commercial mesh kits are not cost effective [Murray 2011]. The authors included estimated cost of managing recurrent prolapse and extrusions in the analytic model after performing a meta-analysis of 18 papers relating to anterior compartment repair to determine operating and admission time, recurrence rate and mesh extrusion rate for the three groups. The cost of non kit mesh was $3,380, AC was $3,461 and mesh kit $4,678. Non kit mesh repair is cost-effective, compared with AC, if extrusion rates remain below 25%. One way cost sensitivity analysis demonstrates that when the reoperation rate for AC reached 28% the commercial mesh kits became cost effective. The balance of cost of AC and non-mesh kits depends significantly on recurrence and extrusion rates. Two-way cost sensitivity analysis demonstrated that if re-operation rate of AC is below 20%, AC is more cost effective even if extrusion rate is 0%. When reoperation rate of AC is 30% the non-mesh kit repair is the most effective option if the extrusion rate is less than 25%. Recently, Maher et al reported a cost minimisation analysis of a RCT comparing total vaginal mesh [TVM n=55] and LSC [n=53] in the management of vault prolapse at 2 years[Maher 2011]. The clinical outcomes have been reported in this document previously. Similarly to Hull-fish’s model above the authors captured inpatient, consumable and direct reoperation cost within the two year period. Opportunity cost defined as economic cost to the women associated with recovery time were added to above cost to define total economic cost. Mean total economic costs were significantly lower in the LSC group as compared to the TVM ($4,013.07 95% CI 3107.77, 4918.37). Labour costs were significantly greater for the LSC reflecting that the operating time was twice as long as compared to the TVM procedure. These higher labour costs were offset by lower consumable, inpatient, opportunity? and reoperation costs for the LSC as compared to the TVM.

One way cost analysis for the LSC and TVM demonstrates that cost equivalence would be achieved once the consumable cost reduced to zero, or the reoperation rate was zero in the TVM group or the operating time in the LSC was 130 minutes longer than the TVM. The cost model reported by Maher et al would provide an excellent model that all clinicians could utilise in audit and authors when reporting prolapse outcomes, by simply substituting their own institutions and community cost. The reporting of such cost analysis data is urgently required so that we can deliver efficient and cost effective pelvic organ prolapse procedures that our community requires.

Conclusion

In conclusion, despite the high prevalence and frequency of surgery for POP, there is little information relating to cost. Our findings can be summarised as:

- Economic cost of POP surgeries annually is significant in United States and Europe and over the next decades will grow at twice the rate of population growth due to our aging population
- Programs aimed at reducing the burden of this disease are urgently needed.
- In a single institution study vaginal reconstructive surgery and pessary use were more cost-effective than expectant management, traditional abdominal sacral colpopexy (ASC) or robot-assisted sacral colpopexy (RSC) (Grade C).
- Two studies have demonstrated that ASC has lower inpatient cost than LSC or RSC (Grade C)
- Data from a single RCT demonstrated the LSC to have lower inpatient cost than RSC specifically relating to lower operating time in the LSC group (Grade B)
- Data from a single RCT demonstrated LSC to be a more effective cost minimising surgery than total vaginal mesh for vaginal vault prolapse.(Grade B)
- Data from a meta-analysis of anterior vaginal compartment prolapse operations demonstrated that commercial mesh kits for anterior repair are less cost-effective than non kit mesh and anterior colporrhaphy. (Grade B)

X. ALGORITHM

REFERENCES
I. INTRODUCTION

The definitions of anal incontinence and faecal incontinence, adopted at the previous consultations, [1] are maintained:

“Anal incontinence is the involuntary loss of flatus, liquid or solid stool that is a social or hygienic problem.”

“Faecal incontinence is the involuntary loss of liquid or solid stool that is a social or hygienic problem.”

There is no consensus on the best definition, anal incontinence or faecal incontinence, to use for an outcome in treatment trials or evidence to guide when one may be more appropriate; this impacts comparison and evaluation of study findings because different criteria for successful outcomes have been employed. The committee recommends that whichever outcome is used in studies and publications, the conceptual and operational definition be made explicit and used in a consistent manner. The terms anal incontinence and faecal incontinence are not synonymous. As the majority of intervention studies have focused on faecal incontinence rather than anal incontinence as an outcome measure, faecal incontinence is covered in this chapter, except where anal incontinence is specified.

This chapter addresses assessment and diagnosis, and conservative management, including medications, of faecal incontinence in adults and the impact of faecal incontinence on quality of life as assessed by qualitative methods. New to this chapter are the topics of faecal incontinence assessment and quality of life. The following related topics, some of which may have appeared in this chapter previously, are reviewed by other committees, often together with their urinary incontinence counterpart: epidemiology of faecal incontinence (Committee 1), faecal incontinence in frail or institutionalized older adults (Committee 11), faecal incontinence in persons with neurological disease or injury (Committee 10), faecal incontinence in children (Committee 9), surgical management of faecal incontinence (Committee 17), faecal incontinence management using technologies (e.g., products and devices) (Committee 20), and quality of life and faecal incontinence severity as measured by quantitative instruments of patient reported outcomes (Committee 5B), primary prevention of faecal incontinence (Committee 21). The one study of primary prevention of faecal incontinence (avoiding or delaying the initial occurrence) using conservative therapies [2] is included in this chapter.

As some knowledge gained in these specific groups may have applications to an adult population, the interested reader is encouraged to review the work of those committees. There is at present a relatively limited evidence base from high quality experimental trials of faecal incontinence, and it remains challenging to provide strong evidence for most interventions. However, expert consensus in this committee and the world literature is unanimous in recommending conservative interventions, singly or in combination, for the majority of patients with faecal incontinence as first-line management.

Conservative management is defined as a non-operative intervention designed to improve faecal incontinence incontinence or prevent deterioration. It includes pharmacological treatments. Reducing the severity and related complications of faecal incontinence are included from the view of conservative management outcomes rather than secondary and tertiary prevention. Patient selection for operative versus conservative management remains largely empirical. The committee recommends a trial of conservative management, in the vast majority of patients, before considering surgical options, because these conservative options are comparatively inexpensive and involve no significant morbidity (see algorithm). Exceptions would be patients with acute traumatic anal sphincter rupture or an endosonographically confirmed major defect in the external anal sphincter in the presence of gross faecal incontinence: these patients would be referred for surgical evaluation as first line treatment.

II. CLINICAL ASSESSMENT

Normal anorectal physiologic function is complex and relies on a several different factors, including...
anatomic and neurology factors. Consequently, anorectal dysfunction may affect all ages [1] and symptoms necessitate careful clinical assessment and sometimes specialised tests to assess the background to patients’ symptoms. Several different questionnaires and tests are used and they are frequently used in conjunction with each other, but the clinical utility is sometimes limited.[2, 3]

1. SEARCH STRATEGY

The following search terms were used for PubMed, Web of Science and Cochrane reviews: faecal incontinence, anal incontinence, symptoms, signs, clinical assessment, history, examination, digital examination, clinical features.

2. HISTORY

History gathering requires sensitivity in dealing with this taboo symptom, but also a willingness to ask direct questions about the complaint. Although there are questionnaires about the severity of faecal incontinence or anal incontinence and their impact on quality of life (See Chapter 5B), they are most often used in research and sometimes in clinical practice. Currently there are no uniform set of questions to elucidate the comprehensive set of factors involved in faecal incontinence, and recommended approaches of experts [3] and clinical experience continue to guide practice. In taking a history, the necessary first step is to determine the nature of the incontinence being experienced by the patient. The aim of a history and examination is to identify conditions that are amenable to management and to characterise symptoms so they might be reduced.

a) Type of incontinence

Additional characteristics of faecal incontinence or types of incontinence other than faecal and anal may be identified during assessment. Passive faecal incontinence is the involuntary soiling or leakage of faeces without forewarning of the patient. Flatus incontinence is the inability to control flatus. Passive and flatus incontinence are frequently related to internal anal sphincter dysfunction.[4] Urge incontinence is an inability to defer defecation once the urge is perceived, for long enough to find a toilet. Soiling after defecation can also occur, and is typically related to either a defect in the internal sphincter or poor “snapping shut” of the external sphincter after voiding.[5] It is also important to determine if the incontinence is for liquid stool only, and, if so, then the possibility of a colonic cause of diarrhoea needs to be considered.[6]

b) Etiology

The history of faecal incontinence should include questioning about its potential etiology:

- Dietary history – including intake of caffeine and sorbitol as they may stimulate GI transit or diarrhoea.[7] (Recommendation Grade C)
- Medical history – particularly anti-anginal and antihypertensive medications which may reduce sphincter tone and ferrous sulphate or antacids which may provoke diarrhoea.[8] (Recommendation Grade C)
- Presence of benign anal disease – haemorrhoids, fistula, anal warts.[9] (Recommendation Grade B)
- History of chronic straining or constipation.10 (Recommendation Grade B)
- Obstetric history[11] (Recommendation Grade B) - particularly with regard to number of vaginal deliveries, need for forceps or Ventouse, birth weights of all children, duration of second stage(s) of labour, episiotomy
- Perianal surgery history [12,13] (Recommendation Grade B) particularly:
  - Anal fissure surgery (spincterotomy or anal stretch), fistula surgery, rectal resection surgery
- History of pelvic radiation – due to risk of radiation proctitis (that can cause decreased rectal compliance) and internal anal sphincter radiation damage.[14] (Recommendation Grade B)
- Symptoms of other pelvic floor problems (urinary incontinence and pelvic organ prolapse), which have similar risk factors [15] (Recommendation Grade C)
- Cognitive assessment in appropriate patients [16] (Recommendation Grade C)

3. PHYSICAL EXAMINATION

a) General, perianal, and digital rectal exam

Examination is focused towards the detection of evidence of incontinence and identifying the cause of incontinence, if possible. Physical examination should include inspection of underclothing for soiling and staining by stool, pus, or mucus. Perianal skin should be examined for signs of irritation such as erythema, rash, and excoriation [17] (Recommendation Grade C). Perianal inspection should also include attempts to identify a patulous anus or one which gapes on gentle traction of the anal verge and/or a “keyhole” deformity of the anal canal which suggests a persisting sphincter defect [18-20] (Recommendation Grade B). Inspection may reveal scars from previous episiotomies or obstetric tears. Abnormalities at the anal verge from previous surgery or a gaping anus suggestive of marked loss of function may be present. Perianal inspection or digital rectal examination should identify the following [14,18,20] (all recommendations Grade C):

- Scars from previous surgery
- Perianal disease – prolapsing haemorrhoids, fistula, anal warts
Digital examination should also assess for [18-20] (all recommendations Grade C):

- Rectal contents – if faecal impaction is present this could explain incontinence
- Resting tone – indicative of internal anal sphincter function
- Voluntary and reflex squeeze pressure – indicative of external anal sphincter function and potential function, respectively. The latter is elicited most commonly by asking the patient to cough while assessing sphincter tone – a cough causes a reflex near-maximal external sphincter contraction (analogous to the guarding reflex in the bladder)
- Regional sphincter defects – detected as asymmetry
- A thickened sphincter – suggestive of chronic straining and occult rectal mucosal prolapsed
- Paradoxical puborectalis contraction – this may be valuable in assessing constipated patients to identify paradoxical contraction as a cause of retained stool, and hence overflow incontinence

True faecal incontinence must be differentiated from conditions that cause seepage such as prolapsing external haemorrhoids, fistulas, low rectal or anal tumors, and poor perineal hygiene. Diagnostic administration of an enema may be useful in this respect; retention of the enema suggests that the patient does not have clinically significant faecal incontinence. This serves to both clarify the patient’s history, but also begins to suggest the anatomical deficit causing the incontinence.

If suggested by earlier findings (history of straining, thickened sphincter), the patient should be asked to sit on a commode and attempt voiding — the perineum should then be inspected for evidence of a rectal mucosal or full thickness prolapsed on straining [10] (Recommendation Grade C).

b) Proctoscopy

Proctoscopy with a rigid instrument, or flexible sigmoidoscopy, is a bedside test of value in excluding potentially treatable causes of faecal incontinence: anal tumors or polyps, rectal cancers or adenoma [21] (Recommendation Grade B), solitary rectal ulcer syndrome – a functional disorder of evacuation, in which repeated straining at stool and or rectal self-digitalization may result in an ulcerated area of the anterior rectal wall [22] (Recommendation Grade B).

c) Vaginal examination

Vaginal examination using a Simms speculum may show a rectocele, cystocele and/or uterine prolapse, all of which may contribute to developing faecal incontinence [23] (Recommendation Grade C). Physiological and complimentary radiological tests are used to confirm clinical suspicions and provide objective data on the function of the anorectum. Pelvic floor dysfunction is a complex problem and multiple tests may be needed based on the initial findings and complexity of the planned intervention.

d) Recommendations for practice

- Perform a baseline assessment including a focused medical history, a general physical examination, and an anorectal examination with inspection of perinanal skin. (Recommendation Grade B-C)
- Several conditions should be specifically assessed for in the history and physical examination, as they may be amenable to definitive treatment, including rectal prolapse, haemorrhoids, faecal loading, potentially treatable causes of diarrhoea (e.g., Inflammatory bowel disease and irritable bowel syndrome, infection, adenomas), acute anal sphincter injury, and acute disc prolapse/cauda equina syndrome. (Recommendation Grade B)
- Conduct a digital exam (Recommendation Grade C)
- Perform a proctoscopy (Recommendation Grade B)

e) Recommendations for research

- Assess inter-rater variability of digital rectal examination
- Assess positive and negative predictive value of digital rectal examination to diagnose pelvic floor diseases associated with faecal incontinence

III. SPECIALIZED TESTING

1. ANORECTAL MANOMETRY

a) Indications

Anorectal manometry measures the pressures in the anal canal and the distal rectum. This test
serves as one of the most accepted and used inves-
tigations to measure the function of the internal anal
sphincter and the external anal sphincter. Evaluation
of the sphincter function in patients with faecal
incontinence is the primary indication for manom-
etry [24-26] (Evidence Level 2). However, prelimi-
nary evidence suggests that rectal sensation should
be treated as well.[27]

b) Equipment and testing

Anorectal manometry can be performed with differ-
ent types of catheters, including solid state, water
perfused, air charged, or microballoon catheters. [28]
The diameter of the probe should not exceed
5-6 mm and the probe usually includes sensors ra-
dially distributed to measure several pressures at
each level. Any manipulation of the rectum, such as
digital rectal examination or administration of ene-
ma prior to a test should be followed by a minimum
of 5 minutes of rest to allow sphincter activity to re-
turn to baseline.

The stationary pull-through technique is today com-
monly used, since this technique avoids the reflex
sphincter contraction caused by some dynamic
techniques. The stationary pull-through measures
the resting pressure and the squeeze increase at 6,
5, 4, 3, 2, and 1 cm from the anal verge by extract-
ing the probe in increments of 1 cm from the rectum
to the anal verge. Allowing a waiting period between
each measurement minimizes artifacts.

c) Anal resting pressure

The anal resting tone is a composite pressure gener-
ated by the internal anal sphincter (55%), external
anal sphincter (30%) and the anal cushions (15%).
[29] There is some radial asymmetry in pressures in
the different parts of the anal canal [30] and therefore
the pressures in the four quadrants is usually aver-
aged to account for this asymmetry.[25] New equip-
ment provides a more precise measurement of ra-
dial asymmetry, but more complete evaluation of this
high resolution technique is still lacking. The length
of the functional anal canal or high pressure zone is
defined as the length of the anal canal with resting
pressures exceeding 30% of the rectal pressure.[31]

Patients with faecal incontinence usually have a
lower anal resting tone than continent patients or
normal controls (Evidence Level 2). [24,32] The
degree of faecal incontinence will however not only
depend on the anal sphincter tone, since there are
many other factors (i.e. stool consistency, rectal
compliance, etc.) that play an important role. There
is also a lack of defined values of what is the normal
range for the anal resting tone.

d) Squeeze increase

The squeeze increase of the anal canal pressure
is generated by contraction of the external anal
sphincter and can be calculated as the increase in
pressure from the anal canal resting tone during
maximal anal squeeze. The squeeze increase is
also usually measured at 6, 5, 4, 3, 2, and 1 cm from
the anal verge with the stationary pull through tech-
nique. Decreased squeeze pressures are frequently
correlated to injuries in the external anal sphincter,
neurologic damage or just poor patient compliance/
voluntary control.

The fatigability of the external anal sphincter can
be estimated by measuring the patients’ ability to
sustain the squeeze effort over time. The squeeze
duration is often reduced in patients with inconti-
nence. The squeeze durability may be measured as
a fatigue index.[33]

e) Recto-anal inhibitory reflex

Rectal distension or attempted defecation results
in an inhibition the tonic activity of the internal anal
sphincter and relaxation of this muscle. Presence
of an intact internal anal sphincter is dependent
on an intact myenteric plexus and it is usually im-
paired in patients with severe constipation due to
Hirschsprung’s disease. The value of react-anal in-
hibitory reflex testing in patients with faecal inconti-
nence is limited.

f) Rectal sensation and compliance

Rectal sensation (and rectal compliance) can be
measured by intermittent balloon distension in the
distal rectum and simultaneously monitoring the pa-
tient’s response. The first sensation, the first urge
and the maximal tolerable volume are usually re-
corded. Rectal compliance can also be assessed
by measuring the pressure and volume relationship
when a balloon is inflated in the rectum.

Reduced sensory threshold levels of the rectum
(rectal hypersensitivity) in patients with faecal incon-
tinence could indicate a presence of urge faecal inconti-
nence and increased frequency of defecation
[34,35] (Evidence Level 3), whereas incontinent
patients with increased sensory threshold levels
(rectal hyposensitivity) may suffer from passive
(overflow) incontinence [36] (Evidence Level 3).

g) Recommendations for practice

• Anorectal manometry can objectively assess
  anal sphincter function in patients with faecal
  incontinence. (Recommendation Grade C)

• Focused expertise to perform manometry is
  required; each center/laboratory should es-
  tablish its own control values for anorectal
  manometry and check for reproducibility of
  the test. (Recommendation Grade B)

h) Recommendations for research

• Assess normal values for rectal manometry
  in large healthy control samples spanning all
  ages to serve as comparisons for abnormali-
  ties in faecal incontinence
2. ENDOANAL ULTRASOUND IMAGING

a) Introduction
Endoanal ultrasound (EAUS) is established as an important part of a colorectal diagnostic work-up [37] and has been recommended as the gold standard investigation to identify anal sphincter injury by the International Urogynecological Association/International Continence Society joint report.[38]

b) Endoanal ultrasonography technique

EAUS is usually performed with high multi-frequency (9-16 MHz), 360° rotational mechanical probe or radial electronic probe (frequency: 5-10 MHz). During examination, the patient may be placed in the dorsal lithotomy, in the left lateral or in the prone position. However, irrespective of the position, the transducer should be rotated so that the anterior aspect of the anal canal is superior (12 o’clock) on the screen, right lateral is left (9 o’clock), left lateral is right (3 o’clock), and posterior is inferior (6 o’clock). The length of recorded data should extend from the upper aspect of the PR to the anal verge.

Three-dimensional (3D) EAUS offers a synthesis of a high number of parallel transaxial 2D images and it is possible to analyze coronal, anterior-posterior, or posterior-anterior as well as sagittal right-left views, together with any oblique image plane. The 3D image can be rotated, tilted, and sliced to allow the operator to infinitely vary the different section parameters. Volume Render Mode (VRM) is a special feature that can be applied to high-resolution 3D data volume so information inside the cube is reconstructed to some extent. The volume-rendered image provides better visualization performance when there are not large differences in the signal levels of pathologic structures compared with surrounding tissues.[39]

With EAUS, the anal canal is divided into three levels of assessment. The upper level corresponds to the hyperechoic ring of the puborectalis muscle and the concentric hypoechoic ring of the internal anal sphincter. In males, the deep part of the external anal sphincter is also identified at this level. The middle level corresponds to the complete ring of the superficial external anal sphincter (concentric band of mixed echogenicity), the conjoined longitudinal layer, the complete ring of internal anal sphincter, and the transverse perinei muscles are visualized. The lower level corresponds to the subcutaneous part of the external anal sphincter.

c) Endoanal ultrasonography in faecal incontinence

EAUS has become the gold standard for the morphological assessment of the anal canal. It can differentiate between incontinent patients with intact anal sphincters and those with sphincter lesions (defects, scarring, thinning, thickening, and atrophy) due to vaginal delivery or anal surgery (i.e., hemorrhoidectomy, sphincterotomy, fistula surgery).[40]

Tears are defined by an interruption of the circumferential fibrillar echo texture. Scarring is characterized by loss of normal architecture, with an area of amorphous texture that usually has low reflectivity. The operator should identify if there is a combined lesion of the internal anal sphincter and external anal sphincter or if the lesion involves just one muscle. The majority of lesions of the internal anal sphincter are easily recognized given the prominent appearance of the normal anal sphincter in the mid anal canal, and they appear as hyperechoic breaks in the normally hypoechoic ring. The appearance of an external anal sphincter defect is a break in the circumferential integrity of the mixed hyperechoic band. A defect can have either a hypoechoic or a hyperechoic density pattern. This corresponds to replacement of the normal striated muscle with granulation tissue and fibrosis. A limitation of EAUS remains the identification of external anal sphincter atrophy in patients with idiopathic faecal incontinence because of the vague contours of the muscle ring.

The number, circumferential (radial angle in degrees or in hours of the clock site) and longitudinal (proximal, distal or full length) extension of the defect should be reported. In addition, 3D EAUS allows to measure length, thickness, area of sphincter defect in the sagittal and coronal planes and volume of sphincter damage.[40,41] Two scoring systems have been proposed to define the severity of the sphincter damage.[42,43] Both systems have demonstrated a good intraobserver and interobserver agreement in classifying anal sphincter defects. [41,44]

EAUS has an important role in detecting clinically occult anal sphincter injuries after vaginal delivery. [45,46] In another study, Oberwalder et al.[47] reported that faecal incontinence related to sphincter lesions is likely to occur even in an elderly population of women who experienced vaginal deliveries earlier in life. They found that 71% of women with late-onset faecal incontinence (median age 61.5 years) had occult sphincter defects on EAUS.

Ultrasonographic imaging is useful to evaluate the result of treatments. Dobben et al.[48] reported that patients with a persistent ultrasonographic external anal sphincter defects after sphincteroplasty had a worse clinical outcome than those without an external anal sphincter defect. Using 3D-EAUS, de la Portilla et al. [49] demonstrated that all the implants of silicone to treat faecal incontinence were properly located in the intersphincteric space three months after injection.
d) Alternative Ultrasound Modalities in Faecal Incontinence

1. Transperineal Ultrasonography

Perineal ultrasound is performed with the patient placed in the dorsal lithotomy position. Conventional convex transducers (main frequency between 3 and 6 MHz, field of view at least 70°) are applied in the perineum between the mons pubis and the anal margin. Perineal ultrasound provides sagittal, coronal and oblique sectional imaging, with the mid-sagittal plane the most commonly used as this gives an overall assessment of all anatomical structures (bladder, urethra, vaginal walls, anal canal and rectum) between the posterior surface of the symphysis pubis (SP) and the posterior part of the levator avulsion (LA). The imaging is usually performed at rest, on maximal Valsalva maneuver and on pelvic floor muscle contraction. The access to the mid-sagittal plane allows the following evaluation of the integrity of the perineal body, measurement of ARA, and dynamic assessment of the posterior compartment.

3D perineal ultrasound imaging may be performed with volumetric probes developed for obstetric imaging. The most important clinical application is the assessment of LA injuries. At these injuries, the muscle disconnects from its insertion on the inferior pubic ramus and the pelvic sidewall and is a muscle disconnect from its insertion on the inferior pubic ramus and the pelvic sidewall and is a common consequence of overstretching during the second stage of labor.[50,51]

2. Endovaginal Ultrasonography

Endovaginal ultrasound is performed with the patient placed in the dorsal lithotomy position. The most frequently used transducer for pelvic floor 3D transvaginal ultrasound is a high multi-frequency (9-16 MHz), 360° rotational mechanical probe. The pelvic floor is divided into four levels of assessment.[52] At level I, the bladder base is visualized on the screen in the 12 o’clock position and the inferior third of the rectum in the 6 o’clock position. Level II corresponds to the bladder neck, the intramural region of the urethra and to the anorectal junction. Level III: corresponds to the midurethra and to the upper third of the anal canal. Level IV corresponds to the perineal muscles, the perineal body, the distal urethra and the middle and distal third of the anal canal.

e) Summary of Evidence

- EAUS is considered as an integral part in the investigation of faecal incontinence. (Evidence Level 2).

f) Recommendations for practice

- EAUS is an important part in the assessment of patients with faecal incontinence, since the examination will define the possible presence of anal sphincter injuries. (Recommendation Grade A)

g) Recommendations for research

- Evaluate the role of levator ani damage, visualized with pelvic floor ultrasound, on faecal incontinence symptoms and therapy results.
- Further characterize and standardize the utility of pelvic floor ultrasound in patients with faecel incontinence.

3. Magnetic Resonance Imaging

a) Introduction

Recently, there has been evidence to show that magnetic resonance imaging (MRI) is accurate in detecting external anal sphincter defects potentially suitable for repair in patients presenting with faecal incontinence [53-66] (Evidence Level 2). MRI can be performed with endoluminal MRI technology or surface phased-array antennas. MRI is an alternative, with relative accuracy in the detection of external anal sphincter defects, although there is reduced local spatial resolution using this technology and less experience in the specific assessment of external anal sphincter defects.[67-71] Recently, there has been evidence to show that the longer-term functional outcome following sphincteroplasty for obstetric-related external anal sphincter defects (the principal cause of clinical faecal incontinence in this population) is somewhat dependent upon the presence of attendant pudendal neuropathy [72-74] and that worse outcome is correlated with neuropathy-associated external anal sphincter atrophy. [75-77] This technique has also been shown to accurately identify external anal sphincter atrophy in comparison with endoanal ultrasound.[78,79]

b) Normal anal sphincter anatomy at MRI

The bulk of useful images are obtained with T2-weighting where contrast is described in relation to the surrounding structures, as there are no absolute values for tissue contrast (as there are, for example in computed tomography). In a series of 100 normal volunteers, age- and gender-related differences are demonstrable on endoanal MRI,[80] as women have a significantly shorter external anal sphincter than men.

c) Anal sphincter defects on MRI

External anal sphincter lesions are detected as alterations in the normal external anal sphincter anatomical integrity or as scarring, local atrophy, or a definitive defect. The full extent damage is best appreciated in a combined evaluation of the axial and longitudinal plane sequences. Secondary changes to the architecture of adjacent structures (longitudinal muscle, perianal fat) provide
supportive evidence of a sphincter tear. Variations in normal anatomy of the anal sphincter may be misdiagnosed as sphincter defects, with constitutive differences in the external anal sphincter being observed.

Internal anal sphincter defects are identified as either internal anal sphincter discontinuity or as replacement of the normal smooth muscle by fibrous tissue with concomitant muscle thinning. Internal anal sphincter defects are often found in combination with external anal sphincter defects, especially in women presenting with incontinence. Solitary internal anal sphincter defects are more common in iatrogenic cases of incontinence.

Several studies have evaluated the accuracy of endoanal MRI in detecting anal sphincter defects. Tears of both the internal anal sphincter and external anal sphincter are readily visualized, with an accuracy of 95% for external anal sphincter lesions.[56,58,63]

d) Anal sphincter atrophy at MRI

Recent publications on endoanal MRI imaging reemphasize the importance of external anal sphincter atrophy with its potential predictive clinical implications on sphincteroplasty outcome. [54,56,58,81]

e) Role of MRI in the assessment of faecal incontinence

EAUS can be used as a primary imaging technique, given the similar results when compared with endoanal MRI in detecting sphincter defects, the widespread availability of endoanal ultrasound, and the lower costs. There is no doubt, however, that endoanal MRI technology is accurate. Its role in defining and diagnosing external anal sphincter atrophy can both direct sphincter repair and provide some prognostic information.

f) Recommendations for practice

- The place for MRI assessment of anal sphincters is limited. (Recommendation Grade D).
- Patients with faecal incontinence after repeated anorectal surgeries may benefit from assessment with MRI. (Recommendation Grade C)
- Patients with possible, but not proven, external sphincter defect on ultrasound may benefit from further assessment with MRI. (Recommendation Grade C)

g) Recommendations for research

- MRI can define atrophy of the anal sphincter muscles. Study to assess the degree of atrophy influences the outcomes after treatment with surgical sphincter repair and sacral nerve stimulation.

4. DEFECOGRAPHY

a) Introduction

Defecography, also termed as evacuation proctography, is the radiological assessment of the voluntary rectal evacuation of semisolid contrast material, and provides information on anorectal structure and function. It is useful and widely used in the diagnosis and management of obstructed defecation, but the technique is less often utilized in the assessment of faecal incontinence. [82-84] Rao [85] did not include defecography in commonly performed diagnostic tests for faecal incontinence in an evidenced-based summary and American Gastroenterological Association medical position statement [86] concluded that defecography is not of established value in patients with faecal incontinence. Whitehead et al.[87] concluded that defecography is useful in the assessment of perineal descent, pelvic organ prolapse, rectocele, defecation and puborectalis contraction, but they did not include it in the algorithm for the diagnosis and management of faecal incontinence.

On the other hand, defecography was used by 56% of physicians in the routine diagnostic work-up of patients with faecal incontinence in a recent Dutch study.[88] There are several studies reporting that surgical correction of rectal intussusception [89-92] or rectocele [93,94] result in improved faecal incontinence.[93,94]

There is a suboptimal correlation between symptoms and defecographic findings. Abnormal findings of defecography can be seen in many normal subjects without any anorectal symptoms.[86,95-98] Another problem in performing defecography in patients with faecal incontinence is that those with weak anal sphincters have problems retaining the semisolid contrast material in the rectum when seated on a commode.

b) Examination technique

There are no universally consented standard methods of defecography. Usually, a viscous barium contrast material is injected into the rectum of the patient in the left decubitus position. The semi-solid contrast material can be made by mixing barium with flour, oatmeal or mashed potato. The volume of the injected material is either fixed at around 150ml or up to the volume at which the patient feels the urge to defecate. A radiopaque marker can be placed close to the anus to facilitate interpretation. Barium contrast in the vagina facilitates interpretation of enterocele and prolapse in the anterior and middle compartments.

The patient sits on a commode attached to the footboard of the fluoroscopy table and lateral views of the film are taken at rest and maximum squeeze before rapid film sequences are taken at one frame per second during evacuation, followed by a film taken after the completion of the evacuation at maximum straining. The sequential films is usually by a video recording; cinedefecography.
c) Parameters studied at defecography

The anorectal junction is the distally tapered point of the rectal contrast column caused by posterior impression of the puborectal muscle. The anorectal angle (ARA) is measured by the angle between the line along the anal canal and the axis of the rectum. Normal subjects should be able to evacuate more than two thirds of rectal contrast material within 30 seconds. In addition to assessing rectal evacuation, defecography can reveal rectal intussusception, rectocele, sigmoidocele and enterocoele. Rectal intussusception is defined as the invagination of the rectal wall into itself and the degree of rectal intussusception can be classified by Oxford. [89] Rectocele is defined as the outpouching of the anterior rectal wall beyond the normally expected anterior rectal wall at straining. Sigmoidocele and enterocoele are defined as the herniation of the lining of the peritoneum by the sigmoid colon or the small bowel, respectively, into the rectovaginal septum and may push on the anterior rectal wall.

Perineal descent may be a sign of the weak pelvic floor muscles and possible pudendal neuropathy. An obtuse ARA implies weakening of the puborectal muscle and possibly the entire pelvic floor muscles. In a study by Piloni et al.,[99] the mean ARA at rest differed significantly between patients with faecal incontinence and those without. The normal range of ARA, however, is wide and some patients with normal ARA are continent to stool, whilst some with abnormally obtuse ARA are continent.

Karasick[100] stated that the major indication for performing defecography in patients with faecal incontinence is to diagnose rectal intussusception (Evidence Level 3). Collinson et al.[89] performed defecography in 40 patients whose faecal incontinence could not be explained by anorectal physiology and endoanal ultrasound, recto-anal intussusception was observed in 63% of the patients. Surgical correction of rectal intussusception has been shown to improve faecal incontinence, indicating a possibility that rectal intussusception can be a cause of faecal incontinence (Evidence Level 3). Lazorthes et al.[90] performed defecography in 51 patients with faecal incontinence. Fourteen patients had a recto-anal intussusception and were operated with transabdominal rectopexy. Faecal incontinence improved in all 14 patients and completely resolved in 6 patients. When Collinson et al.[89] performed laparoscopic ventral rectopexy in 24 patients with rectal intussusception and a combination of obstructed defecation and faecal incontinence, incontinence symptoms significantly improved in 92% of the patients.

It is more controversial whether a rectocele can cause faecal incontinence (Recommendation Grade C). Collinson el al.[89] claimed that one of its mechanisms is faecal trapping in the rectum that allows post-defaecatory leakage to occur.

d) Recommendations for practice

- Defecography is of limited value and not always utilized in the diagnosis and management of faecal incontinence. (Recommendation Grade B)

- Defecography can be useful in the diagnosis and management of faecal incontinence by measuring perineal descent and ARA, evaluating involuntary leakage of the contrast material as well as diagnosing rectal intussusception and rectocele. (Recommendation Grade B)

- Defecography might be useful in diagnosing the existence and extent of rectal intussusception and rectocele as a cause of faecal incontinence. (Recommendation Grade B)

e) Recommendations for research

- Identify and characterize the degree of rectal intussusception and prolapse at defecography and correlate this to treatment outcomes after ventral rectopexy.

- Defecography may be superseded by magnetic resonance imaging (MRI) defecography, which can visualize the pelvic floor and organs as well as avoids radiation exposure.[101-103] The latter technique is, however not widely available at present, because of higher cost and most equipment does not allow examination in the sitting position.[83,104] Further investigation is needed to determine whether an open-magnet unit of MRI may solve this postural problem.

5. CLINICAL NEUROPHYSIOLOGIC TESTING

a) Introduction

The clinical use of neurophysiologic testing in patients presenting with incontinence has a long history, but appears to be diminishing in practice because of improvements in clinical sphincter imaging and as a result of the understanding that some neurophysiologic parameters have only minimal influence on decision-making.[105,106] Despite the rise of sacral neuromodulation (SNS) in the selective management of incontinent patients, there is no clear guideline for specific predictive neurophysiologic testing,[107,108] reseating its specific use in complicated cases of incontinence secondary to particular neurological diseases and following spinal injury.

b) Types of neurophysiologic testing for faecal incontinence

Neurophysiologic testing for faecal incontinence incorporates a range of different testing modalities, including somatic motor testing, somatosensory testing, determination of clinical reflexes, and autonomic nervous system (ANS) testing. Somatic
motor testing assesses the somatic nervous system responsible for skeletal muscle motor innervation plus sensory innervation from cutaneous sites to the muscle spindles. This testing incorporates all forms of electromyography (EMG), including pudendal terminal motor latency studies (PNTML), motor nerve conduction studies, and motor evoked potentials. Somatosensory testing includes somatosensory evoked potentials and sensory neurography. ANS testing: assesses the ANS which provides motor innervation to the viscera and other end-organs and which assess its visceral afferent pathways at peripheral, spinal and supraspinal levels.

c) Electromyography

The specific use of this EMG technology in faecal incontinence in the past was for the differentiation of those patients with potential voluntary sphincter defects from those without sphincter defects thought to be reparable but who had an attendant presumptive neurological cause for their incontinence. Concentric needle electromyography (CN-EMG) is performed with single-use needles used at multiple sites. Inherent differences exist at rest in sphincter musculature when compared with peripheral (non-sphincteric) musculature showing basal resting activity whereas non-sphincter musculature is electrically silent. [109,110] Denervation is diagnosed as a reduction in the number of continuously firing low-threshold MUPs. CN-EMG has disappeared with improved accurate sphincter imaging; however, it may have a specific place in those patients where ultrasonography and/or MR imaging is equivocal. Single Fibre EMG (SF-EMG) has a smaller recording surface with a pickup of activity from a smaller muscle volume than that recorded with CN-EMG, recording generally 1-3 single muscle fibres from the same MU.

d) Pudendal nerve conduction testing

Pudendal nerve conduction testing measures the nerve conduction velocity in the pudendal nerve. There is a customized (Dantec Electronic Tonsbaek en 16-18 DK-2740 Skovlunde, Denmark) St. Mark’s electrode that has been designed. Prolongation of the pudendal nerve terminal motor latency (PNTML) is common after vaginal delivery and with aging. [111-113] It has been suggested that the delay in PNTML is associated with a worse overall prognosis of external anal sphincter repair for patients presenting with faecal incontinence, [75-77] although there is little available evidence to suggest that PNTML measurement alters specific surgical decision-making.[114] There is little available evidence that the presence or extent of a pudendal neuropathy correlates with objective incontinence[106] or with the specific response to biofeedback therapy with or without the presence of an external anal sphincter defect. [115]

e) Sensory system testing

Anorectal sensitivity plays a significant role in the defaecation process and in maintaining faecal continence. Variation in anorectal sensibility is also important in pain disorders and in irritable bowel syndrome. Basic sensory testing of light touch and pinprick and sensation of bladder filling is standard. The ano-cutaneous sensation of the perianal area and in the anal canal below the dentate line is conveyed by the efferent fibers of the pudendal nerve (S2-S4).[116]

f) Anal mucosal electrosensitivity

Anal mucosal electrosensitivity (MES) testing was originally described independently by Roe et al.[117] and Siegel [118] using two electrodes with a constant square wave of current with variable intensity. It is unknown precisely which receptors are involved in this standardized and reproducible response.[119] Incontinent patients invariably have a high MES whereas patients with anal sphincter defects, (with or without faecal incontinence), show an increased MES with the highest values found in patients with a combined internal anal sphincter and external anal sphincter defect.

g) Recommendations for practice

- Neurophysiologic testing is of limited value in the assessment of patients with faecal incontinence. (Recommendation Grade C)
- PNTML may be useful in the preoperative assessment of patients before sphincteroplasty or sacral nerve stimulation. (Recommendation Grade C)
- PNTML may be useful in the assessment of patients with possible pudendal neuralgia. (Recommendation Grade D)
- CN-EMG may have a specific role when ultrasonography and/or MR imaging is equivocal. (Recommendation Grade D)

h) Recommendations for research

- Assess reproducibility of testing of anorectal sensation on predicting outcome of surgical and medical treatment for faecal incontinence in large patient samples

IV. EDUCATION AND LIFESTYLE INTERVENTIONS

1. BACKGROUND

Most patients with faecal incontinence do not know how the bowel works and what might improve bowel function. Many patients also have attitudes toward defaecation that are influenced by stigma and taboos present in their particular family and their wider cultural group within a society.[120] Expert opinion supports the use of general health education, patient teaching about bowel function and advice on lifestyle modification,[121,122] but the evidence
base is small. Little is known about whether interventions designed to modify lifestyle factors might improve faecal incontinence.

2. SEARCH

Because a small number of studies on these topics were identified in past reviews, two independent searches using their own search strategy were conducted to maximize yield. The following databases were searched: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, 2011 MEDLINE 2008- Nov, 2011 and EMBASE 2008- Nov, 2011. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and faecal incontinence was also reviewed.[123]

Searches included both Medical Subjects Heading (MeSH) terms that were exploded and text searches. The following terms were searched: anal, ano-rectal, bowel, faecal, faecal, f?ecal, feces, rectal, stool and continent$ or incontinent$, or diarrhea, diarrhoea, diarrh?a; and the relevant lifestyle or intervention term: education, educat*, health education; exercise, exercise*, exercis*, exercise therapy, exercise movement techniques, physical exertion; primary prevention, prevent*, preventive health services, preventive health services for older people; weight loss, diet+, diet low carbohydrate, diet fat-restricted, diabetic diet, macrobiotic diet, restricted diet+, diet gluten-free, diet reducing; irrigat$ and rectal, rectum, anal, transanal; smoking, tobacco smoke pollution, tobacco use disorder, tobacco, tobacco$, cigarette$, smok$, smoking cessation; toileting, toilet$, toilet facilities; herbal medicine, plant extracts, drugs, Chinese herbal, plant preparations, plants, medicinal, medicine, Chinese traditional; carer, caregiver, spouse, family, families, famil*, parent$, caregiver burden, caregiver support, and nursing or care. All seemingly relevant abstracts were reviewed, then salient articles were retrieved and reviewed, and the reference lists searched for further studies. Results of the two searches were virtually identical.

3. REVIEW OF EVIDENCE ON THE EFFECT OF EDUCATION AND LIFESTYLE CHANGES ON FAECAL INCONTINENCE

a) Weight loss

Obesity has been proposed as a risk factor for faecal incontinence but the evidence is inconsistent. In 2008, one study of the effect of weight loss after bariatric surgery on faecal incontinence was identified with positive results. In the current review, results of two new studies are included, one using surgery; neither showed a benefit for decreasing faecal incontinence. The effect of a weight loss (i.e., dieting) versus a control (i.e., education) intervention, on reducing faecal incontinence, was compared in a subgroup analysis of 80 women with dual (faecal and urinary) incontinence who participated in a study examining the ability of weight loss to improve UI.[124]

There was no significant difference in the Faecal Incontinence Severity Index (faecal incontinenceSI) or faecal incontinence type (i.e., consistency) between the weight loss and control groups. The 6 month intervention focusing on dietary intake was not correlated with a decrease in faecal incontinence. Women who showed improvement in faecal incontinence had a lower weight at baseline (89 kg) than those with no improvement in faecal incontinence or no faecal incontinence (97 kg). In one study of women who underwent bariatric surgery for morbid obesity (mean (sd) body mass index (BMI) = 48.9 (7.2) kg/m2), there was a decrease in the prevalence of faecal incontinence of solid or liquid stool from 19.4% preoperatively to 8.6% at 12 months (p=.018; 95% CI= 2.1–19.4%).[125] In a later study of 193 morbidly obese patients, bariatric surgery was not beneficial in reducing faecal incontinence.[126]

Faecal incontinence was worse two years after gastric bypass or gastric banding surgery than before surgery despite an average 48 kg weight loss in more than half of the patients. Worsened faecal incontinence was attributed to diarrhea that occurred postoperatively. When men and women were analyzed together, liquid stool was significantly more common after gastric bypass than gastric banding surgery, a finding not seen when either gender was analyzed separately.

b) Smoking

Nicotine is thought to slow upper gut motility and increase total transit time.[127] but it seems that it can speed recto-sigmoid transit,[128] and this stimulation of distal colonic motility may exacerbate a tendency to faecal urgency. This fits with many anecdotal reports that smoking a cigarette facilitates initiation of defaecation. No association has been found between antenatal smoking and postnatal faecal incontinence.[129] In a survey of 271 pairs of identical twin sisters, smoking was not significantly related to faecal incontinence or flatus incontinence.[130] In a longitudinal observational study of community-living elderly men and women, smoking was not predictive of prevalent or incident faecal incontinence.[131] No new or intervention studies were identified in the current literature search.

c) Medication side-effects

Medication used specifically to treat faecal incontinence is covered in section 6 below. A vast number of drugs have direct or indirect effects on the gastrointestinal system, tending to cause constipation, diarrhoea, or either in different people. A case report was found reporting that a combination of olestra in the diet and orlistat given to treat obesity led to symptoms of faecal incontinence, which resolved when the olestra was stopped.[132] Patients reporting soiling while on treatment with orlistat for obesity
have been found to have pre-existing impaired ano-
rectal function, thus predisposing them to symptom
development.[133] It is beyond the scope of this
chapter to review drug effects in detail, and pre-
scribers should be aware of the possible unintend-
ed side-effect of faecal incontinence. A careful drug
history (including all over the counter or “herbal”
preparations) should be taken in each person with
faecal incontinence. No studies were identified that
evaluated the benefits of patient or provider edu-
cation regarding the gastrointestinal side-effects of
medications in the past or current literature search.

d) Toilet facilities

An environment with physical or social obstacles
may impair the ability to maintain continence. This is
particularly relevant to individuals who have physi-
cal or mental disabilities. Environmental obstacles
include toilet facilities that are physically inacces-
sible, too few, or distant, require obtaining a key or
money to access, or are restricted to the public alto-
gether; they also include clothes that are difficult to
manipulate in a hurry and a variety of other fac-
tors which vary with abilities of the individual. The toilet
itself may be too high, leaving the feet dangling and
thus making abdominal straining difficult. The toilet
may be too low, making sitting and rising difficult
for those with immobile hips. Commode use is re-
viewed in by Committee 20.

Public laws, such as those in some U.S. states that
require businesses in public spaces that have toi-
let facilities to make them accessible for public use,
reduce environmental obstacles to continence.[134]

There are many adaptations that can be made to a
toilet to facilitate access and stability in use.[135]
Effective bowel evacuation is helped by sitting well-
supported, with feet slightly raised upon a small
step stool if needed to enable appropriate use of
abdominal effort, and leaning forward slightly.[136]
Horizontal grab rails assist pushing up from a seat-
ed position, while vertical ones can enable pulling
up. A raised seat or foot blocks can adjust the height
as needed. For lateral transfer from a wheelchair,
both seats need to be at the same height. Where
it proves impossible for a person to use the toilet,
alternative commodes or chemical toilets are avail-
able with appropriate features for the individual’s
needs. No studies were found examining the effect
of modifying the physical or social environment for
toileting to manage faecal incontinence in the previ-
ous or current literature search.

e) Patient and care-giver education and attitudes

The strongest data on education and lifestyle comes
from a single RCT identified in the previous review.
The study compared nurse-led education and advice
about conservative faecal incontinence management
(e.g., advice on diet, medication titration, and bowel
retraining) alone or as part of a combined intervention
that added exercises and/or biofeedback.[137] The
education and advice group showed reduced frequen-
cy of faecal incontinence and was as effective as the
combination therapies.[137] Other support for the ben-
efits of patient education comes from a study reported
in abstract form [138] which showed that education
and standard medical care, when provided systemati-
cally to a group of faecal incontinence patients, who
had failed prior attempts at medical management, led
to a successful outcome in 38%. Success in this trial
was defined as a patient’s report that they had experi-
enced adequate relief of bowel symptoms.

An RCT of a nurse-led education-focused inter-
vention for bowel problems, in 146 stroke patients
found that a single educational visit with a detailed
information booklet increased patients’ help-seek-
ing from their family practitioner for bowel problems,
demonstrating a heightened awareness of the pos-
sibility of treatment.[139] Education also changed
diet and fluid behaviour, up to one year later, com-
pared to controls who received routine care. How-
ever, there was no difference in the rates of faecal
incontinence between the intervention and control
groups. No new studies using an education focused
intervention to reduce faecal incontinence were
identified in the current literature search.

For people with dementia or other severe intellectual
impairments, expert opinion holds that the attitude
and management methods adopted by care provid-
ers are as important as bowel function in maintaining
continence.[139] An assessment checklist of toileting
difficulties in individuals with intellectual disabilities,
has been developed to identify the need for inter-
vention, and guide its focus, was identified in the
current literature search.[140] No controlled studies
on managing faecal incontinence in this population
were found. One quasi-experimental study examined
care-givers’ knowledge and compliance before and
after an educational intervention.[141]

Forty home care-givers of people with dementia,
over half of whom had some degree of faecal in-
continence, completed a study-specific ques-
tionnaire before and after receiving a videotape and
information booklet entitled, “A practical approach
to maintaining bowel control in people with demen-
tia.” Ninety percent of the care-givers accessed
the information and there was an improvement in
post-intervention knowledge scores, measured on a
55-point scale, with the mean score increasing from
23 pre-test to 32 post-test (p=<0.001). However, it
is not known if this improved knowledge translates
into improved care or reduced faecal incontinence.

f) Complementary therapies

There have been no studies of the use of acu-
puncture, reflexology, homeopathy or any other
complimentary therapeutic approach identified in
the previous or current literature search. The use of
cognitive therapy for managing incontinence has
been proposed but not studied.[142]
g) Summary of evidence on education and lifestyle interventions in faecal incontinence

There is at present limited evidence for any lifestyle intervention for faecal incontinence.

• Educating patients and caregivers about their bowel function and faecal incontinence can improve faecal incontinence (Evidence Level 5)

• Obesity: no benefit from weight loss without surgery (Evidence Level 5) and conflicting evidence about the effect of weight loss after bariatric surgery for morbid obesity (Evidence Level 3)

• Smoking: No association with faecal incontinence (Evidence Level 3); no studies of effects of smoking cessation on faecal incontinence

• Medication side effects may cause faecal incontinence related to diarrhoea (Evidence Level 4)

• Environmental modifications in public facilities or private homes to reduce faecal incontinence (Evidence Level 4)

h) Recommendations for practice

• Medication side effects: consider alternatives if causing diarrhoea (Recommendation Grade C)

• Ensure appropriate toilet facilities and convenient access especially for people with disabilities (Recommendation Grade C)

• Improvement in education of patient (Recommendation Grade B/C), and of carer (Recommendation Grade C)

• Complementary therapies cannot be recommended: no evidence (Recommendation Grade D)

There is insufficient evidence to recommend or discourage most lifestyle modifications either for the prevention or treatment of faecal incontinence. The committee recommends patient education about the causes of faecal incontinence and a systematic effort to remove barriers to effective toileting, as an intervention that is likely to be beneficial, based on the consensus of experts (Evidence Level 3 evidence). This may be provided at relatively low cost and involves no significant risk to the patient.

i) Recommendations for research

• Based on encouraging preliminary reports that patient education, combined with conservative management, can reduce the frequency of faecal incontinence, we recommend further research. An RCT may not be possible, due to the challenge of identifying a suitable control for expectancy and attention, but a study which demonstrates a sustained benefit from a limited educational intervention (provided to patients or caregivers), would provide useful guidance for clinical management.

• Further investigation of the benefits for faecal incontinence of weight reduction, especially in moderately obese patients, using non-surgical interventions

• Exercise programmes, when incorporated into a multi-component intervention, have produced promising preliminary results and should be tested further. Such trials should differentiate between constipation-associated faecal incontinence and diarrhoea-associated faecal incontinence, as exercise may be more beneficial to the former group.

• Evaluation of the incremental or additive value of different lifestyle interventions in the patient pathway.

• Research on the contribution of complementary therapies.

V. DIET AND FLUIDS

1. INTRODUCTION

Community-living adults and elderly individuals, especially women, report that they manipulate their diet and eating patterns as a strategy for managing their faecal incontinence.[143-145] Dietary manipulation is employed by the approximately 20% of patients with irritable bowel syndrome (IBS) who also have faecal incontinence [122,146] and by the approximately 19% to 40% of patients with inflammatory bowel disease who have faecal incontinence.[122,147-151] Empirical observations of a suspected relationship between diet and changes in bowel pattern are not limited to faecal incontinence but have been reported by, individuals with constipation, those with IBS with constipation (IBS-C) and some healthy individuals, and together with physiological principles of gastrointestinal (GI) function, supported an investigation of the evidence and discussion of possible mechanisms.

2. LITERATURE SEARCH

The following databases were searched for studies to include in this review of dietary interventions for faecal incontinence management: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, 2011 MEDLINE 2008-Nov, 2011, and EMBASE 2008-Nov, 2011. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and faecal incontinence [140] was also reviewed.

The following terms were searched: anal, anorectal, bowel, faecal, faecal, rectal, stool, continent or
incontinent, with diarrhea, diarrhoea, digestive or digestive disease with: alcohol, ethanol, alcoholism, alcoholic beverages, ethanol, drinking; beverages, fluid, fluid intake; liquid, water; coffee, caffeine, cola; diet, dietary therapy, diet, eat, intake, consum and fat or lipid, diet+, diet low carbohydrate, diet fat-restricted, diabetic diet, macrobiotic diet, restricted diet+, diet gluten-free; dietary fibre, fiber, fibre and also with constipation; lactose, lactose intolerance, lactose tolerance, lactose tolerance test, lactose factors, lactose synthase, dairy, dairy products, milk; prebiotic, probiotic, symbiotic; oligofructose, oligofructose, oligosaccharides, fructans, fructose, fos, fructooligosaccharide; sorbitol, glucitol, isosorbide, meglumine; spice, spicy, hot; yogurt, bifidibacteria, Bifidobacterium, Lactobacillus acidophilus, acidophil. All seemingly relevant abstracts were reviewed; then salient articles were retrieved and reviewed, and the reference lists of these articles searched for further studies.

a) Criteria for considering studies for this review

- Types of studies

Only studies in the English language were reviewed. Systematic reviews and meta-analyses of randomised controlled trials and full-length manuscripts reporting individual studies published in a peer-reviewed journal were considered.

- Types of study participants

Studies that involved people who were 18 years or older, had faecal incontinence, and received a dietary intervention were included. People who were tube-fed or had an intestinal ostomy of any type were ineligible.

- Types of dietary interventions

A dietary intervention was defined as any type of food, supplement, dietary product, or fluid that is purposefully consumed or restricted, limited or avoided to manage faecal incontinence. Studies were excluded if it was not possible to distinguish any direct effect of the dietary intervention from other interventions introduced simultaneously. For example, a study was excluded if it combined pelvic floor muscle training and a dietary intervention and compared it to another intervention such as drug therapy making it impossible to determine the effect of the dietary intervention alone.

- Types of outcome measures

A change in faecal incontinence was required to be a primary outcome measure of the studies. Studies which focused primarily on the outcomes of stool consistency or form, stool amount, volume or bulk, defaecation frequency, diarrhoea, or constipation, without including any measure of faecal incontinence, were excluded.

b) Method of review

The reviewers examined the list of citations and abstracts yielded from the electronic search strategy. Potentially relevant papers were retrieved in full text. The reviewers were not blind to the journal titles, authors’ names or their institutional affiliations.

3. REVIEW OF EVIDENCE ON DIET AND FLUIDS

a) Diet modification

Studies of diet modification primarily used observational or qualitative research methods and provide background and rationale for examining the effects of diet. One new descriptive study with a large sample size was identified in the current literature search. Findings support those of earlier studies. A survey about faecal incontinence and self-care practices, administered to 1,352 community-living elderly people, showed that many of the respondents changed their diet and skipped meals as a management strategy for faecal incontinence. Changing diet was a significantly more common practice among women (35.4%) compared to men (12.5%).[144]

A qualitative interview of 10 women with faecal incontinence revealed that some avoided eating anything on days they were going to be away from home or restricted the amount eaten while out in public. [145] Many also restricted foods that they thought worsened faecal incontinence (for example, fried or spicy foods or caffeinated beverages and chocolate), or foods that increased flatus (for example, cabbage, onions); a few purposely ate certain foods as a therapy to decrease faecal incontinence (for example, yogurt). Using a trial and error approach, women with faecal incontinence often modified their diet based on recommendations for other gastrointestinal problems (e.g., lactose intolerance and IBS) that were available in the professional or lay literature. [145] Interviews of 189 community-living men and women showed similarities with previous reports regarding aggravating types of foods that are restricted to lessen faecal incontinence. [152] In order of frequency these were: vegetables, spicy foods, fruits, fatty or greasy foods, caffeine containing foods, and dairy. More women (40%) than men (18%, p=.008) avoided foods. There were also differences by age. Younger adults were likely to report that fatty foods and alcohol worsened their faecal incontinence. Individuals with faecal incontinence also modified how they prepared food preferring blander and baked foods.

The effectiveness of these diet modifications was unmeasured and described as variable. Concerns of diet manipulation are nutritional deficiencies and subsequent poor health. However, Bliss et al. [7] found few significant differences in the nutritional composition of usual diets of persons with faecal incontinence compared to the usual diets of age and gender matched controls with normal bowel function.
Those faecal incontinence had a greater intake of carbohydrates, manganese, and vitamin B1.

### b) Fluids

Faecal incontinence occurs in association with faecal impaction or constipation, mainly in elderly residents in long-term care institutions.[153,154] General clinical recommendations for faecal incontinence management in these cases are for an adequate intake of fluid to prevent hard stool consistency and constipation (See Chapter 11). Some community-living individuals report increasing fluid intake especially when faecal incontinence is loose or liquid to replace additional fluid lost.[145] However, there are no research-based data to support the recommendation of increased fluids either for constipation or for faecal incontinence, and there is no evidence that the diets of patients with faecal incontinence or constipation are deficient in fluids.

c) Lactose, yogurt, sorbitol, fructose, caffeine, and alcohol

Certain dietary components such as lactose, sorbitol, fructose, caffeine, and alcohol may cause loose stools that can potentially aggravate faecal incontinence. A deficiency of the intestinal enzyme, lactase, prevents hydrolysis of the disaccharide lactose and its absorption. The presence of lactose creates an osmotic shift of intestinal water into the small intestine and speeds transit. In the large intestine, fermentation of lactose by colonic bacteria may result in flatulence, distension, diarrhea, and cramps. However, the majority of adults who have lactase deficiency can tolerate a small amount of lactose in foods.[155] Yogurt is usually well tolerated by lactase maldigesting individuals because the lactose is partially digested by the beta-galactosidase of the bacteria used to ferment the yogurt. However, yogurt has not been found to aid the digestion or tolerance for additional lactose simultaneously consumed with it.[156]

Due to its prevalence in approximately two-thirds of the world’s population, hypolactasia is currently regarded as a normal physiological pattern rather than a disease.[157] The prevalence ranges from highs of nearly 100% in some Asian countries and 70% in Italy to lows of 2% in Scandinavia and 15% in U.S. Whites.[158] Malabsorption of fructose and sorbitol results in osmotic diarrhea and adverse symptoms, similar to lactose. A diet, reduced in fructose and sorbitol content, is suggested for some patients with irritable bowel syndrome to reduce adverse GI symptoms.[159] No studies in the current literature search on the effect of modification of intake of lactose, sorbitol, or fructose, on faecal incontinence were found.

Caffeine, of which coffee is a popular source, induces a desire to defecate.[160-164] Caffeine has also been observed to stimulate defaecation urgency in some patients with faecal incontinence.[131] However, regular consumption of coffee was not associated with prevalent or incident faecal incontinence in elderly men and women.[131] No studies were found on caffeine restriction to improve faecal incontinence.

Chronic consumption of alcohol has been associated with accelerated gastric emptying and small bowel transit in animal studies whereas a single large dose has an inhibitory effect on these parameters.[165-167] Excessive alcohol consumption leads to damage to the duodenal and upper jejunal mucosa and inhibition of sodium and water absorption. There is an increased prevalence of bacterial overgrowth in the small intestine of alcoholics, which may contribute to loose stools, diarrhea, incontinence, and other GI symptoms.[168] No studies were found in which alcohol restriction was reported to reduce faecal incontinence.

d) Prebiotics, probiotics, and synbiotics

A prebiotic is a general term describing a food ingredient that is not digested in the human small intestine and thus stimulates the growth and/or activity of one or more types of bacteria in the colon that have the potential to improve the health of the host. Because of its ability to stimulate growth of bacteria in the colon, dietary fibre can be considered a prebiotic. Fructo-oligosaccharides and galacto-oligosaccharides are popular prebiotics. A probiotic is a food supplement containing live non-pathogenic and non-toxic microbes that have the potential to affect the balance of colonic microbes and thereby improve the host’s health. Bifidobacteria and lactobacilli are the most commonly used probiotics, and yogurt which has active microbial cultures can be considered a probiotic. A synbiotic refers to a product that combines a prebiotic and probiotic. Probiotics have been investigated for their ability to prevent or reduce diarrhea associated with antibiotics, Clostridium difficile infection, ulcerative colitis, acute infant dehydration due to diarrhea and in treating Helicobacter pylori infections.[169,170] However, there are no published data on the use of probiotics or synbiotics to treat faecal incontinence.

e) Dietary fibre

1. BACKGROUND

Dietary fibre is the non-starch, polysaccharide component of plant cell walls and lignin that resists digestion by human intestinal enzymes.[171] In a recent study of weight loss for incontinent and overweight women, analysis of a subsample of 55 women with faecal incontinence showed that those with faecal incontinence were 2.5 times as likely to have a low fibre intake (≤ 10 g/d) than those without faecal incontinence.[124] Moreover, persons with normal bowel function, who had diarrhea induced by administration of phenolphthalein, reported that they had fewer days with urgency to defaecate, or fear of faecal incontinence, when they ingested the soluble fibre psyllium compared to wheat bran, cal-
Adverse gastrointestinal (GI) symptoms are a potential problem mediating tolerance of dietary intervention, including dietary fibre supplementation,[175] but few studies have examined this outcome systematically. In a recent secondary analysis of a larger trial that compared the symptoms associated with supplementation of 16 g of fibre from psyllium, gum arabic, or CMC supplements to placebo among 189 community living adults living with faecal incontinence, the severity of symptoms in all groups was minimal.[176] Adjusting for study segment and day, a greater feeling of fullness in the psyllium group was the only symptom that differed from symptoms in the placebo group. However, subjects with greater symptom severity, especially a feeling of fullness or bloating, were more likely to request a reduction in the amount of fibre to be ingested or withdraw from the study, across groups. There was a positive association between symptom severity and being emotionally upset.

2. Review of evidence on dietary fibre

There are four studies investigating the effect of dietary fibre for managing faecal incontinence.[177-180] Two are RCTs [177,178] and were included in the previous review (Table 1). The methods and findings of these previously reported studies differed. In three of the four studies of dietary fibre for faecal incontinence in this review, dietary fibre was adjunctive to other therapies.[177,179,180] In two of those studies, dietary fibre was the initial treatment of a staged intervention [179,180] and, in the third study, dietary fibre was added to antimotility medication in an RCT design.[177] In the fourth study,[178] supplementation with one of two soluble dietary fibres of moderate (psyllium) or high fermentability (gum arabic), was compared to placebo in an RCT design.

In one RCT,[178] subjects were community-living adults living in the United States with incontinence of loose or liquid stools. The intervention was supplementation with one of two soluble dietary fibres of moderate (psyllium) or high fermentability (gum arabic) compared to placebo. This study provided Evidence Level 1 evidence suggesting that dietary fibre can reduce the percentage of incontinent stools. The percentage of stools that had a loose/liquid consistency was also significantly lower in the fibre groups.[178]

Lauti et al.[177] investigated two combination treatments consisting of an antimotility medication, a diet advice sheet for a high or low fibre diet, and a fibre supplement or placebo in an RCT design. Subjects were outpatients of a colorectal service in Australia who were incontinent of mucus, liquid, or solid stools (i.e., this study was not limited to patients with faecal incontinence of loose or liquid stools). Results showed no additional benefit of a dietary fibre supplement and advice for a high vs. low fibre diet, over use of the antimotility medication, loperamide, for reducing incontinence of flatus, mucus or solid or liquid stool.[177] This study had a low level of control of threats to internal validity and intervention fidelity.

Two studies included dietary fibre as part of a staged intervention and used a non-randomized design.[179,180] In one study using a tailored staged intervention,[179] female outpatients with faecal incontinence of either liquid or solid faeces, who agreed to follow the intervention, were instructed to consume one heaped tablespoon of methylcellulose twice per day that could be increased to two heaped tablespoons as needed. If faecal incontinence did not cease within two weeks, the women were instructed to add one capsule of loperamide twice a day that could be increased up to two capsules three times per day as needed. Fluid intake was also regulated by subgroups: those with solid stool were instructed to drink 60 ml per day (doesn’t seem much!) and those with liquid stool were to avoid drinking 30 minutes before and after every meal. The control group was comprised of women who did not agree to follow the intervention but who agreed to report follow-up data. faecal incontinence was cured in 46% of women in the intervention group and none in the control group.[179]

In another study, 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited from two clinics in the Netherlands, and 47 completed the protocol. 180 For two months, patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water daily for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily. Faecal soiling resolved completely in 79% (37/47) of patients. In 12 patients (24%), soiling resolved after psyllium supplementation alone. Of the 37 who added rectal irrigation to psyllium supplementation, 24 (48% of 50) resolved soiling. Of the remaining 11 who added cholestyramine to psyllium supplementation rectal irrigation, 2 (2% of 50) resolved soiling.

One study of institutionalized frail elderly showed that treating faecal impaction or constipation using...

</table>
lactulose, a nondigestible sugar with osmotic properties, and a laxative or enema did not reduce faecal incontinence, [181] but no studies were found treating faecal incontinence associated with constipation in non-institutionalized adults.

3. SUMMARY OF EVIDENCE

Patients consider diet a factor affecting the severity of their faecal incontinence and they use diet modification as a self-care strategy (Evidence Level 3). Dietary fibre supplementation appears to be a safe and tolerable intervention that reduces faecal incontinence of loose stools (Evidence Level 1). However, findings about its effectiveness when added to an anti-motility medication differ (Evidence Level 2). Dietary fibre as an adjuvant to rectal irrigation can reduce faecal incontinence (Evidence Level 3).

4. RECOMMENDATIONS FOR PRACTICE

- Soluble dietary fibre is recommended for the management of faecal incontinence especially when stool consistency is loose or liquid. (Recommendation Grade B).

- Soluble dietary fibre is recommended as part of a combination therapy involving rectal irrigation (Recommendation Grade B).

- No recommendations about the use of dietary fibre as an adjuvant to antimotility medications can be made because evidence is conflicting and study methods vary in quality. (Recommendation Grade B)

- The effectiveness of food restrictions, timing of eating schedules, and modifications of eating patterns and food preparation on reducing faecal incontinence should be evaluated for their usefulness. (Recommendation Grade C)

- Patients should be asked about dietary restrictions and meal skipping to assess nutritional impact especially in groups who may be at higher risk for malnutrition. (Recommendation Grade C)

5. RECOMMENDATIONS FOR RESEARCH

Further studies on the effect of dietary fibre and other diet modifications on faecal incontinence are encouraged to build a greater body of evidence:

- Determine the optimal type and amount of fibre to use for faecal incontinence as dietary fibres differ in their chemical composition and properties

- Determine the extent to which a dietary intervention can augment other behavioural interventions, such as pelvic floor muscle exercises or bowel training, needs further study.

- Assess the effect of modifying usual diet and eating pattern as a management strategy for faecal incontinence

There are several recommendations for methodological rigour in future studies. Theory-based, adequately powered, controlled trials are sought. Studies should control for variability in an individual’s baseline severity of incontinence and any adjuvant therapies. In staged interventions, the effect of the order of dietary fibre and other components, should be assessed. Monitoring adherence to the dietary intervention and intervention fidelity are recommended. A common set of outcome measures that includes tolerance to diet interventions is recommended. Reporting outcomes of faecal incontinence in addition to those of anal incontinence (which incorporates flatus incontinence) is recommended.

VI. BOWEL MANAGEMENT AND RE-TRAINING PROGRAMMES

1. BACKGROUND

Bowel management programmes are used by individuals with constipation and although constipation is a risk factor for faecal incontinence in children and older people, it has not been found to be a consistent risk factor for faecal incontinence in adults of other ages. Committees 9 and 11 have reviewed the evidence for bowel retraining programmes in children and older adults, respectively. Bowel management after spinal cord injury also involves other bowel problems in addition to faecal incontinence, such as constipation or incomplete evacuation; therefore, combinations of therapies for both faecal incontinence and constipation are common. Few bowel management approaches have been tested for their effectiveness for faecal incontinence only in adults with non-neurogenic faecal incontinence. Any studies found which addressed bowel management or training for multiple bowel problems in adults with non-neurogenic faecal incontinence that did not separate results for faecal incontinence, were excluded from this review.

2. SEARCH

The following keywords were searched: anal, anorectal, bowel, faecal, faecal, rectal, stool and continent or incontinent, or diarrhea, diarrhoea and the relevant lifestyle or intervention term: bowel and train or retrain; digital and stimulat); crede or massage; enema; and suppository, toileting, toile, toilet facilitiest. The following databases were searched: EBSCOHost® databases including Academic Search Premier, Alt HealthWatch, Health Source; Nursing/Academic Edition, CINAHL 2008-November, and 2011 MEDLINE 2008- Nov, 2011 The Cochrane library and a recent systematic review of the epidemiology
and prevention of urinary and faecal incontinence was also reviewed.[123]

All seemingly relevant abstracts were reviewed, after which salient articles were retrieved and reviewed, and the reference lists searched for further studies. Studies that included patients with a variety of bowel disorders, but did not report results of bowel management/retraining for patients with faecal incontinence separately, were excluded. Studies in which results of retrograde irrigation were not reported separately from those of antegrade irrigation were also excluded.

3. REVIEW OF EVIDENCE ON BOWEL MANAGEMENT AND RETRAINING PROGRAMMES

a) Bowel habit and toileting

Expert opinion supports the importance of attempting to establish a regular, predictable pattern of bowel evacuation by patient teaching and adherence to a routine.[121,182] Because peristaltic contractions of the colon, that are associated with defaecation, increase in frequency following awakening from sleep and following meals,[183,184] the period after breakfast is the best time for scheduled defaecation. No studies of bowel habit training or regular toileting in non-institutionalised adults with mobility or cognitive limitations, or with normal cognitive function, were found in the current literature search.

b) Resisting urgency

The strong sensation of urgency to defecate is frequently associated with diarrhoea, and it is a recognised risk factor for faecal incontinence in adults.[185] In contrast to urinary incontinence, particularly the overactive bladder syndrome (Committee 14), for which a body of knowledge has developed on the efficacy of bladder training techniques (i.e., voiding at specific intervals rather than in response to urge and deferment techniques), the possibility of bowel retraining for resisting urgency to defaecate is relatively unexplored. Some biofeedback protocols focus on altering rectal sensory thresholds as discussed below.

In the previous review, one RCT[173] that compared patients who received education, including urgency resistance techniques and dietary advice, to a group of patients who received the same training plus anal sphincter exercises with or without home or clinic biofeedback showed no significant difference in outcomes.[137] No new studies of resisting urgency to reduce faecal incontinence were identified in the current search.

c) Evacuation training

A common factor in the genesis of pelvic floor problems may be chronic straining with perineal descent from constipation; this may lead to pelvic floor damage (direct or neurological).[186,187] and may be associated with pelvic organ prolapse or UI or faecal incontinence. In one small study, women who reported straining were more likely to develop urogynaecologic symptoms such as prolapse and stress urinary incontinence.[188] However, straining has not been shown to be a risk factor for faecal incontinence. No studies were identified in the previous or current search that examined the effect of decreasing straining on preventing or treating faecal incontinence in non-institutionalised adults.

Clinically, many patients with faecal incontinence are taught evacuation techniques or are encouraged to use laxatives, suppositories or enemas in an attempt to ensure that the rectum remains empty most of the time, thus giving less chance of faecal incontinence. This is known to improve continence in children (Committee 9) and elderly patients (Committee 11). One RCT of a combination treatment package for faecal incontinence in adults included training on evacuation techniques and noted that patients reported improved ease of evacuation after treatment.[137] No separate data on faecal incontinence were presented. No new studies were found utilising specific evacuation training to treat faecal incontinence in younger adults in the current literature search.

Committee 10 has reviewed the evidence for digital rectal stimulation and manual evacuation in patients with neurogenic faecal incontinence. The use of these techniques to assist complete evacuation in non-neurological populations has not been evaluated.

d) Rectal irrigation

Irrigation of the lower bowel has been used for many years to manage both faecal incontinence and constipation by patients with spinal cord damage (Committee 10). Surgical construction of a portal for antegrade irrigation is covered by Committee 17. Various equipment has been used for retrograde irrigation, including a stoma irrigation cone held in place manually against the anus,[189,190] a mechanical pump[191] and specifically designed anal irrigation equipment.[192,193] Rectal irrigation for faecal incontinence secondary to spina bifida is common.[192]

Five studies that investigated rectal irrigation for faecal incontinence and met the criteria were found in the current literature review. Three of the studies examined the effect of rectal irrigation in patients whose faecal incontinence did not improve after using other conservative therapies.[194-196] Three studies had an observational design[180,194,197] and two studies reported results of one group before and after using rectal irrigation.[196,198] One study included rectal irrigation as part of a staged intervention along with dietary fibre,[180] and two studies allowed addition of other therapies such as laxatives or dietary fibre on an uncontrolled basis.[196,198] Sample sizes were small in all studies and none used a randomised between groups design.
The effects of rectal irrigation using tap water for a mean duration of 18 months to treat faecal incontinence were reported in one study of 32 patients who had faecal soiling (n=16) or faecal incontinence (n=16) (the distinction between the two conditions was not defined).[197] Overall, approximately half (57%) of subjects reported improvement of faecal incontinence on a questionnaire; improvement was less in those with faecal incontinence (38%) compared to those with faecal soiling (79%). Ten patients discontinued rectal irrigation after 1 month due to lack of benefit, adverse symptoms or time required.

In a survey of patients with a variety of different bowel disorders, retrograde colonic irrigation was observed as being effective in reducing soiling in 41% of 32 individuals and reducing faecal incontinence in 47% of 71 persons.[194] However, irrigation was discontinued by 67% of those with soiling and 17% of those with faecal incontinence despite a benefit. Reasons for discontinuation included the time required, difficulties with the irrigating procedure, and incontinence of irrigation fluid later in the day.

One prospective study followed 18 patients with faecal incontinence who used a rectal irrigation pump and tap water. Subjects could add soap to the irrigation fluid and take laxatives or dietary fibre as needed.198 Six patients added psyllium dietary fibre and three added medications. Compared to baseline Parks incontinence scores (3.6 (0.50 SD)), faecal incontinence significantly decreased at 3 months (2.3 (1.03)), 6 months (2.7 (1.3)) and one year (1.6 (.92)). Eleven patients (61%) were considered “pseudo” continent at 3 months.

A prospective study of a nurse practitioner-led rectal irrigation program for adult and pediatric patients (age = 52 (5-85 mean (range) years)) with functional bowel disorders included 51 adult patients with predominant faecal incontinence.[196] Faecal incontinence symptoms were reported on a non-validated linear analogue scale at the start and after an average of 42 months using rectal irrigation with water, plus laxatives if needed. Faecal incontinence symptom scores improved in the faecal incontinence only group from 7.5 (6.5-8.5 range) before to 4.9 (3.5-6.4) after the rectal irrigation program.

Rectal irrigation was included as part of a staged intervention for faecal incontinence in an already mentioned, study of 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited.[180] For two months, all patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily; 47 patients completed the protocol. Faecal soiling resolved in 12 patients (24% of 50) consuming psyllium alone, 24 of 37 (48% of 50 patients) who added rectal irrigation to psyllium supplementation, and 2 of 11 (2% of 50 patients) who added cholestyramine to psyllium supplementation rectal irrigation.

e) Combinations of therapies

It is recognised that in many people, the symptom of faecal incontinence is the result of a complex combination of disordered anatomy and physiology, stool consistency and gut motility, emotional and psychological status and restricted access to toilet facilities, amongst other factors (see Committee 5). Hence in clinical practice many patients use a combined approach, for example, adjusting diet, medications, lifestyle, muscle function and bowel habit simultaneously, depending on the result of an initial assessment. [199,200] Studies of combinations of education, diet or fluid, and behavioural therapies, which have been identified in this review, are included by topic of the intervention in the respective section above. A limitation of these studies is that the contribution of the individual components to the overall effect, or the effect of the order of components, has not been determined and remains unknown.

f) Summary of evidence on bowel management and retraining programs

There is limited evidence on many topics in this area. In particular there are no studies on effects of bowel habit training, scheduled toileting, resisting urgency, and rectal evacuation in adults with faecal incontinence. However, rectal irrigation can reduce faecal incontinence when first-line conservative therapies fail (Evidence Level 2).

g) Recommendations for practice

- Rectal irrigation is recommended for patients who do not respond to other conservative therapies and as part of a combined approach of therapies (Recommendation Grade C)
- Attempt to establish a bowel routine (Recommendation Grade C)
- Urgency resistance training is possibly useful for urgency. (Recommendation Grade D)
- No recommendation on toileting methods is given due to lack of evidence. (Recommendation Grade D)

h) Recommendations for research

- Randomized clinical trials of rectal irrigation are needed.
- Research is needed in all other areas of bowel training.

VII. TREATMENT WITH MEDICATION

1. GOALS

With the recognition that severity is subjective, treatment should be allocated according to symptom
profile and patient lifestyle. The goals of this section are to identify the drugs and other medical interventions that have been used to treat faecal incontinence and to evaluate the evidence regarding their efficacy (See Table 2). Drugs can be combined for synergistic effect, helping reduce individual doses; loperamide plus codeine phosphate, and loperamide plus amitriptyline are examples. Conservative management of faecal incontinence has focused exclusively on three mechanisms:

- Reduction of diarrhoea. Diarrhoea is consistently found to be a strong risk factor for faecal incontinence.
- Increasing resting anal canal pressure. Low resting anal canal pressure is a risk factor for passive faecal incontinence, and is commonly seen following some types of anorectal surgery (e.g., ileal pouch procedures, sphincterotomy, abdominoperineal pull-through for imperforate anus).
- Treatment or prevention of constipation. Constipation is frequently found to be a risk factor for faecal incontinence, especially in children and the elderly.

2. SEARCH METHODS

The Medline database and the Cochrane reviews [201,202] were searched for studies in any language and any year through October 2011 which matched the following search terms: “Faecal incontinence” OR “anal incontinence” AND “drug” OR “medical management” OR “medical treatment;” “Faecal incontinence” OR “anal incontinence” AND “loperamide” OR “diphenoxylate;” “Faecal incontinence” OR “anal incontinence” AND “laxative” OR “polyethylene;” “Faecal incontinence” OR “anal incontinence” AND “phenylephrine gel.” Additional articles were identified by examining systematic reviews.[202-204]

3. REVIEW OF EVIDENCE ON MEDICATIONS FOR FAECAL INCONTINENCE

a) Treatment of diarrhoea-associated faecal incontinence with antidiarrhoeal drugs

1. LOPERAMIDE AND DIPhenoxylATE

The most extensively tested drug treatment for diarrhoea-associated faecal incontinence is loperamide. We identified 7 studies in adult subjects [177,205-209] and 3 studies in children.[210-212] These studies all have methodological weaknesses including small sample sizes, use of crossover designs, or they are case series. Loperamide is a synthetic opioid with μ-agonist activity and coincidental calcium channel blocking actions. By slowing gut transit, increasing fluid reabsorption and reducing secretion, loperamide thickens stool consistency and reduces stool frequency. It also has direct sphincter actions, attenuating the anorectal inhibitory reflex and increasing resting anal pressure. It is at least as effective as codeine, and superior to diphenoxylate in chronic diarrhoea, with a tendency to reduce faecal incontinence more effectively than the other agents. The availability of a syrup formulation offers the opportunity of titrating the dose more finely to avoid the side-effect of constipation. Some authors advocate using the drug before meals to reduce postprandial bowel urgency. Tolerance does not seem to develop with chronic administration, and the safety profile is excellent with both regular and as-required use.

Diphenoxylate, a natural opioid, is usually combined with atropine to reduce abuse potential. It crosses the blood–brain barrier to produce central nervous system side-effects and, when combined with atropine, can cause anticholinergic effects. It is less effective than loperamide. Codeine phosphate is another opiate derivative, with side-effects of nausea, tolerance and dependence. Its clinical effects are similar to those of loperamide, but it is harder to titrate and adverse effects become prominent with time.

Studies generally support the efficacy of loperamide for decreasing diarrhoea-associated faecal incontinence. The most important of these studies are briefly summarized below: Palmer and colleagues[205] compared loperamide (average of 4.6 mg per day) to codeine (average of 103 mg per day) and diphenoxylate (average of 12.5 mg per day) in 30 patients with diarrhoea, of whom 19 had faecal incontinence prior to treatment. However, change in faecal incontinence was not the primary outcome measure. Loperamide was superior to diphenoxylate and similar to codeine with respect to decreased stool frequency, improved stool consistency, and reduced side-effects. Although not statistically significant, there was a trend for less faecal incontinence while taking loperamide compared to diphenoxylate.

Fox and colleagues [209] tested different doses of loperamide against placebo in a double-blind crossover study of 10 obese subjects who were soiling as a result of taking orlistat for weight control. These 10 subjects were selected for study because they had previously been found to soil while taking orlistat. In this study, loperamide decreased soiling and faecal incontinence and increased resting anal canal pressure. Lauti’s group [177] compared loperamide plus fibre supplementation to loperamide with a low fibre diet and placebo fibre supplement in the first adequately powered study. This was a double-blind crossover study with order of treatments counterbalanced. Results showed a significant improvement in continence relative to baseline in both groups, but the addition of fibre to loperamide did not increase benefit.

Sze and Hobbs [179] investigated the additional benefit of loperamide over methylcellulose in an unblended study of 69 patients. Forty-six percent of patients were “cured” by the combined treatment, although loperamide had a tendency to cause constipation, which

was modified by dose reduction. Taken together, these studies suggest that loperamide may be more effective than fibre supplementation alone for the treatment of diarrhoea-associated faecal incontinence. An earlier study by Bliss et al.[178] which is reviewed in Section 16.5, showed that fibre supplementation with either psyllium or gum arabic improved diarrhoea associated faecal incontinence, more than placebo.

2. OTHER ANTIDIARRHOEAL DRUGS

Santoro and colleagues [213] carried out an uncontrolled study of the tricyclic antidepressant, amitriptyline, given 20 mg at bedtime, in 18 patients with faecal incontinence; diarrhoea was not required. Thirteen of 18 became continent and 3 reported improvement. The authors attributed the benefits to increased anal resting pressure and decreased numbers of “rectal motor complexes.” This study suggests that amitriptyline and other tricyclic antidepressants are of possible benefit for treating faecal incontinence. Sucralfate is a formulation of aluminium hydroxide used primarily for the treatment of duodenal ulcers; it has the property of coating the stomach lining. An early study suggested that sucralfate might reduce diarrhoea secondary to radiation proctitis in patients receiving radiotherapy for pelvic cancer.[214] However, subsequent large randomized controlled trials have shown no significant benefit for diarrhoea [215] and a worsening of faecal incontinence [216] in this patient population. Bharucha et al.[217] undertook a 4 week trial of a clonidine patch. There was a modest reduction of stool frequency and improvement of continence.

3. MECHANISM OF ACTION

Three possible mechanisms of action have been identified in these studies of the drug treatment of diarrhoea-related faecal incontinence: loperamide, diphenoxylate, amitriptyline and clonidine appear to work in part by decreasing bowel movement frequency through an effect on motility and absorption. Fibre supplements (reviewed in Section 4 above), on the other hand, work by binding more water into the stools. Resting anal canal pressures were reported to be increased in response to loperamide [206,207] and amitriptyline.[213]

b) Drugs for increasing anal canal pressure in patients with passive faecal incontinence

A subgroup of patients with faecal incontinence has passive incontinence, defined as faecal incontinence that is not preceded by a sensation of urgency to defecate and that occurs without awareness. This is believed to be related to decreased resting pressure in the anal canal, due to an impaired internal anal sphincter and/or to decreased sensation for rectal distension. A specific aetiology for passive faecal incontinence is the patient with a colectomy (usually for ulcerative colitis) with a surgically constructed ileal reservoir connected to the anal canal.[218]

1. PHENYLEPHRINE GEL

Phenylephrine gel, an alpha-1 adrenergic agonist, has been investigated for the treatment of passive faecal incontinence in several studies.[219-223] In an initial study of 36 patients with intact sphincters, no significant benefit was seen.[223] Two subsequent studies [219,222] suggested a benefit of phenylephrine gel, but a recent randomized controlled trial in 35 patients with passive incontinence secondary to low anterior resection failed to show a benefit.[221] Thus, the clinical utility of phenylephrine gel (if any) may be limited to patients with passive incontinence associated with ileal pouches.L-erythro methoxamine gel, an alpha-1 adrenoreceptor agonist similar to phenylephrine, has also been shown in two proof-of-concept studies to increase internal anal sphincter resting pressure.[224,225] although no clinical trial data are available as yet.

2. VALPROATE SODIUM

The gamma-amino butyric acid transaminase inhibitor, valproate sodium, also increases anal canal resting pressure. It was compared to placebo in a double-blind, randomised crossover study [226] in 17 patients with diarrhoea-related faecal incontinence secondary to colectomy and ileal pouch-anastomosis. The drug decreased faecal incontinence episodes and stool frequency relative to baseline and increased anal canal pressure, whereas placebo did not have these effects. In a second randomized controlled trial by the same investigators [227] patients with ileal pouches were treated with valproate sodium or placebo. There was a significant improvement in anal canal pressures, pouch capacity, and continence. Therefore, valproate sodium is of possible benefit in this population.

c) Drug treatment of constipation-associated faecal incontinence

Constipation-associated faecal incontinence, sometimes referred to as “overflow incontinence.” It is more common in children, nursing home residents, and in patients with spinal cord injury. The proportion of faecally incontinent nursing home residents whose faecal incontinence is attributable to “overflow constipation” is not known. No studies of treating constipation-associated faecal incontinence in adults, outside these groups, were found.

1. SUMMARY OF EVIDENCE ON MEDICATION AND FAECAL INCONTINENCE

- Loperamide is useful for diarrhoea-associated faecal incontinence. There is some evidence that the loperamide may be superior to diphenoxylate (Evidence Level 2).

2. RECOMMENDATIONS FOR PRACTICE

- Treat faecal incontinence with diarrhoea with anti-diarrhoeal medication (Recommendation
Pelvic floor muscle training (PFMT), biofeedback, and electrical stimulation are distinctly different therapeutic techniques for treating faecal incontinence; see descriptions below. These techniques are compared to each other or combined in some studies (e.g., biofeedback combined with electrical stimulation).

1. PELVIC FLOOR MUSCLE TRAINING

Pelvic floor muscle training (PFMT) is also called Kegel exercise training, after its developer. [231] The patient is instructed to contract the pelvic floor muscles including the external anal sphincter and puborectalis while keeping abdominal wall muscles relaxed and to do this multiple times each day with the goal of strengthening pelvic floor muscles. In a typical protocol, the patient may be instructed to squeeze for 10 seconds while continuing to breathe deeply so that the abdominal wall muscles do not also contract. Ten to 20 such 10-sec squeezes are separated by 20 second periods of pelvic floor relaxation. Often patients are instructed to squeeze 10-20 times in a block and to repeat this block of exercises 3-5 times a day. The patient may be taught how to perform this exercise using only verbal or written instructions,[232] or they may be given verbal feedback on their performance by the therapist during a digital rectal examination.[233,234] However, electronic or mechanical devices are not often used to amplify the sensory information available to the patient on how well they are performing the exercises.

2. BIOFEEDBACK

Biofeedback training is distinguished from PFMT by the use of electronic or mechanical devices to augment the intrinsic sensory information available to the patient on how well they are contracting their pelvic floor muscles. The purpose of this type of training is to ensure that patients learn the appropriate way to contract the pelvic floor muscles while keeping abdominal wall muscles relaxed. Such training is intended to strengthen pelvic floor muscles and it is usually combined with instructions to practice PFMT at home between clinic visits. Another feature of many biofeedback training protocols is sensory training or coordination training. As a consequence of neurological injuries, many patients lose the ability to recognize sensations associated with the movement of stool into the rectum and may fail to contract the pelvic floor muscles in order to avoid stool leakage. In sensory training, a balloon-tipped catheter is introduced into the rectum and distended with varying volumes of air to help the patient learn to recognize weaker distensions. Coordination training is a variant of sensory training and refers to having the patient practice contracting pelvic floor muscles in response to any sensation of rectal distention until this becomes a well-practiced habit.[138]

3. ELECTRICAL STIMULATION

Electrical stimulation from probes placed in the anal canal or from electrodes on the perineum adjacent to the anus has also been used to treat faecal incontinence. In typical applications, stimulation is performed daily at home using a battery operated electrical pulse generator connected to the anal electrodes. [234] Different theories have been advanced to account for how this might facilitate continence. [234] In the earliest applications, electrical stimulation was used at intensities that triggered a contraction of the pelvic floor muscles, and patients were encouraged to try to augment the contractions produced by electrical stimulation or to try to reproduce these contractions. [234] Others have suggested that the stimulation of afferent nerves by lower intensities of electrical stimulation may help by increasing the sprouting of synapses peripherally or the size of the receptive fields for these nerves in the brain. [235] Electrical stimulation is sometimes combined with biofeedback. [236]
Cochrane Reviews, and (for drug treatment) EM-BASE. These searches were limited to studies in which the subjects were adult humans. No restrictions were placed on language of publication. The search terms were: (Faecal incontinence OR Anal incontinence) AND (Biofeedback OR Neuromuscular conditioning OR Pelvic floor exercise OR Kegel exercise OR Neuromodulation OR Drug treatment OR Antidiarrheal OR Loperamide OR Laxative OR Nifedipine OR Phenylephrine OR Cholestyramine OR Clonidine). In addition, the following individual authors were searched: A Bharucha, C Norton, B Southwell, SS Rao, MMKamm, AWald, F Azpiroz, PEnck, MCrowell, and RMittal. The bibliographies of identified studies were also searched for additional references.

This search identified 665 references which were reviewed by title and abstract for relevance and the relevant ones were assigned to the following 4 sets. Minor overlap between lists was allowed and reviews were included to allow us to check for additional references. The reference sets were (1) Biofeedback (69 references), (2) Pelvic floor exercise (9 references), (3) Electrical stimulation without implanted device (13 references), and (4) Drug treatment (25 references). These reference sets were assigned to separate reviewers and read carefully to identify randomized controlled trials (RCTs), cohort studies with appropriate comparison groups, and a few uncontrolled cohort studies which were included because they addressed key issues such as long-term maintenance of treatment effects. After eliminating duplicate references and studies containing fewer than 10 patients per treatment condition, 6 studies published since January 2008 met inclusion criteria (Table 3).

5. SUMMARY OF ICI 2008 ASSESSMENT

a) ICI 2008 assessment of pelvic floor muscle exercises

The review of the literature in the previous ICI report [173] identified several RCTs in which PFMT was used as a control condition to determine whether the addition of biofeedback to PFMT yielded greater improvements, but only one RCT which attempted to isolate the contribution of PFMT by comparing education and advice alone to education and advice plus PFMT. [137] This study (described above) was well designed and adequately powered. No greater benefit was observed for PFMT compared to advice. Based on this evidence, the reviewers in 2008 concluded that PFMT may be as effective as biofeedback and that advice alone may be as effective as PFMT.

b) ICI 2008 assessment of biofeedback therapy [173]

In the last International Consultation on Incontinence [173] the working committee concluded that, “In contrast to the mostly favourable outcomes reported in uncontrolled studies, randomized controlled trials have generally found no additional benefit when biofeedback was added to either a comprehensive behavioural and medical management program, or to digitally taught sphincter exercises” [page 1358]. The reviewers noted that very few studies have reported process measures, such as pre-post changes in sphincter strength or rectal sensory thresholds, which are targeted by biofeedback therapy, and presumed to account for any improvements in continence, and they questioned whether this should be required, before a biofeedback treatment protocol can be said to be responsible for an improvement in faecal incontinence. The committee concluded that biofeedback “…is possibly effective but currently unproven” [page 1359]. Only the following three RCTs were available for review in 2008:

Heymen et al. [237] randomized 40 patients with faecal incontinence to one of 4 groups: (a) EMG biofeedback during clinic visits, (b) EMG biofeedback plus sensory training with a balloon during clinic visits, (c) EMG biofeedback in the clinic plus use of an EMG biofeedback trainer at home, and (d) EMG biofeedback plus sensory training in the clinic plus daily use of an EMG biofeedback trainer at home. There were no significant differences between groups, but the study was underpowered with only 10 patients per group.

Norton et al. [137] randomized 171 patients to one of 4 groups: (a) education and management advice provided by a nurse clinical specialist; (b) advice plus PFMT taught verbally and by digital rectal exam; (c) advice, PFMT, and instrumented biofeedback which included both sensory and strength training; and (d) advice, PFMT, biofeedback, and daily home practice with an EMG biofeedback unit. There were up to nine 40-60 minute sessions in each group (median number of sessions completed was 5). There were no significant differences between groups in subjective rating of improvement, change in Vaizey Continence Scale scores, or change in frequency of faecal incontinence. Specifically, there was no greater rate of improvement in the biofeedback group (53% improved) compared to the advice and education only group (54% improved). A limitation of the study was that 49% of patients rated their incontinence severity as “minor” at baseline, and the median frequency of incontinence before treatment was only once per week.

Solomon et al. [233] randomized 120 patients with mild to moderate faecal incontinence to one of three groups: (a) manometric biofeedback, (b) trans-anal ultrasound biofeedback in which the ultrasound image was visible to the patient in real time, and (c) PFMT taught by a therapist who provided verbal feedback during digital rectal exami-
nation. There were no differences between groups on the Pescatori or St. Mark’s incontinence severity scales, subjective ratings of improvement, quality of life, or manometrically measured squeeze pressures. However, there were significant differences from pre-treatment to post-treatment on most outcome measures.

c) ICI 2008 assessment of tibial nerve transcutaneous electrical stimulation from non-implantable devices

In the previous ICI report, [173] studies of tibial nerve transcutaneous electrical stimulation were reviewed by the faecal incontinence surgery committee. [238] In the absence of any controlled studies, this committee concluded that tibial nerve stimulation was an investigational technique and did not endorse it for clinical use.

6. UPDATE: REVIEW OF EVIDENCE FOR 2008-2012

Five studies published between January 2008 and January 2012 met criteria for review (Table 3). Two studies were RCTs comparing manometric biofeedback to PFMT, [232,239] a third RCT compared different methods of performing PFMT, [240] and the last evaluated the effects of PFMT vs. no PFMT on the prevention of anal incontinence (i.e., inclusion of flatus incontinence) during pregnancy and post-partum. [241] Another large cohort study [242] was included because it addresses the duration of biofeedback effects by following subjects until 60 months.

The Heymen et al. study [232] is important because of its novel design: All patients were first treated for 4 weeks with a conservative treatment protocol that emphasized patient education and normalization of stool consistency with fibre or non-prescription medication. This run-in protocol included only what is considered standard care for faecal incontinence, but the educational component was enhanced by (a) using schematics of the anatomy of the pelvic floor and images from defaecography to teach them why they were incontinent, and (b) having patients keep diaries of bowel accidents and stool consistency. At the end of 4 weeks, patients were asked whether they had experienced “adequate relief” of faecal incontinence, and the 21% who answered affirmatively were excluded from the rest of the trial. The remaining patients who did not report adequate relief had been randomly assigned before the run-in period to either biofeedback plus PFMT or PFMT alone. These interventions were presented in such a way that there were no differences between groups in the expectation of benefit. The biofeedback intervention combined strength training with sensory and coordination training, and was delivered in 5 one-hour sessions spaced approximately 2 weeks apart. PFMT was taught by verbal instruction, not with the benefit of digital rectal examination. The primary assessment was at 3 months follow-up as determined a priori, and patients who reported adequate relief at 3 months were followed up again at 12 months. All patients not reporting adequate relief at 3 months were assumed to be non-responders at 12 months.

An intent-to-treat analysis at 3 months showed that significantly more patients in the biofeedback group reported adequate relief compared to the PFMT-only group (76% vs. 41%). Continence (zero faecal incontinence episodes in the previous month) was achieved by 44% of biofeedback-treated patients compared to 21% of PFMT-only patients. Scores on the validated Faecal Incontinence Severity Index [243] confirmed significantly greater improvement in the biofeedback patients compared to the PFMT-only patients at 3 months and again at 12 months follow-up. Heymen et al. [232] also showed that biofeedback-treated patients increased their anal canal squeeze pressures and decreased their abdominal wall tension during pelvic floor contractions significantly more than PFMT-treated patients, but changes in sensory thresholds were not significantly different.

The results of Heymen et al. [232] suggest that biofeedback plus PFMT is superior to PFMT alone in patients with moderate to severe faecal incontinence. They also show that treatment benefits for both biofeedback and PFMT are not explained by nonspecific treatment effects of conservative management such as education and normalization of stool consistency. Furthermore, these data provide evidence that PFMT is more effective than conservative management alone.

Bols et al. [239] reported an RCT which also compared manometric biofeedback plus PFMT to PFMT alone. Eighty patients with moderate to severe faecal incontinence were randomized to these two conditions. Up to 12, 35-minute training sessions were provided, and the primary outcome was the Vaizey Incontinence Severity Score. There was no significant difference between groups, although there was a trend favouring manometric biofeedback: 82.5% of the manometric group vs. 66% of the PFMT-only group improved by more than one point on the Vaizey scale. Limitations of this study were lack of power, only 75% of the numbers calculated beforehand as needed for adequate power were enrolled, and the fact that the intervention was provided by 25 different physiotherapists in private practice settings.

Bartlett et al.[240] compared exercise regimens, i.e., whether the patients were trained to perform fast twitch exercises (1 sec duration contractions) in addition to slow contractions (10 second squeezes) or they only performed slow contractions (10 second squeezes). The 72 patients enrolled in this

<td>72 patients with onset of faecal incontinence following colorectal cancer surgery were randomized to two groups. Mean age 62 years; 73.6% female</td>
<td>All patients received 4 weekly manometric BF sessions plus PFME training in sustained, 10 sec squeezes. The experimental group received additional practice of 1/sec rapid maximal contractions.</td>
<td>Equivalent number and type of BF sessions combined with PFME training of sustained, 10 sec contractions. The only difference was no rapid exercises.</td>
<td>Both groups improved with no difference between groups. Attrition rate was 22-29%.</td>
<td>Major limitation: Heterogeneity of population and small sample sizes (type 2 error</td>
</tr>
<tr>
<td>Bo et al. 241 Norway</td>
<td>105 sedentary primiporous women without history of faecal incontinence</td>
<td>PFME taught as part of group exercise class 2X/week for 12 wks. Patients performed 3 sets of 12 maximal contractions per class. Only group verbal instructions provided.</td>
<td>Controls received usual care.</td>
<td>No difference in number of women reporting flatus or faecal incontinence during pregnancy or at 6 wks. post-partum.</td>
<td>Study was underpowered.</td>
</tr>
<tr>
<td>Lacima et al. 242 Spain</td>
<td>Cohort of 95 patients incontinent of solid stool referred for BF. Mean age 61 years; 85% females. Excluded patients with recent obstetric injury, cloaca defect, and rectal prolapse</td>
<td>Manometric BF combined strength training, sensory training, and coordination training for five 45-min. sessions. Daily PFME were also prescribed.</td>
<td>No treatment. Cohort of 40 patients referred to the same clinic for evaluation but BF was not recommended and no treatment for faecal incontinence was prescribed.</td>
<td>At 60 months follow-up 86% of the BF group were continent or had &gt;75% reduction in faecal incontinence frequency compared to 26% of untreated controls.</td>
<td>Strength: 60 month follow-up. Weakness: patients were not randomized to treatment. The BF group had greater average faecal incontinence severity than controls at baseline.</td>
</tr>
</tbody>
</table>
study had an onset of faecal incontinence following colorectal cancer therapy. Both groups improved with no difference between groups.

Lacima et al. [242] followed a cohort of 95 patients whom he treated with biofeedback and PFMT and followed up 60 months later. What makes this study worth including is that the authors showed that even at 60 months following training, 86% of the biofeedback/PFMT group were continent or had at least a 75% reduction in the frequency of faecal incontinence.

7. TIBIAL NERVE PERCUTANEOUS STIMULATION

There has been persisting interest in the use of tibial nerve stimulation for the treatment of faecal incontinence, reflected by the publication of several uncontrolled case series. [244,245] The theory behind this treatment derives from traditional Chinese medicine which identifies the posterior tibial nerve as an acupuncture point where stimulation can inhibit bladder contraction. Stimulation is done either using surface electrodes applied over the tibial nerve at the level of the ankle or by inserting a needle electrode into the region of the tibial nerve. Published case series [244,245] show a modest benefit for approximately half of patients tested, and in the absence of controlled studies, this technique must still be regarded as investigational.

Another variation of electrical stimulation is transabdominal electrical stimulation accomplished by passing electric current between an electrode on the abdominal wall and one on the back. This has so far been used only in children with slow transit constipation, [246] many of whom have encopresis. Reports show improved transit time, [247] improved quality of life, [244] and reduced encopresis. [245] This technique may find application in adults with overflow faecal incontinence but is currently regarded as investigational.

8. SUMMARY OF EVIDENCE

- Manometric biofeedback training is possibly effective. A new high quality study provides support for the hypothesis that biofeedback, when provided by an experienced therapist, is more effective than pelvic floor exercises alone, but the variability between studies suggests that results may be dependent on the training and experience of the therapist. (Evidence Level 1)

- PFMT is possibly effective for the treatment of faecal incontinence. New evidence shows that PFMT alone significantly improves outcomes for patients who have not responded to conservative management. [232] (Evidence Level 2)

- There is no support for the hypothesis that adding “fast twitch” contractions to PFMT improves continence outcomes. (Evidence Level 2)

- There is no support for the addition of electric stimulation from non-implanted devices in the treatment of faecal incontinence. (Evidence Level 2)

9. RECOMMENDATIONS FOR PRACTICE

- PFM exercises are recommended as an early intervention in the treatment of faecal incontinence as part of a conservative management bundle of interventions, based upon low cost and morbidity and weak evidence suggesting efficacy. (Recommendation Grade B).

- The use of biofeedback as a treatment for faecal incontinence is recommended after other behavioural and medical management has been tried, if adequate symptom relief is not obtained, given the numerous positive outcomes from uncontrolled trials, limitations in the current RCTs and low morbidity associated with its application. (Recommendation Grade B).

- Based on currently available evidence it is not possible to recommended electrical stimulation for faecal incontinence. (Recommendation Grade C)

10. RECOMMENDATIONS FOR RESEARCH

- There is a need to conduct further RCTs to determine whether specific biofeedback and pelvic floor muscle exercise protocols can alter physiological parameters of ano-rectal function with concomitant changes in bowel control.

- Clear description of modalities and evaluation of different elements of biofeedback

- Adherence monitoring

- Standardisation of outcome measures

- Long term follow up

- Robust patient-focused outcome measures

- Understanding of physiological effect and relationship to symptom change

- Work on clinically meaningful improvement and distinguishing cure from improvement rates

- The exploration of possible synergies between urinary and faecal incontinence interventions and evaluations should be considered in study designs.

IX. QUALITATIVE RESEARCH ON THE EXPERIENCE OF FAECAL INCONTINENCE AND QUALITY OF LIFE

1. BACKGROUND

The experience of faecal incontinence has been studied from a qualitative perspective since 1999 and tied with quality of life. Qualitative methods focus on
the intensive investigation of the particular, and the meaning of a phenomenon, in this case, faecal incontinence. Because qualitative studies generate large amounts of quality text data small purposeful sample sizes are used to accomplish their aims. These studies focus on studying the context or experience of a phenomena rather than measurement of variables. Sample sizes in the 14 studies included in this review ranged from 9 to 100 for qualitative phenomenological, grounded theory and descriptive studies, to 186 participants in an open ended questionnaire interview, for a total of 462 participants. Three studies received a grade of C but were included in the review because the evidence was relevant and substantiated by other quality studies.

The studies below have used a number of qualitative methods to explore the experiences of quality of life using phenomenological, grounded theory and qualitative descriptive designs using in-depth interviews, one study used one question with a rating scale, and one study used a semi-structured interview questionnaire. A thematic analysis was completed on the content of the quality of life studies, and the following five themes were derived and used as categories for the review of content: issues relating to relationships, time, body, sexuality and diet. Of the twelve studies reviewed on faecal incontinence, 4 studies focused on community living women, one study of women in a nursing home with pelvic floor dysfunction, one study of community living men, 4 studies of community living adults, and studies of specific diseases causing faecal incontinence including spinal bifida and multiple sclerosis.

2. CRITERIA FOR EVALUATION

Over the last 25 years there has been an extensive debate about the best methods and criteria to evaluate qualitative research studies. Criteria for the evaluation of qualitative research was synthesized using the most recent literature on quality and rigor, and is included here. These criteria were used to critique studies, strengths and limitations were noted, and a grade was given for practice recommendation.

In the last 10 years new ideas and criteria have been designed and are now being applied to evaluate qualitative studies.[248-257] The qualitative research studies on faecal incontinence (faecal incontinence) and quality of life, related to faecal incontinence, will be analyzed according to these new criteria summarized below. The strength of the evidence provided by an individual study depends upon the individual study design to maximize application to practice. A grading procedure has been developed here to rate studies for their applicability to practice from A to C.

a) Type of study – The qualitative evidence pyramid

1) Qualitative metasynthesis
2) Interpretive designs including phenomenology, grounded theory, ethnography.

3) Descriptive qualitative designs using content analysis (including inductive and deductive content analysis approaches, analysis of focus group data, photovoice, participatory action research, single or multiple case studies).

4) Surveys with semi-structured open-ended questions.

b) Criteria for evaluation of qualitative studies

1) There is a set of discernable research purposes or questions that are suitable for qualitative inquiry.
2) The purpose or questions are linked with a critical review of the literature and key studies are included identifying a gap or misunderstanding of the phenomenon.
3) There is a guiding frame of reference for the study that fits the target phenomen.
4) There is congruence between the method and the research purpose.
5) The sampling plan is purposeful and fits the purpose and method.
6) The sample size and configuration fit the purpose and sampling strategy.
7) Inclusion and exclusion criteria are described and appropriate for the purpose.
8) Data collection techniques and sources fit the purpose, method and sample.
9) The analysis plan fits the purpose and method.
10) Data are sufficiently analyzed and interpreted, data is re-represented and category or thematic meaning is apparent. The interpretation or description is distinguishable from the original data collected.
11) The participants’ voices are heard through examples highlighting the categories or themes of the findings.
12) Concepts and ideas are well developed and linked to each other and to the data.
13) The results offer new insight into the phenomenon studied and transferability of findings is evident.
14) Reflexivity is addressed within the context of the study.
15) Evidence of an audit trail of how key decisions were made is clear. Strategies to achieve rigor are described.
16) Study specific limitations are summarized.
17) Ethical considerations are attended to and described.
c) Levels of evidence

Level 1: A study would include all criteria. Excellent evidence leads to a practice recommendation.

Level 2: A study should include criteria numbered 1, 4 - 13, 17. Moderate evidence leads to a possible practice recommendation (more evidence is needed).

Level 3: A study does not include the majority of criteria for evaluation. Poor evidence does not lead to a practice recommendation.

d) Grades of recommendation

Grade A recommendation: Grade A recommendation includes studies with evidence levels 1-2 (the qualitative evidence pyramid).

Grade B. Grade B recommendation includes studies with evidence levels 2-3.

Grade C. Grade C recommendation includes studies with evidence levels 3 or lesser quality.

3. SEARCH METHOD

In order to gain a deeper understanding of the experience of having faecal incontinence from the perspective of the client, the PUBMED database (from 2000 to 2011) was searched using the following subject headings and key words: qualitative research; anal, bowel, faecal and incontinence; quality of life and faecal incontinence; and quality and rigor in qualitative research. Additional articles were identified by examining reference lists from articles, articles in press by the authors and other systematic reviews. This search yielded over 600 studies of which only 16 used qualitative methods and 11 were used for evaluation of qualitative methods. These articles included topics on the experience of faecal incontinence from the perspectives of men and women, faecal incontinence and colorectal cancer, incontinence and sexuality, quality of life and faecal incontinence, pelvic floor dysfunctions and frail elderly women, diet strategies to manage faecal incontinence, goals of faecal incontinence management, life with post-natal faecal incontinence, and spina bifida.

4. REVIEW OF EVIDENCE ON THE EXPERIENCE OF FAECAL INCONTINENCE AND QUALITY OF LIFE

The review of the evidence on the experience of faecal incontinence and quality of life begins with a study review including the study purpose, design and critique of the design and the evidence level. The findings were overlapping for most studies so that the study findings are summarized in a following section using five categories of experience/quality of life that were identified: relationships, time, bodily symptoms, sexuality, and diet.

A descriptive qualitative study conducting unstructured interviews of 20 women’s experiences of faecal incontinence from Britain focused on the assessment of symptoms of incontinence, coping strategies and the provision of continence aids.[258] The quality of the study was fair to good. Details of the analysis procedure were not clear and participant’s voices were not included in the report. Additionally reflexivity concerns were not addressed.

The purpose of a descriptive qualitative study in the United Kingdom was to identify question items for a quality symptom and quality of life assessment for individuals with anal incontinence.[259] Three sub-studies addressed the purpose. First, seven clinical experts were asked to characterize symptom items of anal incontinence, second.[284] free text comments from patients involved in a treatment intervention trial were collected, and third, 31 qualitative interviews were conducted with people with anal incontinence. The study design was strong and inclusive of clinicians and patients. A grounded study method was mentioned as the study design but no substantive theory was developed and reflexivity was not addressed.

Another descriptive qualitative study in Sweden explored faecal incontinence in adults with spina bifida.[260] Using semi-structured interviews with 11 subjects, themes were generated using content analysis. The rigor of this study was good with insightful findings and powerful quotations used to illustrate the interpretations of the participants’ experiences. Specifics of the analysis process were not given which was a weakness. The concept of reflexivity was not addressed.

A phenomenological study using 10 community dwelling women was conducted on dietary issues in the US.[145] The study was a secondary analysis of the dataset collected in a larger study by Peden-McAlpine, Bliss, and Hill.[261] Content focused specifically on diet and the meaning of the role of diet and food related to faecal incontinence. Narrative interviews were conducted with the women and the design of the study was strong with few limitations although reflexivity was not mentioned.

A descriptive qualitative study, conducted in the US on frail elderly women, with pelvic floor dysfunction, in nursing homes, interviewed 25 women ages 65-96.[262] The purpose of the study was to increase understanding of the views of frail elderly women in residential care related to quality of life, and values and preferences for pelvic floor care. The study design was strong and used NVIVO as a tool to identify representative categories. The categories derived were not specifically related to the aims. One limitation was that the criterion of reflexivity was not addressed.

A study in the U.S.[263] interviewed clients about their goals for faecal incontinence management as part of a RCT on dietary fibre. The main purpose and source of data in this study was not an interpretive qualitative
exploration. A semi-structured interview questionnaire was used to elicit goals from 189 people with faecal incontinence. The study design was methodologically sound and the overall quality was excellent.

A phenomenological study on community living women was conducted in the USA to investigate the lived experience of women managing faecal incontinence.[261] The study used in-depth narrative interviews with women between the ages of 37 and 78. The study design was excellent although issues of reflexivity were not mentioned.

A study from England was conducted to explore the impact of incontinence on an individual's sexuality and to identify the impact of health interventions for the management of incontinence on sexuality.[265] A quota sample of 27 subjects who were being successfully managed and those being unsuccessfully managed were interviewed. The study design was strong although the inclusion/exclusion criteria used for quota sampling was not specific and reflexivity and limitations were not addressed.

A study from England was conducted to explore the lived experience of men, between the ages of 48-85, in managing faecal incontinence.[264] The study used in-depth narrative interviews with men between the ages of 37-78. The study design was excellent although issues of reflexivity were not mentioned.

A qualitative descriptive study completed guided interviews with 22 community living adults with faecal incontinence.[270] The aims of the study were to explore the participants' experiences of faecal incontinence on lifestyle, quality of life and how they adapted management strategies. Another aim was to learn about their disclosures and reasons for seeking help from health professionals. Grounded theory was stated as the method although a substantive theory was not produced in the findings. The findings were not well interpreted and linked together. Some insightful information was learned from the study, about faecal incontinence, that was corroborated by other quality studies.

A descriptive qualitative study was conducted in Britain to validate a draft questionnaire measuring quality of life issues with community living women with faecal incontinence.[271] Twenty-seven women with longstanding faecal incontinence problems were invited to participate in one of 2 focus groups. The mean age of the women was 51. No specific procedures for data analysis were included and reflexivity and ethical issues were not mentioned. Study findings were similar to those of other quality studies.

5. LIVING WITH FAECAL INCONTINENCE AND RELATIONSHIPS – SUMMARY OF EVIDENCE

- Men and women found that faecal incontinence was a perceived threat to their social acceptability, privacy and relationships. [258,261,262,264,265,269] (Evidence Level 1)

- Who to tell about the faecal incontinence problem and when was a matter of great concern. Usually family, close trusted friends and co-workers were told because it could not be kept a total secret.[258,261,264] (Evidence Level 1)

- Discussing the problems with others who suffered from faecal incontinence was comforting and allowed conversation about how to manage the problem.[261,264] (Evidence Level 1)

- Humor was used as a resource to avoid humiliation and embarrassment in dealing with daily symptoms of faecal incontinence and relationships, even though feelings of shame and humiliation persisted.[259, 261, 264] (Evidence Level 1)

- Men and women spoke about their discomfort in being with ‘mixed company’ and their concerns about a possible accident. Gender was an issue in relation to perceived social risk [261,264] (Evidence Level 1)
• Men and women described trying to protect themselves from the unpredictability of their symptoms and kept up a façade to keep the secret of faecal incontinence from others. [259] (Evidence Level 2)

• Support from spouses was noted to be very important for men and women. [258, 261, 264, 266] (Evidence Level 1)

• Relationships with healthcare providers were not helpful in providing advice concerning symptom management and control. Misinformation or no information was commonly given. [258-261, 264] (Evidence Level 2)

• Women reported feeling embarrassed and humiliated by having their faecal incontinence problem minimized or trivialized by rude or blaming health care providers leading, to the feeling of marginalization. [259, 261] (Evidence Level 1)

• Women had concerns about entering into new relationships and there was an expressed concern about fear and shame of having to disclose their bowel problems. [259] (Evidence Level 2)

• Anxiety was present in both men and women who suffered from the uncertainty of social isolation because of faecal incontinence. [145, 258-261, 264, 266] (Evidence Level 2)

### a) Recommendations for practice

• Health care providers need to acknowledge the problem of faecal incontinence compassionately, and initiate the assessment and discussion of faecal incontinence symptoms, so they can be properly managed. The stigma, embarrassment and sensitivity associated with faecal incontinence compel clinicians to refrain from giving dismissive or blaming responses that may retard future care seeking and contribute to the under reporting of faecal incontinence. (Recommendation Grade A)

• Health care professionals can facilitate gender sensitive support groups and sharing of practical knowledge of faecal incontinence symptom management. (Recommendation Grade A)

• Primary care/generalists should refer patients to incontinence specialists when unable to provide therapeutic advice or treatment. (Grade B)

### b) Recommendations for research

• Investigate the use of humour as a therapeutic coping strategy for dealing personally with the symptoms of faecal incontinence

• Defining the attitudes and treatment goals of health professionals treating faecal incontinence would be helpful to the identify some of the barriers to effective treatment.

6. LIVING WITH FAECAL INCONTINENCE AND TIME AND PLANNING – SUMMARY OF EVIDENCE

• Participants describe spending a significant amount of time planning for and worrying about accidents. [261, 264] (Evidence Level 1)

• Men and women perceived that their symptoms of faecal incontinence grew worse with aging in relationship to severity, onset and duration. [261, 264] (Evidence Level 1)

• Men and women had symptoms for months or years before seeking help for the condition. [261, 264] (Evidence Level 1)

• Women reported that the frequency of stool leakage was unpredictable and because of this, they needed to be vigilant and prepared for the unexpected. [259, 261] (Evidence Level 2)

• Planning and management strategies of faecal incontinence to avoid an accident included: morning bathroom rituals, changing the location of their workstation (relative to the bathroom), altering eating habits (foods and timing), taking a fibre supplement, or using anti-diarrheal products. [258-261, 264] (Evidence Level 2)

• Many women discussed packing ‘kits’ of absorbent products, cleansing supplies, extra clothing as a routine part of planning to leave their home. [258, 261] (Evidence Level 2)

• Women postponed business meetings because of the faecal incontinence. [261] (Evidence Level 1)

• Women reported the frequency of stool leakage was unpredictable and because of this they needed to be vigilant and prepared for the unexpected. [258, 261] (Evidence Level 2)

• Space was experienced as a measure of risk exposure for faecal incontinence and personal space shrank inward or expanded related to perceived comfort or lack of perceived social safety. [258, 260, 261, 264, 265, 268, 272] (Evidence Level 2)

• Seeking out the location and availability of a bathroom was a major consideration in all dimensions of space outside the home. [258-262, 264, 267] (Evidence Level 2)

• Travel was limited to places that felt comfortable and significant planning was done to prevent an accident. faecal incontinence limited travel for the family. [254, 261, 264, 266] (Evidence Level 2)

• Women and men experienced heightened anxiety about faecal incontinence symptoms
and the risk of accidents in public spaces. [258,260,261,264] (Evidence Level 2)

- Work life presented complicated situations for both men and women and limited some people’s ability to engage in productive work outside the home. [261,264,268] (Evidence Level 2)

- Symptoms related to faecal incontinence were a common reason for early retirement for both men and women. [268,261,264] (Evidence Level 2)

a) Recommendations for practice

- Recommend that clinicians share findings of practical management strategies, such as preparing cleansing kits and locating public restrooms, with other patients who have faecal incontinence to help them self-manage their experiences better. (Recommendation Grade A)

- Recommend coaching clients on how to plan for and reduce unpredictable incontinence accidents and/or their embarrassment; teach patients strategies to go to social situations and into public more confidently by supporting self-efficacy (this could include education on products, packing a change of clothes, disposable wipes, using a bowel diary to plan schedules, etc.). (Recommendation Grade B)

b) Recommendations for research

- Study interventions that promote enhanced self-efficacy

- Evaluate effectiveness of using a bowel diary or keeping a routine schedule to reduce incontinence accidents in public

- Evaluate effect of public education campaigns on normalizing elimination and raising awareness that incontinence is a treatable condition

7. LIFE LIVING WITH Faecal INCONTINENCE AND BODILY SYMPTOMS, SELF ESTEEM AND BODY IMAGE – SUMMARY OF EVIDENCE

- Across all studies feelings of shame and embarrassment related to faecal incontinence were noted. (Evidence Level 1)

- Women felt stigmatized because of the faecal incontinence problem and stigmatized themselves. [258,261,266] (Evidence Level 2)

- Men and women reported that their emotional life and self-confidence was undermined because of the faecal incontinence and embarrassment. [258,261,264,266] (Evidence Level 2)

- Men and women reported changes in body image and self esteem as a result of their inability to control the symptoms of faecal incontinence. [259,261,264] (Evidence Level 2)

- Not talking about the problem and denying the faecal incontinence was a coping mechanism used to protect themselves from a threat to self-esteem and to prevent public embarrassment. [266] (Evidence Level 2)

- Faecal incontinence caused women to view themselves as shameful, impure, or unworthy. [260,266] (Evidence Level 2)

- Some women reported the need for psychological consultations because of the feeling of being insufficient and vulnerable. [259,266] (Evidence Level 2)

- Unpredictability of the type and timing of a faecal incontinence event and its magnitude were key issues discussed by men and women. [145,261] (Evidence Level 2)

- Faecal incontinence was a consequence of exercise, heavy chores, and lifting. [260] (Evidence Level 2)

- Bodily sensations associated with the symptoms included sensations in the intestines, itching, burning, cramping, feelings of incomplete bowel movements, and odour associated with flatus. Other symptoms discussed included leaking stool without feeling the need to defecate and false abrupt and urgent sensations usually indicative of defecation. Men lost confidence in symptoms to alert them to faecal incontinence due to the unpredictability of faecal incontinence. [260,261,264] (Evidence Level 2)

- Skin excoriation around the anus was reported, because of frequent bowel movements, soiling and excessive cleaning. [261] (Evidence Level 2)

- Women were attentive to their body image and dressed carefully to conceal pads and wore dark clothing when outside the home to hide stains if an accident should happen. [259,261,265] (Evidence Level 2)

- Men and women wore only small disposable pads that were not obvious through their clothing. Large diaper like, pads were avoided because of their visibility beneath clothing. [259,261,264] (Evidence Level 2)

- The essential theme in the phenomenological study of men managing faecal incontinence was ‘secret resignation’ where men came to accept that the consequences of faecal incontinence were normal for them. [264] (Evidence Level 1)

- The essential theme in the phenomenological study of women managing faecal incontinence was ‘controlling the body out of control’ as women tried to control all aspects of their life in relationship to the faecal incontinence and avoiding accidents. [264] (Evidence Level 2)
Major goals of people experiencing faecal incontinence were to have fewer dietary restrictions, eliminate faecal leakage especially during exercise, less reliance on public toilet accessibility, more confidence in controlling faecal incontinence symptoms and a normal daily routine.[263] (Evidence Level 2)

A sense of mastery and new self-confidence was perceived by some after years of successfully dealing with the symptoms of faecal incontinence.[270] (Evidence Level 2)

a) Recommendations for practice

- Acknowledge and provide empathy for the common feelings of shame and embarrassment (Recommendation Grade B)
- Raise awareness with clients and general public that faecal incontinence can often improve with conservative treatment and is not something that must be “put up with” in private (Recommendation Grade A)
- Recommend that conservative symptom management for faecal incontinence includes education about causes of faecal incontinence, diet modifications including fibre supplements, behavioural strategies such as pelvic floor muscles exercises and biofeedback, anti-motility medications, and use of absorbent products such as pads and briefs. (Recommendation Grade A)
- Recommend that health care professionals share positive coping strategies identified by participants, with other people managing the symptoms of faecal incontinence, that include privacy issues in the bathroom, counseling, restricting activity, carrying a change of clothes, humour, knowing the location of toilets when out, care of diet, choosing clothes carefully, careful cleansing and use of pads. (Recommendation Grade B)
- Recommend that clinicians consider patient’s goals when developing a plan for faecal incontinence. (Recommendation Grade A)
- Requesting that people complete a daily stool diary is recommended when accurate information of faecal incontinence severity is important. (Recommendation Grade A)
- Appropriate referral to psychologists should be made to manage issues of self-efficacy, self-esteem and depression. (Recommendation Grade B)

b) Recommendations for research

- Determine how goal setting and tailoring interventions for faecal incontinence is effective in promoting adherence to a management plan.

- Evaluate whether training to pay attention to body sensations might reduce incontinence accidents.
- Studies of the effectiveness of interventions to promote a positive body image and increase self-esteem despite faecal incontinence are needed.
- Future studies should focus on the phenomenon of secret resignation as a method of coping by men, and effective techniques for treating these attitudes to assist them with improved communication with healthcare providers and care seeking.
- Studies are needed on approaches to educate and support men and women in adopting practices for managing faecal incontinence, the associated odour and urgency symptoms as well as to evaluate the successfulness of their practices.[264]

8. LIVING WITH FAECAL INCONTINENCE AND SEXUALITY – SUMMARY OF EVIDENCE

- Although asked about sexuality and intimacy women were reticent to discuss their sexuality or the effect of their symptoms on their sexual functioning.[259,261] (Evidence Level 2)
- Some women felt there were no changes in their sexual drive.[266] (Evidence Level 2)
- Women arranged timing of sex to meet their needs and the needs of their husbands in relation to the symptoms of faecal incontinence. [266] (Evidence Level 2)
- Women reported a range of psychosocial issues including lack of sexual arousal or a desire for abstinence.[259,260,265] (Evidence Level 2)
- Choice of clothing was an outward expression of sexuality and faecal incontinence and UI restricted clothing to wearing patterned materials in order to avoid people detecting an accident.[265] (Evidence Level 2)
- Men and women reported continually washing themselves to avoid smelling.[272] (Evidence Level 2)
- There was a lack of discussion of sexual concerns by health care providers after surgeries that affected sexual functioning.[265,268] (Evidence Level 2)

a) Recommendations for practice

- Recommend that clinicians ask directly about the impact of faecal incontinence on clients’ sexuality. (Recommendation Grade B)
- Recommend that clinicians establish a comfortable, stigma-free climate in order to elucidate
the impact on sexuality and teach practical strategies. (Recommendation Grade A)

**b) Recommendations for research**

- Interventions that minimize stool leakage during intercourse, such as pelvic floor muscle therapy
- Develop and test interventions to improve sexuality altered by faecal incontinence

9. LIVING WITH FAECAL INCONTINENCE AND DIET ISSUES – SUMMARY OF EVIDENCE

- Men and women discussed fasting or not eating for a number of hours or days as a strategy to deal with faecal incontinence symptoms outside the home.[145,259,261,264,266] (Evidence Level 2)

- Altering the timing of meals to avoid an accident was a common management strategy for faecal incontinence.[145,258,261,264] (Evidence Level 2)

- Restricting foods noted to lead to faecal incontinence, included sweets, alcohol, onions.[145] (Evidence Level 2) chocolate, rich and spicy foods, caffeine, fruits, greasy, fat, fried foods, and dairy products [145] (Evidence Level 2)

- Limiting portion or meal size was a strategy to limit faecal incontinence.[145,261] (Evidence Level 2)

- Avoiding gas producing foods such as pea soup, onions, cabbage, cauliflower and dairy products, was used as a treatment for flatus. [145,254,261,264] (Evidence Level 2)

- Increasing fluids was another practice used as a management technique for constipation. [145,261] (Evidence Level 2)

- Some women reported using protracted voluntary constipation as a management technique for leakage for up to 1 month.[260] (Evidence Level 2)

- Increasing dietary fibre and taking fibre supplements along with digestive enzymes and yogurt were noted as treatments for faecal incontinence.[145,261,264] (Evidence Level 2)

- Women reported eating foods they enjoyed at home and then dealt with the consequences of faecal incontinence symptoms.[145,261,269] (Evidence Level 2)

- Women lacked therapeutic guidance regarding diet modifications and adapted recommendations from other gastrointestinal disorders such as IBS and lactose intolerance or approached diet modification by trial and error.[145,261] (Evidence Level 2)

**a) Recommendations for practice**

- Diet is an important self-care strategy for faecal incontinence. Recommend that clinicians include teaching of successful strategies including timing of food intake, restricting food amounts to minimize leakage, avoiding aggravating foods, increasing water intake, and increasing the consumption of yogurt, high fibre foods or a fibre supplement. Recommend Grade B

- Recommend clinicians ask about dietary restrictions, as not all strategies employed by clients with faecal incontinence are helpful or evidence-based. (Recommendation Grade B)

**b) Recommendations for research**

- Determine the effectiveness of diet restrictions and supplementation and modifications in food preparation in reducing faecal incontinence
- Assess the effect of timing of food intake in a bowel management program

**X. ALGORITHM**

A revised algorithm for the initial management of faecal incontinence has been developed based on a review of new evidence in the literature within the context of previous evidence and consensus of an international group of experts on faecal incontinence. (See summary of the recommendations and algorithms at the end of this book.)

I. INTRODUCTION

Therapy for faecal incontinence is readily divided into non-surgical and surgical therapy. Selection of specific therapy is based upon a number of considerations, including the severity of incontinence and structural integrity of the anal sphincter.

Conservative therapy is most applicable to relatively mild cases of incontinence. Biofeedback retraining can be attempted for incontinence of any cause or severity, as the therapy is painless and risk-free. These treatments are discussed in detail elsewhere in this monograph.

The most widely accepted surgical therapy for faecal incontinence is overlapping sphincteroplasty. Typical of other well-established therapies, the evidence base supporting this approach is paradoxically less robust than that supporting more recent treatment options. Sphincteroplasty is useful only in cases in which there is an anatomic sphincter defect, and it has been reported to provide satisfactory results in many case series. However, several recent studies have now shown that results of sphincteroplasty deteriorate with time [1,2].

A number of operations were developed in the early to mid 20th century to provide a treatment option for patients whose native sphincter was either intact but weak or not reparable. Muscle transposition procedures using either gluteus maximus or gracilis were devised to create a functional biological neosphincter, but the approach did not gain widespread popularity. The Parks postanal repair was devised in 1975 to treat patients with incontinence due to pelvic neuropathy [3].

Dissatisfaction with available operations for faecal incontinence led to development of a variety of novel procedures during the last 20 years. The stimulated (dynamic) graciloplasty and the artificial anal sphincter were devised as salvage procedures for patients who had failed or were not candidates for standard therapy. A more recent approach is the use of sacral nerve stimulation, which was adopted for this purpose from its previously better-defined role in detrusor overactivity incontinence and idiopathic urinary retention. Moreover, there has also been a trend towards development of minimally invasive approaches to faecal incontinence, such as the use of injectable biomaterials.

Several important caveats apply to interpretation of the results of surgery for faecal incontinence reported in the literature. First, the vast majority of reports are uncontrolled case series. Randomised controlled studies are rare, and those reported include only small numbers of patients [4]. Second, numerous quantitative measures have been used to report outcomes, but only recently have any of these been validated, such as the Faecal Incontinence Quality of Life (FIQL) instrument. Third, criteria for “successful” outcomes have been variable and often arbitrary. Fourth, the quality of data reported is variable, though it has generally improved with the passage of time. Chart review has been supplanted by patient questionnaires and interviews by independent data auditors; daily continence diaries, the most stringent form of data collection, have become increasingly commonplace (though not routine). Despite the fact that studies using lax data collection are certain to report better results than those using methodology that is more stringent, of necessity, composite reviews of surgical results include studies using various methods of data collection. Finally, results are not always reported on an intention to treat basis, particularly in the implantable device literature.

Search Methods

Pubmed search was conducted to identify studies published on the use of surgery for faecal incontinence in children and adults. Keywords used were faecal incontinence and surgery. Full text copies of studies deemed to be potentially relevant were obtained. Priority was given to systematic reviews, randomised controlled trials, and controlled clinical trials; if those were unavailable or inadequate, comparative observational studies, case series, case reports and narrative reviews were also included. Reviewers were not blinded to the names of studies’ authors, institutions or publications. In view of the nature of the guideline, priority was given to the...
reports with large number of patients and long follow-ups assessing efficacy of surgical interventions. Particular emphasis was placed on those reporting techniques and functional outcome including quality of life after an operation.

Non-English language papers were noted but excluded from the review unless they contained an English-language abstract providing sufficient information.

II. SURGERY FOR ADULT FECAL INCONTINENCE

1. SPHINCTER REPAIR

Anal sphincter repair is the term used to describe primary repair of the anal sphincter mechanism following direct trauma. The most common indication is following childbirth and repair in this situation is usually performed by the attending obstetrician. Colorectal surgeons are more commonly involved in primary repair of injury that is the result of blunt or penetrating trauma. Occasionally, the anal sphincter mechanism is damaged during anorectal surgery for other anal pathology particularly surgery for anal fistula.

In Western obstetric practice, the incidence of overt anorectal sphincter injury (grade 3 or 4 tear) is low, 3-5% following primiparous delivery and 0.5-1% following second and subsequent deliveries [5]. When prospectively looked for with endoanal ultrasound, the actual incidence of anal sphincter injury is higher [6,7]. A meta-analysis of 717 vaginal deliveries found an incidence of new anal sphincter defects of 27% in primiparous and 9% in multiparous women using 2D endoanal ultrasound [8]. 3D ultrasonography suggests that the incidence is somewhat less, perhaps 11%, following primiparous delivery [9]. The risk factors for sphincter injury include instrumental vaginal delivery, prolonged second stage of labor, fetal macrosomia, and a persistent occipital position of the fetal head [7,10-12]. Midline episiotomy is associated with higher incidence of anal sphincter injury and the angle of mediolateral episiotomy may also influence perineal outcome [13]. A policy of restrictive use of episiotomy may reduce the incidence of anal sphincter injury [14].

Obstetric injury of the perineum is classified as a first degree tear if confined to vaginal epithelium and skin, second degree if the perineal muscles are torn, third degree if the anal sphincter muscles (external: EAS; internal: IAS) are torn, (3a: less than 50% EAS torn; 3b: more than 50% EAS torn; 3c: IAS torn) or fourth degree if both EAS and IAS and rectal or anal mucosa are torn [15]. Primary repair of an obstetrical tear is correctly termed anal sphincter repair and is usually performed by the obstetrician immediately after delivery, most commonly in the delivery room under local or epidural anaesthesia. However recent guidelines issued by the Royal College of Obstetricians and Gynaecologists in the UK recommend that all such repairs should be performed in an operating room with adequate exposure, lighting and adequate anaesthesia [16]. By tradition, the technique of repair has been a direct oppositional repair of the severed EAS, however an overlapping technique, as commonly used in secondary repair (vide infra), has been recommended as it obligates identification and adequate mobilization of the severed ends of the EAS [17]. The IAS, if damaged, is difficult to identify separately and is usually repaired en block with the anal canal mucosa in a complete or 4th degree tear. Mahoney et al [18] however have shown that persistence of an IAS defect is adversely associated with continence outcome following repair of a 3rd or 4th degree tear, while Roos et al [19] have found that women with major tears (grade 3c or 4) were significantly more likely to have ultrasound evidence of a persisting IAS or combined IAS and EAS defect following obstetric repair. Such women were more likely to have poor functional outcomes. Separate repair of the IAS has been advocated [17]; however as with overlapping EAS repair, separate repair of the IAS requires good anatomical knowledge and meticulous technique and it is probable that these factors are reflected in the improved outcomes reported, rather than the actual technique used. Thus, McNiccol et al [20] have reported full continence in 39/45 (86%) women who underwent primary repair using a standardized overlapping repair without separate identification and repair of the IAS.

There have been six randomised clinical trials [17,21-25], one meta-analysis [26], and a systematic review [27] that have investigated different techniques of immediate primary anal sphincter repair following obstetric injury. Four trials have found no difference between the overlapping and end-to-end repairs. One trial found the overlapping procedure superior and one found the end-to-end procedure to be superior. Thus it appears inappropriate to favor one type of repair over another [26]. [LEVEL OF EVIDENCE: 1] However, all studies were small and it is difficult to control for the skill of the individual obstetrician performing the repair. With regard to the suture material used in repair, a randomised trial found no difference in outcomes between braided and monofilament absorbable sutures with 12 months follow-up [22], while Parnell et al [28] found no difference in outcome in a case series of patients between absorbable and permanent sutures. [LEVEL OF EVIDENCE: 2]

As colorectal surgeons are in general more familiar with the anatomy of the anal canal, it has been suggested that primary anal sphincter repair might be best performed by a colorectal surgeon than an obstetrician [29]. Nordenstam et al [30] concluded, in a single institution study of 165 women, that technique and expertise impact on the outcome of pri-
mary repair and that if needed, the repair could be safely delayed until such expertise was available. In a similar study, Soerensen et al [31] found no adverse outcome with delayed primary repair; thus, repair can be safely delayed until adequate expertise is available. Co-operation between obstetric and colorectal surgical colleagues can result in much improved outcomes [20], while a structured training programme for obstetric trainees also improves clinical outcomes [32]. [LEVEL OF EVIDENCE: 2]

There have been two randomised trials of post-operative management of the bowel after primary anal sphincter repair. These have shown benefit in use of a laxative rather than a constipating regimen but no advantage to the addition of a stool bulking agent [33,34]. [LEVEL OF EVIDENCE: 1]

Alteration in faecal continence occurs in approximately 13 - 17% of women following primiparous vaginal delivery, even in the absence of a recognised sphincter tear [6,35,36]. The prevalence is greater if urgency of defaecation is included as a symptom [7]. MacArthur et al [37] found flatal incontinence in 27% of 7,879 women surveyed 12 weeks after delivery. [LEVEL OF EVIDENCE: 2] Fenner et al [38] found that women who had sustained third and fourth degree tears were more likely to have bowel incontinence than women without anal sphincter injury 6 months following delivery. This was more pronounced in women with a history of 4th degree tear. Samarasekera et al [39] have found long-term effects on anal continence and quality of life following postpartum anal sphincter injury. Oom et al [40] have suggested that concomitant injury to the pelvic floor may be an associated determinant of outcome in addition to adequacy of sphincter repair. [LEVEL OF EVIDENCE: 2]

Management of subsequent labor following a previous anal sphincter tear must take account of obstetric risk factors, symptoms of incontinence and patient preferences. Harkin et al [12] found an approximately 5 fold increase in the incidence of recurrent sphincter tear compared to the incidence of first sphincter injury during second labor. Fynes et al [41] found that women with altered continence after first vaginal delivery were at risk of deterioration if delivered vaginally on their second pregnancy. Cesarean delivery before the onset of the second stage of labor was found to be protective [42]; however, Nelson et al [43] in a systematic review found that pregnancy rather than delivery was a more important in predicting post partum continence. Recently, Scheer et al [44] have confirmed that subsequent vaginal delivery is reasonable in asymptomatic women after a previously repaired third degree tear. [LEVEL OF EVIDENCE: 3]

A number of studies have looked at long-term outcomes after repair of a 3rd or 4th degree tears and all have shown an increasing prevalence of continence disorders with age. These findings parallel those of the general population of parous women who have not had a recognised tear [45-47]. Eogan et al [48] found in a study of women, 10, 20 and 30 years following delivery that onset of menopause was the most significant determinant of symptoms, whereas Mous et al [49] found the incidence of incontinence increased with age irrespective of menopausal status. Fornell et al [50] found that subjective and objective anal function after anal sphincter injury deteriorates with time and subsequent deliveries. A persistent defect in the IAS was also found to be an important determinant, an observation supported by Mahony et al [18]. [LEVEL OF EVIDENCE: 3] There is some evidence that hormone replacement therapy may be of value in women who develop symptoms post menopause [51]. [LEVEL OF EVIDENCE: 2]

2. SPHINCTEROPLASTY

The term anal sphincteroplasty is used to describe secondary or delayed reconstruction of the anal sphincter musculature, injury to which has either not been recognised at the time of injury or the outcome of primary repair has been unsatisfactory. Anterior sphincteroplasty is the most common type of reconstruction performed because of the association with obstetric injury. In this situation, the anal sphincter muscles and perineal body have separated leaving a horseshoe type configuration to the anal sphincter mechanism, with a large defect in the anterior quadrant. Occasionally, the defect is such that the anal and vaginal mucosa have healed to form a cloacal defect. Anal sphincter defects related to previous anal fistula surgery or direct trauma are usually less complex and are not associated with a deficient perineum.

The decision to perform anal sphincteroplasty is based on an assessment of symptoms and the anatomical extent of the sphincter defect [52]. In assessing symptoms one of several continence scores should be used. The two most commonly applied are the Cleveland Clinic Continence Score [53] and the St Mark's Continence Score [54]. In addition a quality of life instrument should be applied [55]. Endoanal ultrasound is helpful in defining the extent of anal sphincter injury. 3D endo anal ultrasonography may provide further information [9]. Pelvic floor assessment using fMRI [56] or multiple contrast defaecating proctography [57] are valuable in the assessment of a more global pelvic floor injury. The American Society of Colon and Rectal Surgeons considers as surgical indication those symptomatic patients with localized defects, without defining exactly the minimum size of the injury detected as indication for this surgery [58]. [LEVEL OF EVIDENCE: 4]

Other causes of disordered continence should be excluded e.g. inflammatory bowel disease, colorectal cancer and neurological lesions. Patients with background IBS are more likely to be symptomatic
than those more predictable bowel habit and equivalent anal sphincter defects [59]. Pelvic floor electrophysiological assessment, while not essential, if performed, should be comprehensive and not confined to measurement of pudendal nerve terminal motor latency [60].

For symptomatic patients with a less than one quadrant anal sphincter defect, a trial of dietary modification, stool regulating drugs and physiotherapy is appropriate. There are limited data regarding the role of biofeedback with or without electrical augmentation [61,62], however a recent Cochrane review concluded there were insufficient data to allow definitive assessment [63]. [LEVEL OF EVIDENCE: 2]

For patients with a more than one quadrant anal sphincter defect, anal sphincteroplasty is appropriate [4,15,52]. Preoperative counseling should identify post operative wound healing as the most common difficulty. The majority of patients can expect significant improvement in continence after the procedure with a mean of 66% reporting excellent of good results in the short term [52]. Concomitant repair of a cloacal defect or vaginal fistula should be undertaken [64-66]. There is no evidence that a defunctioning colostomy improves outcome. The results of anal sphincteroplasty in recent series reporting more than 50 patients are given in Table 1 [1,2,52,67-84].

Anal sphincteroplasty is usually performed in the lithotomy position although adequate exposure can be obtained in the prone jack-knife position. Full bowel preparation is not needed, although most would give a cleansing enema pre-operatively. The conventional incision is an inverted ‘V’ that may be closed as an inverted “Y” as described by Parks [85]. If anterior levatorplasty or rectocele repair is contemplated, a posterior fourchette incision with the patient in lithotomy may have advantages [76]. The external anal sphincter is usually repaired using an overlapping technique without separate identification and repair of the IAS [15], however, Maslekar et al [82] attribute their good long term results to a selective policy of separate repair of the IAS. There has been one small randomised trial of direct versus overlapping sphincteroplasty which showed similar outcomes [86]. Occasionally the EAS defect is not full thickness and overlapping repair in such circum-

$ defined as “successful”
stices would require division of the residual intact fibres to facilitate overlap. Oberwalder et al [87] have found in a small series of patients that imbrication of the EAS in such cases is associated with outcomes similar to formal overlapping sphincteroplasty.

Initial success of sphincteroplasty is related to whether the anal sphincter defect is corrected [68,88]. Early failure is usually associated with a persisting defect identifiable using endoanal ultrasound [89]. This may be amenable to a further attempt at repair [88,90,91]. There is however increasing evidence that continence outcomes deteriorate with long-term follow-up [15,52,92]. Zutshi et al [93] found in a cohort of 31 patients followed for 10 years after overlapping sphincteroplasty that continence deteriorates over time. Mevik et al [94] also identified significant deterioration over time while Bravo Gutierrez et al [77] found that only 6% of patients retained full continence 10 years follow­ing anal sphincteroplasty. The effect of age at time of operation on long-term function is controversial [93,95,96], however long-term effects of aging and menopause coupled with atrophy of the sphincters may be relevant [15,97]. [LEVEL OF EVIDENCE: 3]

Pre-operative physiologic testing is helpful in the overall management of patients with faecal incontinence, however the value of anal manometry and pelvic floor electrophysiological assessment as prognostic indicators for outcome following sphincteroplasty is controversial [98]. There are no established parameters that reliably predict outcome following sphincteroplasty [82,99]. Patients with an unsatisfactory clinical outcome follow sphincteroplasty may be considered, if sufficiently symptomatic, for adjunctive sacral neuromodulation (vide infra) [100]. [LEVEL OF EVIDENCE: 4]

3. POST-ANAL REPAIR

Post-anal repair was first reported by Sir Alan Parks in 1975 [3]. This procedure was designed to increase the length of the anal canal, restore the ano-rectal angle and re-create the flap valve mechanism, which at the time was thought essential for maintaining faecal continence. Success rates ranged from 15% to 83%, depending on the definition of the success, the length of follow-up, and possibly the cause of incontinence. The published studies regarding post-anal repair include three systematic reviews of randomised controlled trials (level 1) [4,101,102], two randomised controlled trials (level 1) [103] and [2], two non-randomised cohort studies (level 2) [105,106], 8 case series of good quality (level 3) [107-114] and 11 case series of poor quality (level 4) [3,115-124]. The results of post-anal repair are shown in Table 2 [3,103-124].

ns: not stated; PAR: postanal repair; ALP: anterior levatorplasty; TPFR: total pelvic floor repair
Subsequent observational studies with a median follow-up of more than 5 years revealed that continence deteriorated with time. Despite 60% to 80% of patients reporting persistent symptomatic improvement, only one-third were actually continent to liquid or solid stool [109,112,114,123]. Even in the most recent study reporting the long-term outcome of post-anal repair [124], only 26% reported none to minimal incontinence, with the Cleveland Clinic incontinence score being between 0 and 5, while 79% improved symptomatically with a mean follow-up of 9.1 years. Possible explanations for deterioration of continence following initial improvement included unrecognised denervation and/or muscular injury of the sphincter and pelvic floor musculature, and the presence of occult anal sphincter disruption, particularly in the studies reported before endoanal ultrasonography or magnetic resonance imaging were available. Moreover, physiological and radiological evaluations before and after postanal repair have not demonstrated consistent changes in anal canal length, resting pressure, voluntary contraction pressure, anorectal sensitivity and movement of the ano-rectal angle [104-107,125]. These reports of increasingly poor outcomes have diminished the popularity of this procedure significantly.

Deen et al [103] in a randomised controlled trial, comparing three procedures in 36 women with neuropathic faecal incontinence, found that complete continence was achieved in 42% of patients after post-anal repair, 33% after anterior levatorplasty and 67% after total pelvic floor repair. In contrast, van Tets et al [104] conducted a randomised controlled trial comparing post-anal repair and total pelvic floor repair in 20 women with neurogenic faecal incontinence. Complete continence to solid or liquid stool was achieved in 27% of patients after post-anal repair and in 22% after total pelvic floor repair.

4. NON-STIMULATED MUSCLE TRANSPOSITION

A variety of muscle transposition procedures have been devised for the treatment of faecal incontinence. Early efforts focused upon the use of transposed skeletal muscle to supplement the function of a weak or disrupted anal sphincter. Early in the 20th century, a number of surgeons utilized glutus maximus muscle, transposed in a variety of configurations, to create a neosphincter [126,127]. In 1952, Pickrell et al [128] described the use of transposed gracilis muscle to create a neosphincter for incontinent children.

Published series of gracilis transposition are uncontrolled and demonstrate variable success rates [129-138]. [LEVEL OF EVIDENCE: 3] One study reviewed the functional results of graciloplasty longitudinally in 22 patients followed for a median 63 months [139]. 18 patients (81%) were improved at 6 months, though only one regained normal continence. Results deteriorated in 5 patients during subsequent follow up. Bilateral gracilis transposition has been used successfully in several small series [130,140].

Success rates following gluteus transposition have likewise been variable [141-145]. [LEVEL OF EVIDENCE: 3] A prospective randomised trial in women with post-obstetric neuropathic incontinence showed similar significant degrees of improvement following both glutus maximus transposition and total pelvic floor repair [146]. A recent retrospective review of 25 gluteoplasty patients reported restoration of continence in 18 patients (72%) and partial restoration in an additional 4 patients (16%). Donor-site and peri-rectal complications occurred in 16 patients (64%) [147].

5. STIMULATED MUSCLE TRANSPOSITION

The transposition of the gracilis muscle to reconstruct the anal sphincter was first performed in children in 1952 [128]. The blood supply is primarily from a single proximal artery that allows excellent mobility for transposition [148]. Successful electrical stimulation of a previously transposed gracilis muscle was first reported in 1988 [149], and case series from 2 independent centers were simultaneously reported in 1991 [150,151]. Baeten et al [150] showed improved continence in 8 of 10 patients; Williams et al [151] in 12 of 20.

Even after successful muscle transposition, functional outcomes are limited by two physiological factors. First, patients are unable to consciously maintain tonic contraction of their neosphincters over long periods of time. Furthermore, even if patient volition were not a problem, gracilis muscle is poorly suited to tonic contraction. While the external anal sphincter comprises predominantly slow-twitch, fatigue-resistant type I fibres, the gracilis muscle comprises predominantly type II, fast-twitch fibres that are rapidly fatigable [152]. Graded electrical stimulation transforms type II into type I muscles fibres [153], and use of an implantable electrical pulse generator has been shown to convert transposed gracilis to a muscle with predominantly type I fibres [150-152]. The gracilis muscle is well suited to electrical stimulation due to the relatively constant proximal location of the neurovascular bundle, which is easily identified at surgery [154].

The results of stimulated graciloplasty are shown in Table 3 [155-165]. [LEVEL OF EVIDENCE: 2] In 1995, Baeten reported his results in 52 patients, with 38 (72%) becoming continent after surgery [155]. In a subsequent paper by this group published in 2003, 200 patients followed for a median of 261 weeks were reported [163].
The overall success rate was 72%. Patients with incontinence due to trauma had the best results (82% success), while patients with incontinence due to congenital anorectal malformation had the worst results (52% success). 138 complications were reported, including disturbed evacuation in 32 patients (16%), infection in 24 (12%), pain in 16 (8%) and pulse generator displacement in 12 (6%). Ten patients (5%) had anorectal perforations, 7 of whom eventually obtained a successful outcome. Rosen et al [166] reported restoration of continence in 9 of 10 patients treated by dynamic graciloplasty using a “split-sling” wrap configuration. Sieleznoff et al [167] treated 16 patients and 13 had improved continence. However, 8 patients suffered morbidity, resulting in 33 subsequent admissions and 23 reoperations.

Three multicenter prospective trials of dynamic muscle plasty have been performed to date [158-160]. In each of these studies, patients served as their own controls. No randomised prospective trials have been performed.

Madoff et al [158] studied 139 patients from 12 centers, 128 of whom had gracilis wraps and 11 gluteus wraps. Of those patients, 104 were treated for faecal incontinence, and 35 underwent total anorectal reconstruction following abdominoperineal resection for cancer. Success rates for graciloplasty were 71% for patients with acquired incontinence and 50% for those with incontinence due to a congenital abnormality. There were a total of 138 complications for the entire group. Wound complications (41 major and 35 minor) were both the most prevalent and the most consequential. Other complications included pain in 28 patients (22%), hardware problems in 14 (11%) and tendon detachment in 4 (3%). Centers with significant prior experience with the procedure had substantially fewer major wound complications (17.4 vs. 33.1%) and significantly higher success rates (80% vs. 47%).

Mander et al [159] reported the results of dynamic graciloplasty in 64 patients with refractory faecal incontinence treated at 7 centers. There were 24 infectious complications, 5 of which involved perineal wound breakdown and 3 of which required reoperation. 44 (69%) patients became continent to solid stool 1 month following stoma closure. Evacuation problems developed in 16 patients (25%), and this lead to failure in 14. At a median of 10 months follow-up, 29 patients had a good functional result.

Baeten et al [160] reported the results of dynamic graciloplasty in 123 patients treated at 20 centers as part of the Dynamic Graciloplasty Therapy Study Group (DGTSG). The aims of this study were

* variable definitions; does not necessarily denote perfect continence. Issues of divergence in technique arose from these studies, each of which has seen increasing consensus in the literature despite a lack of randomised trial data. Thus, intramuscular (vs. epineural) electrodes are now universally employed, and diverting stomas and ‘vascular delay’ prior to muscle transposition are no longer utilized.
to assess both the safety and efficacy of this treatment; 189 adverse events occurred in 91 patients, including one death due to pulmonary embolism. There were 18 major and 31 minor infectious complications. There were 42 instances of therapy-associated pain, occurring variably in the donor leg, at the anal canal, or at the device site. There were 11 lead dislodgements but no problems with lead breakage or pulse generator malfunction. A follow-up study showed full or partial recovery from these complications in 87% of patients. [161] This study, in contrast to others, was based upon data from daily continence diaries. A successful result (defined as a 50% or greater decrease in incontinent events in patients without pre-existing stomas) was achieved in 63% of patients after one year. Another follow-up of this patient cohort demonstrated stable success rates at 18 months (55%) and 24 months (56%) [162]. Statistically significant improvements in the physical and social function scales of the SF-36 were also recorded at 12 months.

A multicenter retrospective trial from Belgium using dynamic graciloplasty treated 60 patients with 27 failures [164]. Continence was achieved in 78% of the group. However, more than half (26 patients) required the use of antegrade continence enemas or other measures to maintain continence. Seven patients had a permanent stoma constructed. Seventy-five complications occurred with 61 total operations. Loss of muscle stimulation occurred in 22 patients; 10 were due to issues specific to the stimulator and leads, 4 were due to technical failure of the muscle wrap. Functional outcome was directly associated with a maintenance of stimulation and initiation of stimulation within 50 days of surgery.

Very few studies have examined the long term results with dynamic muscle wraps. Thornton et al [168] reported on the 5-year follow up of 38 patients who had undergone dynamic graciloplasty. Of the 33 patients available for follow-up by telephone interview, obstructive defaecation was a problem for 11% of the cohort and 16% had been converted to a permanent colostomy. Of those with a functioning graciloplasty (22 patients) who reported a faecal incontinence score of less than 12 (range 0-24), 50% reported problems with obstructive defaecation and 64% felt their bowel habits had negatively impacted their quality of life. Long-term complications were primarily related to stimulator issues; ten patients required 15 operations to replace stimulator components. However, 72% of patients reported pain, swelling or paresthesias of the donor leg and 27% reported sexual dysfunction. Hassan et al [169] reported follow-up of 31 patients who underwent gracilis muscle transposition with periodic electrical stimulation and postoperative supplement of biofeedback. Twenty-two patients (71%) reported improvement at five-years. Nine patients (29%) were deemed failure requiring further surgical intervention (colostomy formation, contralateral dynamic gracilis muscle transposition, implantation of artificial bowel sphincter).

Six patients developed perineal wound infections (5 resolved with antibiotics, 1 required surgical drainage), and 2 patients had evacuation difficulties requiring regular enemas. Those who underwent operation due to traumatic injury to sphincters had better outcome (82% improvement) compared to patients with congenital faecal incontinence (55%).

Tillin et al [165] performed a prospective case-comparison study of 49 patients who had a dynamic graciloplasty and 87 patients who either refused the surgery or were not offered the surgery. The primary outcomes evaluated were symptoms, quality of life, anxiety, and depression. Of the treated group, the procedure failed completely in 15 patients. At two year follow-up, two-thirds of patients were either never or rarely continent to liquid or solid stool. Up to 50% of patients with a satisfactory outcome reported disorders evacuation and 8 other patients were deemed failures due to this problem. However, in comparison to the 87 patients who did not undergo treatment, there were significantly more patients in the dynamic graciloplasty group who reported a greater than 20% improvement in their incontinence scores. However, the treated group also had a significantly worse pain as assessed on a validated pain scale.

Chapman et al [170] performed a systematic review of dynamic graciloplasty for faecal incontinence on behalf of the Australian Safety and Efficacy Register of New Interventional Procedures- Surgical (ASERNIP-S). The authors reviewed 37 original articles published between 1991 and October 2000. All of the papers were judged to be of low-evidence quality, as all but one paper were case series, and the sole comparative study utilized historical controls. Mortality excluding cancer deaths was 1% (95% confidence interval 1-3%) and morbidity 1.12 (95% CI 0.14 - 2.08) events per patient. Success was variably defined between studies, but was reported as ranging from 42-58%. The ASERNIP-S Review Group determined that “the safety of the procedure cannot be determined at the present time due to an incomplete and/or poor-quality evidence base" and that “efficacy is established.” Tan et al [171] examined three treatments for faecal incontinence including dynamic graciloplasty, artificial bowel sphincter and end stoma. They concluded that the most cost effective intervention was an end stoma, the artificial bowel sphincter was most cost-effective after 10 years and that dynamic graciloplasty should only be considered as an alternative in highly specialized centers.

6. ARTIFICIAL ANAL SPHINCTER

Artificial sphincters can be defined as any kind of implanted device intending to replace or reinforce the sphincteric mechanism that normally closes the bowel end. They aim to be a substitute to the normal sphincters. As such, it is necessary that they be efficient for both terminal bowel functions: continence and evacuation; that their implantation be safe and reproducible, with a limited need for patient/medical
intervention and follow-up after implantation; and finally that they be cost effective.

There is active laboratory research at a preclinical phase for new artificial devices. Different parts of the world are involved, including China with a novel electro-magnetic anal sphincter with sensor feedback currently tested on animals [172-174], US with bioengineered tissue designed to mimic the function of the internal anal sphincter [175,176], and Germany with a new version of the previously described "German artificial sphincter system" (GASS), now consisting of an inflatable cuff connected to a combined implantable micropump, fluid reservoir and microprocessor [177]. These various prototypes have not been implanted yet in humans but clinicians have to be aware of any development of these innovations.

Artificial sphincters currently used in humans are silicone-made, pressure-regulated devices restoring continence through an inflatable cuff placed around the lower rectum or upper anal canal. Three models have been proposed on the market. Over the 5 last years, no publication has reported any results from the implantation of two of them: the prosthetic bowel sphincter (PBS) developed by Finlay in UK and the Agency for Medical Innovations (AMI) soft anal band system once popular in Germany and Austria. The only currently available data concern the Acticon Neosphincter (American Medical Systems, AMS) artificial bowel sphincter (ABS).

The ABS, a modified model of the AMS 800 artificial urinary sphincter has been in use since 1996 for faecal incontinence management. In short, it comprises a fluid-filled cuff that encircles and compresses the anal canal. A pressure-regulating balloon is implanted in the retropubic space of Retzius. The system is controlled by a pump placed in the labia majora or scrotum which is accessible to the patient. To initiate defaecation, squeezing the pump empties the cuff by a fluid transfer into the balloon, allowing for the passage of stool. The cuff then refills automatically from pressure built up in the balloon.

The role of the ABS in the treatment of faecal incontinence has been confirmed in reports from different groups [178-182]. [LEVEL OF EVIDENCE: 2] ABS use has been supported in the current recommendations of both the United Kingdom's National Institute for Health and Clinical Excellence (NICE) and the American Society of Colon and Rectal Surgeons (ASCRS) [58,183]. The ABS is especially indicated for patients with “severe end-stage faecal incontinence,” especially those with major sphincter disruptions that preclude direct sphincter repair, or those in whom sphincter repair has failed. For many of these patients, creation of a permanent end colostomy is the only remaining therapeutic alternative. However, generalizability of the published results remains doubtful as the majority of the series come from expert centers that have developed particular expertise in the implantation of artificial sphincters.

a) Functional Results of ABS

The artificial bowel sphincter provides good restoration of continence for solid and liquid stool in patients who retain the device, with all studies reporting almost similar data (Table 4) [179-181,184,185]. Implantation of an ABS was successful in 27 out of 33 patients in a Dutch series with a significant improvement in Williams faecal continence score at 17 month follow-up [180]. In a series from France, a new transvaginal approach to implant the cuff has been tested [178]. It was successful in 23 out of 32 patients (71.9%), with a device that remained activated for a mean follow-up of 41 (range 18-75) months, resulting in a significant decrease in Wexner incontinence score from 18.4 to 6.8 and no dyspareunia in sexually active patients [179]. Long term data from Spain reported a final success with an activated ABS in 9 out of 17 cases (53%) allowing for a decrease in CCF score from a median of 17.5 preoperatively to 10 at 66 month follow-up and a significant improvement in QOL [184]. In the report of a large single-center experience of ABS implantations, including 52 patients (46 women) implanted over the past 10 years, no publication has reported any results from the implantation of two of them: the prosthetic bowel sphincter (PBS) developed by Finlay in UK and the Agency for Medical Innovations (AMI) soft anal band system once popular in Germany and Austria. The only currently available data concern the Acticon Neosphincter (American Medical Systems, AMS) artificial bowel sphincter (ABS).

CCF-FI: Cleveland Clinic Florida Fecal Incontinence (0: full continence - 20: worst incontinence); ns: not stated.
“Success” is defined as “continence to solid and liquid stool without significant obstructed defaecation, otherwise defined in each study”
years with 85 devices and a mean follow-up of 64.3 ± 46.5 months, 35 patients (67.3%) had a functioning device at review. A significant improvement in both CCF (P < 0.0001) and FIQL (P = 0.0286) was observed [185]. Some patients of this study with an activated ABS were matched to a group of successful SNS patients to compare their respective functional outcomes. Although this study had several limitations, it showed that the ABS achieved significantly better control of continence, albeit at the expense of more symptoms of outlet obstruction postoperatively and a similar quality of life for the 2 groups of 15 patients each [186]. [LEVEL OF EVIDENCE: 2] This risk of constipation after implantation of an ABS is a real concern as the cuff, even when opened, can narrow enough the anal canal to prevent a complete and easy evacuation. It has been well measured in a series of 44 patients with 55% of them expressing some sort of constipation or outlet obstruction [187].

b) Surgical Risks and Postoperative Complications of ABS

Besides an evident beneficial effect in treating severe faecal incontinence, the above-mentioned studies have confirmed the high risk of failure after implantation due to infection and mechanical failure. However severe morbidity is rare and no mortality has been ever reported. Explantation of the device generally solves the problems without long term sequela.

The primary concern with ABS implantation is infection. In the report from the Cleveland Clinic 23 of 51 (41.2%) implantations became infected [181]. Among these, 18 (35.3%) developed as an early-stage (before ABS activation) and 5 (9.8%) a late-stage infection. On multivariable analysis the authors found that the time between ABS implantation and first bowel movement and a history of perineal sepsis were independent risk factors for early-stage infection. This may explain some variations in infection rate when compared to European reports where great care is taken in bowel preparation before device implantation. Series from France and Holland each reported a 21% infection rate [179,180].

Mechanical failure is now a well-recognised complication after ABS implantation. The most common cause is microperforation at the folds of the cuff membrane, which leads to a loss of fluid and pressurization of the system. Cuff perforation is easily perceived by the patient as both a return to incontinence and development of a non-functioning control pump. Cuff perforation reflects intrinsic wear-and-tear of the device components over time and contributes to the number of revision procedures, especially in patients with satisfactory functional ABS results. Revision rate is directly proportional to the length of follow up. With a mean follow-up of more than 5 years, half of a series of 52 patients required revision surgery in the above-mentioned studies. Although ABS reimplantation is usually easy in the encapsulated area of the previous device, the risks of infection and impaired function are real and account for some long-term failures. Furthermore, the need for reimplantation increases the overall treatment costs. These concerns suggest that an appropriate component upgrade by the manufacturer might lead to improved long term results and a lower cost basis for this therapy.

Cost issues have been assessed in a complex health economics study [188]. The authors aimed to assess cost-effectiveness of ABS, dynamic graciloplasty and end-stoma in the treatment of faecal incontinence. Based on an assessment of incremental cost-effectiveness ratio (ICER), they concluded from published data and expert opinion that the all three procedures were cost-effective with the end-stoma most cost-effective over a 5-year period (ICER £4,719/QALY) and the ABS most cost-effective over a 10 year period (GBP5,387/QALY).

Careful patient selection and sound operative technique are critical components of success for artificial sphincter implantation. Exclusion criteria include morbid obesity, insulin-dependent diabetes mellitus, Crohn's disease, pelvic sepsis and radiation proctitis. Individuals who practice anoreceptive intercourse are not candidates for the procedure. It is also vital to ensure that all patients are adequately motivated and have sufficient manual dexterity to operate the device independently.

At present, ABS is not commercially available due to a manufacturing hold by the FDA. This situation is especially difficult for those waiting for revision surgery.

Studied in small trials, but not yet clinically available, the magnetic anal sphincter (MAS) (FENIX™; Torax Medical, Inc., Shoreview, MN - US) is a novel device designed to augment the native anal sphincter. It consists of a series of titanium beads with magnetic cores hermetically sealed inside. The beads are interlinked with independent titanium wires to form a flexible ring that rests around the external anal sphincter in a circular fashion. The device is manufactured in different lengths based on the number of beads (14 to 20) necessary to accommodate the variation in anal canal circumferences.

One of the advantages of this still investigational device over the previous artificial sphincters is that it begins working immediately once implanted, without the need for further manipulation by either the patient or surgeon. The procedure for implantation is also substantially simpler than the ABS because access to the perineum alone is required. The device is place under fluoroscopic guidance.

A recent multicenter feasibility study demonstrated good short-term restoration of continence with limited complications [189]. In a subsequent non-randomised comparative cohort study assessing results of the magnetic anal sphincter and the ABS,
it was shown that the 2 devices were similarly effective in restoring continence and quality of life, without any difference in morbidity [190]. [LEVEL OF EVIDENCE: 3] Further comparative studies with other innovative treatments of faecal incontinence such as SNS are getting underway.

Based on these results, FENIX™ has been granted CE mark on November 2011 and its commercial use has started in selected centers in Europe. Further reports from more centers are expected.

Presently the place of the magnetic anal sphincter in the treatment algorithm of faecal incontinence remains to be determined. It appears to be a promising innovation as it offers a less invasive and simpler alternative of anal reinforcement than the ABS. However, with only short-term follow-up available, it remains to be seen if the MAS can withstand the test of time.

7. SACRAL NERVE STIMULATION

Sacral nerve stimulation (SNS) was first applied for the treatment of faecal incontinence in 1994 by Matzel et al [191] in patients with functional deficits of the anal sphincter but no morphologic defect. The concept of recruiting residual function of an inadequate anorectal continence organ by electrostimulation of its peripheral nerve supply, i.e. the sacral spinal nerves, was adapted from the field of urology in the early 1990s [192], where it has been used since 1981 [193]. The rationale for applying SNS to faecal incontinence was based on both clinical observations and anatomic considerations (from the former, the beneficial effect on bowel habits and anorectal continence function and increased anorectal angulation and anal canal closure pressure seen in urologic patients; from the latter, the demonstration by dissection of a dual peripheral nerve supply of the striated pelvic floor muscles that govern these functions [192], with the sacral spinal nerves being the most distal common location of this dual nerve supply). It was hypothesized that stimulating the sacral spinal nerves could both enhance physiologic function and improve the symptoms of faecal incontinence.

a) Technique

SNS has become a minimally invasive technique with low morbidity. The surgical technique can be divided into two stages:

As no other predictors of SNS outcome exist at present, patients are uniformly selected for operative implantation of a permanent neurostimulation device on the basis of clinical improvement during test stimulation. This first stage, termed percutaneous nerve evaluation (PNE), is used to confirm a satisfactory neural response and then to evaluate the clinical effect of stimulation before implantation of a permanent device. Therapeutic trial stimulation is performed for one to three weeks, a period sufficient to prove its therapeutic effect—commonly considered a decrease in the frequency of incontinence episodes (documented by bowel-habit diary) by at least 50% and reversibility after discontinuation. Two technical options are used for PNE: a temporary, percutaneously placed, unipolar test stimulation lead (or multiple leads) that will be removed at the end of this phase; or operative placement of a quadripolar lead, the so-called “foramen electrode,” close to a target nerve. This electrode can stay in place and be used for permanent stimulation if the trial is effective. Today most commonly a minimally invasive technique places this foramen electrode with a modified anchoring device, the so-called “tined lead,” through a trochar. For screening, both types of leads are connected to an external pulse, the tined lead with a percutaneous extension cable.

The second stage is implantation of a permanent electrode and neurostimulator if screening is successful. Patients with a temporary lead require simultaneous implantation of the pulse generator and the quadripolar lead, most commonly as a tined lead procedure. Those with a foramen electrode already in place for screening will undergo removal of the percutaneous extension before placement of the pulse generator (so-called “two-stage implant”) [194]. Bilateral placement of foramen electrodes remain the exception, based either on improved outcome of bilateral stimulation during the screening phase [195] or on conceptual considerations [196]. The pulse generator is placed subcutaneously, usually in the gluteal area or under certain circumstances in the abdominal wall. It is activated and stimulation parameters are set early after surgery by telemetry; it can be deactivated by the patient with a small, handheld device commonly referred to as a “patient programmer.”

A small retrospective study, comparing the earlier use of an open electrode placement technique to the current tined lead placement demonstrated no difference in outcome [197]. The infection rate was slightly higher in patients undergoing open electrode placement (11% vs. 8%). Although responses to temporary stimulation and the permanent device are comparable, therapeutic outcome for permanent SNS appears to be best when both sensory/anal motor and toe flexion responses are achieved during test stimulation [198].

b) Patient Selection and Indications

Today, a variety of causes leading to faecal incontinence can be treated with SNS. During the initial SNS experience, only patients presenting with deficient function but no morphologic defect of the striated anal sphincter and levator ani were eligible [192,199,200]. However, because of the high predictive value of the test stimulation, a more pragmatic, trial-and-error approach to patient selection evolved. Patients are now selected for SNS based upon PNE results rather than conceptual considerations of the potential mechanism of action. Test stimulation is in-
dicated, not by an underlying physiologic condition, but by the existence of an anal sphincter with reduced or absent voluntary squeeze function and existing reflex activity, indicating an intact nerve-muscle connection (confirmed by intact anocutaneous reflex activity or by muscular response to pudendal stimulation with the St. Mark’s electrode) [199].

At present, the test stimulation is the only reliable mode for selecting patients who will likely benefit from permanent therapeutic stimulation. Various studies have focused on potential predictors of success of SNS. In a study by Gourcerol et al [201], age was the only variable related to success of temporary stimulation. In patients with a permanent implant, neurologic disorders, delay of the left bulbocavernous reflex and a prolonged or absent bulbocavernous reflex were more frequent in patients with successful outcome. In another cohort analysis, the need for repeated temporary procedures was associated with failure during the screening in univariate and multivariate analysis [202]. A low threshold to obtain motor response during temporary lead placement was revealed to be associated with improved outcome only in univariate, but not in multivariate, analysis. Evidence of anal sphincter injury was related to a greater risk of failure during temporary testing, but not with permanent implant.

In a large single-center study comprising 245 patients with test stimulation and 169 patients with permanent implant, Govaert et al [203] determined in univariate analysis that older age (>70 years), presence (but not size) of an external sphincter defect, and the need for repeated procedures after initial failure were significantly related to failure of test stimulation. In multivariate regression analysis presence of an external sphincter defect and need for repeated procedures remained significant. The permanent implant was successful in 76.9% of the patients, but no predictor was found to be significantly related. In a cohort of 55 patients with permanent SNS, Brouwer and Duthie [100] demonstrated that continence scores did not differ significantly in those with a defect, pudendal neuropathy, or previous sphincter repair. Melenhorst et al [204] found no difference in outcome with chronic SNS in patients after sphincter repair and those with an external sphincter lesion of up to 33% of the circumference; they concluded that a morphologically intact sphincter is not a prerequisite for successful SNS. In 244 patients undergoing test stimulation with a success rate of 78.3%, Maeda et al [205] determined that low amplitude of the sensory threshold during PNE and lead placement anterior to the sacral cortex are positive predictors of PNE outcome. No other demographic, physiologic or morphologic variable was a negative predictive factor. In a cohort of 200 patients with permanent SNS from 6 centers [206] only loose stool consistency, a history of diarrhoea management by medical treatment, and low stimulation intensity were associated with improved medium-term outcome. Multivariate regression analysis confirmed that stool consistency and stimulation intensity were independent predictive factors of success or failure of SNS.

In a cohort of 45 consecutive patients, temporary stimulation was successful in 32 (71%). At a median follow-up of 33 months, the neurostimulator remained in place in 25 (55%) and active in 23 (51%). No statistically significant differences were found in the characteristics (including anorectal physiologic workup) of the 32 patients who underwent implantation and the 13 who did not or in those 23 with a functioning stimulator [207].

Altmare et al [208] in a comparative study of 48 patients demonstrated in univariate and multivariate analysis that quadrupolar electrode use for test stimulation leads to better clinical outcome than a unipolar electrode.

In summary, none of the variables usually considered in a preoperative workup are of any help in selecting the appropriate patient for chronic SNS. [LEVEL OF EVIDENCE: 3]

Contraindications to SNS include pathologic conditions of the sacrum preventing adequate electrode placement (such as spina bifida), skin disease at the area of implantation, anal sphincter damage requiring a sphincter substitute (e.g. artificial bowel sphincter, dynamic graciloplasty), trauma sequelae with micturition disorders or low bladder capacity, pregnancy, bleeding complications, psychological instability, low mental capacity, limited cognitive function that interferes with the operation of the neurostimulation device, need for magnetic resonance imaging, and the presence of an implantable defibrillator or a cardiac pacemaker. A case series has shown the relative safety of the use of SNS in the presence of a cardiac pacemaker when monitored intraoperatively. If the distance between the devices is greater than eight inches, interference is unlikely [209].

c) Mechanism of Action

The mechanism of action of SNS remains uncertain. Clinical outcome has been seen to correlate with results of anorectal physiology studies, but the effect of chronic stimulation varies greatly among published reports [199,200]. Data are in part contradictory and inconclusive and sometimes not reproducible. The effect appears to be somatomotor [210-217], somatosensory [210], autonomic nervous system-based [210,212,218], and mediated by somatovisceral reflexes [219,220]. The effects appear not to be limited to the continence organ per se, but also to the central nervous system: corticoanal excitability in patients with faecal incontinence was found to be reduced with SNS [221]; in successfully treated
patients cerebral somatosensory evoked potential (SEP) latencies were higher at baseline than in the normal population, whereas they were normal in patients with SNS failure. Success was also associated with a fall of the SEP latency to the normal range after one month of SNS at 40 Hz [222]. SNS induces changes in anal representation on the primary somatosensory cortex [223]. The central nervous effect induced by SNS changes during its course: at its initiation, changes are seen in the contralateral frontal cortex, reflecting focus attention; subsequent changes are found in the ipsilateral caudate nucleus, an area related to learning [224].

Qualitative (or quantitative?) changes are seen in anal, rectal and colonic motility, such as reduction of spontaneous rectal motility complexes [225,226], spontaneous anal sphincter relaxation [225], reduction of antegrade transport from the ascending colon and increased retrograde transport from the descending colon at defaecation [227], increase rectal perception thresholds [228,229] and improve pelvic floor contraction during SNS [229]. The findings on rectal capacity with SNS have been inconsistent: unaltered [230-232] or increased [225,233]. No changes in gastric retention, gastric emptying, small bowel transit or colonic passage were seen with scintigraphic measurements during SNS [234].

An effect on mucosal neurochemistry during SNS has also been shown, with elevation of Substance P and TRPV1 levels [235], although the relevance of each of these has not been proven in specific pathophysiological conditions. The mechanism of action is most likely multifactorial and dependent on the underlying condition. [LEVEL OF EVIDENCE: 4]

d) Outcome

The results of permanent SNS after pragmatic, trial-and-error patient selection are shown in Table 5 [100,206,207,210-213,235-251]. Most studies have encompassed patients with heterogeneous pathophysiologic conditions, and they vary with regard to design and patient number, but there is general agreement regarding the test stimulation for selection for permanent implant. Most commonly, clinical outcome is reported as an improvement in the number of incontinence episodes or days with incontinence during the period of observation, changes in the Cleveland Clinic Incontinence Score, and quality of life.

In a first multicenter prospective trial of SNS adherent to the initial, confined spectrum of indications, Matzel et al [238] reported 37 patients, 34 of whom underwent a permanent implant. Not only were the frequency of incontinence episodes and the CCIS score improved significantly, so too was the ability to postpone defaecation. These effects were attained immediately.

Leroi et al [240] reported a double-blind, cross-over multicenter study in 34 patients with faecal incontinence treated with SNS. Three months after implantation, patients were randomised in a double-blind manner to on- or off-stimulation for a 2-month period, with reversal of the activation mode after 1 month. Of these, 24 of 27 randomised patients completed the 2-month trial. A significant decrease in median frequency of faecal incontinence episodes was noted during the on-stimulation period. No significant change was observed between on- and off-stimulation for frequency of urgency episodes, delay in postponing defaecation, or median number of bowel movements per week (10.2 and 11.1 for on and off, respectively). There was a trend towards greater improvement in the Cleveland Clinic Incontinence Score during on-stimulation (8.5 vs. 10.5; ns). A total of 24 patients (89%) considered that they had improved during the on period compared with 17 (63%) during the off period.

Melenhorst et al [213] published the largest mid-term follow-up, single-center study, with 100 patients undergoing permanent SNS. Late failure occurred in 21 patients as defined by a relapse of symptoms to less than 50% improvement over baseline, implementation of another therapy for faecal incontinence, or patient dissatisfaction. The mean time for definitive failure was 13.6 months (range 3-42.4). There was no evidence of technical failure such as lead migration or lead breakage.

A report by Rosen et al [210] highlights the effect of SNS in a cohort of patients of whom 75% suffered from faecal incontinence of neurologic origin. Frequency of incontinence episodes/week was reduced from 6 to 2 at 15 months’ follow-up.

In a recent larger multicenter study Wexner et al [247] confirmed the efficacy of SNS in reducing symptoms of faecal incontinence: of 112 patients with permanent SNS followed for a mean of 28 months (2-69), 83% experienced a ≥50% improvement, including 41% who gained complete continence (at 12 months).

Mellgren et al [251] reported the same cohort after a mean follow-up of 3.1 years (0.2 – 6.1 years). With a complete or partial data set available in 64% of the patients, a ≥50% reduction of incontinence episodes was seen in 86%, with 40% achieving perfect continence. Symptom improvement resulted in improved quality of life, which was stable over follow-up. If a “last observation carried forward analysis” is performed, the 50% reduction of symptoms at 3 years is a 78% success rate; in a “modified worst-case analysis”—with all missing data classified as failure—the success rate at 3 years is 59%.

The findings of sustained symptomatic improvement with extended follow-up are in accordance with several other series focusing on long-term outcome: a sustained effect was seen in 74% of 52 patients after 5 years [245]; in 84% after a median follow-up of 7.1 years (5.6-8.7) [252]; and in 6/9 with follow-up of 7 – 14 years [253].

*CCIS: Cleveland Clinic Faecal Incontinence Score: 0 = fully continent, 20 = worst incontinence; †Limited to studies reporting incontinence episodes/week and/or CCIS at last follow-up ‡Denotes median; otherwise all data are presented as mean. ns: not stated; FU, follow-up
In most studies, quantitative measures are used to describe the clinical benefit, such as days with incontinence episodes or absolute numbers of incontinence episodes per period of observation, ability to postpone defaecation (in minutes), and percentage of improvement. Even though published reports differ with regard to patient population, a general pattern of outcome can be observed: when compared with baseline status, the clinical outcome is significantly improved.

The majority of studies report the outcome based on a per protocol approach (PP): the outcome reporting is limited to those patients with a permanent implant after successful testing. The infrequently used intention-to-treat protocol (ITT) approach analyses all patients considered for the therapy and undergoing PNE test. Thus, those are included who failed PNE, who are lost for follow-up or who died. In one study with 245 patients undergoing PNE and 176 patients subsequently being implanted, 132 patients were treated with SNS for a median follow-up of 33 months (ITT 53.9%, PP. 75.0%). Outcome was good or acceptable in 103 patients (ITT: 42.1%, PP: 58.5%), limited or reduced requiring additional or alternative treatment in 20 patients (ITT: 11.8 %, PP: 16.5%) [254].

In a meta-analysis of publications from 2000-2008 comprising 790 patients, 28 studies compared incontinence episodes per week before and with SNS, and 14 studies compared incontinence scores. Both outcome criteria were significantly decreased. Another nine studies documented the ability to postpone defaecation, and this criterion also was significantly improved [255]. [LEVEL OF EVIDENCE: 2]

An increasing body of evidence indicates that SNS may also be a treatment option for patients with sphincter defects, unrepaired or after attempted anatomic reconstruction. The presence of an internal anal sphincter defect on endoanal sonography is reportedly unrelated to the success of permanent SNS [202]. Since the first report that three of five patients with ultrasound evidence of sphincter disruption measuring 25–33% of the circumference benefited from chronic SNS [256], several studies have been published (Table 5) [100,204,257-262]. The origins and morphologic findings regarding the extent of the sphincter gap differ in these studies, but lesions up to 180° have been treated. It appears that outcome is not dependent on the radial extent [257,260]. A significant improvement in clinical function, measured either as frequency of incontinence episodes or Cleveland Clinic Incontinence Score, has been seen in a substantial number of patients in all studies [100,204,257-262]. Follow-up is still limited.

Melenhorst et al showed that the primary use of SNS in patients with a sphincter gap 17-33% of the circumference appeared to result in an outcome similar to its use after failed sphincter repair [204]. In another study, SNS in 6 of 8 patients with faecal incontinence related to obstetric full-thickness anal sphincter lesions of >30-150° resulted in improved frequency of incontinence episodes (from 5.5 to 1.5 per week), improved ability to postpone bowel emptying, and improved FIQL quality-of-life scores at a median follow-up of 26.5 months [257]. No correlation between improvement and the radial extent of the sphincter defect was seen. In patients with internal and external sphincter disruption owing to Crohn’s disease SNS was demonstrated to be beneficial in one study [258].

In a comparative cohort study [259], the effect of permanent SNS was reported in 53 patients with either an intact external anal sphincter (N= 32 (37.5% after sphincter repair)) or an external anal sphincter lesion (N=21 (81% after prior sphincter repair)) of <90° (N=11) or 90-120° (N=10). Improvement in symptoms and quality of life was achieved, and outcome after 12 months was not statistically significantly different between both groups. [LEVEL OF EVIDENCE: 3]

The therapeutic potential of SNS has also been demonstrated in some, mostly small, case series and individual case reports of patients with distinct pathological conditions or well defined anorectal physiology findings (Table 5) [196,242,263-268]: e.g. muscular dystrophy [269], proctocolecotomy with ileoanl J-Pouch reconstruction for colitis [270], neurologic dysfunction including spinal disc prolapse [267], rectal prolapse repair [265,266], and rectal resection for cancer [263] with or without neo-adjuvant chemoradiation [196,264,271], and after neoadjuvant and adjuvant chemoradio/radiotherapy for endometrial and anal cancer [272,273]. [LEVEL OF EVIDENCE: 4]

In a randomised controlled trial Tjandra et al [274] compared the effect of SNS for severe faecal incontinence with supervised optimal medical therapy that comprised pelvic floor exercises, bulking agents, and dietary manipulation. Permanent SNS in 53 patients was significantly better than conservative treatment in 60 patients: Cleveland Clinic Continence Score 1.2 vs. 14.1; incontinence episodes/week 3.1 vs. 9.4; days with incontinence/week 1 vs. 3.3; lifestyle 3.31 vs. 2.31; coping/behavior 2.68 vs. 1.86; depression/self-perception 3.25 vs. 2.64; embarrassment 2.76 vs. 1.78. [LEVEL OF EVIDENCE: 2]

e) Quality of Life

As with indications, outcome assessment has also evolved, and aspects of quality of life have been added to the evaluation (Cleveland Clinic Continence Scoring System, SF-36 and FIQL Score.) The therapeutic impact of SNS is most evident when a disease-specific quality-of-life instrument, the FIQL scale, is applied.

In the first study to apply this instrument, the multicenter clinical trial by Matzel et al [238], FIQL score was significantly increased in all 4 scales; SF-36
scores improved in 7 of 8 scales, the greatest being social functioning and mental health, but only the former reached statistical significance. A similar result was published by Leroi et al [240] with the French version of the FIQL: at the final follow-up visit, improvements in lifestyle, coping behavior, depression, and self-perception and embarrassment were significant. Hetzer et al [243] demonstrated a significant improvement of the median Gastrointestinal Quality of Life Index score with permanent SNS from a baseline of 96 (range 47–128) to 107 (range: 36–128) at 6 months post-implantation.

In most studies on outcome, quality-of-life evaluation is a secondary endpoint [196, 200, 210, 238, 240, 242, 243, 249 - 252, 259, 263, 265, 267, 274, 275]. When used, the finding of improved quality of life is consistently related to symptom relief and remains stable with longer follow-up [245, 251, 252, 276]. In a meta-analysis [255] of 34 studies with 790 patients, SF-36 score data were analysed from 7 studies with 98 to 102 patients and ASCRS FIQL data from 9 studies comprising 199 patients: SF-36 outcome was significantly increased in all categories (physical functioning, social functioning, role physical, role emotional, mental health, vitality, general health) with one exception (bodily pain). FIQL outcome was significantly increased in all categories (lifestyle, coping/behavior, depression/self-perception, embarrassment).

In a two-center study of patients with permanent SNS for a median of 46 months (11-122), 108 of 127 patients responded to questionnaires regarding bowel habits and quality of life. Using a non-validated score, 75.8% reported satisfaction, which in most was related to clinical improvement. However, at last follow-up 11 of 23 patients who had failed to achieve a 50% reduction in incontinence episodes reported satisfaction, and 6 of these had more incontinence episodes than at baseline [268]. [LEVEL OF EVIDENCE: 2]

f) Cost Benefit

Permanent SNS is expensive; however, its cost-effectiveness has been demonstrated in several European nations. Hetzer et al [277] compared the costs of SNS with those of conservative treatment, anterior sphincteroplasty, dynamic graciloplasty, and stoma creation in 34 consecutive patients. The 5-year cumulative cost for SNS was €19,333, compared with €35,965 for a stoma (with annual costs of €5,339) and €34,953 for dynamic graciloplasty (annual costs €1,659). The equivalent cost for conservative treatment was €3,895, and the overall median real cost for an anterior sphincteroplasty was £5,327. Muñoz-Duyos et al [276] analysed the direct medical costs of SNS in a series of 47 patients undergoing 57 PNEs and the consequent 29 patients with a permanent unilateral implant for a median follow-up of 34.7 (2.3 - 81.2) months. The cost totaled €371,434, including €31,7791 for the devices. In patients without anal sphincter damage SNS provided 0.34 incontinence-free life-years and entailed additional costs of €1,054, which generates a cost-effectiveness ratio of €16,181 per quality-adjusted life-year (QALY). The nationally accepted threshold is around €30,000/QALY. The economic impact of the introduction of SNS would be to add 0.07-0.1% to the care of these patients.

In a decision-analysis model based on prospectively collected data in 70 patients undergoing test stimulation and implantation of the permanent SNS device, incontinence episodes/week were reduced from 6 at baseline to 0.5. Dudding et al [278], based on direct medical and non-medical costs, found an incremental cost-effectiveness ratio (ICER) for SNS of GB£25,070 per QALY gained. It cost GB£1,038 per year to achieve a median reduction of 238 incontinence episodes, equal to GB£3.61 per reduced episode. The ICER of GB£25,070 per QALY was within the nationally accepted GB£30,000 per QALY threshold.

In a similarly designed study based on published reports and expert opinion, Indinnimeo et al [279] found that the ICER is £28,285 per QALY gained in patients with a structurally deficient anal sphincter and £30,662 per QALY in patients with an intact anal sphincter. Both are below the national threshold of £40,000 per QALY gained. Budget-impact analysis demonstrated that the implementation of SNS would have an estimated impact of 0.56% over a 5-year period on the budget allocated for faecal incontinence treatment. [LEVEL OF EVIDENCE: 3]

g) Safety

SNS is a relatively safe procedure [247,280]. A recent meta-analysis [255] is in accordance with earlier reports, which describe a relatively low rate of complications [199,200] and a need for device removal in only approximately 5% because of loss of effect, symptom deterioration, pain from lead dislocation, or infection. The results of the meta-analysis, which covered the period 2000 – 2008 and included patients undergoing the more invasive, open-approach electrode placement technique, found a complication rate of less than 15% in 665 patients with a permanently implanted device. In only 3% did the device need to be removed. In patients in whom infection has necessitated removal, re-implantation at a later date has reportedly been successful [274].

In a recent FDA study with strict monitoring of adverse events, 334 were reported in 99 patients at three-year follow-up; 67% occurred in the first year, and most required no or minimal intervention. The adverse events included pain at the implant site (28%), paresthesia (15%), change in the sensation of stimulation (12%), implant site infection (10%) [247], urinary incontinence (6%), diarrhoea (6%), and leg pain (6%). Half of the infections required surgical intervention with removal of the device in 5 of 6 patients [251]. A single report with a consecutive series of 87 patients over a mean follow-up of 48.5
months describes the need for revisional surgery in 41%, one-third for device-related failure, including 24% for removal [281]. In a French multicenter study comprising 200 consecutive patients with a mean follow-up of 12 months, the rate of device-related adverse events was 24.5% [206].

Major complications are rare: one case report of a life-threatening haemorrhage after elective tined lead electrode removal has been published [282].

A recent review of 48 cohort studies (45 for faecal incontinence and 3 for constipation) documented the postoperative issues in the 1661 patients with test stimulation and 1600 patients with a permanent SNS implant [283]: it found that the incidence of suboptimal outcome was 12.1%, pain 13%, and infection 3.9%. The most common problem during test stimulation was lead dislodgement (5.3%). The reported incidence rate for suboptimal outcome – loss of efficacy or lack of efficacy – ranged between 0% and 27%. Systematic literature review suggests a possible underreporting of suboptimal outcome and adverse events. In one single study, the rate of adverse event reached up to 85.2% in patients with a median follow-up of 11 months: loss or lack of efficacy and event reached up to 85.2% in patients with a median follow-up of 11 months: loss or lack of efficacy and pain or discomfort accounting for 88.5% of these [254]. [LEVEL OF EVIDENCE: 3]

8. POSTERIOR TIBIAL NERVE STIMULATION

a) Introduction

Posterior tibial nerve stimulation has its origin in pain treatment as transcutaneous electrical stimulation (TENS). Its use for the treatment of faecal incontinence (first published in 2003 [284]) is an adaptation of its successful application in the field of urology, stemming from the early 1980s [285-287]. Only recently, based on the therapeutic success of sacral nerve stimulation, has there been an increasing interest in this alternative approach of neuromodulation. The number of publications is still limited and the evidence low; however, several clinical trials are currently ongoing. Larger patient studies are awaited.

b) Techniques

Two different techniques are used: percutaneous stimulation with a needle electrode [288] and transcutaneous stimulation with surface adhesive electrodes [289]. In both techniques current is delivered by positioning the active electrode close to the posterior tibial nerve proximal to the medial malleolus. Adequate placement is confirmed by inducing digital plantar flexion, and the ground pad is placed in the proximity. Both systems are powered by a portable pulse generator. The stimulation parameter are set arbitrarily, mostly to 0.2 ms, a current below the threshold for motor response ranging between 0.5-9.0 mA, and a frequency usually to 10 – 20 Hz.

Although the stimulation parameters themselves are fairly uniform, there is no general agreement regarding the protocol: duration and pattern of stimulation; interval between sessions; basic or “top-up” treatment (Table 6) [289-295].

c) Patient Selection and Indications

Indications vary substantially among the proof-of-principle studies. A prospective observational design

predominates, with mostly single-center trials and a limited number of patients. Inclusion criteria range from idiopathic faecal incontinence [289,290,292] and incontinence owing to inflammatory bowel disease [294], to faecal incontinence with internal or external sphincter lesions or a combination of both, some after obstetric trauma [290,292,296]. PTNS has been applied for passive, urgency, and mixed incontinence [293]. Symptom improvement has been demonstrated with PTNS for faecal incontinence after partial spinal injury in two cases [297].

d) Mechanism of Action

No studies have been performed to elucidate distinctly the effect of PTNS on symptoms of faecal incontinence. Several hypotheses of a potential mechanism of action have evolved based on the experience of the use of PTNS in urology and on an analogy drawn from findings of physiological changes with sacral nerve stimulation, but none of these hypotheses has been systematically explored. In one study significant changes in maximal squeeze pressure only was seen after 6 months [290]; others demonstrated no changes in physiological measurements [289]. An improvement in rectal sensory threshold and resting and squeeze pressures was reported in two patients after partial spinal injury [297]. In another study the clinical efficacy of PTNS was found to be independent of damage to the anal sphincter [298]. [LEVEL OF EVIDENCE: 4]

e) Outcome

All studies demonstrate an improvement in outcome measures, although outcome is not described uniformly (Table 6). Most commonly, clinical efficacy is monitored with the Wexner Incontinence Score and/or the recording of faecal incontinence episodes. Where incontinence episodes per month were reported and differentiated by stool consistency, in a study of 13 patients, reduction at 3 months was significant for all categories: wind, baseline 6 (0-17.5) vs. 0 (0-0) episodes/month; liquid, 10 (5-29.5) vs. 0 (0-4); and solid, 18 (0-30) vs. 0 (0-0) [290].

In all studies outcome reporting is limited to short-term follow-up. Postponement of defaecation was found to be significantly increased at 6 weeks and sustained at 12 months [291]. In one study the median increase in the ability to defer was 3 minutes (0-26) in patients suffering from urge incontinence [292]. [LEVEL OF EVIDENCE: 4]

f) Quality of Life.

If measured, instruments of quality-of-life recording also demonstrate an improvement with therapy [291]. Comparisons between success and failure, however, have not depicted conditions predictive of symptomatic improvement [291,295]. In patients with subjective improvement, quality of life was significantly better after 3 and 6 months' follow-up [295,296]. [LEVEL OF EVIDENCE: 4]

g) Safety

Reports on safety are limited, but none of the studies found relevant side effects. Mild, procedure-related reversible adverse events, such as gastrodynia and numbness in the leg for 2 hours, were reported in one study [291]. [LEVEL OF EVIDENCE: 4]

9. INJECTABLE BIOMATERIALS

Injection of bulk-enhancing agents into the anal canal to treat faecal incontinence has continued to gain popularity since the last review. Although injectable agents for urinary incontinence (UI) have had variable success, they offer the benefit of performing an outpatient procedure without anesthesia and with minimal morbidity. This has resulted in their continued use for urinary incontinence [299,300], as well as in more research on different injectable agents for use in faecal incontinence. The ideal agent for injection should be biocompatible, non-allergenic, non-immunogenic, easy to inject, and should not migrate within the tissues. No agent currently has all these properties. Agents that have a diameter of 80 mm are felt to be less prone to migration, but agents with a larger particle size require a larger bore needle to inject, which put them at a higher risk for leakage from the injection site. The results of all injectable biomaterials used for faecal incontinence to date are shown in Table 7 [301-324].

Injectable agents for faecal incontinence were first used in 1993 when Shafik [301] treated 11 patients with injections of polytetrafluoroethylene paste into the anal submucosa. After 18-24 months of follow-up, 64% reported complete cure and 36% had partial improvement. Shafik [302] subsequently treated 14 patients with autologous fat injections with a reported 100% success rate at 2-3 months and all patients who lost continence to gas or stool became continent after repeat injections. There were no complications using either agent. However, other reports of autologous fat injection have resulted in death from pulmonary fat embolism [325], and a randomised clinical trial using fat for UI demonstrated no efficacy over placebo; thus, it is currently not used for faecal incontinence [325].

Other agents used for injection in the past, that have not achieved widespread use include micro balloons, bovine dermal collagen, and polyacrylamide hydrogel (Bulkamid). A series of six patients injected with self-detaching cross-linked silicone micro balloons with a biocompatible filler material demonstrated fairly good results, with Browning-Parks incontinence scores for the group decreasing from 16 to 5 (range 0-20) [305]. However, sterilization issues have prevented the ongoing use of this product. The first reported injections of glutaraldehyde cross-linked synthetic bovine dermal collagen (Contigen) for faecal incontinence included 17 patients [303], 11 (65%) of whom showed marked

AMS: American Medical Systems score
FISI: Faecal Incontinence Severity Index
symptomatic improvement at 8 months. A much larger series of 73 patients was then reported [308] in which subjects received injections of 1.7 ml of collagen transanally into the rectal submucosa in three separate areas just proximal to the anal canal. Overall, 63% reported an improvement in their incontinence and the 49 patients with idiopathic incontinence (no sphincter defect and no pudendal neuropathy) had a significant decrease in their Wexner Faecal Incontinence Score (CCF-FIS, range 0-20). The disadvantages of using synthetic collagen are its potential to be allergenic and degrade over time. Furthermore, its success in urinary incontinence has been limited [299].

A pilot study conducted in 2008 examined two other products, cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (Bulkamid) [313]. Ten patients with passive faecal incontinence to liquid or solid stool who had failed conventional treatments were prospectively randomised to receive either of the two products. The needle was first inserted into the skin 2 cm from the anal margin and the product was then injected trans-sphincterically. The median volume to achieve closure of the anal canal under direct vision was 9 ml for Bulkamid and 15 ml for Permacol. The St Mark’s incontinence score decreased at 6 weeks for both groups, but this decrease was sustained at 6 months only for the Bulkamid group. This pilot study lacked power to determine if these two treatments for faecal incontinence differed significantly. Unfortunately, no other follow-up studies have been reported.

Several other injectables have been used for faecal incontinence with variable results. In one of the few adequately powered, randomised controlled trials using injectables, 44 patients were randomised to receive transdermal injections of polydimethylsiloxane elastomer silicone biomaterial (PDMS) or saline into the intersphincteric space [310]. Three 2.5ml injections were performed using local anesthesia. Only the patients were blinded to the treatment. There was no difference in the percentage of patients in the two groups who had a successful treatment, defined as having a CCF-FIS score <8 or the decrease in CCF-FIS scores post treatment. The saline group tolerated treatment better and had fewer adverse effects overall. Thus, the study concluded that the use of PDMS should not be recommended.

Three smaller studies using other products have shown some promise although the testing was much less rigorous. In one of these studies, calcium hydroxyapatite ceramic microspheres (Coaptite) were injected transphincterically to four submucosal sites using 1ml at each site with the patient under local anesthesia. The average Faecal Incontinence Scoring System (FISS) score for 10 patients decreased from 85.6 to 28 at 12 months (p=0.008) and the lifestyle, coping and behavior/embarrassment subscales of the Faecal Incontinence Quality of Life Scale (FIQL) showed improvements (p<0.05). Ano-rectal manometry also showed better resting pressures (40 to 47 mmHg, p=0.018). There were no complications, but one patient experienced leakage of product from the injection site that required another injection [314]. In the second of these smaller studies, 21 patients received ethylene vinyl alcohol (EVOH) injections with 1-2 ml in up to 8 sites in the intersphincteric space under general or local anaesthesia. At 12 months, Faecal Incontinence Severity Index (FISI) scores dropped from 32.8 to 22 and CCF-FIS scores decreased from 11 to 6.9. Two subscales of the FIQL improved significantly and repeat ano-rectal manometry demonstrated some increase in anal canal length and resting pressures [302]. The third and most recent of these small studies reported on 14 patients who received transdermal injections of polyacrylonitrile cylinders (Gatekeeper prosthesis) into the intersphincteric space. The CCF-FIS score decreased from 12.7 to 5.1 (p<0.01) and there were no complications. Location of the prostheses was documented by ultrasound and no dislodgement was seen at 1 year [323].

The two most common injectables used to treat faecal incontinence are silicone biomaterial (Macroplastique, Bioplastique, PTQ implants) and pyrolytic carbon-coated zirconium oxide beads (DuraspHERE). Injectable silicone biomaterial has been used extensively for urinary incontinence. It consists of polydimethylsiloxane particles suspended in a bioexcretable carrier hydrogel of polyvinylpyrrolidone. Two pilot studies using Bioplastique for faecal incontinence in 2001 and 2002 [304,326] led to increased use of this product in Europe and it was renamed PTQ implants (PTP implants in Australia). Malouf et al [304] studied 10 patients with passive incontinence who received circumferential or single site injections of Bioplastique. At six weeks, six patients showed either marked improvement or complete cessation of leakage and an additional patient improved after a second injection. However, after six months, only two of seven patients had maintained marked improvement. Complications included anal pain and ulceration at the injection site. In the largest study of PTQ injection to date [307] 82 patients with severe faecal incontinence were randomised to receive PTP implants either with or without endo- anal ultrasound guidance for injection. All patients had a significant improvement in their CCF-FIS. At 12 months, this score decreased from 14.5 to 3 in the ultrasound guidance group and from 14.5 to 11 in the non-ultrasound group. Six patients, two from the ultrasound guidance group, complained of pain at the injection sites. There were no other complications. The ultrasound guidance group had more significant improvement in resting pressures and quality of life scores. The same investigators injected PTQ into seven patients with passive incontinence after haemorrhoidectomy and found significant improvement CCF-FIS and quality of life scores in all patients [327].
Several other series have been reported PTQ use for faecal incontinence [311,315,317,319]. In all of them, 2.5ml of product was injected into 3-4 sites in the intersphincteric space and CCF-FIS decreased significantly. In one study of 20 patients, the CCF-FIS decreased significantly from 13.5 to 4.5 at one month and slowly increased to 9.4 at two years, which was a still a significant improvement from the baseline score. Quality of life scores also improved, but there was no effect on resting and squeeze pressures measured at baseline and 3 months after injection. Seventy percent of patients experienced pruritus ani and one patient developed an infection at an injection site [311]. In a study of 33 patients, CCF-FIS decreased from 12.7 to 10.4 at one year, yet quality of life was not improved [315]. Both of these studies examined implant migration and 63-84% of patients had detectable implants at the site of injection by ultrasound, though this did not seem to affect clinical response. The largest of these studies is notable for its sample size of 74 patients and that half of these subjects were men. It found that 70% of patients reported complete satisfaction with their continence (post-treatment CCF-FIS =0) and in the remaining 30%, CCF-FIS decreased from 12 to 3.5 at 33 months with associated improvements in quality of life measures. All patients, but especially those who became continent, had significant improvements in mean resting pressures, squeeze pressure and mean anal canal length. Worse results were seen in women with pudendal neuropathy or those for whom biofeedback had already failed [317]. Another study specifically compared the anorectal manometry of patients injected with PTQ with that of normal controls and found that after injection in the symptomatic patients there was a similar decrease in CCF-FIS with associated improvements in FIQL scores. The symptomatic patients had lower resting and squeeze pressures than controls at baseline and these pressures did not improve with injection. However, these patients did have elongation of their high pressure zone, as well as improvements in the asymmetry index, indicating that morphologic but not physiologic changes had occurred with injection [319]. The only report of long-term results for injectable agents was for Bioplastique [328]. The 5-year outcome for 6 patients injected with Bioplastique in 1999 included a median St. Mark’s incontinence score that was essentially unchanged from 11 to 13 (range 9-20). One patient had undergone a colostomy, but four of the five remaining patients reported subjective improvement in their incontinence and better quality of life scores.

The other commonly used injectable, Durasphere, is non-reactive and not biodegradable. However, the beads are known to migrate within the tissues and require a large bore needle to inject the substance. The injected substance is placed in the submucosal plane using either a transanal or intersphincteric approach. The initial trial [306] assessed the short and long-term efficacy in 18 patients with an internal anal sphincter defect refractory to conservative management. About 1.3ml was injected in the submucosal plane at the site of the sphincter defect in 1-4 sites until adequate anal sphincter symmetry was restored. At 12 months, CCF-FIS and patient satisfaction scores were significantly improved. Fifteen of 18 patients reported improvement in their incontinence. An abstract presented by Weiss et al [329] also demonstrated improvement in ten patients who were only followed for 3 months. In a larger study, 33 patients with minor or medium severity faecal incontinence (CCF-FIS < 14 and/or American Medical Systems (AMS) score < 89) received injections (mean of 8.8 ml (range 2-19 ml) of Durasphere into the submucosa at the level of the dentate line using an 18-gauge needle at four different sites [312]. After a mean follow-up period of 21 months, the CCF-FIS for the group decreased significantly from 12 to 8 and the AMS score from 89 to 73 but the faecal incontinence specific quality of life measures did not change. Resting and squeeze pressures also increased 12 months after injection. Adverse events included anal pain in two patients, asymptomatic leakage of material in one patient, and distal migration of product in two patients. A study of 11 patients in which about 2.8ml of Durasphere was injected into 3-4 sites in the submucosal space reported a decrease in CCF-FIS from 12.7 to 4.9 at 2 years with improvements in the coping and embarrassment subscales of the FIQL at 6 months. Although manometry pressures did not change initially, the resting and cough pressures were higher at 2 years than at 1 year [318].

The most recent study using Durasphere injected the product using a slightly different approach. In all 23 subjects, the product was injected into the intersphincteric space in four sites. Again, about 2.8ml of product was injected at each site. At 12 months, patients had a decrease in the CCF-FIS from 18.7 to 10.9 and an increase in FIQL score from 46 to 55.8. Mean squeeze pressures on anorectal manometry increased significantly at 12 months. Adverse complications included prolonged pain in one patient and a sterile perianal fluid collection in another [321].

Only one trial compared the safety and efficacy of PTQ and Durasphere [316]. Sample size was calculated to detect a 50% reduction in the CCF-FIS post injection. Thus, 40 patients with faecal incontinence (mean CCF-FIS 11.45) were randomised to receive either PTQ or Durasphere. Both groups were similar in terms of age, medical history, faecal incontinence severity and quality of life scores, as well as anorectal manometry results. Although the Durasphere group had a more significant reduction in CCF-FIS at 2 weeks (11.45 to 8.25 vs. 11.45 to 10.9), the PTQ group had a greater reduction in CCF-FIS at 6 weeks, 6 months and 12 months (4.6,2.95 and 3.8 vs. 7.65, 6.2 and 7), and had no complications. The Durasphere group had several complications including anal pain (5%), mucosal erosion (10%),

1509
arthritis and skin rashes (5%). Furthermore, the PTQ group demonstrated significant improvements in general and faecal-incontinence-specific quality of life scores that were not seen in the Durasphere group. Thus, the conclusion was that PTQ was safer and more effective than Durasphere for the treatment of faecal incontinence [316].

The newest injectable agent to be used for faecal incontinence is dextranomer- hyaluronic acid copolymer (Zuidex, NASHA Dx). Dextranomer microspheres are suspended in non-animal stabilized hyaluronic acid. As with other injectable agents, Zuidex has been used to treat urinary incontinence [330] and a pilot study of four patients reported no adverse events and a median decrease in St Marks incontinence score of 3.5 points (19.25 to 15.75) [309]. In a subsequent study of 34 patients who received transanal injections into the submucosa just above the dentate line (about 1ml of product was injected into four sites), the median number of incontinent episodes in a four-week period dropped from 22 to 9 [320]. When response was defined as a 50% or greater decrease in number of incontinent episodes, 56% of patients were defined as responders at 12 months. No adverse events were reported. These findings led to a randomised double-blinded sham-controlled trial of 206 patients randomised in a 2:1 fashion to receive NASHA Dx or placebo injection [324]. The patients and the evaluating investigators were blinded to the treatment. More patients in the treatment group had 50% or greater reduction in the number of incontinence episodes (52% versus 31% of controls; p=0.009), but the change in CCF-FIS did not differ after treatment between groups (14 to 2.5 in the treatment group vs. 13 to 1.7 in placebo group). The FIQL was only significantly improved compared to placebo for the coping and behavior subscale. Both groups had a high retreatment rates: 82% of patients in the NASHA Dx group received reinjection of product and 87% of patients in the control group had repeat sham injection. The NASHA Dx group had significantly more adverse events, including proctalgia, rectal bleeding, pruritus, diarrhoea, constipation, fever, and two serious complications of rectal abscess and prostatic abscess. The control group had more injection site bleeding [324]. The most recent study of NASHA Dx was reported in an abstract of 21 patients who received injections of 1ml of product in four sites of submucosa. There were no adverse events and 61% of patients had a significant decrease in incontinence episodes at 3 months and 56% had a sustained improvement at 22 months. The CCF-FIS decreased from 16.8 to 12.3 but was not significant. Improvement in FIQL scores were noted [331].

In summary, studies of injectable biomaterials comprise several small case series that in general show short-term efficacy and only three randomised trials, two of which compared PMDS and NASHA Dx to placebo, and a third that compared PTQ to Durasphere. These trials indicated that PMDS should not be used, PTQ appears to be better than Durasphere in terms of both safety and efficacy, and that NASHA Dx has some evidence of efficacy compared to placebo. Two systematic reviews [332,333] and a Cochrane review [334] have been published recently that review the data for all injectable agents for faecal incontinence. Due to the poor methodology and small sample sizes of most of these studies, none of these reviews could establish adequate evidence to support the efficacy of any of these agents. However, one review did find that in a multivariate analysis, use of the intersphincteric, instead of transanal or trans-sphincteric routes of injection, was associated with a higher complication rate. Furthermore, PTQ and Coaptite were significant predictors of short-term outcome and use of local anesthesia was associated with a lower likelihood of success [332]. [LEVEL OF EVIDENCE: 3]

10. COLOSTOMY

A permanent colostomy is usually formed as a last resort for severe faecal incontinence when all other interventions have failed. Because colostomy is generally regarded as a failure of treatment, its effectiveness, perioperative complications, and impact on the quality of life have never been properly evaluated except for patients with functional bowel disorders after spinal cord injury [335,336]. For a specific role of colostomy for these patients, please refer to the specific chapter. Not only for patients with spinal cord injury, but also for general population with severe faecal incontinence, colostomy is a frequently successful management strategy that restores dignity and allows them to regain social function.

No randomised controlled trials or non-randomised cohort studies have been reported regarding colostomy for faecal incontinence, and only one systematic review (level 4) [188], one case control study (level 4) [337] and two case series (level 4) [338,339] were identified.

Colquhoun et al [337] conducted a cross-sectional postal survey, comparing quality of life between 71 patients with faecal incontinence and 39 with a colostomy created for rectal cancer, complicated colonic diverticular disease or faecal incontinence. Analysis of the Short Form 36 General Quality of Life Assessment revealed significantly higher social function score in the colostomy group than in the faecal incontinence group (0 vs. -0.6, p=0.022). An age- and gender-adjusted regression analysis of the Faecal Incontinence Quality of Life score revealed significantly higher scores in the coping (2.7 vs. 2.0, p=0.005), embarrassment (2.7 vs. 2.2, p=0.014), and lifestyle scales (3.2 vs. 2.7, p=0.14) in the colostomy group compared to the faecal incontinence group. The authors concluded that a colostomy is a viable option for patients who suffer from severe faecal incontinence and offers a definitive cure with improved quality of life.

Tan et al [188] performed a systematic review, specifically comparing the cost-effectiveness between end stoma (ES), artificial anal sphincter (AAS) and
dynamic graciloplasty (DG). The quality-adjusted life years (QALYs) and the incremental cost-effectiveness ratio (ICER) were compared between the three procedures, by obtaining the probability estimates for patients with faecal incontinence from published data, with being supplemented by expert opinion. The end stoma was the most cost-effective therapy at 5 years, with a QALY gain of 3.45 for GB£16,280 and an ICER of GB£4,719/QALY, compared to AAS (4.38 for GB£23,569; GB£5,387/QALY) and DG (4.00 for GB£25,035; GB£6,257/QALY). After 10 years, AAS became the most cost-effective surgical intervention, with a QALY gain of 8.384 for GB£32,937 and an ICER of GB£3,864/QALY, compared to ES (6.9 for GB£27,910; GB£4,046/QALY) and DG (7.678 for GB£35,165; GB£4,580/QALY). The results of this study, however, must be interpreted with great caution, because it is not an interventional study but a systematic review with a rather complicated methodology and a variety of possible biases.

Norton et al [338] examined patients’ view of a colostomy by conducting a questionnaire study of patients who had a colostomy created to manage their faecal incontinence. Sixty-nine people (58 women) responded. When patients were asked to rate their ability to live with their stoma now on a scale of 0-10, the median score was 8 (range 0 – 10). The majority (83%) felt that the stoma, within the past month, restricted their life “a little” or “not at all”. Eighty-four percent answered that they would “probably” or “definitely” choose to have the stoma again. When they were asked the question “compared to when you were continent, how much change has having a stoma made to your overall quality of life?” on the scale of -5 (much worse) to +5 (much better), the median rating was +4.5 (range -5 to +5). The authors concluded that health care professionals should discuss the option of a stoma with incontinent patients because of the overwhelming positive outcomes.

An end sigmoid colostomy without proctectomy is usually recommended as a procedure of choice for patients who elect colostomy for the management of their refractory faecal incontinence. Creating such a colostomy, however, does not always solve all the problems of patients with faecal incontinence. Catena et al [339] reported a retrospective chart review of 44 patients (35 women) who underwent elective end sigmoid colostomy for faecal incontinence of various etiologies. After colostomy formation 19 patients (43%) were asymptomatic, while the other 25 experienced such problems with their rectal stump as diversion colitis and mucus leakage. Of the 25 patients, 12 (27% of the total) underwent a secondary proctectomy due to the rectal stump problems sufficient to warrant the operation. Histological examination revealed diversion colitis in 6 patients. The factor associated with proctectomy was age, with younger patients being more likely to require rectal excision. The authors concluded that data are insufficient to recommend primary proctectomy in patients with severe faecal incontinence warranting permanent end sigmoid colostomy.

11. PUBORECTAL SLING

The puborectal sling operation was first reported by O’Rourke in 1974 [340]. In this procedure, an artificial sling is routed behind the anorectal junction and its two ends are fixed to the pubic bone, pulling the anorectal junction up forward with some tension. Similar to the postanal repair, the rationale of this operation is the restoration of the anorectal angle normally maintained by puborectal muscle. For the treatment of female urinary stress incontinence, a similar procedure, called tension free vaginal tape (TVT), has been performed with a reasonable success rate of 81-93% [341].

No systematic reviews, non-randomised cohort studies or case control studies have been reported regarding puborectal sling operation for faecal incontinence, whilst one prospective comparative study (level 2) [342], one case series of good quality (level 3) [343] and three case series of low quality (level 4) [340,344,345] were identified. Results of the puborectal sling operation are shown in Table 8 [340,342-345].

O’Rourke [340] first reported the sling operation using Dacron mesh for the treatment of 3 patients with full rectal prolapse as well as 4 with mucosal partial rectal prolapse and faecal incontinence. Two patients developed a sinus or sinus discharge at the site of the insertion of the sling, and the sling was removed in one. Out of the 4 patients with faecal incontinence and partial prolapse, 3 were reported to have “benefited considerably” from the procedure although a formal evaluation of the faecal incontinence was not performed and the follow-up period was not documented.

PCS: prospective comparative study; ns: not stated
O’Rourke and Egerton [344] reviewed 24 patients in whom the sling operation was performed using a strip of rolled mersilene mesh. This procedure, however, was performed mainly for the treatment of rectal prolapse, while it was conducted because of faecal incontinence alone only in two out of the 24 patients, and the outcomes regarding the continence were not formally evaluated.

Shafik [345] reported another sling operation called puborectoplasty utilizing a Teflon sling for faecal incontinence. Out of the 31 patients who had been incontinent to solid stool and underwent this procedure, “good results” were achieved in 26 patients (84%) after a follow-up period of between 2 and 4 years: 20 became continent to solid and liquid stool as well as flatus; 6 to solid and liquid stool but not to flatus; 4 to solid stool only; and only one remained incontinent to solid stool. Postoperative complications included a wound infection only in one patient, which responded to antibiotics without requiring the sling removal.

Shafik and Shafik [342] conducted a prospective study comparing two fascia lata slings (double loop) in 22 patients and one fascia lata sling (single loop) in 22 for the treatment of faecal incontinence. After 12 months follow-up, “good results” were achieved in 14 (63%) and 8 (36%) by the double loop and the single loop, respectively, and its difference was statistically significant. Postoperative complications included superficial infection in two patients of single loop, which responded to antibiotics without requiring the sling removal.

Yamana et al [343] performed the perineal puborectalis sling operation in 8 patients with passive faecal incontinence using polyester mesh sling. A wound infection developed in one patient which responded to antibiotics, while a rectal ulcer developed in one requiring the sling removal. In the 6 month evaluation of the remaining 7 patients, all reported some extent of improvement of their faecal incontinence. Both the Faecal Incontinence Severity Index and the Cleveland Clinic Faecal Incontinence Score significantly improved from 27 to 9 and from 13 to 5, respectively. Moreover, all parameters in Faecal Incontinence Quality of Life Scale significantly improved: lifestyle from 2.1 to 3.6; coping/behavior from 1.5 to 3.4; depression/self perception from 2.3 to 3.7; and embarrassment from 2 to 3.6.

III. SURGERY FOR PAEDIATRIC FAECCAL INCONTINENCE

Faecal incontinence is common in children who have anorectal malformations, spinal problems and surgery for Hirschsprung’s disease. Despite advances in technique for anatomic corrective surgeries, many patients continue to suffer from persistent incontinence. This guideline mainly focuses on anorectal malformations and corrective surgeries along with their results and subsequent management in case of persistent incontinence. Other surgical interventions used less frequently were also reviewed.

1. ANORECTAL MALFORMATIONS

Anorectal malformations occur once in every 3000-5000 live births. Although the severity of malformation varies, it is invariably associated with defaecatory problems including incontinence. The surgical advances have been most prominent in last few decades, particularly with the advent of posterior sagittal approach. [LEVEL OF EVIDENCE: 3] This technique has enabled surgeons to visualise the anatomy under direct vision and perform corrective surgeries more accurately [346,347]. In brief, a mid-sagittal incision is performed and the sphincter mechanism is completely divided in the midline. The rectum is separated from the genitourinary tract and moved down to the perineum. The most challenging aspect of the operation is the separation of the rectum from the vaginal or urinary tract, which effectively requires creating two walls out of one septum without damaging each structure. This approach can also used for reoperation in anorectal malformations [348] and can also be applied for reconstruction of severe perineal trauma [349].

For both male and female babies, urethral-perineal fistula is the simplest fistula to correct. These require the so-called ‘minimal posterior sagittal approach’ which enlarges the stenotic orifice and relocates the rectal orifice posteriorly within the limits of the sphincter complex. For males with recto-urethral bulb fistula or recto-urethral-prostatic fistula and females with recto-vestibular fistula or cloaca with short (less than 3cm) common channel, posterior sagittal approach is the main operation performed. For males with higher fistulas such as recto-bladder neck fistula and other complex and unusual defects and females with cloaca with long (greater than 3cm) common channel and complex defects, the posterior sagittal approach needs to be coupled with abdominal access which can be either laparoscopy or laparotomy [350]. There has been no robust evidence to suggest superiority of laparoscopy in terms of outcome [351,352] though better visualisation and assessment of fistula have been advocated as an advantage of this approach [353,354].

Cloacal repair is the most challenging amongst the corrective surgeries for anorectal malformations. A recent operative advance in cloacal repair is a maneuver called total urogenital mobilization whereby the rectum is separated from the vagina and both vagina and urethra are then mobilized together. The advantage of this technique is to avoid separating rectum, vagina and urethra completely which is not feasible all the time and risks damaging these structures during the procedure. This technique avoids the risk of urethrovaginal fistula and vaginal stricture previously reported as complications in 10% of the cloacal repair and also gives enough mobilization to allow more than 50% of all cloacal repairs without opening the abdomen [355,356].

Functional outcomes depend on the severity of the malformations. A review of more than 1000 anorec-
tal malformation cases showed 100% of babies who had perineal fistula repair achieved continence. Approximately 55% of patients who had been operated for recto-vestibular fistula had bowel control. Any malformations more complicated resulted in only up to 30% achieving continence. All patients who had recto-bladder neck fistula repair were incontinent. In cloacal repair the length of the common channel, shorter or longer than 3cm, appears to be the distinct prognostic factor in terms of functional outcome [357]. Overall it is estimated that nearly 40% will have voluntary bowel movement and no soiling but some of them may still lose bowel control in case of severe diarrhoea and 25% of all repairs will result in total incontinence [358].

For the group of patients with persistent incontinence following the corrective surgery, the next aim will be to keep the colon clean to avoid unpleasant accidents and improve quality of their life. A good option is implementation of a bowel management programme whereby the patient and family are instructed in the use of daily enema, manipulation of diet and medication to remain clean [359]. This is also a good treatment for constipation, which is the most common difficulty after corrective surgery [360].

Although most young children accept their parents administering enemas, when they get older they want privacy and rectal enemas on daily basis becomes an unpleasant routine. In such cases, continent appendicostomy is a feasible option, whereby a conduit for the administration of an antegrade continence enema (ACE) is created. First described by Malone [361] it has become an important option in paediatric surgery for functional bowel disorder.

According to the initial description by Malone, appendicostomy was created by dividing the appendix at its base and reimplanting by a reverse manner into the cecum, which was then exteriorized through the right lower quadrant. Malone later revised it and the reimplantation of appendix is no longer considered necessary [362]. Levitt et al [363] introduced utilizing the appendix in situ and added caecal plication to prevent reflux of stool and exteriorizing through umbilicus fold rendering it less noticeable. This appears to yield good long-term results [364] though a recent study has shown that caecal fixation and wrap may be unnecessary for appendicostomy [365]. The benefit of a variation called orthotopic continent appendicostical stoma is not clear [366]. However, construction of appendicostomy with burial of the appendicostical tip appears to help avoid problems of exposed mucosa such as bleeding and mucus discharge. From this perspective, a few techniques have been suggested such as V-Y flap [362] and Y-appendicoplasty [367]. For patients without an appendix, a neoappendix could be formed from ileum or cecum [368-370]. Laparoscopic antegrade continence enema procedure has been reported to yield as good result as open procedure [371-374].

This procedure is not a cure to the problem but a more acceptable method for many children to engage in a bowel management programme without the need for rectal enemas. Success rate is variable between 61-96% [362,368,375-379] with older children benefiting more [380]. Satisfaction with the treatment is reported to be as high as 93% [363,381,382]. [LEVEL OF EVIDENCE 3]

As with any operation, there are known complications associated with antegrade continence enema. Stomal stenosis is the most common complication and the use of ACE stopper will prevent it in the short-term [383]. Leakage of stool from appendicostomy is another common complication. These complications cause 10-33% of patients to undergo revision of the appendicostomy [358,384]. Stoma prolapse, pressure sore, wound infection, anastomotic leak, stomal granulation, caecal-flap necrosis and caecal volvulus are less common complications reported after ACE [385-387].

2. OTHER CAUSES OF Faecal INCONTINENCE

Some children with Hirschsprung’s disease following pull-through operations and severe constipation may also present with symptoms of incontinence [388]. Patients with spinal problems often lack bowel control due to paralysis and absence of sensation; 50% of the children with spina bifida suffer from incontinence [389]. The majority of these cases can be successfully managed with above mentioned bowel management programme including appendicostomy although wheelchair-bound children with spinal neuropathy is a predictive factor for poorer outcome with ACE [377].

The mechanism of incontinence after an operation for Hirschsprung’s disease, anorectal malformations and severe constipation is thought to be due to impaired bowel motility. Impaired bowel motility causes faecal impaction, which can lead to development of a dilated segment of bowel called ‘megarectosigmoid’. This can subsequently lead to overflow incontinence due to incomplete evacuation [390]. Once the rectum is dilated it is refractory to conservative management, and resection of megarectum or megasigmoid has been associated with improvement [390-392]. A small minority of patients (5%) who fail these options may need colostomy [393].

3. OTHER OPERATIONS

Sphincter augmentation by either palmaris longus transposition, gluteus muscle transposition, graciloplasty or levatorplasty has been used for children with faecal incontinence albeit in small series [394-403]. Dynamic graciloplasty has also been piloted and 50% of patients achieved complete continence although the study only contained four patients [404]. Sacral nerve stimulation has been used in a small open label study with nearly 80% of positive response [405]. [LEVEL OF EVIDENCE: 4]
Data regarding the surgical treatment of faecal incontinence are generally weak. Randomised, controlled studies are few, and practical considerations make the likelihood of such studies improbable. The quality of data reported in older studies was often poor. Problems included heterogeneous patient populations; variable definitions of “continence,” “incontinence,” “success,” and “failure”; non-standardized and non-validated continence scales; underreporting of validated symptom-specific quality of life measures; variable patient follow up and lack of independent assessment of continence outcomes. However, there has been a notable improvement in the quality of studies reported in the past decade.

The spectrum of surgery for faecal incontinence is broad and expanding. Interventions range from simple outpatient procedures to major reconstructive surgery. As the reported outcomes of these various operations are often similar, a sound general principle is to proceed first with the simplest and least invasive procedure. Major operations associated with more profound morbidity should be restricted to patients who have failed simpler measures.

### 1. SPHINCTER REPAIR (GRADE B)
Sphincter repair is indicated for patients with acute traumatic sphincter disruption, such as following obstetrical injury, but many patients experience persisting symptoms.

### 2. SPHINCTEROPLASTY (GRADE B)
Overlapping sphincteroplasty can be offered to patients with significant faecal incontinence and a documented sphincter defect. Most patients improve after sphincteroplasty, but outcomes deteriorate over time.

### 3. POST-ANAL REPAIR (GRADE C)
Post-anal repair can be performed with modest success in carefully selected patients. However, this procedure is now rarely performed due to the advent of newer treatments.

### 4. NON-STIMULATED MUSCLE TRANSPOSITION (GRADE C)
Non-stimulated muscle transposition repair can be performed with modest success in carefully selected patients, notably in children. However, this procedure is now rarely performed due to the advent of newer treatments.

### 5. STIMULATED MUSCLE TRANSPOSITION (GRADE C)
Stimulated muscle transposition has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in selected patients with significant perineal tissue loss or in those who have failed other treatments.

### 6. ARTIFICIAL ANAL SPHINCTER (GRADE B)
Artificial anal sphincter has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in carefully selected patients, particularly those who have failed other treatments.

### 7. SACRAL NERVE STIMULATION (GRADE B)
SNS is an effective therapy for most patients with clinically significant incontinence who fail conservative management. The technique is safe, minimally invasive, and has the unique advantage of allowing a therapeutic trial prior to permanent stimulator implantation.

### 8. POSTERIOR TIBIAL NERVE STIMULATION (GRADE D)
Posterior tibial nerve stimulation is an investigational technique with few available data regarding efficacy and outcome.

### 9. INJECTABLE BIOMATERIALS (GRADE C)
Most series of injectable biomaterials report reasonable success rates. However, the optimal injectable bulking agent and the technique for its insertion have not been established.

### 10. COLOSTOMY (GRADE C)
Formation of an end colostomy is a reasonable treatment option for patients with refractory faecal incontinence who are able to accept the associated alteration in body image. Colostomy provides restoration of a more normal lifestyle and improves quality of life. It also could be the most cost-effective in the short to medium term, compared to more complicated surgical procedures such as artificial anal sphincter and dynamic graciloplasty. Colostomy should not be regarded as a treatment failure but rather a reasonable treatment option for patients whose lives are restricted by faecal incontinence that is not amenable to other therapies. An end sigmoid colostomy alone, without proctectomy, is recommended. The minority of patients who develop significant symptoms from their retained rectal stump may eventually require proctectomy as a secondary procedure.

### 11. PUBORECTAL SLING (GRADE D)
The puborectal sling operation seems promising because it is a simple procedure and yielded reasonably good results so far with low complication rate, although the number of patients was small with a short follow-up period. More prospective studies of larger number of patients with a longer follow-up period are warranted. They are expected to closely evaluate complications such as sling infection, erosion and rectal ulcer that might require the removal of the sling.

### 12. SURGERY FOR PAEDIATRIC FAECAL INCONTINENCE (GRADE C)
Anorectal malformations should undergo surgical repair, most commonly by a posterior sagittal repair.
An antegrade continence enema procedure can be considered for children with persistent or refractory faecal incontinence.

V. RESEARCH PRIORITIES

Despite steady progress in the clinical management of faecal incontinence, including the development of novel treatment methods since the last International Consultation, there remain numerous areas where additional research is needed.

1. BASIC SCIENCE AND PATHOPHYSIOLOGY

Several animal models of faecal incontinence have now been developed that are capable of providing interesting insights into the physiology of normal continence and the pathophysiology of faecal incontinence [223,406-412]. Further use of these and other animal models can be expected to yield valuable information about pathophysiology and treatment, and is strongly encouraged.

2. CELLULAR THERAPY

There is a body of basic research on the use of stem or precursor cells of different tissue of origin (muscle, fat, bone marrow) in supplementation of urinary continence [413]. Recently, Frudinger and colleagues [414] have reported successful treatment of faecal incontinence using autologous myoblasts cultured from a pectoralis muscle biopsy, harvested, and injected into the external anal sphincter defect using ultrasound guidance. Further research relating to the tissue of origin, harvesting and processing of graft cells, the technique of implantation and clinical outcomes is urgently needed.

3. OUTCOME MEASURES

While there is general agreement that patient-based outcome measures are most appropriate for studies of faecal incontinence, standardization of the optimal instrument or combination of instruments remains a central challenge in clinical incontinence research. These instruments should be selected based upon eight general criteria and applied to the specific field of faecal incontinence: appropriateness, reliability, validity, responsiveness, precision, interpretability, acceptability and feasibility [415].

It is unknown if the main outcome measure following incontinence treatment ought to be incontinence severity, incontinence-related quality of life, or a combination of these factors. The FIQL is a well-validated quality outcome measure but it yields separate scores on 4 individual scales. It is desirable that a single score outcome be developed. Furthermore, quantitative changes in FIQL have not been anchored to the corresponding impact on patient quality of life and thus remain rather abstract. Additional studies, for example using time trade-off techniques, are needed to understand the clinical meaning of a given change in FIQL.

The FSI severity score is not as broadly used as the FIQL, and it appears to require additional validation work. Continence diaries have been considered to be the gold standard measurement, but these are highly influenced by the patient’s willingness to stray from a nearby toilet. Standard definitions are needed for such terms as seepage and leakage, and a standardized measure of faecal urgency should be developed. Additional validation work is needed to assess the potential effect of recall bias in recall-based scoring systems such as the Wexner and Vaizey scales. The International Consultation on Incontinence Bowel module (ICIQ-B) has recently been developed, but additional experience with this instrument is required [416].

4. CLINICAL TRIALS

There remains a paucity of randomized, controlled trials in the field of faecal incontinence. Proof of efficacy of novel therapies, numerous in the field of faecal incontinence therapy, is best demonstrated using a randomized trial design, and these types of studies are strongly encouraged.

Long-term outcomes following sphincteroplasty have demonstrated a substantial fall-off in function over many years. Similar long-term data are not available for other therapies, including especially the more recently developed ones such as SNS and injection therapies. Prospective trials funded for long-term follow-up and creation of treatment specific registries are needed.

Much recent research has been industry funded and designed to assess the efficacy of a specific novel therapy. There have been very few studies prospectively comparing different treatments, and randomized comparative treatment trials are urgently needed. The Committee has in particular noted the need for a randomized trial of SNS versus sphincteroplasty for individuals with faecal incontinence associated with a sphincter injury.

5. DECISION AND COST-BENEFIT ANALYSIS

Given the broad range of potential treatments for faecal incontinence and the usual costly proposed devices, additional research is needed in the areas of decision analysis and cost-benefit analysis. In severe faecal incontinence a comparison against stoma care cost would be appropriate.

6. TREATMENT DELIVERY

While there is ongoing research on the epidemiology of faecal incontinence, little is known about the true number of patients who have had treatment, who have access to treatment, or who have adequate knowledge to seek treatment. Research should be directed to identify current treatment needs, improve the accessibility of treatment, and improve the transmission and distribution of information about acceptable treatment options.

GENERAL INTRODUCTION

In the developing world fistula are often a consequence of poor peri-natal care. The epidemiology, aetiology, diagnosis, treatment and prevention have been described in detail during the recent International Consultations on Incontinence.[1, 2]

In contrast to the field of obstetrical fistula where the numbers of patients are high, the prevalence of non-obstetrical fistula seems to be much lower. The published series deal with small numbers, are usually retrospective and have a low level of evidence. The published obstetrical series show impressive numbers and demonstrate the level of skill that many of the fistula surgeons have obtained while working in difficult and isolated situations.

In this consultation the main focus has been put on iatrogenic fistula in the developed world. An entirely new chapter was compiled on this subject.

Despite the fact that the main focus was to write a chapter on iatrogenic fistula, in this edition the scientific summary of the International Consultation on Vesicovaginal fistula in the developing world, which was held in Marrakech, Morocco in 2010 was added to the text.

Both committees are convinced that obstetric fistula surgeons in the developing world and reconstructive pelvic surgeons in the developed countries can learn a lot from each other. Combining the obstetrical and iatrogenic fistula into one chapter will facilitate interaction and exchange of knowledge and ideas in this difficult field of fistula repair.

A. Obstetrical fistula

I. INTRODUCTION

The First ICUD-SIU Consultation on Vesico-Vaginal Fistula was held at the SIU meeting in Marrakech, Morocco, October 13th – 16th 2010. The recommendations are evidence-based, following a thorough review of the available literature and the opinion of recognised experts serving on the six committees. The individual committee reports were developed and peer-reviewed by open presentation and comment. Review of the literature showed no Level 1 evidence in that there were no randomised controlled trials. All evidence was confined to case series and observational data: Level 3 and 4 evidence. Hence, all recommendations were Grade B and C.

The Scientific Committee includes the chairmen of the six committees, who refined the final recommendations. These recommendations published in 2011, will be periodically re-evaluated in the light of clinical experience, technological progress and research. These recommendations are taken from the full versions of the six Consultation chapters, from Epidemiology through to Social Reintegration. These chapters provide the full documentation of the existing scientific literature on the six topic areas.

II. WOMEN, FISTULA SURGEONS, NGOS AND GOVERNMENTS

The effect on a woman, in the developing world, of having a VVF resulting from obstructed labour, is disastrous from her point of view, the family perspective and for her society. It is estimated that there are two million women, in developing countries, mainly in sub-Saharan Africa, the Indian sub-continent and South- East Asia, who have either undetected or untreated VVF. New fistulas are probably occurring at the rate of 82,000 new cases per year, yet only 10,000 operations for fistula closure are being done annually. Hence, this leaves a huge unmet need.

VVF, in itself, is bad enough, but it is also inextricably linked with high maternal mortality rate and high infant death rate. Hence the solution to fistula is similar to the solutions that will drive down the maternal mortality rate and the infant death rate. The solutions are not only medical, but also social and political.

At present, women in developing countries are often dependent on donations that reach their country
through non-governmental organisations (NGOs) and charities. The relationship between the NGOs and the fistula surgeons are critical. The fistula surgeons are the experts and those to whom fistula women turn for help. Hence, it is vital that the NGOs allow themselves to be guided by the fistula surgeons as to the priorities within their sphere of work. The vital role of the NGOs is to provide financial and logistical support. Support is also essential to allow the fistula surgeons to write up their work. This is often a considerable problem, as their commitment to the women means that their academic time is restricted. Nevertheless, the data the fistula surgeons generate is their intellectual property, and it is vital that they retain primary authorship of all published material.

There are an enormous number of committed and dedicated individuals from both within the developing countries and from developed countries who have committed themselves to the cause of helping women with this dreadful condition. However, the long-term solution must see the responsibilities for women’s and children’s health passing to the governments of the individual countries. Nevertheless, in the meantime, those many dedicated individuals will continue to strive to help as many women as possible return to a life in their own community.

1. EPIDEMIOLOGY OF VVF

Epidemiological studies on obstetric fistula are inadequate.

- They are mainly institutionally-based, retrospective cases series, often written from the perspective of a single fistula surgeon
- The geographical coverage of epidemiological reports is uneven
- However, better and more relevant information is emerging.

The incidence of fistula is expressed per 1,000 deliveries and would appear to be between 0.1% rising to 1.5 per 1,000 pregnancies in rural areas.

The major risk factors appear to be age at first marriage, short stature, pregnancy with a male child rather than a female child, failure to attend antenatal care, low socio-economic status, low social class, lack of employment and illiteracy.

The consequences of obstetric fistula include divorce (16-92%), social isolation, worsening poverty, malnutrition, sexual dysfunction and mental illness (including anxiety/depression), insomnia, general ill health and thoughts of worthlessness and suicide.

There are few detailed reports documenting these women’s obstructed labours. The time of onset of labour is rarely recorded and reports from delivery locations may disregard the fact that the woman has laboured at home for days prior to attending the delivery location. The reason for the woman not receiving help rarely differentiates between the absence of health-seeking behaviour and the lack of services. The only observational study showed no substantial difference between VVF patients and women who delivered without fistula, both in terms of their use of orthodox health care services and more traditional forms of support before childbirth.

Recommendations

1. Community-based epidemiological studies using standardised and validated collection tools with acceptable sensitivity and specificity are highly recommended.
2. A validated standardised collection tool should be developed and used in national surveys to facilitate the collection and comparison of data when assessing the regional, continental and global magnitude of VVF and the distribution of fistula world-wide.
3. Prospective longitudinal community-based studies are needed to estimate the incidence of obstetric fistula.
4. Observational studies are needed, utilising advanced epidemiological analyses for:
   - Risk factors (multivariate analysis controlling potential biases)
   - Impacts and consequences of VVF
   - Determining health-seeking behaviour
5. Research that identifies the different profiles of women who manage to overcome the obstacles and successfully access health care, compared to those who do not, is recommended.
6. The contribution of other factors, such as ethnic background and malnutrition, needs to be researched and understood.
7. It is recommended that there is long-term follow up of patients following fistula repair to understand their ongoing quality of life and any long-term sequelae and their ongoing needs.

2. PREVENTION OF VVF

VVF is a characteristic of abject poverty, a clear marker of failure of political, social and health systems to protect and promote women’s health and their rights. Prevention of VVF is ultimately linked to prevention of maternal and infant mortality and is a requirement of MDG5 of 2000.

Prevention, from the medical and public health point of view, mitigates the effect of VVF in the overall burden of pain and suffering the condition imposes, not just on the patient herself, but her family and the entire community. History has shown that improvements in the functioning of local health services dramatically reduce the incidence of maternal death, infant mortality and vesico-vaginal fistula. The following areas of health system improvement and capacity building need to be considered:
• Enhancing professionalism among health care workers to make the system work better.

• Massive infrastructural developments through strengthening existing government health facilities, and advocacy, to maximise the benefits that a political environment sensitive to the needs of these women, is required.

• Ensuring that facilities are properly equipped, monitored and supervised with an emphasis on quality as well as quantity of service provision.

Systematic improvements are required to address the social and economic inequalities, such as the low status of women, lack of education for girls, early marriages and pregnancy, malnutrition, poverty, inadequate health and transportation infrastructure, and harmful traditional practices, such as female genital mutilation.

Health and maternal care are inextricably linked to the availability of financial resources, to the individual in the community and within the country as a whole: as economic conditions improve, the risk of VVF diminishes.

Another key stratagem, in preventing VVF, is the empowerment of women and their spouses, to develop birth preparedness plans, within the context of family planning. Family planning in wealthy regions is available according to the choice of the individual, whilst in other developing areas, such as China, it is actively encouraged, or even enforced. Other components of public health care, such as addressing the special nutritional needs of girl children and the requirements of improving their physical health, in order to improve their physical growth and maturity, are also very important.

Education of the community is vital so that young women understand what VVF is, are made aware of the need to engage in the ante-natal care process, and plan for their delivery, including making transportation plans for use when they go into labour.

Prevention strategies can be considered in public health terms as primary, secondary or tertiary:

• Primary prevention addresses many of the indirect causes which are essential the root causes of fistula. It attempts to reduce or eliminate the risk of the disease and by, amongst other actions, reducing the high levels of illiteracy among women. It also seeks to widen the cadre of care workers by involving, for instance, traditional birth attendants (TBA)

• Secondary prevention attempts to limit the severity of the disease by detecting it at its earliest stages.

• Tertiary prevention aims to mitigate the effects of the existing disease, for example by effective treatment.

The work of Haddon and Maine in the Haddon Matrix and Maine’s Three Delays provide documented approaches to the problems.

Maine’s Three Delays:

• The first delay: the decision to seek care is influenced by the socio-economic and cultural factors in that woman’s environment. These can include the need to obtain permission from a husband or male family member to seek care, or the community perception that only weak women need assistance with delivery and that strong women can manage delivery on their own.

• The second delay is delayed arrival at the health facility. Once the first delay has occurred, the second delay becomes more serious. Road conditions, transportation and communication deficiencies may conspire to delay the woman’s arrival at a hospital or birthing centre.

• The third delay is the delayed provision of adequate care at the facility, and may be due to lack of staff, supplies, or electricity. If the lights are out and there is no back-up generator or fuel, a caesarean section cannot be done. If there is no way to reach a doctor or medical officer because there are no telephones, or if equipment hasn’t been sterilised, then timely surgery cannot be performed.

These three stages of delay disproportionately affect the world’s poor and, in particular, those women living in rural areas.

Recommendations

1. Strong community support is required to develop solidarity groups which include village volunteers working with trained, skilled and traditional birth attendants, depending on the local customs and resources.

2. The components of the three delays need to be identified and targeted in order to minimise the effect of obstructed labour. By this process there will be other benefits for maternal and child health.

3. There should be provision of adequate health facilities and birthing centres to which women move either as soon as they go into labour, or if labour is delayed. Such facilities must provide emergency obstetric care, including caesarean section.

4. National policies for maternity care should be developed for all countries whether or not VVF is a common complication of childbirth.

5. Data collection by local, national and regional bodies should help to define the incidence of birth complications, and factors leading to the “3 Delays”.

6. The components of the “Three Delays” need to be identified and targeted for each community where there is a high prevalence of complications of childbirth.

7. Girls, women and communities should be educated about normal and abnormal labour, and facilities such as waiting houses should be available for pregnant women at risk for complicated deliveries.

8. Solidarity groups including local volunteers and skilled and trained traditional birth attendants should be developed for maternal care.

9. Birthing centres with the capability for caesarean section should be accessible and sufficiently affordable for women to use.

10. Funding should be made available to retain adequate trained staff for waiting houses and birthing centres.

11. Partographs should be employed to track the progress of delivery in order to identify problems and for data collection.

3. UNMET NEEDS IN VVF

There is unmet need at every level of the healthcare service in those developing countries where VVF is a significant problem. These needs span from family planning through obstetric care, the availability of emergency obstetric services and the provision for dealing with maternal and infant post-partum problems.

Unmet need has not clearly been defined, although the increasing gulf between the prevalence and incidence of fistula and its prevention and treatment is exceedingly worrying.

In low resource countries there is a need for stable and enduring collaboration and partnerships between governments and non-governmental organisations (NGOs), such as, UNFPA, Engenderhealth, WHO and MSF. These partnerships will go some way to identifying unmet need and ensuring that unmet need is reduced.

One of the most important aspects of the unmet needs in fistula surgery training has been the lack of standardization. In order that the recommendations below can even be partially met, there has to be a global strategy in developing training, education, and ancillary support for the surgeons and their associated teams. This will be partially met by the creation of the global competency-based fistula surgical training manual, created by the International Federation for Gynaecology and Obstetrics (FIGO) with International Society of Fistula Surgeons (ISOFS). The purpose of this manual is to enable health care providers to acquire the required knowledge, skill and professionalism to prevent fistula and provide holistic care to fistula patients that includes medical, psychosocial and surgical care. A multi-disciplinary team-based approach is encouraged in the training of each doctor and his/her team nurses, physiotherapists and other health professionals. The course is structured at three levels: standard, advanced and expert levels of fistula training.

The manual is made up of several components:

- Curriculum Modules

Each module has an outline of the course content, that the trainee is expected to be aware of. It needs to be used in conjunction with recommended references, and in some cases with specific Performance Based Assessments (PBAs). There are 7 modules that need to be undertaken.

- Logbooks of Competency

These are records of the work carried out by each trainee. Each must be signed off by each trainer, who will determine if the trainee has observed a procedure, has assisted with a procedure or is able to work independently. The trainer will determine if the trainee needs further training in a particular area.

- Performance Based Assessment (PBA)

Each aspect of surgical training will be assessed separately and specifically. The trainees will complete each PBA to a standard, advanced or expert level and ideally need the signature of two or more trainers, from two or more training centres. It is expected that each trainee will undergo a prolonged period of fistula training at one or more centres. There are 15 PBA to be completed before a fistula surgeon would be deemed to be an expert, and will often require the full 24 months of training. However, this is a competency-based training manual and each trainee will require different lengths of time to achieve each level of expertise.

This structured approach of the competency-based manual will attempt to standardise and support surgical training in fistula repair. In the process of achieving this aim, it is envisaged that there will eventually
be an increase in the number of training centres accredited for training and eventually surgeons trained.

**Recommendations**

1. Unmet need has to be defined in each country, and within each country, in each geographical region.

2. The unmet need in ante-natal services needs to be rectified urgently in order to minimise the number of new fistulae occurring.

3. The need for education and training has to be addressed for birth attendants, community nursing and fistula surgeons.

4. Training centres for fistula surgeons need to be identified and new ones established, according to population matrix. Training should be systematic and structured, using assessment tools such as those developed by FIGO with ISFOS.

5. Audit and research must be developed in order to ensure that quality and advances in treatment methods are ensured.

6. National strategies need to be developed to empower individual nations to take charge of the women’s and children’s services in their country.

**4. MANAGEMENT OF NEW AND ESTABLISHED VVFS**

Management of VVF depends on whether the fistula is diagnosed within two or three months of its occurrence or whether the woman presents late with an established fistula. There is evidence that early catheter care will result in the cure of a significant minority of VVFs. Algorithm 1 (Figure 1) describes the management of women who have both early fistulas, defined as those that have occurred within 75 days of presentation, and established fistulas, that is those that are discovered more than 75 days after obstructed labour.

**5. CLASSIFICATION OF VVF**

The Consultation believes that fistula audit research is considerably hampered by the plethora of VVF classification systems, of which we believe there are 32. The Consultation feels that the fistula system that is able to relate its classification to outcome is the classification that should be used in the next few years. The Waaldijk Classification is the only one that has been used to document sufficient numbers of patients from diagnosis to follow-up (Figure 2). Figure 2 shows the Waaldijk Classification which involves precise measurements of the distances between the external urinary meatus and the distal edge of the fistula, together with the widest diameter of the fistula. Fistulas are classified into types 1, 2 and 3. Type 3 fistulas are those fistulas other than vesico-vaginal fistulas and include recto-vaginal fistulas and uretero-vaginal fistulas. The Waaldijk Classification of Types 1 and 2 is illustrated in Figure 3 and described below.

If catheter drainage fails, then fistula repair will be necessary. There are certain principles behind fistula repair:

- Necrotic tissue must be removed prior to fistula repair.
- Fistula repair must only be undertaken by a properly trained surgeon.
- Adequate post-operative care is essential.
- Proper follow-up should be arranged.

![Figure 1. Algorithm to describe the management of fistula detected early (less than 75 days after obstructed labour) or later](image-url)
Table 2 indicates the type of fistula closure that should be used depending on the type of fistula.

Bladder / urethra direction of closure Pubocervical fascia / urethral support Ant vagina wall closure

**Recommendations**

1. The comprehensive use of an indwelling catheter with free urinary drainage should be instituted for all patients who have undergone either an emergency caesarean section or a traumatic vaginal delivery after obstructed labour.

2. When fistula surgery is necessary the woman must be assured of the surgeon’s competence to carry out her procedure.

3. It is recommended that further research is needed into the classification of fistula, not only to further validate the Waaldijk Classification, but also if other classifications are proposed for development.

4. There is a need to compare different surgical approaches to fistula within the context of randomized controlled trials, using the Waaldijk Classification to precisely describe the fistulas.

5. Long-term follow up of fistula patients is recommended in order to study the outcome of both conservative and surgical management and, in particular, to determine its effect on quality of life.

*Figure 2: The Waaldijk Classification for Fistula*  
*Figure 3: The Waaldijk Classification for Vesico-Vaginal Fistulas*
6. When reporting the outcome after fistula repair, authors should make a clear distinction between fistula closure rates and post-operative incontinence rates, specifying the time at which follow-up was carried out.

6. MANAGEMENT OF THE COMPLICATIONS OF VVF

The complications of Vesico-vaginal fistula are many but include:

- Persistence or recurrence of urinary incontinence
- Persistence of lower urinary tract symptoms or occurrence of new lower urinary tract symptoms, including overactive bladder
- Urinary tract infections
- Upper urinary tract symptoms, including loin pain
- Dyspareunia and sexual dysfunction
- Infertility
- Neurological symptoms
- Psychological problems and mental illness

Recommendations

1. A care programme for failed repairs with persisting incontinence after a successful repair, needs to be in place.

2. It is recommended that surgical treatment of post-operative stress incontinence should only be considered six months after fistula repair.

3. Autologous material should be used when a graft or sling is required and there is no place for synthetic sling material.

4. In order to prevent new fistulas in women who become pregnant after a fistula repair, waiting homes should be provided to ensure that each woman is able to have an elective caesarean section when she goes into labour.

5. In recurrent identifiable fistula make sure of the size and number and this kind of fistula is better repaired by a well experienced fistula surgeon. It is important to use tissue interposition like a Martius flap or fibrin glue.

6. With urinary tract infections or abscess formation, antibiotics must be given before and after the repair, according to culture and sensitivities.

7. Patients complaining of persistent leakage due to urgency incontinence may try antimuscarinics, botulinum toxin injection or even augmentation cystoplasty in small contracted or poorly compliant bladders.

8. Those with a shortened or disrupted urethra, before or after repair, must be treated with urethral reconstruction, autologous slings or injection of bulking agents, delivered trans or peri–urethrally.

9. In cases with unilateral or bilateral ureteric ligation or injury, the early diagnosis is life saving. Patients must be promptly treated by endoscopic ureteral stenting, PCN or ureteric reimplantation.

10. Patients complaining of contracted vagina and dysparunnea with sexual dysfunction may use local estrogen, vaginal dilatation or may require the surgical creation of vaginal flaps to augment the vagina.

11. Patients who develop dropped foot may respond to physiotherapy or require tibialis tendon transfer. Women with neurogenic OAB may benefit from detrusor muscle botulinum injections if antimuscarinic drugs fail.

12. Psychological trauma, social isolation and depression is best treated by counselling and psychological rehabilitation.

7. SOCIAL RE-INTEGRATION OF TREATED WOMEN

Social integration is defined as appropriate interventions that help women with obstetric fistula overcome physical, psychological and socio-economic challenges, freely identified by themselves, in order to enhance their return to the communities and social networks of their choosing, such that the risk of them presenting with another fistula is minimized.

The aim of social re-integration is to break the fistula recurrence/occurrence cycle in which the woman’s physical state is inextricably connected to her mental state and her socio-economic situation.

Social re-integration should be seen as happening from the time the leaking of urine becomes manifest, and every subsequent intervention should have the re-integration of the woman, back into her community, as the primary goal. So, social re-integration is the responsibility of everyone who cares for the woman.

Social re-integration can be usefully looked at within a matrix, as shown in Table 3 where the three elements of physical, psychological and socio-economic status are looked at in terms of the facility for treating the patient within her community and the political environment.

**Recommendations**

1. Social re-integration is important for all women with obstetric fistula. It is the process by which women are helped to overcome physical, psychological and socioeconomic challenges, freely identified by themselves, in order to enhance their level of social functioning in communities and social networks of their choosing, so that the risk of will presenting with another fistula is minimised.

2. Social re-integration should be used for all women. However this series of interventions can be performed by any trained care worker, providing it focuses on making the woman part of her social fabric again, and commences from the time leaking of urine becomes manifest.

3. Social re-integration should be designed to break the fistula recurrence cycle in which the woman’s physical state is inextricably connected to her mental state and her socio-economic situation.

4. Early successful surgical repair or catheter management is highly recommended and is likely to be the only thing needed for social re-integration. Surgery should be performed as soon as possible by a skilled surgeon, and preferably within 3 months of developing the fistula, as this is likely to limit the length of time the woman is seen as abnormal by her family or community and thus perceived as an outcast.

5. Social re-integration should start in a designated space where women can recuperate, perhaps within the repair facility or nearby, rather than going home and encountering the risk of behaviours which may make it likely that a recurrence of fistula occurs, due to an exacerbating physical event such as early sexual intercourse or heavy work. Also, peer counselling is more likely to be available in this space.

6. Surgeons and other care workers should consider social re-integration as not just a social tool but also as a means of ensuring that adequate follow-up of the postsurgical improvement in quality of life is done and reported on. At the least, there should be a review of individually defined success of surgery and surgical outcomes, including continence and return to fertility and/or sexual life, as desired by the woman.

7. Appropriate counselling messages about the risk factors and causes associated with fistula should be targeted at family members (including husbands) and the community, as this can help to overcome the stigma, discrimination and misconceptions surrounding the condition and enhance her community inclusion. It is then an opportunity to make changes so that
the woman does not present with another fistula in the future.

8. Counselling should be seen as an opportunity for health providers to understand the socioeconomic, psychological and physical experiences that are faced by girls and women living with fistula, before and after surgery, so that they may give meaningful help. This will also help to generate knowledge on social re-integration processes and will help in the planning of a broader range of outcomes for women living with fistula.

9. Social re-integration should include assistance with education and life skills, and encouragement of private initiatives through vocational skills development and microcredit support. If this is freely chosen, it will not keep a woman away from her community unduly, and will help her regain or improve her previous economic status and enhance her self-sufficiency and community inclusion.

10. Social re-integration should include vocational skills training with the aim of providing women with alternative ways to generate income, without jeopardising their recuperation, by teaching them a trade which is economically viable within their community.

11. Institutional re-integration services should be incorporated into existing community activities or programmes directed to empower women (e.g. education, skills training, income generation, self-esteem).

12. Re-integration programmes should develop criteria to determine where support with socioeconomic interventions should be given, as funds may be limited and fistula consequences can vary dramatically by country and region. They should also be careful not to increase the burden of stigma and therefore inadvertently impede re-integration. Of particular concern should be women who are still incontinent, those who are deemed incurable, those who have no children and those who have lived with fistula for a long period of time.

13. Social re-integration programmes need to consider the potential ethical dilemmas in re-integration such as providing targeted financial support or high value goods to women with fistula in poor communities, other than as part of a community approach.

14. Social re-integration should seek to involve women who have been successfully re-integrated into their communities. These women can be termed motivational mobilisers and can contribute to community mobilisation movements for safe motherhood, fistula case mapping and referrals for treatment. Women should have a choice as to whether they wish to be involved in such advocacy activities.

15. Social re-integration programmes should be monitored and evaluated in order to collect correlates of success and failure and to help understand socio-cultural backgrounds, so that a context specific approach can be used to design and deliver effective, feasible reintegration programmes.

Below is set out the committee structure for the Consultation, within whose chapters full details of each committee’s work can be found.

### I. INTRODUCTION

Iatrogenic urogenital fistulae are known complications of pelvic surgery and oncological treatments such as radiotherapy. For example, a high quality population-based case-control study from Sweden found that the risk of urogenital fistula was 25 times higher amongst women undergoing hysterectomy ($n=180,000$) compared to an age matched control population ($n=525,826$) without hysterectomy. The risk appeared to be highest for laparoscopic hysterectomy and lowest for sub-total hysterectomy but absolute numbers were small with a number needed to harm of 5,700.[3]

This section is based on electronic searches of Medline, EMBASE (from 1980 to November 2011), the Cochrane Database of Systematic Reviews, Central Register of Controlled Trials (CENTRAL), Database of Abstracts of Reviews of Effects (DARE), Database of Health Technology Assessments, and Database of NHS Economic Evaluations, and the NICE website (all accessed November 2011); references included in identified systematic and non-systematic reviews were evaluated separately. Hand searching of recent (Jan-December 2011) issues of major American, European and British journals in urology, gynaecology and urogynaecology was undertaken, to capture recent publications not yet included in the online databases. ICS, IUGA, AUA, AUGS and SGS conference proceedings for 2011 were also reviewed. It was assumed that studies and trials presented earlier than this would be in press if they were of sufficient quality and maturity to justify inclusion; hence older abstracts have not been considered. Papers offering any relevant data were considered. This included systematic reviews, randomised and quasi-randomised trials, non-randomised cohort studies, case controlled studies, longitudinal studies and case series or reports. Those papers considered for inclusion were assessed for quality where relevant, in terms of sequence generation, allocation concealment, blinding, and handling of incomplete data, selective reporting and freedom from other biases. An evidence level [EL] was then assigned to all included studies according to the ICUD modified version of the Oxford Centre for Evidence-based Medicine system.[4] Where quality was considered to be poor – as in most of the studies included in these sections – the evidence level was reduced accordingly. Recommendations (graded A-D) were made on the basis of consistent or ‘majority evidence’ identified.[4]

### II. EPIDEMIOLOGY

#### 1. POST-GYNAECOLOGICAL SURGERY

Fistulae involving the lower urinary tract can occur following any surgical procedure or traumatic event to the female reproductive tract, bladder, or rectum. In developing countries, the most common aetiology of fistulae involving the lower urinary tract is clearly obstetric trauma. [5] In most developed countries in which antenatal and intrapartum care is more readily available, obstetrical fistulae are relatively rare and the majority of fistulae are related to gynaecological surgery. The ratio of obstetric to gynaecological fistula appears to be consistent at about 10:90 in developed countries. [6] In some developing countries, as gynaecological procedures to treat benign and malignant conditions of the female reproductive tract are more commonly performed, the rate of iatrogenic fistulae is increasing (e.g. Pakistan). [7]

The types of fistula associated with gynaecological procedures may include communication between any reproductive organ (uterus, cervix, Fallopian tube, vagina), intestinal tract (colon, rectum), genitourinary organ (bladder, ureter, urethra), and cutaneous system (abdominal wall, perineum). The combinations, locations, and severity of gynaecological fistulae vary with each patient. In general, vesicovaginal fistulae (VVF) are the most common type. The most common causes of VVF as a consequence of surgery, in developed countries is an injury to the urinary tract during hysterectomy for benign conditions (60-75%), followed by hysterectomy for malignant conditions (30%), caesarean section (6%), and obstetric injuries (1%). [8][9] At the Zekai Tahir Burak centre in Turkey 25,998 gynaecologic and obstetric operations were performed over a 3-year period. The bladder was the most frequently injured organ. Urinary tract injury rates were reported to be 0.49% for the bladder and 0.24% for the ureter in gynaecological operations, and 0.18% for the bladder and 0.01% for the ureter in obstetric operations.[10] Overall, the risk of pelvic organ fistula following hysterectomy has been reported to be between 0.1 and 4%. [11] It is important to recognize that most urinary tract injuries do not result in a fistula.

The prevalence of genitourinary injury and fistulae vary slightly from centre to centre. In one US retrospective study from the Mayo clinic, gynaecologic surgery was responsible for 82% of the fistulas, obstetric procedures for 8%, and various forms of irradiation for 6%, and trauma or fulguration for 4%. The majority of fistulae followed treatment for benign conditions. [12] The relative proportions of the types of urinary fistula have changed with urethral fistulae having increased from 6 to 13%, while ureteral, bladder and/ or urethral fistulae having dropped from 20 to 16 and 11 to 7%. [2]

Given the various indications for, and types of hysterectomies, it is important to have an understanding of the type of hysterectomy since genitourinary or colonic fistula is reported with all of these procedures. The overall incidence of hysterectomy complications is estimated to be <2%, with bladder injury (1.3%) and ureteral injury (<1%) being most commonly reported. [13] Traditionally, the most common route used to
remove the uterus for benign and malignant gynaecological conditions is abdominal (open incision, laparotomy); referred to commonly as total abdominal hysterectomy (TAH). The types of hysterectomies also include total vaginal (TVH), laparoscopically-assisted vaginal (LAVH), total laparoscopic (TLH), and subtotal or supracervical abdominal (SCH) or laparoscopic (LSH). Laparoscopic procedures may be done using traditional laparoscopic techniques, robotic assistance, and more recently, the single-site umbilical technique.

Benign and malignant conditions confined to the uterus are usually treated with a simple hysterectomy using any of the methods mentioned above. More advanced malignant conditions are usually treated with a radical hysterectomy in which parametrial and/or vaginal dissection and removal may be involved. In rarer cases, exenterative procedures to remove the bladder or colon may be required if malignant extension to these organs is found. In some centres, robotic radical hysterectomies have been more commonly employed to treat gynaecological malignancies. The rate of urogenital fistula associated with simple abdominal hysterectomy for benign disease is often described as being of the order of 1 in 1000. In a national study from Sweden the rate of women undergoing any fistula surgery was reported as 0.28% in women having had a hysterectomy compared to 0.0007% in those not exposed to hysterectomy, with the 'number needed to harm' being estimated at 5700.[14] From Finland the rate of vesicovaginal fistula was reported to be 1 in 1250 after all hysterectomies, 1 in 455 after laparoscopic, 1 in 1000 after total abdominal, and 1 in 5000 after vaginal hysterectomy.[15] The publicly available tables from the national hospital database in England give similar figures of 1 in 600 after total abdominal hysterectomy, and 1 in 5000 after vaginal hysterectomy.[16, 17] More detailed longitudinal analysis of patient-level information from the same dataset suggests a rate of 1 in 788 for all types of hysterectomy, 1 in 540 for abdominal hysterectomy for benign disease, 1 in 896 following vaginal hysterectomy for benign disease (excluding prolapse), and 1 in 3861 following vaginal hysterectomy for prolapse.[18]

Naturally, caesarean hysterectomy is a recognised cause of fistula,[19] and, with the increase in the number of caesarean deliveries there have been more fistulae related to obstetricsurgical trauma. [2]

The degree of bladder injury appears to be a major factor in iatrogenic fistula formation. In one study, 1,317 benign hysterectomies were reviewed (46% abdominal, 48% vaginal, and 6% laparoscopically assisted vaginal) with reference to risk factors for VVF following intraoperative injury to the urinary tract. In all, 34 cystotomies occurred with 4 (11.7%) developing a VVF. Patients who developed a VVF were more likely to have a large cystotomy and these individuals trended toward greater tobacco use, larger uterine size, and more operative blood loss. [20] Another study involving 3,076 vaginal hysterectomies with or without additional gynaecological procedures, one ureteral injury and 54 bladder lacerations were noted yielding a total of 4 VVF. The bladder lacerations occurred during the hysterectomy portion of the surgery in 61% of cases and during the additional procedures in 39%. [21](see Table 1)

VVFs associated with hysterectomy may require ureteral reimplantation in as many as one-third of the cases. [22] Ureteric trauma should be considered in any hysterectomy or operative obstetric procedure regardless of the difficulty but certainly in more difficult cases. [23] Iatrogenic ureteric injury may occur after less common procedures such as ureteroscopy, lumbar sympathectomy, abdominal trauma, and iliac vessel ligation.[24]

Altered intraabdominal anatomy such as that due to previoustomy, extensive endometriosis and pelvic inflammatory disease have previously been thought to lead to an altered operative field increasing the risk for genitourinary injury; recent evidence from a cohort of over 300,000 women having hysterecmy for a variety of indications suggests that this may not be the case. [18]

The overall rate of ureteric injury from 4998 procedures in these studies was 1.5%; the overall sensitivity was 96.1%, specificity 99.5%, positive predictive value (PPV) 74%, and negative predictive value 99.9%. The modest PPV related to 21 cases in one study where cystoscopic examination revealed abnormal (sluggish or absent) flow of indigo–carmine dye through one or both ureteric

Confidence interval 1% 30%
orifices, but subsequent findings failed to confirm injury. For every 200 cystoscopies undertaken at gynaecological surgery therefore one might expect to diagnose three otherwise unsuspected ureteric injuries but at the expense of one false positive ‘injury’ that would ultimately be shown to be normal.

Visco et al. using a decision analysis model concluded that the cost-effectiveness of routine intra-operative cystoscopy depends on the rate of ureteric injury; if the rate exceeds 1.5% for abdominal hysterectomy and 2% for vaginal or laparoscopically-assisted vaginal hysterectomy, then routine cystoscopy is cost-effective. These data would suggest that whilst the routine cystoscopy might be considered clinically and cost-effective at the time of prolapse and incontinence surgery, its place at hysterectomy is less clear.

2. ONCOLOGICAL FISTULA

This section considers, where the literature permits, the epidemiology of fistula relating to malignant disease and its treatment by surgery, radiotherapy and chemotherapy. The literature relating to fistula of oncological aetiology is limited both in quantity and quality. Seventy-six papers of possible relevance were identified, of which only 52 contained any relevant material. Only one randomised trial was directly identified from the literature searches,[25] although one non-systematic review of relevance,[26] and two systematic reviews were found;[27, 28] each of the latter contained only one further randomised trial. One national cohort study, and one non-randomised cohort study, are included,[18, 29] but all other identified material comprised case series or case reports, and represent level 3 or lower evidence. Two cases of duplicate publication (i.e. the same paper in two journals) were found.

In the oncological context, fistulae may occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, chemotherapy, or a combination of therapies.

Traditionally, malignancies involving the uterus, cervix, vagina, or ovaries are often treated with hysterectomy, bilateral oophorectomy, and pelvic lymph node dissection. In many cases, a radical hysterectomy is performed in which the uterus, cervix, and upper vagina are removed. It is generally accepted that the more advanced the cancer, the more radical the surgical dissection will necessarily be. With cervical and uterine carcinoma, oophorectomy is performed when indicated. Pelvic lymphadenectomy is done when invasive carcinoma is suspected or diagnosed. In one study, 536 women underwent a radical hysterectomy for invasive cervical cancer. More advanced stage of disease, obesity, diabetes, and postoperative surgical infection were predisposing factors to urinary tract complications. In this study, ureteral injury occurred in 1.32%, bladder injury in 1.49% with VVF forming in 2.61% and ureterovaginal fistula in 2.43% of cases, respectively. [30] In a similar report, 1,092 women with cervical cancer underwent a radical hysterectomy with obligatory pelvic lymphadenectomy. A VVF occurred in 0.3% and a ureterovaginal fistula occurred in 1.4%. [31] The rate of GU injury likely varies between centres. For example, in one report of 479 women undergoing different methods of radical hysterectomy for cervical cancer over a 15 year period, 52 (10.8 per cent) had urological complications (17 bladder and ureter injuries, 35 fistulae and strictures). [32] In contrast, one institution reported that, with modifications and careful dissection, ureteric and bladder injury have almost been eliminated.[33]

In two recently published case series, one of fistulae specifically associated with gynaecological cancers,[26] and one of urogenital fistula from all causes,[17] those relating directly to primary cancer were uncommon, (2/20=10%) [26] and (2/348=0.6% - 2/66=3% of the oncological cases in this series), [17] respectively. Fistulae associated with cancer surgery (3/20=15% and 30/348=8.6% - 30/66=45% of the oncological cases in this series) or radiotherapy (15/20=75% and 34/348=9.8% - 34/66=52% of the oncological cases in this series) made up a much larger proportion of both series.

Immune-deficiency may be a further contributory factor, and enterovesical fistula has previously been reported in association with non-Hodgkin’s lymphoma in HIV-AIDS,[34] and vesicovaginal fistula has been seen in association with classical Hodgkin’s affecting the vagina in a long-term pessary user.[35]

3. CANCER SURGERY

It is likely that all operations carried out in the pelvis can be complicated by genital tract fistula in some circumstances. [17] Operations carried out with the intention of curing malignant disease will inevitably carry a higher risk of subsequent fistula formation, as compared to those undertaken with less radical intent.

Following radical hysterectomy for cervical cancer (Wertheim-Meigs procedure) the rate of fistula formation reported from case series is between 0.6% and 4.4%.[30, 36-41] It should be noted that these data are very heterogeneous, some reporting all types of fistula together, i.e. intestino genital plus urogenital fistula, and some reporting these separately; some report all urogenital fistulae together, and some separating vesicovaginal and ureterovaginal. Where they are reported separately, the rates of vesicovaginal and ureterovaginal fistula appear to be of the same magnitude with both being reported in between 0.9% and 2.5%, of cases [30, 42, 43, The data from UK
cited above suggests a urogenital fistula rate of 1 in 95 following radical abdominal hysterectomy in women with malignant disease as compared to 1 in 540 for total (simple) abdominal hysterectomy for benign disease, and 1 in 2041 for vaginal hysterectomy for all benign disease (including prolapse).[18] Overall, the rate of urogenital fistula appears to be approximately 9 times higher following radical hysterectomy in women with malignant disease as compared to that following simple hysterectomy (abdominal or vaginal) in women with benign conditions.[18]

The risk of visceral injury or subsequent fistula formation following radical hysterectomy undertaken in pregnancy, or immediately following Caesarean section is not obviously increased over those carried out electively in non-pregnant individuals; Monk & Montz described inadvertent cystotomy followed by vesicovaginal fistula in one of 21 women operated on during or immediately after pregnancy.[44]

Several modifications to the conventional Wertheim-Meig’s procedure of radical hysterectomy have been described in an effort to reduce the associated morbidity. The Miami modification includes vaginal reconstruction and closure using bladder and rectosigmoid serosa, retroperitoneal drainage through abdominal suction catheters, and suspension of the denuded ureters with the ipsilateral obliterated hypogastric artery. One prospective study of 978 women treated by this procedure reported a urinary fistula rate of 1.4% compared to 4.4% from a literature survey following the conventional procedure.[36] The Ohkawa procedure involves peritoneal sheathing of the ureters; Blythe et al. undertook a non-randomised comparison with retroperitoneal suction drainage, and found the conventional method to be associated with fewer ureteric complications (0/34 vs. 4/26 (15.4%).)[45] Similarly, Bostofte & Serup found no benefit in operative or postoperative morbidity following the application of the Okabayashi procedure for radical hysterectomy.[32]

Given the increased risk associated with radical surgery for malignancy, it is intuitive that the risks would increase with the stage of disease and with the extent of the surgery undertaken. There are few published reports of fistula following exenterative surgery. One study noted a 16% vesicovaginal fistula rate in 19 women following exenteration for vulvar carcinoma;[46] while another describes a 15% bowel fistula rate and an 8% urinary fistula rate from a series of 75 exenterations for recurrent cervical cancer.[47] In contrast, Ungar et al. describe only one ureterovaginal fistula and one pouch–vaginal fistula in 212 women undergoing exenteration out of a total of 2540 women treated for cervix cancer in one centre over a 13 year period (0.9%).[48]

Harkki-Siren et al. found the rate of vesicovaginal fistula to be over twice as high following laparoscopic hysterectomy compared to abdominal hysterectomy, and the rate of ureteric injury to be some 35 times higher.[15] The introduction of laparoscopic surgery within oncology is seen to have considerable advantages in terms of patient recovery; the risk of operative injury to bowel and the urinary tract, and subsequent fistula formation may however remain a concern in such cases. Although some studies, both case series and non-randomised cohorts, describe similar rates of injury to those described following open radical surgery,[29, 42, 43, 49, 50] others have reported injury or fistula rates several times higher following laparoscopic radical hysterectomy.[37, 51] A single non-randomised cohort study found that the risks of both injury to the urinary tract and of subsequent fistula formation were higher following laparoscopically-assisted radical hysterectomy as compared to that following laparoscopically-assisted radical tracheectomy (Dargent’s operation).[29]

The risk of urinary tract injury from minor surgical interventions is in general low, although the use of repeat procedures may confer a significant increase in risk. Vesicovaginal fistula has been reported following repeated use of CO2 laser for vapourisation of vaginal condylomata,[52] and following cone biopsy of the cervix.[53] In one personal series of 370 urogenital fistulae, 4 were associated with large loop excision of the transformation zone (LLETZ) of cervix, 3 of which followed a second LLETZ procedure (Hilton, personal communication).

Rarely, localised malignancies have been associated with VVF. One example is a primary mixed mullerian vaginal tumour reported in a 48-year female.[54] The mechanism for fistula formation is likely to be direct invasion into the bladder.

4. RADIATION FISTULA

Pelvic irradiation can be delivered by external beam as well as locally (intracavitary/brachytherapy). Fistula formation appears to be slightly higher for postoperative external radiation (1.9%) compared to intravaginal brachytherapy (0.8%).[55] It does not appear that pre-treatment factors accurately predict those who will develop fistula related to radiotherapy.[56]

The literature in this area is particularly heterogeneous in nature, with wide variation in (and some lack of clarity over) the tumour type and stage being treated, the form of radiation and the site and dose delivered. In a series of urogenital fistulae from the UK, 34/348 or 9.8% were associated with previous radiotherapy; of those related to gynaecological cancer, 34/66 or 52% had undergone radiotherapy.[17] In a further series of cases specifically related to gynaecological malignancy, 15/20 or 75% had undergone previous radiotherapy.[26] In both series most cases followed radiation used
for the treatment of cervical cancer, although, 5/34 or 15% followed treatment of endometrial cancer, and 1/34 or 3% followed treatment of a multifocal gynaecological cancer in one series. [17] Amongst a series of 216 radiation-induced fistulae, the time to diagnosis of the fistula was made between 3 months and 10 years (mean 21 months) following radiation.[57] In other series fistulae have been reported to develop or present up to 30 years after the ‘causative’ influence.[17, 58](Figure 1a and 1b)

The incidence of any deleterious clinical impact on the gastrointestinal and urinary tracts following radiation varies in the literature between 1% and 12%,[28, 59-65] with fistula rates of 1% to 5%.[26, 66]. In a retrospective review of 2096 patients treated for cervical cancer over a 10-year period using unspecified regimen/s of radiotherapy, 38 patients (1.8%) were found to have developed fistulae, all of whom had stage IIIa/b or IV disease at presentation.[62] Of these cases, approximately 3/4 involved the rectum, with 1/3 being combined rectovaginal and vesicovaginal fistulae; 1/4 were vesicovaginal only.[62]

Following a clearly defined regimen of external beam radiation plus brachytherapy for the treatment of primary squamous cell carcinoma of vagina in 91 women, de Crevoisier et al. reported 10.0% grade 2-3 urinary tract toxicity (using the Franco-Italian glossary)[67] and 12.1% grade 2-3 gastrointestinal toxicity.[60] Unsurprisingly, they found anterior tumour location to be correlated with increased risk of bladder toxicity and decreased rectal toxicity. Two women in this series developed rectovaginal fistulae (2%), and one ureterovaginal fistula (1%).[60]

Figure 1a. Left: Acute radiation fistula; Right: fistula 20 years after radiotherapy, both for cervixcarcinoma

Figure 1b. Supratrigonal vesico-perineal radiation fistula in a small contracted bladder that occurred 22 years after cobalt irradiation for a gynaecological tumour.
In a series of 10,709 women treated by telebrachytherapy (67.5 Gy) for a range of gynaecological cancers in one centre over a 22 year period, 133 (1.2%) developed urological complications of which 35 (0.3%) developed fistulae.[64]

In a series of 28 women treated by brachytherapy for recurrent corpus or cervix cancer, four patients developed chronic morbidities related to treatment. Three fistulae were reported in two patients (7.1%): one combined rectovaginal and vesicovaginal fistula and one ureterointestinal fistula; a further patient developed a ureteric stricture and small bowel obstruction requiring resection.[65]

These data tend to suggest a higher rate of fistula formation following the application of radiotherapy in locally recurrent disease than in primary disease. From a small series of urological complications following radiotherapy for gynaecological cancers, 14 had developed vesicovaginal fistula; of these 4 (29%) had evidence of tumour recurrence.[63] In the series reported by Jones at al. 326/1161 (28%) developed urological complications over a 20 year period; 46 developed fistulae (4%), of whom 33 (72%) had evidence of active malignant disease.[39]

When a fistula occurs after radiotherapy, it is considered good clinical practice to exclude tumour recurrence before attempting a fistula closure.

5. CHEMOTHERAPY

There are few reports of fistula formation in association with the use of chemotherapy. One case report described a patient who developed a vesicovaginal fistula having undergone abdominal hysterectomy for atypical endometrial hyperplasia whilst taking tamoxifen following a previous modified radical mastectomy. Surgical repair of the fistula was initially unsuccessful, although after discontinuing the tamoxifen and continued bladder drainage, healing occurred.[68] It was hypothesised that the impaired healing was a result of the administration of the hormone therapy.

6. COMBINATION THERAPIES

Adjuvant or neoadjuvant therapies are used to increase the efficacy of the primary treatment, compared to its use in isolation. It might be anticipated that this would also increase the range and magnitude of adverse effects.

In a case control study examining the urinary tract complications of radical hysterectomy only a single vesicovaginal fistula was seen in 50 patients (2%) – in a patient receiving preoperative irradiation (45-50 Gy).[69] A small case series found 2/20 or a 20% rate of urinary fistulae following preoperative irradiation and radical hysterectomy in a heterogeneous group of ‘high risk’ cervix cancers.[70] A further case series described the impact of combined external whole pelvic irradiation (50 Gy) and intravaginal cone boost (20-26 Gy) following radical hysterectomy in 108 women. The overall rate of fistula formation was 3.7%, 2.2% following ‘prophylactic’ radiation, and 10.5% in ‘salvage’ cases where recurrent disease was present.[71]

Modarress et al. reported a randomised comparison of preoperative combined chemoradiation (cisplatin plus external beam therapy) and neoadjuvant chemotherapy (cisplatin plus vincristine) followed by radical hysterectomy in stage IB-IIIB bulky cervical cancer.[25] Four patients developed hydrourephrosis (3 in the chemoradiation group – 13.3%) and two vesicovaginal fistula (both in the chemoradiation group – 6.7%).[25] Two further case series reported 2/36 or a 5.6% rate of fistulae following preoperative chemoradiation (cisplatin plus brachytherapy) followed by radical hysterectomy,[72] and 4/46 or 8.7% rate of fistulae following the use of neoadjuvant and postoperative chemotherapy using irinotecan, cisplatin and nedaplatin.[73]

III. URETERIC FISTULA

A large prospective case series from Finland found an incidence of ureteric injury associated with hysterectomy for benign pathology of 0.2% [10/5279] with the lowest rate associated with vaginal hysterectomy and no difference between open and laparoscopic abdominal hysterectomy.[74] The incidence of immediate and delayed ureteric injury during radical hysterectomy was found to be 1.3% [7/536] and 2.4% [13/536] respectively in a series from Serbia; injuries appeared more common after prolonged surgery and in patients with diabetes, obesity or wound infection.[75] A registry study from the United States found an overall incidence of ureteric injury during radical hysterectomy of 0.8%.[76] Case series from referral centres in India, Pakistan, and Egypt showed that the proportion of urinary tract injuries resulting from obstetric or gynaecological surgical trauma that primarily affected the ureter varied from 1% to 23%.[77-80]

IV. FISTULA INVOLVING THE GI TRACT

The literature relating to non-obstetric fistula involving the gastro-intestinal tract is sparse and of poor quality. Although literature searching identified 78 papers of possible relevance, less than half of these contained any useful material; no randomised trials or truly systematic reviews were identified. One case controlled study is included, but all other identified material comprised case series or single case reports, and is considered to represent level 3- evidence.

It should be recognised that, whilst in most papers the term ‘enterovesical’ is used to describe fistulae between small bowel and bladder, and ‘colo/recto-vesical/vaginal’ to describe those between
large bowel and bladder/vagina, in some reports ‘enterovesical’ appears to be employed generically to include all fistulae involving the gastrointestinal tract. In this chapter, the term ‘intestino-vesical’ will be used in circumstances where the generic term is clearly more appropriate.

Whilst occasionally reported congenitally,[81] the most common non-obstetric causes of fistula involving the gastro-intestinal tract are diverticular disease, Crohn’s disease, and malignant disease or its treatment. There are few data on the incidence of fistula formation in these conditions, although published estimates are in the range 2-6% in Crohn’s disease,[82-84] and 20% in diverticular disease.[85]

Intestinal fistulae in Crohn’s disease most typically involve the small bowel, although communication with urinary tract and large bowel are also found; involvement of the bladder was reported in 27% and of the colon in 14% in one series.[86] Two large series examining the urological complications in association with Crohn’s disease reported that whilst a majority of patients were female, the most serious complications were seen in males; most significantly, 13/14 or 93% of the ileo-vesical fistulae (described in these series were in men).[82, 87]

Whilst clearly diverticular disease involves the large bowel primarily in all cases, diverticu- fistulae have been reported to communicate with the bladder in 65% of cases, the vagina or uterus in 28% and small bowel in 7%.[85] Diverticular disease is the most common cause of colovesical fistula in most reports, accounting for up to 75% of cases,[88-95] with colon cancer, bladder cancer, radiotherapy and Crohn’s disease accounting for the remainder.

Although there are no direct comparisons between racial groups, the distribution of these causes may vary between populations. Malignancy and/or previous radiotherapy account for 53-93% of cases of colovesical fistula reported from China,[96, 97] presumably reflecting the previously low prevalence of inflammatory bowel disease.[98]

Previous hysterectomy appears to be a significant factor in the incidence of fistula associated with diverticular disease.[99] In a national case controlled study from Sweden, involving a total of 783,245 women over a 30 year period, the risk of undergoing fistula surgery increased four-fold in hysterectomised women without diverticulitis (hazard ratio (HR) 4.0 (95% confidence interval (CI) 3.5 to 4.7)), seven-fold in women with diverticulitis without hysterectomy (HR 7.6 (95% CI 4.8 to 12.1)) and 25-fold in hysterectomised women with diverticulitis (HR 25.2 (95% CI 15.5 to 41.2)).[100] Another study described previous hysterectomy in 50% of colovesical and 83% of colovaginal fistulae associated with diverticular disease.[85]

**Recommendations**

The development of fistula following radiotherapy for primary treatment should trigger a search for evidence of tumour recurrence D
1. CLINICAL DIAGNOSIS

Leakage of stool, urine, or possibly both is the hallmark sign of a fistula. The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intraoperative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula. [101] In one study, 36% of VVF presented within 1 week of a laparoscopic hysterectomy and 50% in the second week. Most of the patients after trans-abdominal hysterectomies had leakage in the second week (90%). [102] As discussed above, more extensive dissection is a factor when lower urinary tract injury results in a fistula. However, other than a frank injury such as ureteric transection, not all injuries result in the formation of a fistula. With laparoscopic or abdominal dissection, ureteral injury may occur anywhere along the retroperitoneal ureter usually below the pelvic brim. Since the injury may not be recognised during surgery, post-operative pain is a key symptom. The cause of vesicovaginal fistulae after hysterectomy varies with the extent of surgery and the amount of damage that has occurred. In an attempt to determine causative factors of post-operative fistulae, the records of 12 patients who had developed a vesicovaginal fistula after TAH were compared with 12 consecutive TAH patients without fistula formation. Most of the patients who developed VVF had excessive postoperative abdominal pain, distension or paralytic ileus, or both. Haematuria, symptoms of irritability of the bladder, prolonged postoperative fever, and increased white blood cell count were also noted more often in the fistula group. In contrast, the postoperative course was usually uncomplicated in the non-fistula group. The clinical course observed in many of the patients with vesicovaginal fistulas suggests that the patient has an unrecognized or recognized injury to the bladder resulting in urinary extravasation. [103] It may be possible to abort the development of many vesicovaginal fistulae by early recognition and treatment of an unsuspected bladder injury. It is suggested that patients with severe abdominal pain, distension, paralytic ileus, haematuria or symptoms of severe irritability of the bladder after abdominal hysterectomy should be investigated early for a possible genitourinary injury.

Another possible etiology of VVF in the setting of laparoscopic procedures is trocar insertion injury. To prevent this the bladder should be emptied by intermittent or continuous bladder drainage prior to inserting the abdominal and pelvic trocars. During the laparoscopic procedure, gaseous distention of the urinary drainage bag may become evident indicating a hole in the bladder. This intraoperative sign however, has not been associated with fistula formation. [104]

The diagnosis of VVF usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. Direct visual inspection (office evaluation or exam under anaesthesia) may confirm the presence of a fistula however it may not reveal the extent, location, or course of the fistula. Some fistulae are not readily visible. This is particularly true with iatrogenic fistula in which the fistula may be high in the vagina and may involve the ureter, bladder, or both. Therefore, most physicians rely on adjunctive tools for the diagnosis of VVF. This may include imaging studies in combination with other modalities such as cystoscopy. A simple approach in the office setting to confirm that a fistula is present is to fill the bladder retrograde with a coloured fluid. This could be a milky fluid such as baby formula or vital dye-tinted water or saline (methylene blue, indigo carmine). Direct visualisation of dye extravasation or placement of a tampon into the vagina to identify staining may facilitate the diagnosis of a VVF. (Figure 2) A double-dye test
to differentiate between an ureterovaginal and VVF may be useful in some cases. The patient is given phenazopyridine orally which will stain the urine orange while the bladder is filled with blue fluid. Blue tinting of the tampon leads to the presumptive diagnosis of a VVF while orange staining is suspicious for an ureterovaginal fistula. [105]

a) The role of cystoscopy in preventing and diagnosing VVF

A number of studies have investigated the role of routine cystoscopy in avoiding/detecting urinary tract injury at pelvic surgery; Indraratna et al. have recently reviewed these.[106]

Gilmour et al. undertook a systematic review of urinary tract injuries at benign gynaecological surgery including all studies of >500 patients reported between 1966 and 1998. [107] The overall rate of ureteric injury from 17 studies where cystoscopy was not undertaken (mostly hysterectomy) was 168/107,068 = 0.16%. In 10 studies where cystoscopy was undertaken routinely (mainly colposuspension or pelvic floor reconstruction), the rate of ureteric injury was 20/3235 = 0.62%. The corresponding rates of bladder injury were 0.26% (without cystoscopy) and 1.04% (with cystoscopy). Although the rates of detected urinary tract injury were approximately four-fold higher in those studies where cystoscopy was undertaken as a routine, it should be noted that none of these studies was randomised, and routine cystoscopy was undertaken predominantly during those procedures with intuitively the highest risk of injury. Summary statistics for available studies evaluating the place of routine cystoscopy (with or without intravenous indigo-carmine) at gynaecological surgery are given in Table 2.

Cystourethroscopy may provide direct visualisation of the fistula. In several series using cystoscopy (mostly with IV indigo-carmine) the sensitivity and specificity in detecting ureteric injury intra-operatively were >95%. Depending upon availability, radiologic studies (cystography, urography, intravenous urography, and CT urography) may be useful. Ultrasonography and colour Doppler have been used by some, although their use in routine practice remains to be established. [108][109]

Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fistula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared to serum levels. [110]

b) Imaging

An unstructured review by Narayanan et al. suggested that magnetic resonance imaging, particular with T2 weighting, provided optimal diagnostic information regarding fistula associated with pelvic malignancy, with contrast-enhanced CT with late excretory phase an acceptable alternative.[111] These newer modalities were considered to be superior to other X-ray contrast techniques and ultrasound.

2. DIAGNOSIS OF GI FISTULA

Pneumaturia, dysuria and/or recurrent UTI’s are symptoms of a colovesical fistula but may be due to other causes as well. Accepting the limitations of small case series in this regard, a number of studies have investigated the value of a range of investigative techniques in the detection and evaluation of enterovesical or colovesical fistulae.[90, 92, 93, 97, 112-116] Since in each study the authors have presented only results on patients known to have fistulae, sensitivity (true positive/true positive + false negative) may be estimated, however, specificity (true negative/true negative + false positive), positive predictive value, (true positive/true positive + false positive) and negative predictive value (true negative/true negative + false negative) cannot (see Table 3). No test was shown to have consistent reliability; excluding those investigations for which only a single report was identified, CT (53%), cystoscopy (48%), and in the case of colovesical fistula, barium enema (38%) were perhaps the most useful; intravenous urography and sigmoidoscopy or colonoscopy appear to have limited utility in the diagnosis of GI fistula.

3. RECOMMENDATIONS

The literature relating to surgical fistula is extensive, but of limited quality. 356 papers of possible relevance were identified, of which only 173 contained any relevant material. Three systematic reviews were identified (albeit one only as a protocol),[117-119] although none contained information of direct relevance. Six randomised trials were identified including one on causation,[120] one on prevention of urinary tract injury at surgery,[121] two on antibiotic prophylaxis at the time of reparative surgery,[122, 123], and two on surgical techniques applied to obstetric fistulae.[124, 125] There was also one quasi-randomised study of relevance.[126] Four non-randomised cohort studies,[127-130] and one cost-effectiveness study,[131] were also identified. All other identified material comprised case series [99] and individual case reports or procedure descriptions [52], and represent level 3 or 4 evidence. Three examples of duplicate publication were identified.

1. CONSERVATIVE MANAGEMENT

a) Immediate management by catheterisation or defunctionalizing

Before epithelialisation is complete an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed. Normal continence mechanisms, however, involve the physiological contraction and intermittent relaxation of urethral and anal sphincters. As a result, although completely spontaneous closure of genital tract fistulae does occur, it is the exception rather than the rule. Bypassing the sphincter mechanisms, or diverting flow around the fistula, for example by urinary catheterisation, percutaneous nephrostomy or defunctionalizing colostomy, may however encourage closure. Bazi reported a non-systematic review of papers including information on the spontaneous fistula closure of vesicovaginal fistulae; whilst the data quality of all was poor, he identified 30 studies from which 12 could be included; these included cases that were almost exclusively of surgical aetiology; it should be noted that in 9 of these 12 studies the sample size was less than 5 patients.[132] Few studies described catheter drainage in large fistulae, although it seemed that

VI. MANAGEMENT OF VESICO-VAGINAL FISTULA

The literature relating to surgical fistula is extensive, but of limited quality. 356 papers of possible relevance were identified, of which only 173 contained any relevant material. Three systematic reviews were identified (albeit one only as a protocol),[117-119] although none contained information of direct relevance. Six randomised trials were identified including one on causation,[120] one on prevention of urinary tract injury at surgery,[121] two on antibiotic prophylaxis at the time of reparative surgery,[122, 123], and two on surgical techniques applied to obstetric fistulae.[124, 125] There was also one quasi-randomised study of relevance.[126] Four non-randomised cohort studies,[127-130] and one cost-effectiveness study,[131] were also identified. All other identified material comprised case series [99] and individual case reports or procedure descriptions [52], and represent level 3 or 4 evidence. Three examples of duplicate publication were identified.

1. CONSERVATIVE MANAGEMENT

a) Immediate management by catheterisation or defunctionalizing

Before epithelialisation is complete an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed. Normal continence mechanisms, however, involve the physiological contraction and intermittent relaxation of urethral and anal sphincters. As a result, although completely spontaneous closure of genital tract fistulae does occur, it is the exception rather than the rule. Bypassing the sphincter mechanisms, or diverting flow around the fistula, for example by urinary catheterisation, percutaneous nephrostomy or defunctionalizing colostomy, may however encourage closure. Bazi reported a non-systematic review of papers including information on the spontaneous fistula closure of vesicovaginal fistulae; whilst the data quality of all was poor, he identified 30 studies from which 12 could be included; these included cases that were almost exclusively of surgical aetiology; it should be noted that in 9 of these 12 studies the sample size was less than 5 patients.[132] Few studies described catheter drainage in large fistulae, although it seemed that
those of less than 1cm diameter were most likely to heal spontaneously. The time between the insult and institution of drainage in cases of non-surgical closure varied widely, although in most cases this was less than 3 weeks. Similarly, the duration of catheterisation prior to the initiation of conservative treatment was deemed to have been unsuccessful varied considerably, making true estimates of the effectiveness of this approach impossible; generally this varied between 10 days and 3 months.[132] Reported success rates varied between 0% and 100% (although 5 series had a sample size of 1!), although in several series it was difficult to determine how many women had attempted conservative management.[132] In large series of obstetric fistulae where a consistent approach to conservative management has been applied, spontaneous healing has been reported in up to 28% of cases. [133-135] In one series of urogenital fistulae of varying aetiologies, spontaneous closure was seen in 19/238 or 8.0% of surgical cases, 4/38 or 10.5% of obstetric cases, 1/36 or 2.8% of miscellaneous (largely traumatic cases) and 0/34 or 0.0% of radiotherapy related cases.[17] It is likely that in this, and many other reported series, data are an underestimate of the value of this approach to management,[17] nevertheless, combining available data (see Table 4) gives an overall spontaneous closure rate from 348 surgical fistulae treated by initial catheterisation of 13% ± 23%.[8, 17, 21, 136-145]. Patients with ongoing, continuous vaginal leakage despite a functioning indwelling catheter are unlikely to have resolution of the VVF without additional measures such as surgery. Such patients should be spared prolonged catheter drainage and proceed with more definitive repair as soon as medically appropriate. Small epithelialized fistulas may benefit from minimally invasive cystoscopic electrocoagulation of the fistula tract, followed by prolonged catheter drainage. In patients with fistulae less than 3.5mm in diameter, 11/15 had successful fistula tract ablation with cauteryation and catheter drainage in a study by Stovsky et al.[146] In general, conservative measures are successful in small fistulas only, usually less than 2-3mm in diameter.

**b) Pharmacotherapies to assist fistula closure**

Several case reports describe successful fistula closure following the induction of amenorrhoea by oestrogen, oestrogen/progesterone combinations, or luteinising hormone releasing hormone analogues,[147] in the management of vesicovaginal,[148] and more frequently, uretero- or vesico-uterine fistula following caesarean section.[149-153] The overall closure rate in these studies is 88%±16%. Spontaneous closure of vesico-uterine fistula has also been reported on a number of occasions,[150, 154] with a rate of 41/786 or 5% calculated in one review.[150] Whilst comparison across studies is obviously highly problematic (especially where many are single case reports, with success rates of 0% or 100%), it seems highly likely that the rate of closure following hormone treatment [14/16] is significantly higher than that of spontaneous closure [41/786] (p<0.0005 – Fisher’s exact test).

In quasi-randomised controlled study (alternate allocation) in patients with continuing urinary leakage following ureteric or pelvi-calyceal surgery, the use of intranasal desmopressin was shown to significantly reduce the duration of leakage compared to ‘watchful waiting’. The use of such treatment should be avoided in patients with complicating factors such as infection.

It should be recognised that some fistulae may be associated with minimal symptoms, and even if persistent these may not require surgical treatment. Small distal urethro-vaginal fistulae, uterovesical fistulae with menouria, colo-vesical fistulae associated with diverticular disease, and some low recto-vaginal fistulae may fall into this category.

c) Palliation and skin care

During the waiting period between diagnosis and repair, incontinence pads should be provided in generous quantities so that patients can continue to function socially to some extent as well as avoid skin complications related to chronic urinary leakage. Urinary fistula patients usually leak considerably larger quantities of urine than those with urethral incontinence from whatever cause, and this needs to be recognised in their provision of supplies.

The vulvar may be at considerable risk from urinary or faecal dermatitis,[155, 156] particularly if there is additional radiation change in the skin;[157, 158] liberal use of silicone barrier cream should be encouraged. Steroid therapy has been advocated in the past as a means of reducing tissue oedema and fibrosis, although these benefits are refuted and there may be a risk of compromise to subsequent healing. Some authors have recommended local oestrogen, and whilst empirically one might expect benefit in post-menopausal women,[159, 160] or those obstetric fistula patients with prolonged amenorrhoea,[161, 162] the evidence for this is limited.

d) Nutrition

To maximise the prospects for postoperative healing it is essential, that the general health of the patient should be optimised. This is most relevant to obstetric fistula patients, where social ostracism and the effects of prolonged sepsis, may commonly result in malnutrition and anaemia.[163-168] Where there is severe inflammatory bowel disease the question of an elemental diet or even total parenteral nutrition may need to be considered.[96, 99, 169-172] Nutritional support may also be important in patients with malignant or radiotherapy induced fistulae.[173] or in those with complications following diversion surgery.[172, 174, 175]

e) Physiotherapy

Obstetric fistulae are commonly associated with lower limb weakness, foot drop and limb contracture. In a group of 479 patients studied prospectively 27% had signs of peroneal nerve weakness at presen-
tation and a further 38%, whilst having no current signs, gave a history of relevant symptoms.[176] Early involvement of the physiotherapist in preoperative management and rehabilitation of such patients is essential.[177] Although nerve injury is rarely seen in association with fistulae of other (non-obstetric) aetiologies, the value of physiotherapist support in the preoperative management and rehabilitation of patients with complex fistulae or with intercurrent pathologies should not be under-emphasised.[172]

f) Antimicrobial therapy

Active infection in the genital or urinary tracts should be treated prior to attempted surgical repair. In tropical countries the treatment of systemic infections such as malaria, typhoid, tuberculosis and parasitic infections are not uncommon and should be rigorously pursued and treatment undertaken before elective surgery. One randomised trial reported no difference in outcome between single dose IV gentamicin and continued postoperative use of amoxicillin, chloramphenicol or cotrimoxazole obstetric fistula patients (although re-analysis suggests that a difference favouring peri-operative gentamycin may be present).[122] A further placebo controlled trial of ampicillin found no evidence of benefit from prophylactic antibiotics in terms of fistula closure or residual incontinence following repair, although the use of postoperative antibiotics was reduced.[178] A recent review of obstetric fistula practices has called for further trials in this aspect of fistula management.[179] Opinions differ on the desirability of prophylactic antibiotic coverage for surgery in the developed world, some avoiding their use other than in the treatment of specific infection, and some advocating broad-spectrum treatment in all cases. A systematic review found only weak evidence that antibiotic prophylaxis (compared to giving antibiotics when clinically indicated) reduced the rate of bacteriuria, pyuria and symptomatic urinary tract infection in female patients undergoing abdominal surgery who had a urethral catheter for at least 24 hours; this limited evidence related to women receiving antibiotics during the first three postoperative days or from postoperative day two until catheter removal.[180]

g) Bowel preparation

Although many surgeons continue to employ mechanical or stimulant laxative bowel preparation prior to recto-vaginal fistula repair,[181] and may even suggest alternative approaches to surgery where this has not been possible,[94] a recent systematic review that included 18 trials (5805 participants), found no evidence that patients benefit from mechanical bowel preparation, nor the use of rectal enemas, and concluded that bowel cleansing can be safely omitted prior to colonic surgery, without increasing the risk of perioperative complications.[117]

h) Counselling

Surgical (non-obstetric) fistula patients are usually previously healthy individuals, who entered hospital
for what was expected to be a routine procedure, and they end up with symptoms infinitely worse than their initial complaint. In contrast, obstetric fistula patients in the developing world are often social outcasts. In both situations therefore these women are invariably devastated by their situation; significant impact on their mental health has been objectively confirmed.[182, 183] It is vital that they understand the nature of the problem, why it has arisen, and the plan for management at all stages. In the setting of an iatrogenic fistula, there may be considerable medico-legal consequences. Confident but realistic counselling by the surgeon is essential and the involvement of nursing staff or counsellors with experience of fistula patients is also highly desirable. The support given by previously treated sufferers can also be of immense value in maintaining patient morale, especially where a delay prior to definitive treatment is required.[184]

2. SURGICAL MANAGEMENT

Whilst most commonly occurring after hysterectomy, virtually any operation undertaken in the pelvis may be complicated by the development of urogenital fistula.[17] In the series from UK recently published by Hilton, 238/348 or 68% were of surgical aetiology, 172 (72% of surgical cases and 49% of the series) followed excision of uterus and/or cervix.[17] It should be borne in mind also that so-called ‘minimally invasive’ procedures may result in fistula formation, including mid-urethral tape procedures,[119] and peri-urethral injections.[185] Minimally invasive procedures are not without risk as ureterovaginal fistula has been reported following a robotically-assisted procedure.[186]

a) Timing of surgery

The most appropriate timing for repair of vesicovaginal fistulae remains one of the more contentious issues in this area. The debate continues between the advocates of early intervention, in order to minimise the distress to the patient from continuing urinary leakage, vs. those in favour of delaying intervention until local inflammatory change has resolved, necrotic tissues have sloughed, and the patient’s recovery from the causative event completed, so as to optimise results.

There is no consensus in the literature as to the definition of ‘early’ in this context, with different studies either failing to specify at all, or giving a broad range of definition. Although some studies have used the terms ‘immediate’,[187] ‘less than two weeks’,[188] or ‘less than 30 days’,[145] most reports have considered either less than 6 weeks,[189-191] or less than 3 months,[130, 188, 192, 193] as their definition of early intervention. Although relatively few studies have reported their outcomes for both early and late approaches to management, overall the results do not appear to be significantly different (see Table 5). The overall results for early management are estimated at 91%±6% and for later management (where provided) 90%±27% (p=1.00; Fisher’s Exact test).

b) Outcomes from treatment and follow-up

Comparing the outcomes of treatment between different reports and different methods is made difficult by the inconsistent and relatively inefficient outcome measures used. These have ranged from the apparent achievement of a water-tight repair based on dye-testing in the operating theatre, to patient reported symptoms at the time of discharge from hospital. Follow-up in obstetric fistula patients is inevitably difficult in many developing world centres, but even amongst surgical or radiotherapy cases in the developed world, relatively few reports describe examination findings or symptoms at later postoperative review. Long-term outcomes and quality of life measures have only rarely been reported.[194, 195]

Table 5. Data from studies examining outcome from vesicovaginal fistula repair using an ‘early’ approach to management; where comparative data from alternative timings are available these are included.
c) Surgical approaches

Despite the fact that there is no universally agreed upon classification of iatrogenic fistula, it is probable that there is a relationship between the complexity of the fistula and the outcome of the fistula repair.

The WHO published a classification on obstetric fistula in 2006 that divided fistula in simple or complex fistula. We adapted that classification by adding the radiation fistula to the complex fistula group. (Figure 3)

1. VAGINAL PROCEDURES

There are two main types of closure technique applied to the repair of urinary fistulae, the classical saucerization technique described by Sims,[196] and subsequently modified as a partial colpocleisis by Latzko,[142] and the more commonly used dissection and repair in layers or ‘flap-splitting’ technique (variously attributed to Hayward, Collis & Lawson Tait).[197] Individual surgeons inevitably employ these techniques somewhat variably, and in different situations, and there are no data comparing their outcomes.

The conventional dissection and repair in layers is entirely appropriate for the majority of post-surgical fistulae, although modifications may be necessary in specific circumstances. In juxta-cervical fistulae in the anterior fornix, vaginal repair may be feasible if the cervix can be drawn down to provide access. Dissection should include mobilisation of the bladder from the cervix, and the repair should usually be undertaken in such a manner (usually transversely) to reconstruct the underlying trigone and prevent distortion of the ureteric orifices.

Vault fistulae, particularly those following hysterectomy, can again usually be managed vaginally. The vault is incised transversely and mobilisation of the fistula is often aided by deliberate opening of the Pouch of Douglas.[198] The peritoneal opening does not require to be closed separately, but is incorporated into the vaginal closure.

Where there is substantial urethral loss, reconstruction may be undertaken using the method described by ChassarMoir[199] or Hamlin & Nicholson.[200] A strip of anterior vaginal wall is constructed into a tube over a catheter. Plication behind the bladder neck is probably important if any prospect for continence is to be achieved. The interposition of a labial fat or muscle graft not only fills up the potential dead space, but may also provide additional bladder neck support and improve continence by reducing scarring between bladder neck and vagina. These are indeed technically demanding procedures and outcomes of such complex repairs using robust measures as regards continence or sexual function are lacking.

With very large fistulae extending from bladder neck to vault, the extensive dissection required may produce considerable bleeding. The main surgical difficulty is to avoid injuring the ureters. They are usually situated close to the supero-lateral angles of the fistula, and if they can be identified endoscopically, they should be catheterised. Straight ureteric catheters passed transurethrally, or double pigtail catheters may both be useful in directing the intramural portion of the ureters internally; nevertheless great care must be taken during dissection. In such cases where the ureters cannot be visualized cystoscopically, interventional radiological techniques may be utilized to place antegrade ureteral stents from a percutaneous nephrostomy access tract.

Figure 3. Adapted WHO classification of fistula. Although this classification was developed for obstetric fistula initially, it could be relevant for iatrogenic fistula as well. (400)
Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are inaccessible through the vagina; most typically this might be following hysterectomy in nulliparous women, in endometriosis, or in those who have not delivered vaginally. Other indications for transabdominal repair are the need for simultaneous augmentation cystoplasty, or in the setting of a ureteric injury requiring reimplantation or simultaneous VVF and ureterovaginal fistula.

A transvesical repair has the advantage of being entirely extraperitoneal. It is often helpful to elevate the fistula site by a vaginal pack. The ureters should be catheterised under direct vision either endoscopically prior to skin incision, or following opening of the bladder. The technique of closure is similar to that of the transvaginal flap-splitting repair except that for purposes of haemostasis the bladder mucosa is usually closed with a continuous suture.

A simple transperitoneal repair is relatively uncommonly employed (although this technique does seem to be favoured by some using the laparoscopic approach – see below), although a combined transperitoneal and transvesical procedure is favoured by many urologists and is particularly useful for fistula repair following Caesarean section. A midline incision is made in the vault of the bladder; this is extended downwards in a racquet shape around the fistula. The fistulous tract is excised and the vaginal or cervical defect closed in a single layer. The bladder is then closed in two layers.

There are no randomised studies comparing abdominal and vaginal approaches; given that those surgeons undertaking both routes for repair would usually see specific indications for the two such a comparison is most unlikely ever to be seen as feasible, ethical or appropriate. Nine non-randomised cohort studies reporting results from both abdominal and vaginal procedures were identified in the current review.[9, 17, 128, 191, 201-205] In all, these series included 388 vaginal repairs and 345 abdominal repairs with overall closure rates at first operation of 89% and 87% respectively (p=0.367; Fisher’s exact test). The same reports included 255 transvesical repairs with a 93% cure rate, and 399 transperitoneal repairs with an 89% success rate (p=0.130; Fisher’s exact test) (see Table 6).

With respect to attempted repair of a previously failed VVF surgery, the law of diminishing returns appears to be as evident in these types of procedures as in many other forms of surgery. Although repeat operations are certainly justified, the success rate decreases progressively with increasing numbers of previously unsuccessful procedures. In a series of 2484 largely obstetric fistulae, the success rate fell from 81% for first procedures to 65% for those requiring 2 or more procedures.[206] Series of surgical cases are rarely large enough for this effect to be evident, although the recent series published by Hilton found successful fistula closure was significantly more likely in the women who had not had attempts at closure before referral (98.2%) than in those who had one or more previous unsuccessful procedures (88.2%) (p=0.003; Fisher’s exact test).[17]

There is only a single randomised trial comparing aspects of surgical technique; Shaker et al. report an RCT comparing trimming of the fistula edge with no trimming.[125] Although there was no statistical difference in success rates between the two groups, in those cases where repair was unsuccessful and trimming had been undertaken, the fistula tended to become larger, whereas those where there was no trimming were more likely to be smaller upon recurrence (see Figure 4).[125]

### 3. Laparoscopic

Laparoscopic repair of a VVF was first reported by Nezat et al., in 1994.[207] Fifteen series were identified in the current review,[187, 207-220] (plus an additional series in which 2 laparoscopic procedures were undertaken amongst a small series of vaginal and open abdominal operations).[205] All reported series are quite small (1-25 cases, median 6 cases), and in total only 119 patients were included, with an overall cure rate of 92% (confidence interval 4%) (See Table 7). It is not clear from these series whether they include all fistula repairs undertaken in the reporting centres, or whether they were selected in some way; if the latter, it is not clear what selection criteria were used. It is possible that there may be both selection and reporting biases that make it difficult to fully evaluate laparoscopic procedures against alternative surgical approaches.

### 4. Robotic

The first report of a robotically-assisted repair of vesico-vaginal fistula was from Melamud et al. in 2005.[221] Since that time four additional reports have been identified,[222-225] including a total of 17 cases (see Table 7). The reported cure rate is 100% in all series, although the same comments as above, in relation to possible selection and reporting biases, apply equally here. At this stage, whilst one could state that fistula repair with robotic-assistance appears to be feasible, it is not possible to indicate what its place or potential advantages are over alternative approaches.

### 5. Fibrin glue

The use of fibrin glue in urological indications was reviewed by Shekarriz and Stoller;[226] they identified nine reports (eight in human subjects) of the use of fibrin glue in fistula repair, including a total of 16 patients.[227-234] A further six more recent reports were identified in the current review, where fibrin glue was used either by endoscopic injection or direct application, making a total of now 53 patients with fistu-
Table 6. Results from series reporting vaginal and abdominal (transvesical or transperitoneal) repairs in exclusively or largely surgical fistulae.

n.b. those studies highlighted in orange give results for vaginal procedures only, those in blue from abdominal (transvesical or transperitoneal), and those in green provide non-randomised data on both surgical approaches.

(iii) Forest plot of comparison: 1 Trimming vs. no trimming of fistula edge, outcome: 1.3 Recurrence larger than original

Figure 4. Forest plots relating trimming of edges at fistula surgery
lae of various aetiologies.\[124, 229, 235-239\] Several of these publications were individual case reports, although there was also one randomised trial comparing fibrin glue (20 patients) with a Martius graft (20 patients) in obstetric fistula patients.\[124\] All of the case reports described successful repair (1/1 = 100% cure); the RCT reported 13/20 = 65% cure; the overall success rate therefore for the 53 reported patients was 77.4% (confidence interval 7.3%). (See Table 8).

In one case successful closure of a radiation induced fistula was reported from the combined use of bovine collagen and fibrin glue.\[229\] Overall, the indications for, and optimal patient selection for this approach are not defined.

6. ENDOSCOPIC REPAIR

Mackay described a technique for transurethral endoscopic suture repair of vesico-vaginal fistula in 1997.\[240\]; there have been three further papers using a similar technique on between one and four patients (total 10 cases).\[202, 240-242\] Although in three of these series the reported cure rate was 100%, overall, fistula closure was found in 80% (confidence interval 24%).

c) Adjuvant Techniques in the Repair of VVF: Tissue Interposition

Tissue flaps are often added as an additional layer of repair during VVF surgery.\[243-247\] Most commonly, such flaps are utilized in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischemic or obstetrical fistula, large fistula, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high level evidence for the use of such flaps in any of these situations. Furthermore, there is no high level evidence that the use of such flaps improves outcomes in the setting of an uncomplicated VVF.

For those VVF repaired transvaginally, a labial fat pad (Martius flap) or a peritoneal flap can easily be mobilized. From a transabdominal approach, greater omentum can be used as an interposition flap.

A variety of other flaps including gracilis muscle flaps, labial myocutaneous flaps, seromuscular-intestinal flaps, and rectus abdominis flaps as well as free grafts of bladder mucosa have been utilized as adjunctive measures in the repair of complex VVF. \[248-255\]

3. POST-OPERATIVE MANAGEMENT.

a) Catheter type

No studies were identified comparing different catheter types or duration of drainage following fistula repair. Most reports do not describe their catheterisation practices in any detail; in those that do, the majority have employed urethral catheterisation, with a small number preferring suprapubic drainage or a combination of both. The reason for catheterisation is to ensure free urine drainage until such time as the repair is soundly healed; for this reason some have advocated both suprapubic and urethral drainage, arguing that whilst one catheter might easily become blocked, two are unlikely to do so simultaneously.\[17\]

b) Duration

There appears to be no obvious consensus over the duration of catheterisation recommended following fistula repair of various types and aetiologies. In a retrospective study of obstetric fistula patients in Ethiopia, approximately equal numbers of patients were catheterised for 10, 12 or 14 days. Patients were not randomised, and there were differences between the groups in terms of the extent of urethral involvement, fistula size, and degree of vaginal scarring, with the more extensively damaged patients being catheterised for longer. Despite this, there was no significant difference in outcome in terms of the rate of repair breakdown, and the authors therefore suggested that postoperative catheterisation for 10 days may be sufficient in the management of less complicated obstetric vesico-vaginal fistulae.\[256\]

In a recent review of practices amongst obstetric fistula surgeons, Arrowsmith reported a considerable range of practice. For ‘simple’ fistulae, the average duration of bladder drainage used was 12 days (range 5-21 days); for ‘large’ fistulae the average was 17 days (range 0-30 days); and for ‘difficult’ fistulae, the average was 21 days (range 14-42 days).[179]

Studies of non-obstetric fistula management are no more consistent in their description of duration of catheterisation. Most report periods of between seven and 21 days drainage; most typically 10-14 days for surgical fistulae and 14-21 days for radiotherapy-associated fistulae. There is no more than level 3/4 evidence to support any particular practice in these aspects of fistula management.

The summary of the surgical management of VVF can be found in Figure 5-7.

**Conclusions & recommendations**

Figure 7. Algorithm for iatrogenic vesicovaginal fistula
4. MANAGEMENT OF RADIATION FISTULA

The literature relating to the management of radiotherapy-associated fistula is again limited in quantity and quality. Forty-nine papers of possible relevance were identified, of which only 35 contained any relevant material. Seven systematic reviews were identified, although none contained information of direct relevance. No randomised trials and only four non-randomised cohort studies of relevance were identified. All other identified material comprised case series or individual case reports or procedure descriptions, and represent level 3 or 4-evidence.

Injury to the gastrointestinal or urinary tracts may arise following therapeutic radiation, with the incidence of complications increasing when the dose exceeds 50 Gy. The obliterator endarteritis associated with ionizing radiation in therapeutic dosages may proceed over many years and may result in fistula formation long after the primary malignancy has been treated. [17, 58] The associated devascularisation in the adjacent tissues means that conventional surgical repair has a high likelihood of failure, and may also result in re-presentation with several fistulae over a period of many years. In those cases where abdominal repair surgery or urinary diversions are undertaken, a high risk of GI anastomotic leak and progressive sepsis has been reported perhaps related either to inadequate resection of irradiated bowel or to damage to other organs at operation.[59] All these factors often make the management of post-radiation fistulae more challenging than that of post-surgical or even obstetric fistulae. Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer.[203, 257, 258] Spontaneous healing seems rarely if ever to occur,[17, 40] and only one case report was identified, of a radiation fistula presenting 22 years after initial treatment, in which healing occurred following cauterisation (for biopsy) and prolonged catheter drainage.[259]

a) Diversions procedures

Because of the wide field abnormality surrounding many radiotherapy-associated fistulae, several authors have suggested that urinary and/or faecal diversion should be seen as the treatment of choice in such cases.[39, 62, 63, 203] Others have employed a routine policy of preliminary urinary and faecal diversion, with later undiversion in selected cases.[260] In a non-randomised cohort of recto-urethral fistula repairs, Vanni et al. reported 100% closure at first operation in 35 non-irradiated cases, compared to 84% in 39 irradiated cases.[260] Additionally, 97% of the non-irradiated cases subsequently underwent ‘undiversion’, whereas 31% of the irradiated cases required permanent faecal diversion due to a non-compliant rectum or severe sphincter dysfunction.[260]

Some authors have emphasised the place of repair in carefully selected cases of radiotherapy-associated fistulae.[17] Of 36 radiation/malignant fistulae in the series reported by Hilton, although 11 declined surgery or died before treatment, and 6 underwent primary diversion, of the 19 (53%) who underwent repair, 18 (95%) were closed at first operation.[17] Finally, some seem to take the view that diversion has little or no place in the management of radiation-induced vesicovaginal fistula in particular.[57] Of 216 radiation-induced fistula managed over a 47 year period by Pushkar et al., 210 underwent a vaginal and 6 an abdominal repair procedure (although it should be noted that this is a retrospective case series, and whilst not stated in the paper, it is possible that other patients not included in this review actually underwent diversion).[57] It should be noted, however, that with this almost exclusive use of the vaginal repair procedure, whilst a cumulative closure rate of 80% was eventually achieved after 4 or more operations, only 48% were closed after first repair, 40% were closed following a second operation, 52% following a third operation, and 35% following a fourth operation.

In view of the anastomotic problems associated with radiation-induced fistula, the transverse colon has often been favoured over ileum as a conduit in this context, to avoid the risk of employing irradiated bowel and distal ureter.[261-263] Whilst these benefits seem clear, it should be noted that high perioperative morbidity (37%) and re-operation rates (20%) have been reported from this procedure.[262]

As an alternative to the latter operation, where both urinary and faecal diversion are proposed, Hampson et al. described the technique of left colic urinary diversion with distal transverse end colostomy.[264] This technique allows a shorter operation time, and avoids the necessity for an intestinal anastomosis. In patients wishing to remain sexually active following such procedures, the residual bladder or rectal wall may be used to augment the vagina.[265] Where vesicovaginal fistula co-exists with significant bladder contracture following surgery or radiation, an abdominal (transperitoneal) repair might be considered, along with simultaneous ileocystoplasty.[266, 267] or colocystoplasty.[268] Fistula repair concurrently with vaginal reconstruction using sigmoidovaginoplasty has also been described by Verbaeys et al. [269] Whilst one might anticipate a very high operative and postoperative morbidity from such complex multiple procedures, the outcome in the very small numbers reported appears to have been good.

b) Repair techniques

Several different techniques for the vaginal repair of fistulae have been reported, although the methods of ‘flap-splitting’ or dissection and repair in layers (variously attributed to Hayward, Collis & Lawson Tait),[197] and partial colpocleisis,[142] have been the most widely advocated in radiation-associated fistulae. Where patients do not wish to maintain sexual function, complete colpocleisis may be used to good effect.[270] In a non-randomised cohort study, Hilton reported anatomical closure by colpocleisis in 94.7% of radiation-associated cases, compared to 96.1%
from a range of repair procedures in fistulae of surgical aetiology.[17]

The technique of sigmoid exclusion or isolation has been described for the management of radiation-associated colo- or entero-vesical and colo- or entero-vaginal fistulas.[271, 272] Although the results have generally been good, with the avoidance of a permanent urinary or faecal stoma, Levinback et al. reported poorer results than following resection of the affected bowel, largely related to bleeding from the isolated segment, and bacterial infection.[272]

c) Interposition grafts

Several techniques have been described to reinforce fistula repair in different sites depending on the type of repair undertaken. These include the Martius bulbocavernous muscle and labial fat graft, a gracilis muscle or myocutaneous graft, omental pedicle grafts, and peritoneal flaps. Whilst there is no high level evidence to support the use of these techniques, the interposed tissue has been presumed to help by creating an additional layer in the repair, to fill in ‘dead space’ and reduce the risk of haematoma formation beneath the repair, to bring in a new blood supply into the area, and to reduce scarring. For each of these hypotheses, interposition grafts might be considered to have their greatest benefit in the repair of radiation-associated fistulae.

At abdominal repair of vesicovaginal or rectovaginal fistulae, the use of a pedicled omental graft has been widely advocated.[245, 273] The omentum is dissected from the greater curve of the stomach and rotated down into the pelvis on either the right or left gastro-epiploic arteries; this may be used at any transperitoneal procedure, but has its greatest potential advantage in radiation-associated fistulae.

The role of interposition flaps in trans-abdominal repair procedures was reviewed by Evans et al.[247] They reported 37 patients with fistulae of largely surgical aetiology, of whom 12 of 12 treated employing an omental or peritoneal interposition flap were cured, compared to 16 of 25 managed without interposition (64%); this finding was consistent for fistulae of both benign and malignant aetiology. Although their cases were not randomised, and the authors acknowledge that their overall cure rate (75%) was rather lower than many series, nevertheless, they concluded that an interposition flap should be recommended, when a trans-abdominal repair is undertaken, particularly when the repair is performed by a less experienced surgeon.

Although widely employed in the context of obstetric fistula repair in the past, there is no high level evidence to support the use of the Martius graft in this context and there seems to be a general move away from it amongst obstetric fistula surgeons. One small non-randomised cohort study reported benefit in patients with multiple or recurrent fistulae, based on a univariate analysis,[243] another reported no advantage to the experienced obstetric fistula surgeon.[127] In the series of fistulae of all aetiologies from UK reported by Hilton, the fistula closure rate was not significantly different between those procedures where an interposition graft (omentum or labial) was (92.0%) or was not (96.1%) used in the repair (p=0.264; Fisher’s Exact test).[17]

In the situation of vaginal repair of radiation-associated fistula Pushkar et al. strongly advocate the use of the labial fat graft interposed at fistula repair;[57] Hilton advocates its use to fill ‘dead space’ in the lower vagina at complete colpocleisis.[17, 270] (figure 8) With the former technique closure at first operation was 48%,[57] with the latter 95% closure at first operation is described.[17]

Labial skin grafts have also been employed in the repair of radiation-associated fistulae, either as an interposition, or replacement for sloughed or indurated vaginal skin. Labia minora flaps, with the outer surface de-epithelialized,[274] and labia majora flaps,[275, 276] have both been described in this context.

Muscle and myocutaneous grafts have also been employed as interposition in fistula repair. These tend to be very bulky grafts, and are perhaps best used therefore in circumstances of extreme tissue loss. The technique of rectus abdominis flap interposition was described in one series of 10 patients, although none of their cases were radiotherapy related.[277] Viennas et al. reported one case of a radiation-induced vesicovaginal fistula repair by this technique.[252] Gracilis muscle along with selective use of a buccal mucosal overlay graft has been used in recto-urethral fistulae, with 84% cure in radiation-associated cases.[260]

d) Other management approaches

In patients with intractable urinary incontinence from radiation-associated fistula, percutaneous nephrostomy or ureterostomy might be considered.[63] This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteric occlusion might be more appropriate. Several methods have been described, including the insertion of coils,[278] coils with gelatin sponge,[279, 280] clips,[281] nylon plugs with injection of polidocanol,[282] Isobutyl-2-cyanoacrylate,[283] and balloons.[283-286] These were reviewed by Avritscher et al. with success rates ranging from 50% to 100% for the different methods, and with an overall success of 77% in 150 cases from nine papers reviewed.[287]
1. LITERATURE REVIEW

The literature relating to the management of urinary fistula involving the gastro-intestinal tract is limited in quantity and quality. Forty-six papers of possible relevance were identified, of which 39 contained any relevant material. One systematic review was identified, albeit of only indirect relevance, and with no mention of fistula.[117] A single non-systematic review of the management of internal fistulae in Crohn’s disease was identified;[288] this included only a single randomised trial,[289] although this did not include patients with urinary fistulae. No further randomised trials or cohort studies of relevance were identified, either from within the review, or independently. One decision analysis model,[290] 26 case series and 10 individual case reports or procedure descriptions were found, including a total of 852 patients.

2. NON-SURGICAL MANAGEMENT

In the context of colo-vesical fistulae associated with diverticular disease, a surgical approach is most commonly advocated. One non-randomised cohort of 30 patients included six who did not undergo surgery, four of whom remained well for periods of up to 14 years; of the 24 who underwent surgical treatment, five (21%) died in the postoperative period.[291]
Ileo-vesical fistula in Crohn’s disease may be managed with antibiotics, nutritional support, often including total parenteral nutrition, and various combinations of immunomodulatory agents; in a non-systematic review of the management of internal fistulae in Crohn’s disease, Levy & Tremaine describe the drugs that have been reported to close internal fistulas partially or completely including azathioprine, 6-mercaptopurine, mycophenolate mofetil, cyclosporine A, tacrolimus, and infliximab.[288]

One case series of 500 patients with Crohn’s disease included 17 with entero-vesical fistulas; all received sulfasalazine, and most were treated with corticosteroids and antibiotics intermittently, and eight in addition received 6-mercaptopurine. Although it is not clear that their fistulae closed completely, six continued on medical treatment alone for several years.[84]

Present et al. reported a placebo controlled randomised trial of the tumour necrosis factor α (TNFα) neutralising agent infliximab, a murine/human chimeric monoclonal antibody that binds both the soluble subunit and the membrane-bound precursor of TNFα, in patients with externally draining fistulae associated with Crohn’s disease.[289] Adverse events were very common, but complete resolution of all fistulae was achieved in 55%, and 50% reduction in fistulous drainage was achieved in 68% of patients on 5mg infliximab. This latter study did not include intestino-vesical fistulae, although a case of successful use of infliximab in an ileo-vesical fistula has been reported.[169]

3. SURGICAL MANAGEMENT

The most frequently advocated surgical approach to colo-vesical fistula in diverticular disease has been sigmoid resection with primary colorectal anastomosis, and closure of the bladder. Dissection of the fistula track followed by closure of the bladder and bowel, with interposition of omentum, but without resection was described in three patients by Lewis & Abercrombie.[292] This approach should perhaps be reserved for cases with minimal diverticular disease in otherwise healthy bowel, where, were it not for the presence of the fistula, there would be no indication for colonic surgery.

One series of 74 patients described a technique in which only visible or palpable full-thickness defects in the bladder were repaired; otherwise the bladder was not repaired, but simply drained by indwelling catheter for one week following sigmoid colectomy (in diverticular disease) or small bowel resection (in Crohn’s disease).[91] At median 6 month follow-up there was a single recurrence of a colo-cutaneous/vesico-cutaneous fistula, but no recurrence of the colovesical fistulae. Other authors have similarly advocated leaving the bladder unrepaired in patients with Crohn’s ileo-vesical fistulae, to heal by secondary intention with catheter drainage alone.[87, 293]

The main contention in the management of intestino-vesical fistulae has been over the feasibility and role of a one-stage management with resection of the affected bowel segment, primary anastomosis, and closure of the bladder, as compared to a two- or three-stage approach.

The authors of many case series have advocated a one-stage approach in the majority of cases, but have indicated that this should be limited to those patients whose nutritional state is good, and where there is no evidence of severe inflammation, radiation injury, advanced malignancy, intestinal obstruction, major medical problem, or advanced age.[90, 93, 94, 96, 294, 295] More recent series have tended to imply a greater advocacy of the one-stage approach; Garcea et al. in a series of 90 patients with colo-vesical fistula reported primary anastomosis in 61/65=94% of cases where left colon resection was undertaken.[92] Balaguera et al. argue against diverting colostomy or Hartmann’s procedure as being unnecessary, and possibly bringing additional morbidity.[296] Several reports have described a laparoscopic approach to one-stage treatment of colo-vesical fistulae, including a total of 30 patients.[95, 171, 297, 298] The overall conversion rate was seen to be higher for fistulae involving the duodenum, vagina and sigmoid colon, than those involving the bladder (10%), although a low threshold for conversion to open surgery was advocated in one series.[95]

In addition to the above criteria, it is intuitive that the more complex a fistula track, the more relevant a phased approach to treatment becomes. Shackley et al. described a series of 10 patients with highly complex fistulae involving between 3 and 6 separate organs/surfaces.[172] They advocate a three-stage multidisciplinary management package, involving: [1] an acute stage involving proximal defunctioning and distal drainage of both the gastrointestinal and urinary tracts to isolate the fistula, together with the eradication of sepsis; [2] a recovery stage consisting of total parenteral nutrition, organ support, radiological planning of surgical reconstruction and intensive nursing; [3] joint urological and gastrointestinal reconstructive surgery, when the patient was stable, nutritionally replenished, and sepsis was controlled. Whilst the mean time to reconstruction was 5 [1-20] months, the fistulae were treated successfully in all patients, with functional restoration in four, and/or diversion of the gastrointestinal and urological tracts in six.[172]
4. RECOMMENDATIONS

VIII. MANAGEMENT OF URETERIC FISTULA

1. GENERAL PRINCIPLES

The relevant clinical principles are related to prevention, diagnosis, management, and after care. Patients at higher risk of ureteric injury such as those undergoing complicated childbirth, radical or repeated pelvic surgery, or surgery following pelvic radiotherapy require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and also recognize injury promptly when it occurs. Immediate repair of any intraoperative injury should be performed observing the principles of debridement, adequate blood supply and tension free anastomosis with internal drainage using stents. Delayed presentation of upper tract injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvi-calyceal system. Fluid should be sent for creatinine determination to differentiate serous from urinary leak. Repair of such cases should be undertaken by an experienced team and may consist of conservative management with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (<3 months) or delayed (>6 months) surgical repair when required. Surgery should again adhere to the standard principles of tissue repair and safe anastomosis. Functional and anatomical imaging should be used to follow up patients after repair to guard against late deterioration in function of the affected renal unit. These general aspects of care of patients with trauma to the upper tract and subsequent fistula formation are covered in standard textbooks of urology and guideline documents. This review will concentrate on developments in the past six years.

2. EVIDENCE QUALITY

A total of 127 abstracts were screened which were categorised as being not relevant [26], cases reports without useful information [63] and for possible inclusion [38]. After review of full text, 27 were selected for the review and 11 rejected due to duplicate information (n=7) and no relevance (n=4). Four further possible papers were identified from the reference lists of included articles of which two were included in the review. The selected papers [29] included one poor quality randomised trial [302], one poor quality quasi-randomised trial [303], one high-quality population case control study[3], one registry study[76], one systematic review[304], one cost analysis[305], 14 cases series, 8 case reports, and one unstructured review.

3. EVIDENCE SUMMARY

a) Management of Specific Fistula

1. Urinary leak after renal preservation surgery

A large case series identified urinary fistula, defined as urinary drainage from a drain site more than 14 days post-operatively, in 4% [45/1118] of patients undergoing partial nephrectomy. This was associated with larger tumours, higher blood loss, and longer ischemia time, but not the mode of surgery (laparoscopic versus open). The majority resolved without intervention but 30% required ureteric stent insertion or percutaneous drainage. A poor quality quasi-randomised study involving 16 patients with persistent leakage after pelvi-calyceal surgery despite stenting found that use of intranasal desmopressin 40 µg daily resulted in a shorter time to resolution of leak compared to control.

2. Urinary leak after renal transplantation

A case series from Brazil observed a fistula rate of 2.9% [31/1046] presenting at a mean of 28 [1-131] days following transplantation predominantly due to distal ureteric necrosis and with most cases requiring open repair. Fistula occurred more commonly in patients with diabetes and was associated with lower graft survival and two deaths from sepsis. A case se-
ries from China observed fistula development in 3.5% [43/1223] of patients presenting at a mean (range) of 6 [3-20] days following transplantation again primarily due to necrosis of the distal transplanted ureter. [308] Open intervention with re-implantation of the ureter into the bladder or native ureter was required in 34 patients, with one other patient requiring transplant nephrectomy. The occurrence of a fistula did not appear to prejudice graft or patient survival. Initial implantation of the transplant ureter into the native ureter appeared to result in a lower rate of fistula. A further case series from Serbia found a fistula rate following renal transplantation of 2.2% [5/224] and all required open repair.[309]

3. URO-ENTERAL FISTULA FOLLOWING PERCUTANEOUS RENAL SURGERY

Case reports of ureterocolic fistulae occurring after renal cryotherapy, and gunshot trauma all resolved with insertion of ureteric stent.[310, 311] This is in line with previous accounts of this complication following percutaneous nephrolithotomy.[312]

4. URETERO-ARTERIAL FISTULA

A systematic literature review found reports of 139 cases of uretero-arterial fistula published between 1899 and 2008.[304] All patients presented with haematuria with 25% also having other urinary symptoms or back pain. Virtually all cases had a relevant past surgical history particularly pelvic cancer surgery (54%) and arterial surgery with graft insertion (31%), and 61% had a ureteric stent in situ. The great majority affected the iliac segment and pre-operative imaging was not always diagnostic. A total of 18 (13%) patients died as a result of the fistula. Many vascular and urologic interventions were used either alone or in combination. Later cases suggested that endovascular repair of the arterial defect gave the best results with lower mortality. Another, more recent case series of 20 patients also showed a high mortality of 10 – 20% but did not find any difference in outcome between open or endovascular graft insertion techniques.[313]

5. URETEROVAGINAL FISTULA

Ureterovaginal fistula occurring in the early post-operative phase predominantly after hysterectomy is the most frequent presentation to urologists of upper urinary tract fistula. A randomised study involving 3,141 women undergoing open or laparoscopic gynaecological surgery lasting > 30 min found that the incidence of ureteric injury after prophylactic insertion of ureteric stents (1.2 % [19/1583]) was similar to control (1.1% (17/1558)).[302] A previous cost analysis from the United States perspective suggested stenting was only worthwhile if the risk of injury was > 3.2%.[305] If injury does occur, many cases, even those with bilateral injury, can be managed by endoscopic techniques. [314](Figure 9)

Figure 9. Conservative management of bilateral lower ureteric injury. Retrograde ureterogram showing successful cannulation of left ureter by guide wire and successful placement of right ureteric stent.
The use of ureteric stenting in patients with uretero-vaginal fistulae was reported in 11 studies, including 126 patients in total.[315-325] This resulted in closure in 63 cases altogether. Success rates were between 6% and 100%, although the overall closure rate across all series is calculated at 50% ± 18% (see Table 9).

Where retrograde stenting proves impossible, percutaneous nephrostomy and antegrade stenting might be considered if there is some degree of pelvicalyceal dilatation. Ureteroscopy may also be helpful,[320, 324] and a technique for combined antegrade and retrograde ureteroscopic cannulation has been reported.[317] In one report all cases of uretero-vaginal fistula were managed by temporary diversion using a percutaneous nephrostomy followed by delayed repair 4-6 weeks later.[156] and a similar approach was taken in the management of one uretero-uterine fistula.[326]

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. Recent case series suggest that this standard surgery can be performed safely and with reasonable operative times using laparoscopic or robotic techniques if the relevant skills and facilities are available.[327-329] A recent case report has suggested that open repair through the vagina is possible if abdominal access is problematic.[330]

6. **URETERIC FISTULA ASSOCIATED THE TERMINAL PHASE OF PELVIC MALIGNANCY**

Urinary leakage is very distressing for people dying of advanced pelvic malignancy but palliation by open diversion may be associated with a high rate of complications. Recent case series have described the technique of occlusion of the distal ureter with coils or other devices using an antegrade approach combined with chronic urinary diversion using nephrostomy tubes.[331-333] Narayanan et al reported successful management of five patients with two requiring repeat embolization but all achieving good palliation until death without adverse effects.[331] Shindel et al reported on 29 patients with bothersome urinary fistula despite chronic nephrostomy drainage, and poor performance status.[332] In all cases palliation of the urinary leakage was achieved. The majority of patients [23/29] died of their underlying cancer at a mean of 8 months after the procedure. Three patients with benign disease subsequently underwent definitive surgical diversion with the remaining 2 lost to follow up. Coil migration was seen in one patient without serious consequence and there were no other complications specific to the embolization. Kim et al used the technique to temporally palliate five women with ureterovaginal fistula prior to delayed definitive repair.[333]

### IX. MANAGEMENT OF URETHRO-VAGINAL FISTULA

#### 1. INTRODUCTION

Urethrovaginal fistulas are a rather rare complication of some surgical and medical conditions or treatments. Most of the literature consists of small retrospective series or case reports. There are no randomized prospective trials.

#### 2. AETIOLOGY

Excluding obstetric aetiologies, in the developing world, urethrovaginal fistula may occur as a result of obstructed labor with or without associated VVF. In industrialized countries urethrovaginal fistula in adults mostly have an iatrogenic aetiology. (See Table 10)

In feminizing genital reconstructions in children with ambiguous genitalia and surgical repairs of cloacal malformations, urethrovaginal fistula can occur as early or late complications. [334][335, 336][337, 338] Also in transsexual adults undergoing female to male reconstruction, urethrovaginal fistulae have been reported. [339]

In the surgical treatment of stress incontinence in women with bulking agents [340, 341] or synthetic slings several cases of urethrovaginal fistula have been reported.[342-345][119] (see Figure 11) Even conservative treatment of prolapse with pessaries can lead to the formation of fistula, if these pessaries are neglected for an extended period of time, although fistula formation after only 2 weeks of pessary use has been described.[18, 346](see Figure 12).

- Trauma – including inappropriate catheterisation and foreign bodies are obvious causes of fistula. [347-353]
- Urethral diverticula and their surgical repair may also lead to urethrovaginal fistula.[354-356]
- Urethrovaginal fistula have also been described in some Behçet patients with vasculitis and local necrosis of the urethrovaginal septum. [357, 358]
- Irradiation complications can also result in the formation of urethrovaginal fistula.[359]

#### 3. DIAGNOSIS

Clinical vaginal examination is often sufficient to diagnose the presence of an urethrovaginal fistula. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistula. In cases of difficult diagnosis, voiding cystourethrography (VCUG) or ultrasound can be useful. [360] Double balloon urethrogaphy is the classic examination to show urethral diverticulum and urethrovaginal fistula, but 3D MRI or CT scan is becoming utilized more widely. [361-363]

#### 4. SURGICAL REPAIR

Several techniques for urethrovaginal fistula closure have been described. A vaginal approach is mostly used. Surgical correction intends to create a continent urethra that permits volitional, painless, and unobstructed passage of urine. Depending on the size, localisation and aetiology of the fistula and the amount of tissue loss urethral reconstruction techniques may be necessary to restore the urethra and to achieve post-operative continence. [347]

#### a) Vaginal approach

Goodwin described in his series that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, but that an abdominal

approach only leads to a successful closure in 58% of cases. A vaginal approach required less operating time, had less blood loss and a shorter hospitalisation time.[364]

Most authors describe surgical principles that are identical to those of vesicovaginal fistula repair: identifying the fistula, creation of a dissection plane between vaginal wall and urethra, watertight closure of urethral wall, eventual interposition of tissue, and closure of the vaginal wall. Primary closure rates of 53%-95.4% have been described (see Table 11). Pushkar et al. described a series of 71 women, treated for urethrovaginal fistula. 90.1% of fistula were closed at the first vaginal intervention. Additionally 7.4% were closed during a second vaginal intervention. Despite successful closure, stress incontinence developed in 52%. The stress incontinent patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilatation or urethrotomy.[365]

Advancement flaps of vaginal wall can be used to cover the urethral suture line. In some cases more advanced methods are used to close or to protect the urethral closure.

In cases of difficult dissection and visualisation, urethral sectioning has been advocated. [366] This technique is also being used in the repair of complex urethral diverticula.[367] Fistulae that are located in the distal third of the urethra may also be marsupialized without compromising the continence mechanism.[368] Distal urethrovaginal fistula may be entirely without symptoms, and in such cases, repair is not mandated.

Blaivas advocates that vaginal flaps are usually the best option in dealing with urethral reconstruction, next to the possibility of offering anterior or posterior bladder flaps. Options for vaginal repair of fistula include primary closure, peninsula flaps, bilateral labial pedicle flaps, and labial island flaps. Outcomes are optimised by using exacting surgical principles during repair and careful postoperative management by an experienced reconstructive surgeon.[347]

1. Labial and vaginal flaps and neourethra

The simplest flap is a vaginal advancement flap. [369] Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect, but can also be used to create a tubular neo-urethra. [370, 371] The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases a transpubic approach has been used.[372] The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbocavernosus tissue can be incorporated in the pedicled flap and probably offers a better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome stress incontinence would occur postoperatively. [373, 374]

2. Martius flap

While in obstetrical fistula repair, it was not found to have any benefit in a large retrospective study in 440 women, the labial bulbocavernous muscle / fat flap by Martius is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistula where additional bulking with well vascularised tissue is needed. [375] Rangnekar et al. report on 12 patients with urethrovaginal fistula, of whom 8 were treated with a Martius flap and 4 with a conventional repair. Only one out of the 8 had a fistula recurrence, while 3 out of 4 of the conventional repairs broke down; it should be noted however that these cases were not randomised between surgical techniques.[376] Punekar et al. described 15 patients with complex and recurrent fistula, using the skin island flap modification with excellent results.[377] Radopoulos published a small series of 5 recurrent and complex urethrovaginal fistulas that all healed using a Martius flap.[378] The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomized studies.[379, 380] The indications for Martius flap in the repair of all types of fistula remain unclear.

Table 11: Closure rates of urethrovaginal fistula
3. Rectus Muscle Flap

Rectus abdominis muscle flaps have been described by some authors. [381, 382] Transvaginal urethro-vaginal fistula closure was performed followed by a pedicled rectus abdominis muscle flap interposed between the fistula closure and vaginal suture line. The muscle flap was based on the inferior epigastric vessels, and provided additional support to the urethra, bladder neck and bladder base. Urethroraginal fistula repair with the rectus abdominis muscle flap was successful in all cases without recurrence. Of the patients 5 (83%) were continent and able to void to completion at a mean follow-up of 23 months (range 2 to 66).

4. Other Interposition Material

A range of non-traditional interposition flaps and grafts have been reported by several authors. All of the publications only report on small patient numbers without long term outcomes or continence data.

Golomb et al. reported the use of a fascial patch, while adding a rectus fascia sling to a urethrovaginal fistula repair. [383] Omentum is extensively used in abdominal approaches to VVF, but Janez et al. used it during a vaginal approach in 3 patients with good results. [384]

The gracilis muscle can be used as well, although the experience is limited. The graciloplasty was described by Ingelman-Sundberg in 1947 and has been adapted by other surgeons in the treatment of fistula. The number of patients reported is low as is the quality of the evidence. [385-387]

Non-autologous material has been used as well. Lowman et al. described the use of porcine dermis interposition and a synthetic sling in an irradiated patient. Other biodegradable materials have been used, although the quality of available data is low and is insufficient to advocate their use. [388] [389] Non-vascularized tissue grafts should be used with caution in such cases as the aetiology of the initial tissue damage resulting in fistula is often ischemic.

b) Posterior approach

In cases of high fistula with difficult vaginal access, a perineal pararectal approach has been described. Some variations exist in the incisions and dissection planes. The anterior sagittal transrectal approach (ASTRA technique) and the posterior sagittal pararectal approach only have been reported in small observational series. [390, 391] [392-394]

c) Abdominal approach

Female urethral injuries may cause serious morbidity with loss of the entire urethra in some cases. Ahmed et al. reported the results of construction of a neourethra by the flipped anterior bladder-tube technique in five girls aged 3-18 years (mean 8 years). All had pelvic fractures. Three patients came with a suprapubic cystostomy, one was totally incontinent, and another had an urethrovaginal fistula. Three had an associated vaginal injury. All five patients underwent construction of a neourethra using a flipped anterior bladder-wall tube (FAWT) and have been followed for 18-80 months (mean 44 months). All patients were continent in the daytime and three were voiding spontaneously without the need for catheterization. Two were managed by clean intermittent catheterization (CIC), one per urethram and other via a continent abdominal stoma (Mitrofanoff). [395]

A retropubicourethral technique has been described by Koriatim [396] This approach allows a urethrovaginal flap tube to be fashioned to form a continent neourethra. Urodynamic studies showed that the proximal vesical and distal urethral components of the neourethra contribute to sphincteric function. For larger fistula an enwrapping technique has been described as well. [397]

5. Complications

Little information can be found on complications after urethrovaginal fistula repair. A short report on 4 cases by Tehan et al. describes a disappointing experience in the transvaginal repair of these fistulas. These authors advocate a suprapubic bladder flap or bladder tube technique to achieve a functioning urethra. Complications following surgical repair have been fistula recurrence, urethral shortening and retraction, persistent reflux, bladder calculi, and bladder cancer. [398]

6. Follow Up

In most series of urogenital fistula repair, follow-up is of very short duration. Dolan et al. investigated urinary and sexual symptoms and quality of life in a group of 31 women 50 months (median) after successful repair of urogenital fistula using the Bristol Female Lower Urinary Tract Symptom questionnaire. [399] All women had undergone urodynamic investigation prior to their repair surgery, and only36% had normal findings. Almost all women reported one or more symptoms, and for 65%, these caused at least ‘a bit of a problem’, although 87% said that their urinary symptoms had little or no impact on their quality of life. Symptoms were similar in urethrovaginal and vesicovaginal fistulae and were not significantly associated with prior functional abnormality.

7. Recommendations

| Urethrovaginal fistula are preferably treated by a vaginal approach | C |
| A variety of autologous tissue interposition techniques have been described, but their value remains uncertain | C |
| Urethrovaginal fistula repair may be complicated by stress incontinence, urethral stricture and urethral shortening necessitating long-term follow-up | C |

I. INTRODUCTION

1. EVIDENCE ACQUISITION

The unrestricted, fully exploded Medical Subject Heading (MeSH) “interstitial cystitis” (including all related terms as “painful bladder syndrome”, bladder pain syndrome”, or different terms such as “chronic interstitial cystitis”, etc.) were used to thoroughly search the PubMed database (http://www.ncbi.nlm.nih.gov/pubmed) of the United States National Library of Medicine of the National Institutes of Health from the years 2009-2011. Three hundred forty-nine publications in English or with English abstracts were reviewed.

Abstracts if available and titles of the 349 hits were reviewed, focusing on (but not limited to) clinical trials, randomized controlled trials, meta-analyses, scientific guidelines, and core clinical journals. The literature update that achieved was added to the pre-existing database, covering the time period before and during 2008 (generated for the 2008 International Consultation on Incontinence[1]) that was established according to the same protocol.

Rating of the level of evidence and grade of recommendation was performed according to the Oxford Scale. The committee believes that the Oxford system for categorizing levels of evidence is primarily relevant only for the sections on treatment which follow. While the committee’s opinions will be expressed, where applicable, regarding evidence and conclusions for other areas, including diagnosis, aetiology, and pathophysiology, use of the Oxford system in this context is more open to interpretation.

2. DEFINITION

Bladder Pain Syndrome (BPS) is a clinical diagnosis that relies on symptoms of pain in the bladder and or pelvis and other urinary symptoms like urgency and frequency. Based on the evolving consensus that BPS probably is strongly related to other pain syndromes like Irritable Bowel Syndrome, Fibromyalgia and Chronic Fatigue Syndrome, the European Society for the Study of Bladder Pain Syndrome (ESSIC) published a comprehensive paper on definition and diagnosis of BPS.[2]

BPS was defined as chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded. Further documentation and classification of BPS might be performed according to findings at cystoscopy with hydrodistension and morphological findings in bladder biopsies. (see Table 2 in section I.1 ) The presence of other organ symptoms as well as cognitive, behavioural, emotional, and sexual symptoms should be addressed.

This definition has been broadly accepted although actual wording differs somewhat[3]. Because omitting the name “Interstitial Cystitis” might cause serious problems in different health systems by affecting reimbursement and disability determinations, the name Bladder Pain Syndrome/Interstitial Cystitis (BPS/IC) could be used in parallel with BPS for the time being. In this chapter, as in the 2008 Consultation, the term Bladder Pain Syndrome largely replaces the older Interstitial Cystitis term, but the two are essentially interchangeable as there is no accepted definition that clearly delineates the interstitial cystitis syndrome from bladder pain syndrome. The Consultation believes the latter term more appropriately describes the disorder.

Historically, definitions of IC have moved from a severe inflammatory bladder disease to a condition described primarily by symptoms (Table 1)[3].

The International Continence Society [13] (ICS) used the term Painful Bladder Syndrome (PBS) defined as “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology”. ICS reserved the diagnosis Interstitial Cystitis (IC) to patients with “typical cystoscopic and histological features”, without further specifying these. It has however been shown,
Table 1: Historical definitions of interstitial cystitis.

1887 Skene [4]: An inflammation that has destroyed the mucous membrane partly or wholly and extended to the muscular parietes.

1915 Hunner [5]: A peculiar form of bladder ulceration whose diagnosis depends ultimately on its resistance to all ordinary forms of treatment in patients with frequency and bladder symptoms.

1951 Bourque [6]: Patients who suffer chronically from their bladder; and we mean the ones who are distressed, not only periodically but constantly, having to urinate at all moments of the day and of the night suffering pains every time they void.

1978 Messing and Stamey [7]: Nonspecific and highly subjective symptoms of around-the-clock frequency, urgency, and pain somewhat relieved by voiding when associated with glomerulations upon bladder distention under anesthesia.

1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and, glomerulations or Hunner’s ulcer on cystoscopy under anesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc [8].

1997 NIDDK Interstitial Cystitis Database Entry Criteria [9]: Unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable etiologies.

2008 European Society for the Study of Bladder Pain Syndrome (ESSIC)[10]: Chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusuable diseases as the cause of the symptoms must be excluded.

2011 American Urological Association [12]: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks duration, in the absence of infection or other identifiable causes.

that only a fraction of patients believed by experts to have BPS fulfil this definition [14].

In the remainder of this chapter the condition will be referred to as bladder pain syndrome (BPS). Some of the older literature may be discussed using the original terminology in the interests of clarity. Logically “interstitial cystitis” should include some form of demonstrable inflammation in the bladder wall, while “bladder pain syndrome” should include pain in the region of the bladder. The diagnosis of BPS is based on exclusion of other diseases in the bladder, urethra, and other pelvic organs including the musculoskeletal system. As with other diseases without clear objective diagnostic criteria or pathophysiological explanation, countless theories have been put forward without adding much to the delineation or understanding of the disease.

In practice, patients with symptoms of BPS are screened to exclude other relevant diagnoses or confusuable diseases[2], and a focused evaluation is performed at the discretion of the physician or centre. This evaluation might include cystoscopy under local or general anaesthesia, bladder distension with registration of bladder capacity and/or the presence of glomerulations and Hunner’s lesion. Bladder wall biopsies might be obtained and evaluated for inflammation, ulcer, fibrosis, mast cells etc. The evaluation might also include urodynamics with registration of bladder capacity, compliance and bladder stability[15]. One view of the relationship of BPS with OAB is graphically depicted in Figure 1 [16]. The 14% incidence of urodynamic detrusor overactivity in the BPS [17] patients is probably close to what one might expect in the general population if studied urodynamically [18].

In the end, these investigations might prove to be normal and the patients are identified as having BPS as a diagnosis of exclusion. The relevance of urodynamic, cystoscopic and histological findings is limited by a lack of consistency in technique, and it is therefore recommended to use the standardisations described by ESSIC [2].

II. HISTORY/NOMENCLATURE/TAXONOMY

1. HISTORICAL NOTES

Recent historical reviews confirm that interstitial cystitis was recognized as a pathologic entity during the 19th century.[19,20] In his textbook Practical Observations on Strangulated Hernia and Some Diseases of the Urinary Organs, Joseph Parrish, a Philadelphia surgeon, described 3 problematic cases of recurrent, severe lower urinary tract symptoms in which he made repeated attempts to locate a bladder stone, which was the most common source for these symptoms in early 19th century America. [21] As Teichman et al have convincingly argued,
these patients displayed all of the clinical hallmarks of IC including chronic frequency, urgency, dysuria and pelvic pain in the absence of demonstrable pathology.[22] Although he used the term repeatedly in his manuscript, Parrish did not elaborate upon the clinical definition of “tic doloureux,” likely because contemporaneous physicians would have been familiar with the concept. However, Parrish attributed the term Tic doloureux to his mentor, Dr. Phillip Syng Physick, who had applied it to patients with severe lower urinary tract symptoms with no discernible etiology, with the most common etiology during the 19th century being bladder stones.

A review of archival material from the Philadelphia College of Physicians indicates that by 1808 Physick had developed a concept of bladder inflammation, a “bladder ulcer,” that produced lower urinary tract symptoms in the absence of bladder stone.[19] Tic doloureux at its time represented a neurological irritation, most often associated with the trigeminal nerve but applicable to other sensory distributions as well, which produced pain and discomfort in the absence of injury or other specific physical findings. In applying the concept of tic doloureux to bladder sensation Parrish was ascribing the paroxysmal lower urinary tract symptoms occurring in patients to an idiopathic process affecting the nerves of the bladder. This sophisticated concept continues to be a prominent component of modern theories of BPS pathogenesis. Furthermore, Tic doloureux allowed him to formulate a diagnosis for those patients who chronically manifested the symptoms caused by a stone (severe frequency, urgency, dysuria and pelvic pain) but had no stone that could be detected. That is, he considered a neuropathic etiology in the absence of any other tangible causes of bladder pain. Clearly, this experience strongly resonates with the contemporary diagnosis of BPS.

50 years after Parrish’s first publication on the condition, Skene used the term interstitial cystitis to describe an inflammation that has “destroyed the mucous membrane partly or wholly and extended to the muscular parietes”. [4] Early in the 20th century, at a New England Section meeting of the American Urological Association, Guy Hunner reported on 8 women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years.[5,23] He drew attention to the disease, and the red, bleeding areas he described on the bladder wall came to have the pseudonym “Hunner’s ulcer”. As Walsh observed, this has proven to be unfortunate.[24] In the early part of the 20th century,
the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall, he thought they were ulcers. For the next 60 years, urologists would look for ulcers and fail to make the diagnosis in their absence. The disease was thought to be a focal, rather than a pancytisitis.

Hand authored the first comprehensive review about the disease, reporting 223 cases.[25] Many of his epidemiologic findings have held up to this day. His description of the clinical findings bears repeating. “I have frequently observed that what appeared to be a normal mucosa before and during the first bladder distention showed typical interstitial cystitis on subsequent distension”. He notes, “small, discrete, submucosal hemorrhages, showing variations in form...dot-like bleeding points...little or no restriction to bladder capacity.” He portrays three grades of disease, with grade 3 matching the small-capacity, scarred bladder described by Hunner. Sixty-nine percent of patients were grade 1 and only 13% were grade 3. Walsh later coined the term “glomerulations” to describe the petechial hemorrhages that Hand had described.[24] But it was not until Messing and Stamey discussed the “early diagnosis” of IC that attention turned from looking for an ulcer to make the diagnosis to the concepts that 1) symptoms and glomerulations at the time of bladder distention under anesthesia were the disease hallmarks, and 2) the diagnosis was primarily one of exclusion.[7,24] However, this description was not suitable for defining this disease in a manner that would help physicians make the diagnosis and set up research protocols.

The National Institute of Diabetes, Digestive, and Kidney Disorders (NIDDK) held a major meeting in 1987 with researchers and clinicians from around the world[26]. This ultimately resulted in the 1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and, glomerulations or Hunner’s ulcer on cystoscopy under anesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc.[8]

In order to validate the criteria, which were designed not for clinical diagnosis, but rather to ensure that patients enrolled in research trials could be agreed upon to have the disease, a database with broad entry criteria was created. The 1997 NIDDK Interstitial Cystitis Database Entry Criteria: Unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable etiologies[27] Urgency was not defined in the protocol. Participants were given a 10 point scale, and those who scored 2 or higher on self report satisfied the urgency criteria. The protocol was written in 1992, a time when the definition of “urgency” was not a particularly controversial topic.

When a comparison of the NIDDK revised criteria with the database entry criteria was performed, it was apparent that up to 60% of patients clinically believed to have interstitial cystitis by experienced clinicians were being missed when the NIDDK research criteria were used as a definition of the disease. [28] With the demise of the NIDDK criteria as an appropriate clinical definition of the disorder, the last decade became an active one from an international standpoint in terms of wrestling with the issues of nomenclature, taxonomy and diagnosis.[3,29,30]

2. NOMENCLATURE AND TAXONOMY

The literature over the last 170 years has seen numerous changes in description and nomenclature of the disease. The syndrome has variously been referred to as tic doloureux of the bladder, interstitial cystitis, cystitis parenchymatosa, Hunner’s ulcer, panmural ulcerative cystitis, urethral syndrome, and painful bladder syndrome.[4,6,20,22,23,31,32] The term “interstitial cystitis,” which Skene is credited with coining and Hunner for bringing it in to common usage, is a misnomer; in many cases not only is there no interstitial inflammation, but also, histopathologically, there may be no inflammation at all.[33-36] By literally focusing exclusively on the urinary bladder, the term interstitial cystitis furthermore does not do justice to the condition from both the physician’s and the patient’s perspective. The textual exclusiveness ignores the high co-morbidity with various pelvic, extra-pelvic and non-urological symptoms[37] that frequently precede the onset of the bladder condition.[38]

With the formal definition of the term “painful bladder syndrome” by the ICS in 2002, the terminology discussion became an intense international focal point.[13]

• In Kyoto at the ICICJ in March 2003, it was agreed that the term “interstitial cystitis” should be expanded to “interstitial cystitis/chronic pelvic pain syndrome” when pelvic pain is at least of 3 months duration and associated with no obvious treatable condition/pathology[39].

• The European Society for the Study of Interstitial Cystitis (ESSIC) held its first meeting in Copenhagen soon after Kyoto. Nomenclature was discussed, but no decision was reached, as the meeting concentrated on how to evaluate patients for diagnosis[15].

• At the 2003 meeting of the NIDDK titled, “Research Insights into Interstitial Cystitis,” it was concluded that “interstitial cystitis” will inexorably be replaced as a sole name for this syndrome. It will be a gradual process over several years. At the meeting it was referred to as “interstitial cystitis/painful bladder syndrome” in keeping with International Continence Society nomenclature.[40]

• At the 2004 inaugural meeting of the Multinational Interstitial Cystitis Association in Rome, it was
concluded that the syndrome should be referred to as “painful bladder syndrome/interstitial cystitis” or “PBS/IC” to indicate an intellectual and taxonomical hierarchy within the acronym.[40]

• The International Consultation on Incontinence in 2004, cosponsored by the ICS and Societe Internationale d’Urologie in association with the World Health Organization, included the syndrome as a part of its consultation. The chapter in the report was titled, “painful bladder syndrome (including interstitial cystitis),” suggesting that the IC formed an identifiable subset within the broader syndrome. Because such a distinction is difficult to define, within the body of the chapter, co-authored by nine committee members and five consultants from four continents, it was referred to as PBS/ IC (one inclusive entity).[41]

• In June 2006 Abrams and colleagues published an editorial focusing on the nomenclature problem.[42] They noted that: “It is an advantage if the medical term has clear diagnostic features that translate to a known pathophysiologic process so that effective treatment may be given. Unfortunately, the latter is not the case for many of the pain syndromes suffered by patients seen at most pain, gynecological, and urological clinics. For the most part these “diagnoses” describe syndromes that do not have recognized standard definitions, yet imply knowledge of a pathophysiologic cause for the symptoms. Unfortunately the terminology used to describe the condition may promote erroneous thinking about treatment on the part of physicians, surgeons and patients. These organ based diagnoses are mysterious, misleading and unhelpful, and can lead to therapies that are misguided or even dangerous.” The editorial went on to note that a single pathologic descriptive term (interstitial cystitis) for a spectrum of symptom combinations ill serves patients. The umbrella term “painful bladder syndrome” was proposed, with a goal to define and investigate subsets of patients who could be clearly identified within the spectrum of PBS. It would fall within the rubric of chronic pelvic pain syndrome. Sufferers would be identified according to the primary organ that appears to be affected on clinical grounds. Pain not associated with an individual organ would be described in terms of the symptoms.

One can see in this the beginnings of a new paradigm that might be expected to change the emphasis of both clinical and basic science research, and that removes the automatic presumption that the end-organ in the name of the disease should necessarily be the sole or primary target of such research.

• At the major biannual IC research conference in the fall of 2006, held by the National Institute of Diabetes, Digestive, and Kidney Disorders (Frontiers in Painful Bladder Syndrome/Interstitial Cystitis), the ESSIC group was given a block of time in which to present their thoughts and conclusions. Because PBS did not fit into the taxonomy of other pelvic pain syndromes such as urethral or vulvar pain syndromes, and because IC is open to different interpretations, ESSIC suggested that Painful Bladder Syndrome be redesignated as Bladder Pain Syndrome (BPS), followed by a type designation. BPS is indicated by two symbols, the first of which corresponds to cystoscopy with hydrodistention findings (1, 2, or 3, indicating increasing grade of severity) and the second to biopsy (A, B, and C, indicating increasing grade of severity of biopsy findings) (Table 2). Although neither cystoscopy with hydrodistention nor bladder biopsy was prescribed as an

essential part of the evaluation, by categorizing pa-
tients as to whether either procedure was done, and
if so, the results, it is possible to follow patients with
similar findings and study each identified cohort to
compare natural history, prognosis, and response
to therapy [2].

- As Baranowski et.al. conceived it in early 2008[43],
  BPS is thus defined as a pain syndrome with a col-
collection of symptoms, the most important of which
is pain perceived to be in the bladder. IC is dis-
tinguished as an end-organ, visceral-neural pain
syndrome, whereas BPS can be considered a pain
syndrome that involves the end-organ (bladder)
and neuro-visceral (myopathic) mechanisms. In
IC, one expects end-organ primary pathology. This
is not necessarily the case in the broader BPS.

A didactically very demonstrative way to conceptu-
alize the dawning shift in conception of the condition
is with the drawing of a target (Figure 2). There may
be many causes of chronic pelvic pain. When an
aetiology cannot be determined, it is characterized
as pelvic pain syndrome. To the extent that it can
be distinguished as urologic, gynecologic, derma-
tologic, and the like, it is further categorized by organ
system. A urologic pain syndrome can sometimes
be further differentiated on the site of perceived
pain. Bladder, prostate, testicular, and epididymal
pain syndromes follow. Finally, types of BPS can
be further defined as IC, or simply categorized by
ESSIC criteria. Patient groups have expressed their
concerns with regard to any nomenclature change
that potentially drops the term “interstitial cystitis”
because the U.S. Social Security Administration
and private insurances recognize IC but not the term
BPS, and benefits potentially could be adversely
affected. Whether the term “interstitial cystitis”, as
difficult as it is to define and as potentially misleading
as it is with regard to aetiology and end-organ
involvement, should be maintained, is a subject of
ongoing controversy.

Taxonomy and nomenclature in Japan, Korea, and
Taiwan use the umbrella term of “frequency/urgency
syndrome” characterized by frequency (frequent
voiding) and urgency (strong desire to void). It is
an inclusive term incorporating overactive bladder
syndrome (OAB), hypersensitive bladder syndrome
(HSB), and other conditions that are associated with
frequency and urgency. Urgency in OAB is char-
acterized by sudden onset and/or fear of leakage,
while urgency in HSB is of a persistent nature and is
associated with the fear of pain. OAB-wet is a sub-
group of OAB. Painful bladder syndrome (PBS) is a
subgroup of HSB with pain. Interstitial cystitis is one
of the diseases manifest by frequency/urgency and
overlaps with HSB and PBS.[11,44,45] (Figure 3).

The American Urological Association refers to the
syndrome under consideration as “interstitial cysti-
tis/bladder pain syndrome” (IC/BPS) and considers
the terms synonymous [12].

The International Association for the Study of Pain
(IASP) has dropped the terms interstitial cystitis,
painful bladder syndrome, and PBS/IC or BPS/IC
and now recognizes the term “bladder pain syn-
drome” as the occurrence of persistent or recur-
rent pain perceived in the urinary bladder region
accompanied by at least one other symptom, such
as pain worsening with bladder filling and day-time
and/or night-time urinary frequency. www.iasp-pain.
org The reader is referred to the IASP website for
an in depth discussion of pain taxonomy. This work
was spearheaded by Dr. Andrew Baranowski and
the Pain of Urogenital Origin (PUGO) group that is
associated with IASP and contributed to advance-
ment of nomenclature and taxonomy over the last
5 years [42].

The Consultation will continue to refer to the symp-
tom complex as “bladder pain syndrome”.

III. EPIDEMIOLOGY

Since the clinical diagnosis of BPS remains con-
troversial, epidemiology studies of BPS have been
problematic [46]. The lack of an accepted definition, the absence of a validated diagnostic marker, and questions regarding etiology and pathophysiology make much of the literature difficult to interpret. Overlapping patterns of bladder pain, lower urinary tract symptoms and pelvic pain are common and present challenges for clinical practice and research [47]. The other major difficulty in evaluating various prevalence trials is that some are based on unverified self report, others by physician diagnoses (with or without some type of verification) or by identification of BPS symptoms (with or without exclusion of other confusable conditions). This confusion becomes apparent when one looks at the variation in prevalence reports in the United States and around the world. These range from 4.5 per 100,000 females in Japan [48], to a questionnaire based study that suggests a figure in 20,000 per 100,000 in US women [49]. Studies, however, have consistently shown that bladder pain symptoms are more common than suggested by coded physician diagnoses [50]. Therefore it is important to realize when examining epidemiological data in BPS, that the prevalence of this enigmatic condition can be estimated from patient self-reports, physician diagnoses and/or symptom based surveys, all of which will give a different figure. A Conceptual diagram of the various manifestations of pelvic pain illustrates the problems in determining prevalence data. (Figure 2)

1. EARLY EPIDEMIOLOGICAL STUDIES:

One of the first population-based studies [51] included “almost all the patients with interstitial cystitis in the city of Helsinki”. This superb, brief report from Finland surveyed all diagnosed cases in a population approaching 1 million. The prevalence of the disease in women was 18.1 per 100,000. The joint prevalence in both sexes was 10.6 cases per 100,000. Ten per cent of cases were in men.

Another early population study, this in the United States, first demonstrated the potential extent of what had been considered a very rare disease [52]. The following population groups were surveyed: 1) random survey of 127 board-certified urologists 2) 64 IC patients selected by the surveyed urologists and divided among the last patient with IC seen, and the last patient with IC diagnosed 3) 904 female patients belonging to the Interstitial Cystitis Association and 4) random phone survey of 119 persons from the US population. This 1987 study reached the following conclusions (interestingly, most of these conclusions have stood the test of time and many further epidemiological studies described later in this section):

1. 43,500 to 90,000 diagnosed cases of IC in the USA (twice the Finnish prevalence)

2. Up to a five-fold increase in IC prevalence if all patients with painful bladder and sterile urine had been given the diagnosis, yielding up to half million possible cases in the USA

3. Median age of onset 40 years

4. Late deterioration in symptoms unusual

5. 50% temporary spontaneous remission rate, mean duration 8 months

6. 10 times higher incidence of childhood bladder problems in IC patients vs controls

7. 2 times the incidence of a history of urinary tract infection vs. controls

8. Lower quality of life than dialysis patients

2. PATIENT SELF REPORT SURVEYS:

As mentioned earlier, the prevalence of BPS can be estimated from patient self-reports, physician diagnoses and/or symptom based surveys. Jones and Nyberg [53] obtained their data from unverified self-report of a previous diagnosis of IC in the 1989 National Household Interview Survey. The survey estimated an overall prevalence of 500 per 100,00 populations (0.5% of the population), or >1,000,000 people in the United States with a self-reported diagnosis of IC. For women this prevalence figure was 865 per 100,000. As part of the third National Health and Nutrition Examination Survey (NHANES III), patients were answered yes to two questions (pain in the bladder/frequent urination and a diagnosis of IC or PBS) and the figures were remarkably similar with an estimated prevalence of 470 per 100,000 (850 per 100,000 women) [54]. These numbers must be viewed with caution because of inaccurate patient recall or confusion with other pain or bladder related conditions. However these patient-reported diagnoses figures certainly suggest that BPS is a common occurrence.

3. PHYSICIAN DIAGNOSES STUDIES

Estimations of prevalence based on physicians’ diagnoses may be thought to produce more accurate estimates, and while they do provide different figures, these are in part based on the local or geographic diagnostic criteria employed. Bade et al [55] used a physician questionnaire-based survey in the Netherlands yielding an overall prevalence of 8-16 per 100,000 females, with diagnosis heavily dependent on pathology and presence of mast cells. The Nurses Health Study I and II [56] showed a prevalence of IC between 52 and 67 per 100,000 in the USA. This report was based on self-reports with validation using data from medical records. The prevalence of a physician based diagnosis of BPS in men and women in a managed care population in the US Northwest[57] was 197 per 100,00 women and 41 per 100,00 men. However these rates decreased to 99 per 100,000 women and 19 per 100,00 men

1589
If the definition of the condition was limited to individuals who had undergone cystoscopy, Nickel, et al [58] performed a prospective practice audit in outpatient urology practice populations of 65 urologists and noted that the prevalence of IC and IC diagnosis in urology outpatient practice, confirmed by both investigation and symptom scoring, was determined to be 2.8%. This of course does not represent in any way the burden of this condition in the general population, but rather reflects the national referral and practice traditions. There are other limitations using physician diagnoses to determine prevalence. Studies that utilize physician diagnoses to define the presence of BPS will likely underestimate the true prevalence, primarily because they do not identify patients with undiagnosed disease or they may not assign a diagnosis when the symptoms are present (reluctance to label a patient with the condition or alternatively are not familiar with diagnosing it).

4. SYMPTOM BASED SURVEYS

Another and possibly more sensitive method to examine prevalence and incidence of BPS is to assess the presence of symptoms that suggest BPS. A follow-up study utilizing the Nurses’ Health Study (NHS) cohort [59] used a mailed questionnaire followed by a detailed supplementary questionnaire if the participant responded “yes” to a bladder or pelvic pain question. They observed that the prevalence of PBS symptoms was 1.7% in women younger than 65 years and increased progressively to 4.0% in women aged 80 years or older. This study suggested that the prevalence of BPS increases with age. Warren, et al [60] combined a mail-in survey with randomly selected telephone surveys to determine the prevalence of BPS amongst first degree relatives in comparison to that of the general population. They concluded that adult female first degree relatives of patients with BPS may have a prevalence of BPS 17 times that found in the general population. This suggests but does not prove a genetic susceptibility to BPS. The Boston Area Community Health (BACH) 0Survey [61], a population based cross-sectional survey of individuals in the Boston area which included an in person interview, determined the prevalence of painful bladder symptoms to be 0.83% to 2.71% in women and 0.25% to 1.22% in men depending of the definition used.

The O’Leary Sant (OLS) and the Pelvic Pain and Urgency/Frequency (PUF) questionnaires were compared by Rosenberg and Hazard [62] in the same general practice population of 1218 patients. The prevalence of BPS with the OLS was determined to be 0.57%, with the PUF the prevalence was determined to be 12.6%. Leppilahti and colleagues [63,64] estimated the prevalence of BPS in the general Population of Finland using a rather robust definition based on the OLS to be 0.68%. However, when a sample of those women was examined by one of the urologists, the more accurate prevalence was 0.3%.

Clemens et al employed [65] 3 different definitions of BPS related symptoms. The first included only self reported pelvic pain with voiding symptoms. The second included increasing pain with bladder filling and relief with urination. The third included a score of 12 or more on the OLS, including 2 episodes of nocturia and a pain score of 2 or greater. The prevalence estimates based on these definitions were 11,200 per 100,000 women and 6,200 per 100,000 men for definition 1; 3,300 per 100,000 women and 1,400 per 100,00 men for definition 2; and 6,200 per 100,000 women and 2,300 per 100,00 men for definition 3. Using a similar methodology, [66] concluded that the prevalence of BPS-like symptoms in South Korean women appear to be lower than in Europe [67] and the United States, similar to Japan and higher than in China [68]. It is conceivable that the acknowledgement by individual patients of these specific IC/BPS symptoms may be influence by cultural differences.

The most comprehensive and probably most accurate estimation of the prevalence of BPS symptoms involved population based symptom prevalence estimate using 2 validated case definitions to identify bladder pain syndrome/interstitial cystitis in 131,691 adult females [69]. Based on a high sensitivity definition, 6.5% (6,500 per 100,000) of women met the symptoms criteria, while 2.7% (2,700 per 100,000) of women met the criteria for a high specificity definition. These percentages translated into 3.3 to 7.9 million US women over 18 years of age with symptoms of bladder pain and/or interstitial cystitis. But only 9.7% of these identified women reported being assigned a bladder pain syndrome or interstitial cystitis diagnosis. A further study compared 3,397 women identified in this RAND Interstitial Cystitis Epidemiology (RICE) survey [46]with urinary symptoms consistent with a diagnosis of IC/BPS to 277 women with an actual BPS diagnosis recruited from specialist practices in the USA [70]. The two cohorts showed remarkably similar demographics, symptoms and quality of life measures, confirming that BPS is a very prevalent condition that is very likely under diagnosed and undertreated in the USA.

Conclusion:

Based on these studies, it is impossible to determine an accurate estimation of the prevalence of BPS, but a review of studies done in the US shows that this is a very prevalent medical condition (Figure 4). It is clear that the most inaccurate prevalence figures are derived from patients self-reported recollection, while the prevalence of BPS symptom complexes are more common than those based on physician diagnoses. It is apparent that there has been no standardized method of determining the prevalence of BPS, with wide variation of estimates in the same study employing different definitions or criteria for identifying the condition. Many factors including bias, cultural differences, methodology,
geographic variations in diagnostic criteria and/or possibly real differences in different populations lead to further variations between countries.

**Recommendation:**

A reasonable prevalence estimation for patients diagnosed with BPS would be about 100-200 per 100,000 women with a male prevalence of 10% to 20% of the female estimate. The prevalence of women and men with symptoms suggestive of BPS could be as much as 10 to even a 100 times more. *(Figure 4)* Level of Evidence: 1 Grade of Recommendation: A

### 5. INCIDENCE:

Only a few estimates of incidence have been reported. The annual incidence of new female cases in Oravisto et al, 1975 study[51] was 1.2 per 100,000. The overall age- and sex-adjusted incidence rate of physician assigned diagnoses of BPS in Olmstead county [73] was 1.1 per 100,00 per year (1.6 per 100,00 per year for women and 0.6 per 100,000 for men. Another review of physicians’ diagnoses identified a much higher yearly incidence of 21 per 100,000 women and 4 per 100,000 men [57]. A physician-coded diagnosis supplemented with chart review of the Kaiser Permanente database [74] suggested a BPS incidence rate of 15 per 100,000 women per year. The mean average age of patients was 51 years. With such a wide variation between two similar studies in the same country, it is evident that we really do not have an accurate estimation of BPS incidence.

**Recommendation:**

The available data suggests that the incidence of BPS diagnoses is somewhere between 1 and 15 per 100,000 per year. This does not include the women who have developed symptoms but have not been diagnosed with the condition.

Level of Evidence: 1 Grade of Recommendation: A

### 6. OTHER CONSIDERATIONS

**a) Children**

Geist and Antolak [75] reviewed and added to reports of disease occurring in childhood. A childhood presentation of BPS is extremely rare and must be differentiated from the much more common and benign-behaving condition variously called the urinary frequency syndrome of childhood or dysfunctional elimination syndrome, a self-limited condition of unknown etiology. Nevertheless, there is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of BPS. In Close and colleagues’ review [76] of 20 such children, the median age of onset was younger than 5 years, and the vast majority of patients had long-term remissions with bladder distention. Rakow et al [77] assessed 28 women aged 13 to 25 with chronic pelvic pain syndrome and confirmed that 39% had a diagnosis of IC while a further 25% had both IC and endometriosis. The relationship between dysfunctional voiding and bowel symptoms in early life was suggested in a mail based questionnaire study in 215 BPS patients and 823 controls [78]. Another study examining early childhood events [79] showed that early childhood trauma, in particular sexual trauma was more common in IC/BPS patients than asymptomatic control subjects. While not proven in these studies, it may be possible to link early childhood events to the eventual development of BPS symptoms.

**Recommendation:**

C/BPS should be evaluated in young women with complaining of chronic pelvic pain.

Level of Evidence: 1 Grade of Recommendation: A

Physician diagnoses: [56,57]
Patient self report:[53,54]
Symptom surveys: [50,59,69,71,72]

*Figure 4: Prevelence estimates for BPS/IC in USA*
b) Men
Most studies show a female to male preponderance of 5:1 or greater [41,57,80]. In the absence of a validated marker, it is often difficult to distinguish BPS from the chronic pelvic pain syndrome (nonbacterial prostatitis, prostatodynia) that affects males [81,82], and the percentage of men with BPS may actually be higher [83,84]. Men tend to be diagnosed at an older age and have a higher percentage of Hunner’s lesion in the case series reported.

Recommendation:
The Male to Female ratio of BPS cases is 1:5-10
Level of Evidence: 1 Grade of Recommendation: A

**c) Overlapping Non-bladder syndromes**

Observations have shown that BPS patients are more likely than controls to have syndromes manifesting symptoms beyond the bladder and even the pelvis. In 1997, Clauw, et al [37] reported on the symptom overlap between two cohorts of patients, one with fibromyalgia and one with BPS. In the same year an analysis of a survey by Alagiri, et al [85] of over 6,700 persons who had a physician diagnosis of Interstitial Cystitis reported that individuals with IC were 100 times more likely to have inflammatory bowel disease, and that allergies, irritable bowel syndrome, sensitive skin, and fibromyalgia also have an increased association with IC. The presence of non-bladder syndromes (NBSs) and BPS has further complicated the interpretation of epidemiological studies. Investigators have subsequently compared BPS patients to controls on multiple NBSs. Wu et al. [86] compared 749 cases with BPS them to 1498 randomly selected and matched controls. Significantly more cases had FM, IBS, chronic pelvic pain (CPP), endometriosis, depression, anxiety and vulvodynia. Clemens et al.[87] compared 239 women with ICD-coded BPS to 717 matched controls and showed that cases significantly exceeded controls in myalgias, gastrointestinal symptoms, gynecologic pain, headache, back disorders, depression, and anxiety. Warren et al. [88] demonstrated that significantly more BPS cases than matched controls had 11 antecedent syndromes: FM, CFS, IBS, sicca syndrome, Chronic pelvic pain, migraine, allergies, asthma, depression, panic disorder, and vulvodynia. Nickel et al. [89] found significantly higher prevalence of self-reported FM, CFS, IBS, migraine and tension headaches, vulvodynia, temporomandibular disorder and low back pain in 207 female BPS cases than in 117 controls as well as significantly more with depression and anxiety [90] in a study in several urology practices in 3 continents. A recent review confirmed that fibromyalgia (FM), chronic fatigue syndrome (CFS), and irritable bowel syndrome (IBS) were associated with IC/BPS [91]. The etiological and epidemiological questions that remain unanswered is how are these NBSs associated with BPS, do these NBSs precede or follow IC/BPS and do multiple NBSs increase the risk of BPS. Warren and colleagues [92] have introduced a number of hypotheses, however the studies to validate these have not yet been done.

One other NBS that is sometime neglected or forgotten in these epidemiological associations is the association of BPS with sexual dysfunction. Multiple studies have shown that women with BPS diagnoses or symptoms experience very high levels of sexual dysfunction [93-96].

Recommendation:
Overlapping Non-bladder syndromes are common in patients with a diagnosis of BPS.
Level of Evidence: 1 Grade of Recommendation: A

d) Progression:
The disease onset is generally described as subacute rather than insidious, and full development of the classic symptom complex occurs over a relatively short time. It appears that BPS does progress continuously, but usually reaches its final stage rapidly (within 5 years) [97] and then continues without significant change in symptomatology. Subsequent major deterioration is unusual[51]. The duration of symptoms before diagnosis was 3-5 years in the Finnish study [51] while a very early American study quoted 7-12 years [25]. The Interstitial Cystitis Database Cohort (ICDB) of patients has been carefully studied, and the findings seem to bear out those of other epidemiologic surveys [98]. Patterns of change in symptoms with time suggest regression to the mean and an intervention effect associated with the increased follow-up and care of cohort participants. Although all symptoms fluctuated, there was no evidence of significant long-term change in overall disease severity. The data suggest that BPS is a chronic disease and no current treatments have a significant impact on symptoms over time in the majority of patients. There is some data [89] to suggest that some patients undergo a phenotypic progression over time from a purely organ specific (eg. bladder) condition to a regional pain syndrome (eg. IBS, vulvodynia) to a more generalized pain syndrome (eg. FM, CFS). Long term longitudinal studies examining progression issues in BPS are lacking.

Recommendation:
Epidemiological data required to describe progression patterns of BPS is lacking.
Level of Evidence: 1 Grade of Recommendation: A

**IV. ETIOLOGY**

The etiology of BPS is still an enigma. Quite often hypotheses abound with sparse evidence to support...
them and some quickly are found to be untrue. For example disturbed nitric oxide metabolism has been proposed to contribute to BPS, but later controlled studies using L-arginine therapy did not show therapeutic effect and failed to support the hypothesis. It is highly possible that BPS is induced by a variety of causes. Symptoms of urinary frequency and bladder pain are likely the final common presentation of bladder injury resulting from single or a combination of etiologies.

1. MAST CELL ACTIVATION

Mast cells are thought to have a role in the etiology and/or pathogenesis of BPS. They are multifunctional immune cells that contain highly potent inflammatory mediators such as histamine, leukotrienes, serotonin, and cytokines.[99] These cells are the repositories of many potent inflammatory factors. Many of the symptoms and findings in ulcerative BPS such as pain, frequency, oedema, fibrosis, and the production of new vessels in the lamina propria, could possibly be ascribed to the release of mast cell-derived factors. Hence, the mast cell-IgE system and its interaction with other inflammatory cells and the nervous system[100] seems to be of importance when it comes to pathogenesis. There is a ten-fold increase in mast cell count in bladder tissue from patients with ulcerative BPS as compared to controls. In non-ulcer BPS, however, the mast cell count is normal or only slightly increased.[99,101,102]

Other mechanisms have also been put forward. Bouche-louche[103] compared the urinary excretion of leukotrienes E4 and eosinophil protein X in patients in BPS and noted detrusor mastocytosis and both increased urinary leukotrienes E4 and eosinophil protein X.

Level of Evidence: 1 - Grade of Recommendation: A

2. INCREASED PERMEABILITY OF THE UROTHELIUM DUE TO UROTHELIAL DYSFUNCTION/GAG-LAYER DEFECTS

The bladder urothelium plays a key barrier to keep low and high molecular weight solutes in the urine from leaking into bladder interstitium. The barrier includes a dense layer of glycosaminoglycans on the luminal surface and intercellular junctions. Intracellular junctions consist of tight junction, adherence junction, desmosome and gap junction in the order of location from the luminal layer to the basal layer. Studies have shown impaired function of intercellular junctions of bladder urothelium of BPS patients. Zhang et al demonstrated significantly increased paracellular permeability, decreased expression of the tight junction proteins ZO-1 and occludin, and increased expression of the adhesion protein E-cadherin from patients with BPS.[104] Shie et al further showed that in the urothelium of the BPS bladder a reduced E-cadherin expression was associated with a higher level of apoptosis.[105] A defect in the glycosaminoglycan (GAG) layer has been proposed by Parsons and co-workers.[106] With such a defect the sub-mucosal nerve filaments might become accessible to noxious substances in the urine and this might explain bladder pain and urinary frequency. In ulcerative BPS there is granulation tissue indicating a reparative process following repeated disruption of the mucosa.[107] Widened tight junctions and increased permeability have been demonstrated by scanning electron microscopy and other techniques.[108,109]

A study by Parsons et al[110] has shown that Tamm-Horsfall protein is quantitatively different in BPS patients as compared to controls. Tamm-Horsfall protein is synthesized in the kidney and excreted into the urine. It has been suggested to have a role in immune defense and in preventing damage to the urothelial cells by injurious urinary constituents.

Level of Evidence: 2 - Grade of Recommendation: B

3. INHIBITION OF UROTHELIAL BLADDER CELL PROLIFERATION

One explanation of the bladder epithelial dysfunction might be the fact that the cells produce an inhibitor of heparin-binding epidermal growth factor-like growth factor in BPS.[111] It was shown that explanted urothelial cells from BPS patients differ from controls not only as to production of epithelial growth factors but also in the rate of proliferation and the production of an antiproliferative factor (APF). Keay and co-workers[112] studied gene expression patterns in normal bladder urothelial cells treated with APF and with mock APF as compared to patterns expressed by BPS urothelial cells. The results indicate that the mechanism of APF inhibition of urothelial cells may involve both down-regulation of genes that stimulate cell proliferation along with up-regulation of genes that inhibit cell growth. The same group of researchers has indicated that APF seems to be specifically elevated in the urine of patients with BPS but not in normals or patients with confusable diseases. These findings might open up new avenues for identification and development of urine markers for BPS.[113] There has not yet been confirmation of the importance of antiproliferative factor by other laboratories.

Level of Evidence: 2 - Grade of Recommendation: B

4. AUTOIMMUNE MECHANISMS

There are numerous reports on autoantibodies in patients with BPS.[114-117] The precise identity of these of autoantibodies has yet to be determined. Some of the common clinical and histopathological characteristics present in BPS patients show certain similarities with other known autoimmune disturbances. Studies on autoantibodies in BPS have shown that these mainly consist of antinuclear antibodies[116] and these findings are in turn similar to the autoantibody profiles in some systemic diseases like Sjögren syndrome, which is known to be of
autoimmune origin.[118-120] Only a portion of BPS patients have auto-antibodies. It has been proposed that the presence of auto-antibodies in these patients could be a reflection of disease severity.[121]

Vascular immunopathology with immune deposits in the bladder wall was found by Mattila.[122] Further studies also suggest activation of complement. [123] By means of immunophenotyping and flow cytometric analyses of the bladder mucosa and peripheral blood, differences between ulcerative and non-ulcer BPS patients have been demonstrated. In the former group intense T-cell infiltrates and B-cell nodules were seen, compared to far less T-cell infiltrates in non-ulcer BPS.[124] Involvement of the immune system is one feature found in some individuals with BPS, but findings are conflicting and have not been helpful in explaining the etiology. The lack of thorough descriptions of patients in many published studies has made classification and comparison between series impossible.

**Level of Evidence: 2 - Grade of Recommendation: C**

5. INFECTION

No microorganism has ever been revealed as the cause of BPS. Lynnes and coworkers did not find any evidence of recent or remote Gram negative or Gram positive infections in patients with BPS, nor did they find increased urinary IgA and IgG elevation.[125] This makes infection by an untested organism unlikely. Warren et al[126] in a case control study of women with recent onset of BPS symptoms, reported that documented evidence of UTI at symptom onset was found in only a minority of patients. Polymerase chain reaction techniques to amplify bacterial 16S rRNA genes that would be present if there were bacteria in bladder tissue or urine in BPS patients despite negative cultures have been without success.[127] Contrary to what was demonstrated for chronic gastritis, there is no evidence for helicobacter in BPS patients.[128] However, Zhang et al showed that a high prevalence (11 in 27 patients) of nanobacteria (NB) was observed in female BPS patients, and anti-NB treatment effectively improved the symptoms, suggesting that some BPS might be caused by nanobacteria.[129] Nevertheless, the possibility of a microbial contribution to the etiology of BPS remains an open question.

**Level of Evidence: 1 - Grade of Recommendation: C**

6. NEUROBIOLOGY/PELVIC CROSS-TALK

Several authors have described autonomic nerve changes[130-132], but the findings are far from uniform. An increase of sympathetic innervation and activation of purinergic neurotransmission has been reported. The S-100 family of proteins appear in Schwann cells of the peripheral nervous system. [133,134] Decreased levels of S-100 protein in the non-ulcer group as compared to controls has been found[135], which is consistent with a decreased

nerve content in patients with non-ulcer BPS, a finding conflicting with the results of Hohenfellner[131] who used polyclonal antihuman protein gene product 9.5 antibody and found the overall nerve content increased in BPS patients as compared to controls. However, their study did not include subtyping of the disease into ulcerative and non-ulcer type. A distinctive ultrastructural appearance of specimens from patients with non-ulcer BPS prompted Elbadawi and Light to propose neurogenic inflammation as a trigger to a cascade of events taking place in this disease.[136] In this context it should be noted that afferent nerves release transmitters like substance P which could activate immune cells, or vasoactive intestinal polypeptide. These events may constitute a link to the immune cell system and promote a decrease of lymphocyte proliferation.

A prominent increase of tyrosine hydroxylase immunoreactivity in bladder tissue of BPS patients, as compared to controls, has been described.[137] This can presumably be interpreted as a sign of generally increased sympathetic outflow. This lends support to the notion of a neurogenic aetiology and or pathogenesis.

Malykhina and others[138-142] have demonstrated in innovative animal studies that there is a bidirectional neural cross-sensitization of the colon and lower urinary tract. Acute colitis sensitized lumbar-sacral spinal neurons receiving input from the urinary bladder result in spinal neuronal hyperexcitability that may be involved in central cross-organ sensitization of visceral nociception between the colon and urinary bladder. This provides information which not only supports a neurogenic etiology but also may account for the substantial overlap of BPS with other chronic pelvic pain disorders, especially the inflammatory bowel disorders.[85] Rudick and Colleagues have shown in a murine model organ cross talk in pelvic pain and modulation of pain responses by visceral inputs distinct from the inflamed site.[143]

**Level of Evidence: 2 - Grade of Recommendation: B**

7. TOXIC AGENTS

There are a few publications which have suggested that toxic substances in the urine may cause injury to the bladder resulting in symptoms consistent with BPS. One published hypothesis is that heat labile, cationic urine components of low molecular weight may exert a cytotoxic effect.[144] Another group of investigators has suggested that defective constituent cytokine production may decrease mucosal defense to toxic agents.[145]

**Level of Evidence: 3 - Grade of Recommendation: D**

8. HYPOXIA

Decreased microvascular density has been reported to be a feature of bladders from some individuals with BPS.[146] One group of investigators
has reported that bladder perfusion decreased with bladder distension in some BPS patients compared to the opposite effect in control subjects.[147] The hypoxic hypothesis is further supported by a report by Lee et al, who found an increased expression of hypoxia-inducible factor-1 (HIF-1) alpha in bladder tissue obtained from BPS patients.[148] However, it is still unknown why the BPS bladders would become hypoxic.

**Level of Evidence: 4 - Grade of Recommendation: D**

9. THE ROLE OF GENETICS IN BPS

Warren et al[149] report findings from a small cohort of twins which demonstrated a greater concordance of BPS among monozygotic that among dizygotic twins. A later study by the same research group[60] suggested that adult female first-degree relatives of patients with BPS may have a prevalence of IC 17 times that found in the general population. This coupled with the previously reported twin data suggests, but does not prove, a genetic component adds to the susceptibility for BPS. Another study on more than 25,000 twins, Altman et al found that in female twins genetic factors contributed less than one-third of the total variation in susceptibility to BPS, suggesting that there could be a genetic susceptibility to BPS, although environmental factors might also be substantial in the development of BPS. [150]

The report by Weissman et al[151] of the increased frequency of BPS in patients and their first degree relatives with panic disorder and other seemingly disparate disorders, has suggested that there is a familial syndrome consisting of BPS and other disorders of possible autonomic or neuromuscular dysfunction. More recent studies by the same group[152] from a case control study, suggested that this syndrome might include other anxiety disorders as well, and that families with and without this collection of symptoms were genetically distinguishable on chromosome 13.

**Level of Evidence: 1 - Grade of Recommendation: B**

10. CONCLUSIONS:

There have been no significant conclusive advances made in understanding either the etiology or pathogenesis of BPS. It is now believed that the etiology of BPS is more complex than has been previously envisioned.[37,85,87,153-155] The consideration of BPS as a part of a generalized somatic disorder should open new pathways to the study of BPS. Investigators should continue to explore central neurological mechanisms of pathogenesis, as well as genetic/familial, immunological and infectious etiologies of this puzzling, complex disorder.

An algorithm that attempts to illustrate an etiologic schema is presented (Figure 5).

**V. PATHOLOGY**

One can have pathology consistent with the diagnosis of BPS, but there is no histology pathognomonic of this syndrome. The role of histopathology in the diagnosis of BPS is primarily one of excluding other possible diagnoses. One must rule out carcinoma and carcinoma-in-situ, eosinophilic cystitis, tuberculous cystitis, as well as any other entities with a specific tissue diagnosis[107,156,157].

**Level of Evidence: 1 Grade of Recommendation: A**

While earlier reports described a chronic, edematous pancytis with mast cell infiltration, submucosal ulcerations and involvement of the bladder wall and chronic lymphocytic infiltrate[158,159], these were cases culled from patients with severe disease and not representative of the majority of cases currently diagnosed. The pathologic findings in BPS are not consistent. There has been a great variation in the reported histologic appearance of biopsies from BPS patients, and even variation among biopsies taken from the same patients over time[26].

Lepinard and colleagues[160] reported a pancytis affecting the 3 layers of bladder wall. In nonulcerative disease the vesical wall was never normal, epithelium being thinned and muscle being affected. Johansson and Fall[107] looked at 64 patients with ulcerative disease and 44 with nonulcerative IC. The former group had mucosal ulceration and hemorrhage, granulation tissue, intense inflammatory infiltrate, elevated mast cell counts and perineural infiltrates. The nonulcer group, despite the same severe symptoms, had a relatively unaltered mucosa with a sparse inflammatory response, the main feature being multiple, small, mucosal ruptures and suburothelial hemorrhages that were noted in a high proportion of patients. As these specimens were almost all taken immediately after hydrodistention, how much of the admittedly minimal findings in the nonulcer group were purely iatrogenic is a matter of speculation.

One can see completely normal biopsies in the nonulcerative BPS group[161]. Transition from nonulcerative to ulcerative BPS is a rare event[101], and pathologically the two types of IC may be completely separate entities. While mast cells are more commonly seen in the detrusor in ulcerative BPS[162], they are also common in patients with idiopathic bladder instability[163]. Mastocytosis in BPS is best documented by tryptase immunocytochemical staining[164]. Larsen and colleagues recommend taking biopsies from the detrusor of patients with suspected BPS and examining them with tryptase-stained 3 micron thick sections, with every seventh section used for quantification. They consider 27 mast cells/mm² indicative of mastocytosis.[165]

Despite attempts to develop a diagnostic algorithm based on the detrusor to mucosa mast cell ratio and

nerve fiber proliferation[100], mast cell counts per se have no place in the differential diagnosis of this clinical syndrome.

Mast cells could be valuable in clinical phenotyping, but as yet that is unproven. Mast cells trigger inflammation that is associated with local pain, but the mechanisms mediating pain are unclear. In a murine model of neurogenic cystitis, Rudick and colleagues[166] demonstrated that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and tumor necrosis factor respectively. Therefore, pain is independent of pathology and inflammation, and histamine receptors may represent direct therapeutic targets for the pain of BPS and other chronic pain conditions.

Lynes and coworkers[35] concluded that biopsy specimens are often not helpful in confirming the diagnosis. Although BPS patients in his study had a higher incidence and degree of denuded epithelium, ulceration, and submucosal inflammation, none of these findings was pathognomonic. In addition, these “typical” findings occurred only in BPS patients with pyuria or small bladder capacity. Epithelial and basement membrane thickness, submucosal edema, vascular ectasia, fibrosis, and detrusor muscle inflammation and fibrosis were not significantly different in the BPS and control patients.

Attempts to definitively diagnose BPS by electron microscopy have also been unsuccessful. Collan’s group[167], in the first such study, wrote that the similarity of the ultrastructure of epithelial cells in controls and IC patients makes it improbable that the disease process originates in the epithelium. Other investigators found no differences in the morphologic appearances of the glycocalyx and of urothelial cells in patients with IC when compared with controls[168]. Anderstrom and colleagues[109] saw no surface characteristics specific for IC, but believed that the mucin layer covering the urothelial cells seemed reduced in IC compared with controls, a fact disputed by Nickel in a very elegant paper[169]. Elbadawi and Light[136] observed ultrastructural changes sufficiently distinctive to be diagnostic in specimens submitted for pathologic confirmation of nonulcerative interstitial cystitis. Marked edema of various tissue elements and cells appeared to be a common denominator of many observed changes. The wide-ranging discussion of the etiology of IC in his paper is fascinating, but the pathological findings are potentially marred by the methodology, in that specimens were obtained after diagnostic hydrodistention[170].

So what is the place of pathologic examination of tissue in BPS? Attempts to classify the painful bladder by the pathoanatomical criteria described by Holm-Bentzen[171] are of questionable value. There is a group of patients with what she describes as “nonobstructive detrusor myopathy”[172]. In her series, these patients with degenerative changes in the detrusor muscle often had residual urine, a history of urinary retention, and an absence of sensory urgency on cystometry with bladder capacities over 400cc. Most would not be clinically confused with BPS. A similar English series[173], however, included patients who met NIDDK research criteria and associated detrusor myopathy with diminished detrusor compliance and ultimate bladder contracture.

The Interstitial Cystitis Database (ICDB) study worked backwards from symptoms to pathology, and concluded that certain symptoms are predictive of specific pathologic findings[33,174]. Denson et al.[36] analyzed forceps biopsies from 65 females and 4 males with BPS. Ten per cent of specimens showed vasodilatation or submucosal edema. Inflammation was absent in 30% of patients, and mild in another 41%. Cystoscopic changes did not correlate with degree of inflammation. Hanus and colleagues[175] studied 84 biopsies from 112 BPS patients and reported a linear relationship between the mean bladder capacity under anesthesia and severity of glomerulations. They did not find a correlation between severity of symptoms and histopathological changes observed by light or electron microscopy.

Richter and the Danish group showed studied 349 consecutive BPS patients and concluded that nocturia, detrusor mastocytosis, and detrusor intrafascicular fibrosis are associated with multiple treatments and presumed failure of standard urological therapy while bladder capacity and glomerulations are not.[176] In a Belgian study, cystoscopic parameters (glomerulations, bleeding, mucosal tears, bladder capacity) showed no correlations with the histological features of bladder biopsies. No correlations were found between inflammatory infiltrate and detrusor mastocytosis. In fact, detrusor mastocytosis was more elevated in biopsies with normal urinary epithelium than in those with damaged epithelium. The study concludes that the clinical significance of pathological findings awaits future research findings. [177]

Rosamilia reviewed the pathology literature pertaining to BPS in 2 recent publications and presented her own data[34,41]. She compared forceps biopsies from 35 control and 34 PBS/IC patients, 6 with bladder capacities less than 400cc under anesthesia. Epithelial denudation, submucosal edema, congestion and ectasia and inflammatory infiltrate were increased in the BPS group. Submucosal hemorrhage did not differentiate the groups, but denuded epithelium was unique to the BPS group and more common in those with severe disease. The most remarkable finding in her study was that histological parameters were normal and indistinguishable from control subjects in 55% of BPS subjects. Method of biopsy can be important in interpreting findings, as transurethral resection biopsies tend to show mucosal ruptures, submucosal hemorrhage and mild inflammation[107], while
Histology is normal approximately half the time with cold-cup forceps biopsies [34,35,178].

Histopathology plays a supportive diagnostic role at best[179]. Major reconstructive procedures appear to have better outcomes in patients with pathology consistent with Hunner’s lesions.[180] Inflammatory features can be seen in 24% to 76% of patients without a visible Hunner’s lesion.[181] While recent studies suggest that a severely abnormal pathology may be associated with poor prognosis[182,183], this is not necessarily the case [184].

At this point in time, excluding other diseases that are pathologically identifiable is the primary utility of bladder biopsy in this group of patients.[185,186]

VI. DIAGNOSIS

Much work has been put into the attempt to define objective diagnostic criteria based on, among other factors, cystoscopy under local or general anesthesia, bladder distention with registration of bladder capacity and/or possible presence of glomerulations and Hunner’s lesion, bladder wall biopsies evaluated for inflammation, ulcer, fibrosis, mast cells, etc. and urodynamics with registration of bladder capacity, compliance and bladder stability. Results have, however, been frustrating. It is more fruitful to establish a broad clinical diagnosis, mainly on the basis of symptoms and exclusion of other diseases, and then stratify patients by urodynamic, cystoscopic, histological, and other tests on the basis of the significance of these findings for results of treatment and prognosis of disease. Current efforts to phenotype the disorder by the presence or absence of associated syndromes and diseases may also prove useful in the same way.

What follows is based solely on expert opinion.

Level of Evidence: 4 Grade of Recommendation: C

It is hoped that future Consultations will have the data to base such suggestions on a firmer foundation.

1. HISTORY

A general thorough medical history should be taken.

Special emphasis should be given to:

- Previous pelvic operations
- Previous UTI
- Bladder history/urological diseases
- Location of pelvic pain (referred pain) and relation to bladder filling/emptying.
- Characteristics of pain: onset, correlation with other events, description of pain
- Previous pelvic radiation treatment
- Autoimmune diseases

2. PHYSICAL EXAMINATION

A common physical examination should be performed including palpation of the lower abdomen for bladder fullness and tenderness:

- Standing: kyphosis, scars, hernia
- Supine: abduction/adduction of the hips, hyperaesthetic areas

In females physical examination should include a vaginal examination with pain mapping of the vulvar region and vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor. Tenderness might be graded as mild, moderate or severe.

3. PAIN MAPPING

Inspection:

- Vulva
  - exclusion of vulvar/vestibular diseases (vulvitis, dermatosis etc.)
  - evaluation of introital area (endometriosis)
  - tenderness of vestibular glands or vulvar skin (Touch Test: use wet cotton stick or finger tip)

- Vagina
  - tenderness during insertion and opening of speculum
  - cervical pathology
  - vaginal fornices (endometriosis)

- Bimanual physical examination
  - tenderness of urethra, trigone and bladder
  - superficial/deep vaginal tenderness
  - tenderness of pelvic floor muscles (levator, adductor)
  - tenderness in adnexal areas

In males digital rectal examination (DRE) should be performed with pain mapping of the scrotal–anal region and palpation of tenderness of the bladder, prostate, levator and adductor muscles of the pelvic floor and the scrotal content.

4. LABORATORY TESTING

- Urine dipstick (ABS, pH, leucocytes, nitrate), urine culture in all. If sterile pyuria culture for tuberculosis.
- Urine cytology in risk groups.
- Investigations for vaginal Ureaplasma and Chlamydia in females and prostatitis in men are optional.
5. SYMPTOM EVALUATION

- Voiding diary with volume intake and output for 3 days at initial evaluation. Patient sensation at voiding might be recorded (see chapter outcome assessment, Hanno).

- At follow-up only number of voidings during day and night time is necessary. Morning volume might be recorded as a help to monitor highest functional capacity.

- The O’Leary–Sant Symptom Score supplemented should be used as basic symptom score supplemented with the Quality of Life Score from the International Prostate Symptom Score (see chapter symptom scales, Hanno3).

Pain should be recorded using a Visual Analogue Scale (VAS) for pain during the last 24 hours (to fit with the voiding diary). Separate scores for the average, mildest and worst pain should be obtained (see symptom scales)

6. URODYNAMICS

**Level of Evidence:** 4 Grade of Recommendation: C

The NIDDK criteria excluded patients with detrusor overactivity at filling cystometry in order not to confuse the picture in clinical trials.[8] This does not however mean that detrusor overactivity cannot coexist with bladder pain syndrome. In the interstitial cystitis database approximately 14% of BPS patients had overactive bladders[17]. Whether these patients respond better to antimuscarinics than BPS patients with stable bladders has never been systematically investigated. If so, a rationale for routinely employing urodynamics as a part of the evaluation would follow. In males, infravesical obstruction might be a differential diagnosis[187], and it is recommended to do flowmetry in all males and pressure-flow studies in men with a peak flow rate below 20ml/seconds.

There are no data to support the following recommendations:

In females, flowmetry, post void residual urine volume and pressure-flow study are optional. In males, a flowmetry should be done in all, and if maximum flow rate <20 ml/s a pressure-flow study and measure of residual urine volume should be done. It is recommended to perform filling cystometry with a filling rate of 50 ml/s (to comply with the revised Potassium Test - see below) to look for overactivity, volume at first desire to void and cystometric capacity.

7. POTASSIUM TESTING

**Level of Evidence:** 1 Grade of Recommendation: A (not recommended)

Parsons has championed an intravesical potassium chloride challenge, comparing the sensory nerve provocative ability of sodium versus potassium using a 0.4 M potassium chloride solution. The test has proved controversial[188]. Pain and provocation of symptoms constitutes a positive test. Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients, or hypersensitivity of the sensory nerves is unclear. Normal bladder epithelium can never be absolutely tight, and there is always some leak, however small[189]. The concentration of potassium used is 400meq per liter, far exceeding the physiologic urinary concentrations of 20-80meq/liter depending upon dietary intake[190]. Healthy controls can distinguish KCl from sodium chloride, though they don’t experience severe pain[191]. The hope is that this test may stratify patients into those who will respond to certain treatments (perhaps those designed to fortify the glycosaminoglycan layer) [192].

Used as a diagnostic test for bladder pain syndrome, the potassium chloride test is not valid.[193]. The gold standard in defining BPS for research purposes has been the NIDDK criteria. These criteria are recognized to constitute a set of patients that virtually all researchers can agree have BPS, though they are far too restrictive to be used in clinical practice[28]. Thus, this group of patients should virtually all be positive if the KCl test is to have the sensitivity needed to aid in diagnosis. Up to 25% of patients meeting the NIDDK criteria will have a negative KCl test[194]. In the group it should perform the best in, it is lacking in sensitivity. When we look at the specificity side of the equation, in the universe of asymptomatic persons, it performs relatively well and is rarely positive, although a recent study reported a 36% false positive rate in asymptomatic men[195]. It is in the patient population with confounding conditions for which we would want help in sorting out BPS from other disorders. Sixty percent of patients with overactive bladder test positive[196] and virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive[194,197]. The results with chronic prostatitis / chronic pelvic pain syndrome in men are variable, but 50-84% of men have been reported to test positive[195,198,199]. In women with pelvic pain results are similar[200], and based on these findings, Parsons has expressed the view that BPS may affect over 20% of the female population of the United States[201]! Others have reported prevalence in unselected female textile workers in Turkey using similar methods at 32.8%[202]. Another way to interpret the findings would be that the KCl test is very nonspecific, missing a significant number of BPS patients and over-diagnosing much of the population.

Prospective and retrospective studies looking at the KCl test for diagnosis in patients presenting with symptoms of BPS have found no benefit of the test in comparison with standard techniques of diagnosis[193,203,204]. A later modification of the test
using 0.3 molar potassium chloride for potential differentiation between patients with IC and detrusor overactivity (DO) showed that the 0.3 M KCl reduces maximum cystometric capacity in BPS and DO, the effect being more pronounced in DO. Urothelial hyperpermeability was not specific to IC. Comparative cystometry using NS and 0.3 M KCl does not help to differentiate BPS from DO [205,206].

The development of a painless modification of the potassium chloride test[207] using cystometric capacity and a 0.2M solution may improve acceptability among patients. The so-called revised or Comparative Potassium Test has shown prognostic value in bladder irrigation studies[208] but is considered optional by ESSIC. If performed it should be performed according to Daha et al.[207]: A Foley balloon catheter (14F) is inserted and the bladder drained. Instill into the bladder 500 ml saline (0.9%) at a rate of 50 ml/min via an infusion set until the maximum capacity is reached. Drain the bladder and measure the saline filling volume. Repeat the instillation and measurement with 500 ml 0.2 M potassium chloride at a rate of 50 ml/min (taking care that filling lines are emptied of all saline before KCl instillation), and calculate the filling volume difference. A difference in bladder capacity > 30% is considered positive. Besides reduction of bladder capacity with 0.2 M KCl there is a stronger feeling of urgency in IC patients compared to the saline filling, which is also clinically relevant.

8. CYSTOSCOPY AND HYDRODISTENSION

Level of Evidence:2 Grade of Recommendation:B

The classic cystoscopic picture of BPS as an “elusive” bladder ulcer with a corresponding cystoscopic appearance of patches of red mucosa exhibiting small vessels radiating to a central pale scar was described by Hunner in 1915 [5]. (Figures 6, 7 & 8) courtesy of Jorgen Nordling)

After 1978, glomerulations, described as punctuate petechial hemorrhages and observed after hydrodistention, became the primary cystoscopic feature of BPS[7]. (Figures 9 and 10, courtesy of Tomohiro Ueda)

But not all patients with symptoms of BPS have glomerulations[9,28,36,176], and not all patients with glomerulations have symptoms of BPS [196,209-212]. Neither presence nor severity of glomerulations correlate with any of the primary symptoms of BPS [33], although the presence of a Hunner’s lesion is significantly associated with bodily pain and urinary urgency [211]. The finding of a Hunner’s lesion or glomerulations has been somewhat subjective. Some researchers find a Hunner’s lesion in 50% of their BPS patients [213], while others rarely see one [214].

No study comparing individual perceptions and variations in reporting or classifying glomerulations has ever been reported. Bladder capacity during hydrodistention has not drawn much attention, although it is strongly associated with increased urgency [215].

Because considerable variation in the duration of distension, repetition of distension, the pressure used for distension, and the measurement of bladder capacity have been described [216], the ESSIC
has suggested a standardized procedure for cystoscopy and hydrodistension [15]:

A rigid cystoscope is preferred to facilitate taking of adequate biopsies. Glycine or corresponding filling fluid should be used to allow for coagulation after biopsies. Infusion height should be approximately 80 cm above the Symphysis Pubis. (note: some would recommend a pressure of only 60cm to minimize risk of bladder perforation and in the absence of data that a higher pressure is beneficial). A dripping chamber is used and the bladder is filled until fluid dribbling stops. If necessary, a digital block is applied around the urethra to prevent leakage. Pre-distension inspection includes observation for radiating vessels, coagulum or fibrine deposits, white spots, hyperaemia, oedema, cracks, scars or any other mucosal changes. Continuous inspection while filling the bladder is advised. When maximum capacity is reached, the distension is maintained for 3 minutes. The bladder is emptied and the colour of the fluid checked for the degree of bleeding. The total volume drained is the measured maximum bladder capacity. During a second filling, the bladder is filled to approximately 1/3rd to 2/3rd of the bladder capacity to achieve optimal vision for inspection and biopsies. The bladder should not be filled to maximum capacity or distended again to avoid further provocation of changes with doubtful reproducibility.

a) Inspection

Describe lesions in anterior wall, posterior wall, lateral quadrants and fundus. At the fundus one should be alert for possible artefacts if there is blind introduction of the scope. Bladder mapping by drawing is mandatory. Photographs are recommended but optional.

b) Classification

Grade 0 = normal mucosa
Grade I = petechiae in at least two quadrants
Grade II = large submucosal bleeding (ecchymosis)
Grade III = diffuse global mucosal bleeding
Grade IV = mucosal disruption, with or without bleeding/oedema

The importance of the finding of the finding of glomerulations after hydrodistension is however as mentioned been questioned since 45% of asymptomatic females, 20% of males with LUTS suggestive of BOO and 85% of females with OAB and no bladder pain demonstrates typical glomerulations after hydrodistension[196,210,212] and 10-34% of patients with BPS do not [9,176]

c) How useful is hydrodistention?

Hydrodistension results fail to identify any statistically significant differences in post-distention objective findings (anesthetic capacity, glomerulations) or therapeutic benefits when patients are categorized according to presenting symptoms[217]. Cystoscopy with hydrodistention may provide little useful information above and beyond the history and physical examination findings. In one study, 56% of 84 patients reported symptom improvement, but the duration was short lived with a mean of 2 months[218]. It is necessary to distinguish between short term hydrodistension (2-10 min.) for classification of BPS and long term hydrodistension (20-30 min.) for treatment[219]. Many reports on the therapeutic effect of hydrodistension are from Asia and from patient material with IC based on the Asian definition[45], where up to 2/3 of the patients have frequency-urgency and no pain.

Lamale and colleagues examined the relationships between symptoms and cystoscopic findings in 12 women newly diagnosed with BPS who had not previously received treatment. Pain symptoms had consistent positive correlations with the cystoscopic findings. An increase in pain with bladder filling was associated with inflammation (P = 0.011), ulceration, and smaller bladder capacity. Pain relief after voiding correlated with smaller bladder capacity (P = 0.019), hematuria, and total cystoscopic score. Pain
Intensity in the urethra was related to ulceration and hematuria, and pain in the lower abdomen was related to a smaller bladder capacity (P = 0.047), glomerulations, and a larger total cystoscopic score. Daytime frequency correlated negatively with most cystoscopic findings, and nocturnal frequency had a positive relationship with most cystoscopic findings and was significantly associated with a smaller bladder capacity (P = 0.010). Urgency showed no strong associations with any cystoscopic findings. The results of this study contradict those of previous studies that found no relationship between symptom reports and cystoscopic findings suggesting possible effects of treatment on pain perception and therapeutic influence on cystoscopic findings[220].

It is important to keep in mind that the cystoscopic appearance of the bladder wall after hydrodistention may not be constant over time, and the absence of initial findings of glomerulations or terminal hematuria does not preclude further development of these findings of the disease on subsequent evaluation[221]. Rare cases of hydrodistension induced bladder necrosis have been described[222].

9. MORPHOLOGY

Pathological changes in light microscopic and electron microscopic features in patients with BPS have been described including infiltration with inflammatory cells in all or specific parts of the bladder wall. Although these findings are important in our attempt to understand the disease and perhaps as an aid to stratification of patients, there are at this time no pathognomonic findings on biopsy in terms of diagnosis[33]. Expert opinion as per the ESSIC suggests the following procedures when biopsy is planned for BPS evaluation[15]:

a) Biopsies

During cystoscopy the bladder is distended to full capacity. After draining the bladder, bladder biopsies are taken at roughly half full bladder capacity. Biopsy procedures should be performed by using large forceps and include detrusor muscle; alternatively double punch biopsies or resections of lesions can be used.

b) Number of biopsies

At least 3 biopsies from the two lateral walls and bladder dome should be taken in addition to biopsies from visually abnormal areas. The biopsies are to be immediately fixed in neutral buffered 4% formalin.

c) Biopsy handling

Biopsies are treated conventionally. Six adjacent 3 mm sections are cut and placed with 3 specimens on each of two specimen slides. The first slide is stained with H&E, the next with a connective tissue stain suitable for the individual institute. Twenty-four 10 mm sections are then cut and every third section is mounted on a specimen slide for mast cell counting. The specimens are stained by Lederstain (naphtolesterase) according to routine procedures. Finally, a 3mm section is obtained to ensure the presence of detrusor muscle in the specimens.

d) Mast cell counting

The use of a measuring grid (e.g. Leitz periplan 6F 10_N ocular containing a standardized grid) is necessary. Only mast cells containing nucleus are included. When counting the cells those covering or touching the bottom should be excluded whereas those covering the upper and left line are included. At least 3 biopsies must be the subject of mast cell counting and if possible one including a lesional area. Biopsies for mast cell counting should contain detrusor muscle.

e) The pathology report

- Epithelium
  - Not present
  - Present
  - Dysplasia with grading
  - Abnormal but no dysplasia: description is mandatory.

- Propria
  - Normal
  - Inflammation: description with a grading
  - Other findings are described

- Detrusor muscle, Abnormal muscle cells: describe

- Intrafascicular fibrosis
  - Not present
  - Present

- Mast cell count: At least three biopsies should be included in the counting. Only the biopsy with the highest number of mast cells per mm2 should be reported

The enzymatic (naphtolesterase) staining is, for the time being, recommended since standardized values are available:

- less than 20 mast cells/mm2: no detrusor mastocytosis;
- between 20 and 28 grey zone!
- more than 28 mast cells/mm2: detrusor mastocytosis.

Larsen recommends examining the detrusor biopsies with tryptase-stained 3 micron thick sections, with every seventh section used for quantification; 27 mast cells/mm2 is considered indicative of mastocytosis[165].
These guidelines have been reported to be easy to follow. A statistically significant correlation was found between the cystoscopic aspect and inflammatory infiltration, mast cell count in the detrusor muscle and stromal edema. Maximum bladder capacity was negatively correlated with inflammation, detrusor mast cell count, hemorrhages and the overall cystoscopic aspect[223]. Correlations have also been demonstrated between urothelial damage and inflammatory infiltrates and between normal epithelium and detrusor mastocytosis suggesting either 2 different types of BPS or different stadiums in the pathophysiological process of BPS [177]. Also in a large retrospective study of 349 patients with BPS, it was found that treatment intensity ranging from hydrodistension only to major surgery correlated positively to detrusor mast cell count, detrusor fibrosis and nocturia, but not to maximum bladder capacity or glomerulations after hydrodistension [224].

10. BIOMARKERS

The lack of universally accepted clinical diagnostic criteria for BPS affects all aspects of making progress in understanding this disease. Insights into risk factors, pathogenesis, trials for effective therapy, prognosis, and outcome criteria for treatment are all affected by this lack of diagnostic criteria. A major factor affecting the controversy over accepted clinical diagnostic criteria is that the current criteria are predominantly symptom specific. An objective biomarker would advance the establishment of reproducible diagnostic criteria for BPS and also aid in monitoring effects of treatment.

A biomarker for any disease needs to demonstrate high sensitivity and high specificity. In addition, the marker assay needs to be reproducible in many laboratories and should be suitable for use in a clinical diagnostic laboratory.

Many of the published studies on biomarkers for BPS have been on biomarkers isolated from urine. Erickson et.al has published excellent reviews of urine markers for BPS [225,226]. The most thoroughly investigated marker is antiproliferative factor (APF). This factor has been identified and characterized by Dr. Susan Keay and her colleagues at the University of Maryland [227,228]. Control subjects for this study included asymptomatic individuals, patients with bacterial cystitis, and patients with vulvovaginitis. APF is found in urine from the bladder and not from the renal pelvis [229-231]. Treatment of symptomatic BPS by either hydrodistention or neurostimulation normalized the APF levels concurrent with symptom relief [232]. It is not known if other forms of treatment will affect APF levels. Preliminary studies in 58 women with documented BPS demonstrated a sensitivity value of 91.4% and a specificity of 90.6%[233]. A later study with 219 symptomatic BPS patients and 325 controls with and without other urological disorders documented the sensitivity as 94% and the specificity at 95%[234]. APF has been isolated from urine and found to be a frizzled 8 protein-related sialoglycopeptide which interacts with the epithelial cell receptor CKAP4/p63[235,236]. Keay et al have suggested that APF might inhibit cell proliferation by the down-regulation of genes that stimulate cell proliferation along with the upregulation of genes that inhibit cell growth[112]. Cell growth inhibition of human urothelial cells appears to be mediated by p53[237]. APF treatment caused significant increases in the paracellular permeability of normal bladder epithelial cell monolayers and the attenuation of tight junctions compared to mock APF, similar to changes seen in IC cells. APF treatment also decreased expression of the tight junction proteins zonula occuldens-1 and occluding [236].

APF seems an ideal candidate for a biomarker for symptomatic BPS. There need to be additional studies to determine if it can serve as a BPS marker for patients in remission or for those who have not yet become symptomatic. As of 2008, the findings on symptomatic patients have yet to be replicated by laboratories around the world, and the biologic assay has not proven suitable for commercial development as it currently exists. The ultimate fate of APF as an important biomarker and etiologic factor remains to be determined.

GP-51 is a glycoprotein present in both the transitional epithelium and urine of humans and other mammals. Moskowitz et. al have shown that bladder biopsies of BPS patients had decreased staining for GP-51[238] The same laboratory also demonstrated that although GP-51 demonstrates a high specificity for BPS, it is not as sensitive as APF[239].

There have also been many published studies on heparin-binding epidermal growth factor-like growth factor (HB-EGF)[112,230,231,240,241]. HB-EGF is a growth factor found in normal urine. It has been shown that APF inhibits the production of HB-EGF. There have been no large population studies focusing solely on HB-EGF as a biomarker for BPS.

11. CONFUSABLE DISEASES

Criteria for a diagnosis are needed only if the target disease may be confused with other diseases (confusable diseases) because of overlapping features[242]. For a diagnosis, the target disease has to be recognized in a pool of confusable diseases in one of two ways: by recognition of the specific combination of features of the target disease or by exclusion of confusable diseases. For the diagnosis of BPS both methods might be used because:

- Confusable diseases are more common than BPS, so recognition is mandatory because many can be treated.
- Failure to diagnose a confusable disease would automatically incorrectly yield a diagnosis of BPS.
- Patients may have a confusable disease plus BPS.
The diagnosis of BPS can thus be made on the basis of exclusion of confusable diseases and confirmation by the recognition of the presence of the specific combination of symptoms and signs of BPS. If the main urinary symptoms are not explained by a single diagnosis (confusable disease or BPS), the presence of a second diagnosis is possible. Symptoms and signs for use in diagnostic criteria do not need to be specific for the target disease. On the contrary, if a specific symptom or sign existed for the target disease, a diagnosis would only require the presence of the specific feature and diagnostic criteria would not be necessary.

In evidence-based medicine, diagnoses are based on medical history, physical examination, and appropriate clinical investigations to eliminate diseases from a list of differential diagnoses (confusable diseases) and to confirm the final diagnosis. BPS may occur together with confusable diseases such as chronic or remitting urinary infections or endometriosis. Cystoscopy with hydrodistention and biopsies might in this situation document positive signs of BPS thereby making a double diagnosis more probable. For therapeutic studies it makes sense to exclude patients who also have a confusable disease because symptoms and signs may be caused by BPS, the confusable disease, or by both. For prevalence studies of BPS, on the other hand, all cases with BPS should be included, also those with a confusable disease. This approach eliminates the need for separate diagnostic criteria for clinical practice and scientific studies. Table 3 summarizes confusable diseases related to BPS and their mode of exclusion based upon the aforementioned diagnostic proposals and procedures [15,243].

### VII. CLASSIFICATION

Interstitial cystitis was originally described as bladder disease with severe inflammation of the bladder wall described by Hunner as an ulcer[5]. The lesion is however not an ulcer but an inflammatory infiltrate that can crack upon distention, and the name of the bladder lesion has consequently been changed to “Hunner’s lesion[243]”. The finding of a Hunner’s lesion could therefore originally be regarded as a diagnostic criterion for IC. Messing and Stamey introduced glomerulations as another typical finding for IC and this was included in the NIDDK criteria[8]. Magnus Fall proposed, that patients with Hunner’s lesion (classic IC) and patients with glomerulations (non-ulcer type) represented two different subtypes [101] with different clinical pictures, different outcomes, and different responses to treatment [213] meaning that patients fulfilling the NIDDK criteria represents at least two different patient populations. Moreover up to 60% of patients clinically believed to have BPS by experienced clinicians do not fulfill the NIDDK criteria [28] and whether or not these patients are comparable to the patients fulfilling the NIDDK criteria is unknown. Finally Japanese urologists con-

sider that “interstitial cystitis” should be preserved as a disease name for patients with urinary symptoms and cystoscopic findings of glomerulations or Hunner’s lesion as outlined in the NIDDK criteria [45].

In an attempt to unite these different philosophies into a coherent schema, ESSIC proposed a classification of BPS based on findings during cystoscopy with hydrodistension and morphological findings in bladder biopsies [243] (Table 2). The classification includes groups not having had cystoscopy with hydrodistension (group X) as well as groups not having had morphological investigation of bladder biopsies (group XX). By using this classification future research will be able to identify if findings of glomerulations and/or Hunner’s lesion as outlined in the NIDDK criteria [45].

The global response assessment response rate was approximately 57% for adherers in any of the 4 EBMP categories, whereas it was lower for nonadherers. This rate neared statistical significance for diet modification, which demonstrated only a 41% response rate among nonadherers (p = 0.051).

Behavioral therapy should be a cornerstone of treatment for patients with BPS. Women with BPS may have associated pelvic floor dysfunction [247]. Physical therapy for the pelvic floor is said to be effective for genitourinary and anorectal disorders [248]. Biofeedback and soft tissue massage may stimulate the relaxation of the pelvic floor muscles [249, 250]. Lukban et al [251] conducted a direct myofascial release treatment on 16 BPS patients with high-tone pelvic floor dysfunction and sacroiliac dysfunction. The treatment was effective for urinary frequency and suprapubic pain. Fifteen patients (94%) showed improvement in the O’Leary & Sant symptom score. Coital pain relief was observed in 15 of 16 patients, with 9 patients becoming able to resume sexual intercourse [252]. Transvaginal Theile massage was also reported to be effective for 9 of 10 patients of the same group [253]. Mendelowitz et al [250] showed a 69% success rate when treating 16 patients using electromyographic biofeedback. However, it was suggested that a placebo effect may have occurred because the effect did not correlate with the improvement in patient’s awareness of the pelvic floor muscle movement and position before and after the therapy. Weiss [254] reported that 70% of 10 patients with IC showed symptomatic improvement, rating from “effective” to “remarkably effective”.

An NIH study [255] to determine the feasibility of conducting a randomized clinical trial was undertaken to compare 2 methods of manual therapy (myofascial physical therapy and global therapeutic massage) in patients with urological chronic pelvic pain syndromes. The global response assessment response rate was 57% in the myofascial physical therapy group compared

#### 1. BEHAVIORAL MODIFICATION

Behavioral therapy for BPS includes education, timed voiding (scheduled voiding time and interval), controlled fluid intake, pelvic floor muscle training and bladder training (gradually extending voiding interval).

Chaiken et al [244] reported that when they conducted behavioral therapy consisting of frequency-volume chart, timed voiding, controlled fluid intake and pelvic floor muscle training for the treatment of 24 female patients, 50% of the patients showed improvement in the number of urinations and bladder capacity. At the same time, they considered that as the data was collected from 12 weeks’ intensive therapy conducted by skilled therapists for selected patients whose main symptom was urinary frequency, it should not be generalized. Parsons and Koprowski [245] reported that when 21 patients with the main symptom of urinary frequency underwent bladder training using a frequency-volume chart, 15 patients showed improvement. In 15 patients, the mean voided volume after one month increased by 65cc, whereas a persistent sensation of bladder fullness remained unchanged.

Participants in both arms of a large NIH funded randomized placebo controlled trial evaluating amitriptyline in BPS [246] received a standardized education and behavioral modification program (EBMP). Adherence to the EBMP at 6 weeks was assessed in 4 categories of 1) symptom management, 2) fluid management, 3) diet modification and 4) bladder training. For each of these EBMP categories adherence was defined as the overall percentage of participants who reported adhering to each component of the EBMP at each telephone contact or clinic visit. For the 241 subjects evaluable for EBMP adherence, the rate at 6 weeks was 75% (181 of 241) for symptom management, 83% (201 of 241) for fluid management, 82% (196 of 240) for diet modification and 71% (172 of 241) for bladder training. The overall GRA response rate was approximately 57% for adherers in any of the 4 EBMP categories, whereas it was lower for nonadherers. This rate neared statistical significance for diet modification, which demonstrated only a 41% response rate among nonadherers (p = 0.051).

#### Recommendation:

Behavioral therapy should be a cornerstone of treatment for patients with BPS.

**Level of evidence: 2 Grade of recommendation: B**

#### 2. PHYSICAL THERAPY

Women with BPS may have associated pelvic floor dysfunction [247]. Physical therapy for the pelvic floor is said to be effective for genitourinary and anorectal disorders [248]. Biofeedback and soft tissue massage may stimulate the relaxation of the pelvic floor muscles [249, 250]. Lukban et al [251] conducted a direct myofascial release treatment on 16 BPS patients with high-tone pelvic floor dysfunction and sacroiliac dysfunction. The treatment was effective for urinary frequency and suprapubic pain. Fifteen patients (94%) showed improvement in the O’Leary & Sant symptom score. Coital pain relief was observed in 15 of 16 patients, with 9 patients becoming able to resume sexual intercourse [252]. Transvaginal Theile massage was also reported to be effective for 9 of 10 patients of the same group [253]. Mendelowitz et al [250] showed a 69% success rate when treating 16 patients using electromyographic biofeedback. However, it was suggested that a placebo effect may have occurred because the effect did not correlate with the improvement in patient’s awareness of the pelvic floor muscle movement and position before and after the therapy. Weiss [254] reported that 70% of 10 patients with IC showed symptomatic improvement, rating from “effective” to “remarkably effective”.

An NIH study [255] to determine the feasibility of conducting a randomized clinical trial was undertaken to compare 2 methods of manual therapy (myofascial physical therapy and global therapeutic massage) in patients with urological chronic pelvic pain syndromes. The global response assessment response rate was 57% in the myofascial physical therapy group compared...
to 21% in the global therapeutic massage treatment group. This statistically significant difference (P=0.03) was primarily driven by the response seen in women (24 women) compared to the men (24 men) enrolled in this small pilot study. A follow-up randomized trial comparing similar treatments [256] but only in women with BPS and demonstrable pelvic floor pathology showed a clear benefit of directed myofascial physical therapy.

Recommendation:

Physical therapy of selected and motivated patients with BPS, particularly those with demonstrable pelvic floor dysfunction, is indicated.

Level of evidence: 1 Grade of recommendation: A

3. STRESS REDUCTION

It is long been observed that mental stress is one of the factors which aggravate the symptoms of BPS. Koziol et al [97] reported, in a survey of 374 patients, that more than half of the patients experienced intensified pain due to stress. Rothrock et al [257] reported that when comparing patients with BPS and healthy people, increased pain and urgency caused by stress were observed only in patients with BPS. Case-cohort studies have confirmed that patients diagnosed with IC/BPS experience considerably more stress than patients without the condition [90]. Stress was shown to correlate with both the severity of symptoms and quality of life. In another study of patients with BPS identified in urology tertiary care clinic populations [258], mental health disorders were identified in 23 % of IC/BPS female cases compared to 3% of female control subjects. Medications for anxiety, depression or stress were taken by 37% of patients with IC/BPS compared to 13% of female controls.

It is believed that exercise and bathing favorably influence the quality of life by reducing stress [259] however, the effect of such nonspecific therapies are difficult to assess and have not been proven in clinical trials. It would seem reasonable to suggest, when possible, to shorten working hours, choose a job with less stress or create a less stressful home environment. Involvement in patient education programs and patient support groups are considered by most practitioners to be beneficial [259,260]. Worldwide patient support groups, including the Interstitial Cystitis Association (ICA) [261], http://www.ichelp.org/, the International Painful Bladder Foundation, http://www.painful-bladder.org/, are important sources of information for patients with BPS. Patients with BPS frequently suffer depression, which may negatively impact upon the quality of life [90] and perhaps symptoms. Effective self-care strategies taught by psychiatric nurses are considered to be useful [262,263].

Recommendation:

Stress and depression are related to poorer quality of life and increase in severity of symptoms. Level of evidence: 1 Grade of recommendation: A. Reduction of stress and depression may contribute to an overall improvement in quality of life and perhaps even symptoms. Level of evidence: 4 Grade of recommendation: C.

4. DIETARY MANIPULATION

Acidic beverages, coffee, spicy food, and alcohol may aggravate the symptoms of most patients with BPS [97,259,264,265]. The symptoms of the majority of BPS patients are generally believed to be improved by dietary manipulation [259,264,266,267]. However this has proven difficult to document and Nguan et al [268] reported that there was no statistically significant difference in pain and other symptoms, when they evaluated the influence of the changes in urinary pH on the symptoms of 26 patients with BPS by instilling pH5.0 and pH7.5 saline solutions into the bladder. One of the best studies designed to determine the effect of particular foods, beverages and/or supplements (comestibles) on IC/BPS symptoms was undertaken by Shorter et al [269]. One hundred and four patients with IC/BPS were asked to indicate on a validated questionnaire whether each of 175 individual items worsened, improved or had no effect on symptoms. Of the patients surveyed, 90% indicated that the consumption of certain foods or beverages caused symptom exacerbation. The comestible items that had the most effect were caffeinated, carbonated and alcoholic beverages, certain fruits, artificial sweeteners and spicy foods.

Dietary manipulation was ranked in the top five frequently used treatments in a cohort study of the Interstitial Cystitis Data Base (ICDB).[270]. As the influence of diet is variable with regard to food, beverage, and patient, there is no reason for patients to be uniformly on a strict diet. It is advised that each patient experiment to find out the foods that tend to aggravate their symptoms and avoid them. The ICA home page, (http://www.ichelp.org/) introduces the foods often avoided by patients with BPS.

Recommendation:

Personalized dietary manipulation should be part of the therapeutic strategy for patients with IC/BPS.

Level of evidence:2 Grade of recommendation :B

IX. ORAL THERAPY (TABLE 5)

Several categories of medication have been used in the management of patients with bladder pain syndrome including analgesics, antidepressants, antihistamines, Immunosuppressants, and glycosaminoglycans. Many
of these drugs are used empirically. Only a few of them have been studied in randomized controlled trials and none have a grade A recommendation.

1. ANALGESICS

Grade of Recommendation: C - Level of Evidence: 4

The long-term, appropriate use of pain medications is indispensable in the treatment of bladder pain syndrome. Many nonopioid analgesics including acetaminophen and the nonsteroidal anti-inflammatory drugs (NSAIDs) and even antispasmodic agents [271] have a place in pain therapy. Patients with more severe symptoms can often be helped with medical pain management using medications commonly used for chronic neuropathic pain syndromes including antidepressants, anticonvulsants, and opioids.

Gabapentin, introduced as an anticonvulsant, has found efficacy in neuropathic pain disorders including diabetic neuropathy [272] and postherpetic neuralgia [273]. It demonstrates synergism with morphine in neuropathic pain[274]. Two patients with IC showed improved functional capacity and received adequate pain control when gabapentin was added to their regimen [275]. Sasaki et al reported that 10 of 21 male and female patients with refractory genitourinary pain had subjective improvement of their pain following treatment with gabapentin[276]. Recently gabapentin was one compound of a triple mix including amitriptyline and etodolac, a NSAID. The interpretation of the observed efficacy in 74 patients is hampered by an uncontrolled open lable study protocol that additionally allowed uptitration of gabapentin and amitriptyline. The impact and contribution of amitriptyline, whose exclusive efficacy for BPS has been proven better than for any other oral drug, on the reported amelioration was not discussed[277].

Pregabalin has similar structure as gabapentin and also has been shown to reduce the pain of diabetic neuropathy [278]. Pregabalin was proved effective for treating pain associated with fibromyalgia [279]. Pregabalin might be worthwhile to try for bladder pain syndrome, particularly for those with concurrent fibromyalgia, though studies are lacking.
Opioids are seldom the first choice of analgesics in chronic pain states, but they should not be withheld if less powerful analgesics have failed [280]. Chronic opioid therapy can be considered as a last resort in selected patients, who have disabling pain and often receive inadequate doses of short-acting pain medications, which put them on cycles of short-term relief, anxiety, and pain.

The major impediment to the proper use of opioids when they are prescribed for long-term nonmalignant pain is the fear of addiction. Some studies suggest the risk is low [281], but not zero. [282] Using opiates is a difficult decision that requires much thought and discussion between patient and urologist, and a pain specialist. They are best administered in a pain clinic setting, requiring frequent reassessment by both patient and physician [283].

In addition to narcotics, concurrent usage of non-steroidal anti-inflammatory drugs, cyclooxygenase inhibitors, acetaminophen, and tricyclic antidepressants may provide better pain control [284]. The common side effects of opioids include sedation, nausea, mild confusion, and pruritus. These are generally transient and easily managed. Respiratory depression is extremely rare if they are used as prescribed. Constipation is common and a mild laxative is generally necessary. The long-acting narcotic formulations that result in steady levels of drug over many hours are preferable.

2. ANTIDEPRESSANTS

a) Amitriptyline

Grade of Recommendation: B - Level of Evidence: 2

Amitriptyline is a tricyclic antidepressant with the property of blocking H1-histaminergic receptors [285]. It stabilizes mast cells and inhibits mediator stimulated vascular leakage. It inhibits synaptic reuptake of serotonin and norepinephrine, thus inhibiting painful nociception from the bladder at the level of the central nervous system. Its nighttime sedation can be therapeutic in the BPS population and its purported beta-adrenergic receptor stimulation in the bladder may facilitate urine storage [286].

Using a dose titration of up to 75mg taken before bed, Hanno and Wein reported success in about half of 20 patients who could tolerate the medication. Twenty percent of the initial 25 patients dropped out because of fatigue, weight-gain, or dry mouth. In a follow-up report [287], 18 of 28 patients who could tolerate the drug had major relief of symptoms within 3 to 6 weeks of onset of therapy with a mean follow-up of 14.4 months. However, about one-third of patients initially placed on the drug could not continue on it because of side effects. Kirkemo et al [288] treated 30 patients and 90% had subjective improvement in 8 weeks. Pranikoff and Constantino [289] reported improvement in 16 of 22 patients with urinary frequency and pain who did not have a diagnosis of interstitial cystitis, noting that 5 of the 22 could not tolerate the drug.

van Ophoven et al performed the first prospective, double-blind, placebo-control-led study of amitriptyline. Fifty patients were randomized to placebo or a titrated dose of ami-triptyline up to 100mg daily. Forty-two per-cent of amitriptyline patients had greater than 30% decrease in O’Leary/Sant symptom and problem scores at 4 months compared to 13% in the placebo group[290]. They subsequently reported a long-term follow-up of amitriptyline for patients who can tolerate the side effects and continued the medication. With a mean follow-up of 19 months, 64% of 94 patients had response [291].

Foster and Hanno reported a second multicenter, randomized, double-blind, placebo controlled clinical trial of amitriptyline in subjects with interstitial cystitis/painful bladder syndrome who were naïve to therapy. Study participants in both treatment arms received a standardized education and behavioral modification program. Only of the subgroup of 207 subjects who achieved a drug dose of at least 50 mg, a significantly higher response rate was observed in the amitriptyline group (66%) compared to placebo (47%) (p = 0.01). When all randomized subjects were considered, amitriptyline plus an education and behavioral modification program did not significantly improve symptoms in treatment naïve patients with interstitial cystitis/painful bladder syndrome. However, amitriptyline may be beneficial in persons who can achieve a daily dose of 50 mg or greater[246].

b) Doxepin, desipramine, duloxetine

Other tricyclic antidepressants that have been used for bladder pain syndrome are doxepin and desipramine. Wammack et al used the combination of doxepin and piroxicam, a cox-2 inhibitor. Twenty-six of 32 patients (81%) experienced remission of symptoms [292]. One study reported satisfactory outcome with desipramine. [293] Duloxetine, a serotonin-norepinephrine reuptake inhibitor has also been tried but without therapeutic effects [294]
properties and good safety profile, have made it a reasonable candidate for use as a therapeutic agent for bladder pain syndrome. In 1933, Theoharides first reported significant benefits of hydroxyzine in reducing pain and urinary symptoms. His two subsequent reports of totally uncontrolled series further suggested the therapeutic effects of hydroxyzine. However, in an NIDDK randomized controlled trial, the global response rate for hydroxyzine was only 31% compared to a 20% response to those not treated with hydroxyzine. When looked at by itself the response was 23% vs. 13% on placebo. None of the results in this under-powered trial reached statistical significance.

b) Cimetidine

**Grade of Recommendation: C - Level of Evidence: 3**

Cimetidine, a H2 histamine receptor antagonist, has been explored for treatment of bladder pain syndrome. In a pilot study, 9 patients were treated with a dose of 300mg orally twice daily for one month. At follow-up 26 to 42 months later, 4 patients had complete relief of urinary symptoms and suprapubic pain. Lewi reported 31 patients given 200mg three times daily with mean follow up of 6.6 months. Seventy-one percent experienced varying degrees of symptomatic relief, 45% were pain free, and 26% went into remission of all symptoms. In a later report of 69 patients treated over a 4 year period, 67% of patients had complete relief of all symptoms.

A small, prospective, placebo-controlled RCT studied 36 patients who either received oral cimetidine or placebo. Median suprapubic pain and frequency scores improved significantly, but the publication does not state exactly how many patients in each group improved.

### 4. IMMUNOSUPPRESSANTS

**a) Cyclosporine**

**Grade of Recommendation: C - Level of Evidence: 3**

Cyclosporine, a widely used immunosuppressive drug in organ transplantation, was the subject of a novel bladder pain syndrome trial. Eleven patients received cyclosporine for 3-6 months at an initial dose of 2.5-5 mg/kg daily and a maintenance dose of 1.5 to 3mg/kg daily. Micturition frequency decreased, and mean and maximum voided volumes increased significantly. Bladder pain decreased or disappeared in 10 patients. After cessation of treatment, symptoms recurred in the majority of patients.

In a long-term follow-up study, 20 of 23 refractory IC patients on cyclosporine therapy followed for a mean of 60.8 months became free of bladder pain. Bladder capacity more than doubled. Eleven patients subsequently stopped the therapy, and in 9, symptoms recurred within months, but responded to reinitiating cyclosporine. Sairanen et al further found that cyclosporine A was far superior to sodium pentosanpolysulfate in all clinical outcome parameters measured at 6 months. Patients who responded to cyclosporine A had a significant reduction of urinary levels of epidermal growth factor (EGF).

**b) Suplatast Tosilate**

**Grade of Recommendation: D - Level of Evidence: 3**

Suplatast Tosilate (IPD-1151T) is an immunoregulator that selectively suppresses IgE production and eosinophilia via suppression of helper T cells that produce IL-4 and 5. It is used in Japan to treat allergic disorders including asthma, atopic dermatitis, and rhinitis. Ueda et al reported a small study in 14 women with interstitial cystitis. Treatment for one year resulted in a significantly increased bladder capacity and decreased urinary urgency, frequency, and lower abdominal pain in 10 women. Concomitant changes occurred in blood and urine markers suggesting an immune system response. Larger, multicenter, randomized controlled trials in the United States and Japan have been completed and results are unpublished. Further studies with this drug for bladder pain syndrome are not planned and approval for this indication is not expected.

c) Azathioprine and Chloroquine derivatives

**Grade of Recommendation: D - Level of Evidence: 4**

In a single report in 1976, Oravisto et al used azathioprine or chloroquine derivatives for BPS patients not responding to other treatments. About 50% patients responded.

d) Corticosteroids

Reports on outcome with corticosteroid therapy have been both promising and discouraging. Soucy et al (133) have suggested a trial of prednisone (25 mg daily for 1–2 months, afterwards reduced to the minimum required for symptom relief) in patients with severe ulcerative IC, which is otherwise unresponsive to conventional treatment. The side effects of steroids can be very serious, making it difficult to justify their use.

### 5. SODIUM PENTOSANPOLYSULFATE

**Grade of Recommendation: D - Level of Evidence: 1**

Sodium pentosan–polysulfate (PPS), a synthetic sulfated polysaccharide, is available in an oral formulation, 3-6% of which is excreted into the urine and theoretically may replenish the damaged glycosaminoglycan (GAG) layer overlying transitional epithelium of the urinary bladder of BPS patients. An intact urothelial GAG layer has been proposed to be essential to keep the urothelium impermeable to urinary components. A defective bladder GAG layer is hypothesized to be one important cause for BPS.
PPS’s mechanism of action has been attributed not only to correction of a putative defect in the GAG layer, but also its ability to inhibit histamine release from mast cells, [316] and a possible effect mediated by nonspecific binding of the molecule with the inflammatory stimulants of uro-thelial activation, an action that would occur in the urine rather than at the mucosal membrane [317].

PPS is the most intensively studied treatment ever proposed for BPS. It is the only medication approved by the Food and Drug Administration for the pain of interstitial cystitis. Parsons initially administered the drug at a dosage of 50mg 4 times daily or 150mg twice daily in an open trial involving 24 patients. [318] Twenty-two of 24 patients experienced a good or excellent response within 8 weeks. In a subsequent randomi- zed, placebo-controlled trial using a dose of 100mg three times daily in 62 patients, pain and urgency improved in 44% vs. a placebo response of 15%. Urgency improved by 38% vs. 18% on placebo. The average number of daily voids was unchanged [319].

Five randomized controlled trials for pentosan polysulfate have yielded conflicting results of efficacy. Holm-bentzen et. al [320] reported the first multi-center double-blind placebo controlled trial in 1987 looking at 115 patients with bladder pain syndrome. Patients were randomized to a dose of 200mg twice daily vs. placebo for 4 months. The results showed no difference between pre and post trial values with regard to symptoms, urodynaminc parameters, cystoscopic appearance, or mast cell counts in the two groups. The study concluded that the drug had no clinically significant effect.

The first of two pivotal studies for the FDA was performed in the United States in 1990.[321] A total of 110 patients in 5 medical centers were studied for 3 months on a dosage of 100mg three times daily. Twenty-eight per cent of patients on PPS reported “more than slight improve-ment” versus 13% of those on placebo. Pain and pressure to urinate were the main parameters to show benefit with PPS.

The FDA asked for a second study which was reported 3 years later. [322] In a multi-center, placebo-controlled RCT 148 patients were randomized to 100mg three times daily of pentosan-polysulfate vs. placebo. In the primary endpoint of patient self-evaluation of global improvement, 32% of those on PPS reported 50% or more overall improvement vs. 16% on placebo at 3 months. Pain, urgency, and pressure showed significant improvement with drug. Frequency, nocturia, and volume voided showed no significant changes between study groups.

The NIDDK performed their own 2 X 2 factorial study to evaluate PPS and hydroxyzine. [301] Each drug was used alone and in combination and compared to a placebo group. Patients were treated for 6 months. There were 121 participants in 7 centers. No statistically significant response to these medications was documented. A non-significant trend was seen in the PPS treatment groups (34%) compared to non-PPS groups (18%). Of the 29 patients on PPS alone, 28% had global response (primary end-point) of moderately or markedly improved vs. 13% on placebo, very similar in this 6-month study to improvement rates in the 3-month pivotal studies, though not reaching statistical significance in the longer study.

In summary

Of 5 RCTs 2 had unfavorable and 3 had favorable results for PPS. Most recent non randomized studies showed a complex heterogeneity in efficacy as well[323-326]. Such conflicting results might suggest that a minority of patients do respond to PPS, but currently there is no reliable method to identify such patients.

Long-term, open-label studies with PPS have been reported. Populations of patients receiving extended treatment for up to 90 months or more in the com-passionate use program showed no further improvement in symptoms after 1-2 years, though there seemed to be little tachyphylaxis [301,327]. A total of 2809 patients had begun treatment with a 3 month supply of PPS and 21% continued with treatment beyond this point and reordered medication. This seems to correlate with the 28-32% improvement rate previously reported. The dropout rate in the first 6 months was extraordinarily high with only 178 active patients out of 1742 who initially ordered the drug. There was an overall improvement in symptoms in 62% of the patients who did remain in treatment for 6-35 months.

PPS appears to be a very well-tolerated mediation [327] with no common central nervous sys-tem side effects, and appears to be beneficial with regard to improving the pain associated with inter-stitial cystitis in up to one-third of patients, a standard often expected with a placebo. A 3-6 month course is required to see an effect in most patients. Claims suggesting greater efficacy and claims urging its use in patients who do not meet the standard definition of bladder pain syndrome should be regarded with caution.

6. OTHER ORAL MEDICATIONS THAT HAVE BEEN USED FOR BPS

a) L-arginine

Grade of Recommendation: -A - Level of Evidence: 1

Foster and Weiss were the original proponents of L-arginine in the therapy of interstitial cystitis [328]. Eight patients with IC were given 500mg of L-arginine 3 times daily. After one month, urinary nitric oxide synthase activity increased 8-fold and 7 of the 8 patients noticed improvement in IC symptoms. An open-label study of 11 patients showed improvement in all 10 of the patients who remained on L-arginine for 6 months [329].
An open-label study of 9 women in Sweden failed to find any change in symptom scores or in nitric oxide production in the bladder [330]. A placebo-controlled randomized controlled trial of 53 IC patients could find no difference on an intention to treat analysis between drug and placebo-treated patients [331]. A smaller randomized placebo-controlled crossover trial of 16 IC patients found no clinically significant improvement with L-arginine and concluded that it could not be recommended for IC treatment [332].

Data does not support the use of L-arginine for the relief of symptoms of interstitial cystitis.

b) Quercetin

**Grade of Recommendation: D - Level of Evidence: 4**

Quercetin, a bioflavonoid available in many over-the-counter products, may have the anti-inflammatory effects of other members of this class of compounds found in fruits, vegetables, and some spices. Katske et. al [333] administered 500mg twice daily to 22 BPS patients for 4 weeks. All but one patient had some improvement in the O’Leary/Sant symptom and problem scores as well as in a global assessment score. Further studies are necessary to determine efficacy.

c) Antibiotics

**Grade of Recommendation: D - Level of Evidence: 4**

Warren et. al [334] randomized 50 patients to receive 18 weeks of placebo or antibiotics including rifampin plus a sequence of doxycycline, erythromycin, clindamycin, amoxicillin and ciprofloxacin for 3 weeks each. Intent to treat analysis demonstrated that 12 of 25 patients in the antibiotic and 6 of 25 patients in the placebo group reported overall improvement while 10 and 5 respectively noticed improvement in pain and urgency. The study was complicated by the fact that 16 of the patients in the antibiotic group underwent new BPS therapy during the study as did 13 of the placebo patients. There was no statistical significance reached. What was statistically significant were adverse events in 80% of participants who received antibiotic compared to 40% in the placebo group. Nausea and/or vomiting and diarrhea were the predominant side effects. Most patients on antibiotics correctly guessed what treatment arm they were in, and those that guessed correctly were significantly more likely to note improvement after the study. No duration in improvement after completion of the trial of antibiotics was reported.

Burkhard et. al [335] reported a 71% success in 103 women presenting with a history of urinary urgency and frequency and chronic urethral and/or pelvic pain often associated with dyspareunia and/or a history of recurrent urinary tract infection. This was a large, inclusive group and one that is probably broader than the bladder pain syndrome we are focusing on. Nevertheless, he recommended empiric doxycycline in this group. The overwhelming majority of BPS patients have been treated with empiric antibiotics prior to diagnosis. The role of tetracyclines to eradicate nanobacteria in urine of BPS patients has recently been addressed in small Chinese open label study, leaving the significance of nanobacteria as a reasonable pathogen or trigger of the condition open [129,324-326]. At this time there is no evidence to suggest that antibiotics have a place in the therapy of BPS in the absence of a culture-documented infection [336].

d) Methotrexate

**Grade of Recommendation: D - Level of Evidence: 4**

Low dose oral methotrexate significantly improved bladder pain in 4 of 9 women with BPS, but did not change urinary frequency, maximum voided volume, or mean voided volume [337]. No placebo-controlled, RCT has been done with this agent.

e) Montelukast

**Grade of Recommendation: D - Level of Evidence: 4**

Mast cell triggering releases 2 types of proinflammatory mediators, including granule stored pre-formed types such as heparin and histamine, and newly synthesized prostaglandins, and leukotriene B4 and C4. Classic antagonists, such as montelukast, zafirlukast and pranlukast, block cysteinyl leukotriene 1 receptors. In a pilot study, [338] 10 women with IC and detrusor mastocytosis received 10mg of montelukast daily for 3 months. Frequency, nocturia, and pain improved dramatically in 8 of the patients. Further study would seem to be warranted, especially in patients with detrusor mastocytosis, defined as >28 per mm2.

f) Nifedipine

**Grade of Recommendation: D - Level of Evidence: 4**

The calcium channel antagonist nifedipine inhibits smooth muscle contraction and cell-mediated immunity. In a pilot study, [339] 30mg of an extended release preparation was administered to 10 female patients and titrated to 60mg daily in 4 of the patients who did not get symptom relief. Within 4 months five patients showed at least a 50% decrease in symptom scores, and 3 of the 5 were asymptomatic. No further studies have been reported.

g) Misoprostol

**Grade of Recommendation: D - Level of Evidence: 4**

The oral prostaglandin analogue misoprostol was studied in 25 patients at a dose of 600 micrograms daily [340]. At 3 months 14 patients were significantly improved, and at 6 months 12 patients still had a response. A cytoprotective action in the urinary bladder was postulated.
h) Tanezumab

Grade of Recommendation: D - Level of Evidence: 1

A recent randomized, double-blind, placebo controlled phase two 64 patient study investigated tanezumab, a humanized monoclonal antibody that specifically inhibits nerve growth factor as a treatment for BPS pain[341]. At week 6 tanezumab produced a significant reduction from baseline in average daily pain score vs placebo. A significantly higher proportion of patients on tanezumab responded as improved in the global response assessment and tanezumab also significantly reduced urgency episode frequency vs placebo. Studies with this drug have been suspended by the Food and Drug Administration because of the occurrence of osteonecrosis in nonurologic trials.

X. INTRAVESICAL / INTRAMURAL THERAPY (TABLE 5)

Intravesical therapies form one of the staples of BPS therapy, though regulatory approvals and availability throughout the world differ from nation to nation. What follows are treatments that have been reported in the recent literature, some of which are commonly used. Older therapies that are rarely used now include silver nitrate[80,344-347] and chlorpactin WCS90.[7,348-352] These have not been included in this current edition of the Consultation, but have level 3 evidence to support a grade C recommendation based on original reports.

1. DMSO (DIMETHYL SULFOXIDE)

Grade of Recommendation: B - Level of evidence 2

A small number of significant side effects. Not approved in Japan.

DMSO is believed to reduce inflammation, relax muscles, eliminate pain, dissolve collagen, and degranulate mast cells. It has long been used as a therapeutic agent for BPS. Its mechanism of action, however, has not been clarified. Ten articles on DMSO for the treatment of IC were retrieved. Peeker et al[353] reported that in a randomized study, frequency and pain were improved in ulcer-type IC patients, although no improvement was observed in maximum bladder capacity. Perez-Marrero et al[354] reported that in a non-randomized controlled study, 53% of the patients showed remarkable improvement in subjective evaluation (placebo 18%), and 93% in objective evaluation (placebo 35%). Around an 80% improvement rate has been reported in case series and retrospective studies.[355-362]

With regard to side effects after instillation of DMSO, most patients recognize a garlic-like odor, which disappears within a day, and about 10% of patients report bladder irritative symptoms which resolve with or without symptomatic treatment.[363] It is hypothesized that these transient exacerbations occur as the result of mast cell degranulation. The number of significant side effects is considered to be small[362]. Cataracts have been reported in animal studies,[364,365] though not in humans. Negative effects on bladder compliance have been noted in rat detrusor.[366] DMSO may accelerate the absorption of other drugs instilled simultaneously, which could be a source of side effects.

The instillation method has not been standardized. Generally, 50cc of a solution of medical grade 50% DMSO is instilled into the bladder. If pain occurs immediately following instillation, local anesthesia (e.g. 20ml of 2% lidocaine solution) may be instilled. Average retention time is considered to be 10 to 20 minutes.[363] The instillation is performed weekly for 6-8 weeks. After an initial course, treatment is suspended until symptoms recur. If a good result was obtained, another 6 week course (often followed by monthly maintenance) can be initiated. The long-term effect is unknown, although there is no upper limit for the duration of the treatment. DMSO is medically approved in the US, while it has not been approved yet in Japan.

2. HEPARIN

Grade of Recommendation: C - Level of Evidence: 3

Side effects primarily related to effects intravesical catheterization and slight chance of bladder hemorrhage.

The glycosaminoglycan (GAG) layer on the bladder urothelium is a kind of mucopolysaccharide, working as a non-specific defense mechanism. It is believed that a deficiency or abnormality of GAG secondarily causes inflammation of the bladder by increasing the permeability of the bladder mucosa, leading to the pathologic cascade of BPS. Heparin has similarities to the GAG layer of the bladder. When instilled into the bladder, theoretically it might replace the damaged GAG layer. Kuo[367] reported that the International Prostate Symptom Score, as well as bladder capacity at initial desire to void and maximum bladder capacity, improved significantly. According to the report by Parsons et al[368] symptoms were reduced in 56% of patients treated 3 times weekly for 12 weeks. These reports suggest the efficacy of heparin, however, there is no randomized comparative study to give conclusive evidence. One study indicated that intravesical heparin instillations may prolong the response to dimethyl sulfoxide treatment.[369]

No significant side effects have been reported, as it does not affect systemic coagulation parameters. In the case of patients with hematuria, however, it may exacerbate local hemorrhage.

The instillation method has not been standardized. Generally, 10,000-40,000 units of heparin are instilled. It is unusual to have pain or irritation as a
result of instillation, and retention times can be 30 minutes or more. Instillation frequency can be up to every other day and is often administered at home by the patient. Parsons et al [370] recently reported that when 40,000 units of heparin combined with 1 to 2% lidocaine was instilled 3 times a week for 2 weeks, about 80% efficacy was obtained. There is no upper limit for the duration of the treatment, but a long-term effect is unknown. A bleeding tendency may occur. Heparin for intravesical use is not approved by drug regulatory authorities.

3. HYALURONIC ACID

Grade of Recommendation: D - Level of Evidence: 1

No significant side effects.

Hyaluronic acid, like heparin, is a mucopolysaccharide, that could theoretically repair a damaged GAG layer of the bladder mucosa. Seven reports have indicated efficacy.[371-376] In the summer of 2003 Bioniche Life Science Inc http://www.medicalnews-today.com/articles/112053.php and in the spring of 2004 Seikagaku Corporation reported double-blind, placebo-controlled, multicenter clinical studies of their hyaluronic acid preparations (40mg or 200mg per cc respectively) and neither showed significant efficacy of sodium hyaluronate compared to placebo. These negative studies have not been published in peer reviewed literature. Neither preparation has been approved for use for BPS in the United States. At the same time, no significant side effects were observed.

A non-placebo-controlled study has demonstrated a favorable effect of hyaluronic acid on pain reduction [192]. Forty-eight patients with typical symptoms and a positive potassium (0.4 M) sensitivity test were treated with weekly instillations of 40 mg hyaluronic acid for 10 weeks. Visual analogue scale scores showed symptom relief due to hyaluronic acid therapy, irrespective of bladder capacity. The improvement was particularly evident in patients with a reduction in Cmax < 30% compared to patients with a reduction of < 30% with 0.2 M KCl solution (P = 0.003). Long-term effects were investigated in a study of 70 patients previously treated with hyaluronan [377]. Of the initial 70, 48 improved. Of these, 50% reported complete remission with no further therapy. Another 41.7% of patients with symptom recurrence improved after retreatment

A recent interventional study from China suggested a prolonged effect of bladder distension when combined with instillation of hyaluronic acid [378]

4. CHONDROITIN SULFATE

Grade of Recommendation: D - Level of Evidence: 4

No significant side effects.

Chondroitin sulfate is another mucopolysaccharide. Its efficacy was suggested for the first time 2002 when used alone [379] and in another trial when used in combination with hyaluronic acid [364]. Intravesical chondroitin sulphate demonstrated beneficial effects in patients with a positive potassium stimulation test in two non-randomised, uncontrolled, open-label pilot studies. Steinhoff (363) treated 18 patients with 40 mL instilled intravesically once weekly for 4 weeks and then once monthly for 12 months. Thirteen of 18 patients were followed for the entire 13-month study. Twelve of these patients responded to treatment within 3–12 weeks. A total of 6/13 (46.2%) showed a good response, 2/13 (15.4%) had a fair response, 4/13 (30.8%) had a partial response, and 1/13 (7.7%) showed no response. In a second trial [380] 24 refractory patients with BPS/IC were treated with high-dose (2.0%) chondroitin sulphate instillations twice weekly for 2 weeks, then weekly with 0.2% solution for 4 weeks, and monthly thereafter for 1 year. The average symptom improvement reported in 20 patients completing the trial was 73.1% (range: 50–95%). The time to optimum response was 4–6 months. A more concentrated 2.0% solution was needed in eight patients to maintain results. Chondroitin sulphate instillation was effective and well tolerated in the therapy of various chronic forms of cystitis associated with a possible GAG layer deficit including BPS in a large multicenter but open study [381].

Sixty-five patients with IC/BPS were treated in a prospective, randomized, double-blind, inactive vehicle-controlled, 12-week study (6 weeks treatment, followed by 6 weeks follow-up). At the primary endpoint analysis (week 7), 22.6% of the vehicle control group were responders compared with 39.4% of the active therapy group, however, the difference was not significant [382]. A follow up randomized placebo-controlled trial with 98 female patients showed only minor improvements in IC/BPS symptoms and pain and failed to demonstrate a statistically significant drug effect vs. placebo [383]. The authors concluded that the study did not support the use of intravesical chondroitin sulfate as a monotherapy for this condition.

5. PENTOSAN POLYSULFATE

Grade of Recommendation: D - Level of evidence: 4

No significant side effects are considered to be present.

Pentosan polysulfate (PPS) is a mucopolysaccharide similar to heparin, with a similar postulated mode of action when used locally. Like other mucopolysaccharides, it has not been well-studied clinically. Bade et al in a randomized controlled trial found benefit in 4 patients out of 10 on PPS versus 2 of 10 on placebo.[384] A more recent placebo-controlled study of 41 patients found the addition of a 6 week course of intravesical PPS to a regimen of oral PPS significantly improved results.[385]
6. VANILLOIDS (CAPSAICIN, RESINIFERATOXIN)

Grade of Recommendation: -A (ineffective) - Level of Evidence: 1

Significant side effects: local irritation possible

It would seem reasonable that capsaicin, a C-fiber afferent neurotoxin, could alleviate the pain of BPS by desensitizing bladder afferents. Resiniferatoxin (RTX) is considered to have a stronger action than capsaicin, by desensitizing C-fibres more quickly, and causing less initial irritation. Efficacy was indicated in five relatively small clinical trials.[386-390] No severe side effects were reported. A randomized multicenter placebo-controlled clinical trial of RTX failed to demonstrate benefit over placebo.[391]

7. BACILLUS CALMETTE-GUERIN (BCG)

Grade of Recommendation: -A (ineffective) - Level of Evidence: 1

Potential serious complications

Seven articles reported on a BCG instillation therapy. Zeidman et al first reported that 5 patients who did not respond to other therapies showed symptomatic improvement.[392] Peters et al conducted a randomized double blind study showing a 60% improvement compared to 27%[393] placebo response with good long-term results at 27 months.[394] Sixty-five percent of the patients experienced burning sensation, 41% irritation of the bladder, and 35% pelvic pain. One patient was reported to have dropped out due to joint pain.

Peeker et al conducted a randomized double blind study comparing intravesical BCG and DMSO and failed to find any efficacy with BCG.[353] A very large, multicenter randomized placebo controlled trial conducted by the National Institute of Diabetes, Digestive, and Kidney Disorders failed to identify benefit from BCG, although the side-effect profile was surprisingly similar to that of placebo.[395]

8. OXYBUTYNIN

Grade of Recommendation D - Level of Evidence: 4

Side effect profile is unknown

Barbalias et al observed significant improvement when combining intravesical instillation of oxybutynin with bladder training.[396] Randomized trials are lacking.

9. LIDOCAINE

Grade of Recommendation: C - Level of Evidence: 2

No significant side effects.

Lidocaine is a local anesthetic that relieves pain by blocking sensory nerves in the bladder. Four articles[397-400] reported on the electromotive drug administration (EDMA) of lidocaine. Using EMDA, ionized lidocaine is actively introduced into the bladder using an electrical current. Three articles reported that lidocaine and dexamethasone were instilled following hydrodistention. According to the report by Rosamilia et al[400], 85% of the patients had a good result, with the effect persisting for 6 months in 25%. There are two other case reports.[401,402] A report on a pharmacokinetic effect, demonstrated safe levels of lidocaine absorption into the bladder. [403] 102 adult patients (99 women) with a clinical diagnosis of BPS were randomised from 19 centres in the USA and Canada to receive a daily intravesical instillation of alkalinised lidocaine or placebo (double-blind), for 5 consecutive days. Treated patients had significant sustained symptom relief for up to 1 month [404]. However, further randomized, placebo-controlled trials are needed to ascertain efficacy, optimal treatment parameters, and length of response to intravesical lidocaine preparations. [405] Advantages seem to be immediate response, low-cost of generic medication, and ability of patients to self-administer at home.

10. BOTULINUM TOXIN (INTRAMURAL)

Grade of Recommendation: A - Level of Evidence: 1

- Side effects include dysuria, incomplete emptying

Botulinum toxin type A (BTX-A) acts by binding to the nerve endings within muscles, blocking the release of acetylcholine, and probably other neurotransmitters, to modulate muscle contraction and reduce the sensitization of sensory nerve endings. There is increasing evidence for an additional, direct effect on the sensory bladder pathways and subsequent modulation of the efferent overactivity or hyperexcitability involved in the pathophysiology of the detrusor and other muscle dysfunction.[406]

Thirteen BPS patients were injected with 100–200 IU of BTX-A (abobotulinumtoxin A or onabotulinumtoxin A) into 20–30 sites submucosally in the trigone and floor of the bladder. Overall, nine (69%) patients noted subjective improvement, and ICSI scores improved by 70% (P< 0.05). There were significant decreases in daytime frequency, nocturia and pain, and a significant increase in first desire to void and maximal cystometric capacity. However, dysuria occurred in a majority of patients and persisted in a minority for several months after initial injection. Three patients required clean intermittent catheterization for 2-3 months following therapy.[407]

To ascertain effect of repeat injections a total of 13 patients were followed up for 2 years, while 58 injections were administered with a mean of 4.8 ± 0.8 injections per patient. The mean interval between two consecutive injections was 5.25 ± 0.75 months. At 1 and 4 months follow-up, 10 patients reported a subjective improvement. Mean VAS scores, mean daytime and night-time urinary frequency decreased significantly. The three non-responders to
the first intravesical treatment session underwent further treatment 3 months later with satisfactory results. At 1 and 2 years follow-up, the beneficial effects persisted in all patients [408].

These results are in contrast with those in another study from Kuo of BTX-A (onabotulinumtoxin A) in 10 patients with BPS. One hundred units were injected suburothelially into 20 sites in five patients, while 100 U were injected into the trigone in the remaining five. None of the patients became symptom-free; two showed only limited improvement in bladder capacity and pain score.[409]

However in an RCT, Kuo and Chancellor analysed the difference between hydrodistension and hydrodistension plus intravesical, sub mucosal BTX-A (onabotulinumtoxin A). [410] Of the 67 patients, 44 were divided in two groups: one received 200 U and the other 100 U, and cystoscopic hydrodistension was performed after 2 weeks. The remaining 23 patients received hydrodistension only. There was symptomatic improvement in all groups. However, in the hydrodistension group, 70% had returned to their previous symptoms after the first month, while in the BTX-A-treated groups, there was improvement of VAS, functional bladder capacity and cystometric bladder capacity at 3 months. At 12 and 24 months, the results in the active group were 55 and 30% versus 26 and 17% in the hydrodistension group.

Trigonal-only injection seems effective and long-lasting since 87% of patients (n = 23) reported improvement after a 3-month follow-up period in a study by Pinto et al. [411] Over 50% referred continuity of the beneficial effect 9 months after the first treatment. When retreatment was needed, similar results were obtained. No cases of urinary retention were reported. The authors concluded that this treatment is safe, effective and can be repeated.

Further studies will be needed to obtain conclusive evidence for its efficacy, duration of effect, and side-effect profile.

**XI. NEUROMODULATION**

**Grade of Recommendation: B - Level of Evidence: 1**

Sacral nerve stimulation (SNS) involves implanting permanent electrode(s) to stimulate S3 or S4 roots. As early as 1989, Tanago et al showed that stimulation of S3 may modulate detrusor and urethral sphincter function [412]. FDA approved the usage of sacral neuromodulation for treating refractory detrusor overactivity in 1997 and for urinary urgency and frequency in 1999. Although the effectiveness of SNS for detrusor overactivity is largely confirmed by a goodnumber of papers, only a few papers report the effect of SNS in treating BPS.

Zerman et. al reported significant improvement in a 60-year-old woman treated for severe BPS pain using sacral nerve stimulation implant. Pain and accompanying bladder dysfunction were improved by temporary and permanent sacral nerve stimulation for up to six months [413]. Maher et al [414] showed that temporary stimulation was effective in 73% of 15 women with refractory BPS. Mean voided volume during treatment increased and mean daytime frequency, nocturia and pain decreased significantly. As indicated by the Short Urinary Distress Inventory and SF-36 Health Survey, the quality of life parameters of social functioning, bodily pain and general health significantly improved during the stimulation period.

Chai et. al[230] found that percutaneous S3 nerve root stimulation improves symptoms and normalizes urinary HB-EGF levels and antiproliferative activity in patients with BPS. In their report in 2003, Comiter et al.[415] prospectively investigated the effect of SNS on a series of 17 patients with refractory BPS. At an average of 14 months follow-up mean daytime frequency, nocturia and mean voided volume improved significantly. The average pain decreased from 5.8 to 1.6 points on a scale of 0 to 10 and Interstitial Cystitis Symptom and Problem Index scores (ICSI and ICPI) decreased from16.5 to 6.8 and 14.5 to 5.4, respectively. Of the 17 patients 16 (94%) with a permanent stimulator demonstrated sustained improvement in all parameters at the last postoperative visit. Whitmore el al [416] applied percutaneous sacral nerve root stimulation on 33 patients with refractory interstitial cystitis. Statistically significant improvements were seen in pain and urinary symptoms. Significant improvements were also seen in ICSI and ICPI scores.

Peters et al [417] reported a reduction of narcotic usage in 18 BPS patients following SNS for a mean of 15.4 months, although the dose reduction was modest (36%) and only 4 of 18 discontinued the narcotics. However, Elhilali and colleagues [418] found that both of two patients with interstitial cystitis reported no improvement following sacral neuromodulation. Zabihi et al [419] more extensively stimulate S2-S4 by implanting electrodes into epidural space through sacral hiatus. 23 of 30 (77%) patients had successful trial stimulation and were permanently implanted. Among these patients, the symptom score was improved by 35% (p=0.005). The pain score improved by 40% (p=0.04). Patients reported an average of 42% improvement in their symptoms.

In the first prospective, single-blind, crossover trial of sacral nerve stimulation (SNS) versus pudendal nerve stimulation (PNS) for patients with BPS (n = 22), PNS gave an overall 59% improvement in symptoms, whereas SNS gave an overall 44% improvement (P = 0.05). Most patients who tested both a sacral and pudendal electrode chose PNS as the better site. Follow-up showed marked improvements in voiding variables.
and validated BPS symptom questionnaires. Over 90% of patients treated with neuromodulation stated that they would undergo implantation again [420].

Long-term results were verified in a retrospective study of 78 patients treated from 1994 to 2008. Permanent sacral neuromodulation implantation was performed in patients who showed at least 50% improvement in their symptoms with a temporary peripheral nerve evaluation test. Median follow-up was 61.5 ± 27.7 months. Good long-term success of sacral neuromodulation was seen in 72% of the patients. The explantation rate was 28%. The most frequent reason for explantation was poor outcome (54% of the failed patients). The revision rate was 50% [421]. In another observational, retrospective, case-controlled review (January 2002–March 2004), 34 female patients underwent permanent device implants. Mean pre-/postoperative pelvic pain and urgency/frequency scores were 21.61 ± 8.6/9.22 ± 6.6 (P < 0.01), and mean pre-/postoperative visual analogue pain scale (VAPS) scores were 6.5 ± 2.9/2.4 ± 1.1 (P < 0.01). Mean follow-up was 86 ± 9.8 months. Sacral neuromodulation showed adequate improvement for the symptoms of refractory BPS. Reoperation rate was 25%. [422]

Sacral nerve modulation is still considered an investigational procedure for BPS by the Consultation. Pudendal nerve stimulation has shown better results. Therapeutic benefits of both appear to be significant in selected cases. Strict patient selection and detailed discussion with patients prior to surgery is mandatory. Long-term results should be collected and reported, and trial results discussed with patients before employing this treatment modality.

XII. PAIN EVALUATION AND TREATMENT

1. EVALUATION OF PAIN:

The first premise that all physicians treating patients diagnosed with BPS is that they deserve to have their chronic pain assessed and treated. It is now recognized that successful management of BPS is only possible using a multidisciplinary and multimodal treatment approach which must include management of the associated chronic pain. This includes evaluation of the whole patient, not just the urology related symptoms. As described in previous sections, this will involve assessment of clinical symptoms, physical signs and history to best define the underlying diagnosis and overlapping conditions, while not ignoring the problems of mood, sleep and sexual problems. The patient’s self report should be the primary source of assessment. Clinicians should assess pain with easily administered rating scales and should document the efficacy of pain relief at regular intervals after starting or changing treatment. Systematic evaluation of the pain involves the following:

- Evaluation of severity
- Detailed history of the pain including assessment of pain intensity and character
- Evaluation of the psychological state of the patient, including assessment of mood and coping responses
- Physical examination emphasizing the neurologic examination
- Diagnostic workup to determine the cause of the pain
- Re-evaluation of therapeutic strategy and response.

The initial evaluation of pain should include a description of the pain, PQRST has been described for this purpose:

P: Palliative or Provocative factors, ‘what makes it less intense?’
Q: Quality, ‘what is it like?’
R: Radiation, ‘does it spread anywhere else?’
S: Severity, ‘how severe is it?’
T: Temporal factors, ‘is it there all the time, or does it come and go?’

Pain measurement

A number of different rating scales have been devised to attempt to methodically measure pain and to allow patient follow-up. These have been used in research, audit and in clinical practice. They all rely on a subjective assessment of the pain and therefore make inter-individual comparisons difficult. Additionally, pain is a multidimensional complex phenomenon and is not adequately described by one-dimensional scales, however there is value in making some sort of an assessment to aid clinical practice.

- Categorical scales e.g., verbal rating scales: mild, moderate, severe pain
- Visual analogue, Likert or Numerical Rating scale (VAS)
- Complex pain assessment compendiums e.g., Brief Pain Inventory (BPI), McGill Pain Questionnaire [423-425]

The BPI consists of several visual analogue scales grouped together assessing pain at rest, on movement, and other aspects of the pain including interference with function and effect on work. The McGill Pain Questionnaire measures pain quality by asking patients to rate the intensity of 15 verbal descriptors of pain on a 0 to 3 rating scale. The pain rating index is composed of 2 scores, including a sensory pain score and an affective pain score. Some versions also use a standard pain intensity VAS.

2. PHARMACOLOGIC MANAGEMENT OF CHRONIC PELVIC PAIN

Physicians using pharmacologic measures to control BPS pain must be committed to the following principles [426]:

- Re-evaluation of therapeutic strategy and response.
- Physical examination emphasizing the neurologic examination
- Diagnostic workup to determine the cause of the pain
- Evaluation of the psychological state of the patient, including assessment of mood and coping responses
- Detailed history of the pain including assessment of pain intensity and character
- Evaluation of severity
- Categorical scales e.g., verbal rating scales: mild, moderate, severe pain
- Visual analogue, Likert or Numerical Rating scale (VAS)
- Complex pain assessment compendiums e.g., Brief Pain Inventory (BPI), McGill Pain Questionnaire [423-425]
1. drugs are prescribed and monitored with knowledge of the patient's history and risks,
2. patients understand potential benefits and harms and participate in reducing harms
3. clinicians assess outcomes for both effectiveness and harms.

**a) Non-acidic antipyrctic analgesics**

Acetaminophen (paracetamol) is the main representative of this group. It has antipyretic activity and is a simple analgesic. There is very little evidence about its role in chronic pelvic pain [427,428]. Acetaminophen should be considered for only mild pain. Acetaminophen is a common cause of hepatotoxicity [429,430] and risk increases with alcohol use [431].

**b) Acidic antipyrctic analgesics**

The classical non-steroidal anti-inflammatory drugs (NSAIDs) fall into this group and include salicylic acid. They are known to act on the cyclooxygenase (COX) enzyme. The early NSAIDs tended to have little selectivity for COX2 over COX1, and are therefore said to be associated with more side effects than the newer COX2 selective inhibitors [432]. The COX1 enzyme is mainly involved in normal 'housekeeping' functions, such as mediating gastric mucosal integrity, and renal and platelet function. Blocking the COX1 enzyme is the cause of the platelet, gastric and renal complications that can occur with NSAIDs. It has been suggested that the COX2 enzyme is inducible as a result of tissue damage, and that it is the main enzyme involved in inflammation and peripheral sensitization of nociceptors [433]. As a result, the analgesic efficacy of COX2 selective drugs should be as good as that of the nonselective drugs, however the benefit is primarily seen in acute inflammatory type pain. The selective COX2 agents should not be prescribed in patients with increased risk of cardiovascular disease including congestive cardiac failure [434]. There is very little evidence for a role of NSAIDs in the management of chronic pelvic pain and even less evidence for a role for the COX2 selective drugs. Most of the analgesic studies have investigated dysmenorrhoea in which NSAIDs have been found to be superior to placebo and possibly paracetamol [428,435].

For practical purposes the NSAIDs may be divided into:

1. Non-selective, low potency (e.g. salicylic acid, ibuprofen).
2. Non-selective, high potency (e.g. ketoprofen, diclofenac, ketorolac).
3. COX2 selective drugs (e.g. celecoxib).

Non-selective, low potency NSAIDs can be used as first-line analgesics [436]. They are most likely to be of help if there is an inflammatory component to the pain. More potent NSAIDs should be reserved for those conditions in which the low potency drugs have been tried and failed to produce significant benefit. COX2 selective drugs should be used with caution as an alternative to the non-selective drugs where there is an increased risk of gastric complications. They should be avoided in patients with known cardiovascular disease. NSAIDs should be taken with food and consideration must be given to the use of gastric protective agents. The benefits of the NSAIDs must be demonstrated to outweigh the risks. All NSAIDs are contraindicated in active gastrointestinal ulceration/bleeding and renal disease. They may seriously exacerbate asthma and produce fluid retention. Even if stronger analgesics such as opioids are added, the NSAIDs can be continued as they are likely to have a synergistic action improving pain control above and beyond that obtained with opioids alone [437].

**c) Neuropathic analgesics**

1. **Tricyclic Antidepressants**

Tricyclics have a definite analgesic effect on neuropathic pain compared with placebo [438]: 30% of patients should obtain more than 50% pain relief; 30% will have minor adverse effects; and 4% will have to stop treatment because of side effects. Tricyclics are said to work in doses that are too low to affect mood. They may work by increasing levels of norepinephrine and/or serotonin. They also have actions at sodium channels. They are extensively used for pelvic pain and good evidence exists to justify their usage [290,439]. A recent randomized placebo controlled study sponsored by the US National Institutes of Health [246] evaluated increasing doses of amitriptyline with or without standardized education and behavioural modification in treatment naive patients with IC/PBS. While this study did not confirm the overall benefit of amitriptyline plus education and behavior modification was superior to only the education and behavioral changes, they did show that amitriptyline may be beneficial in persons who can achieve a daily dose of 50 mg or greater.

2. **Serotonin Reuptake Inhibitors**

Selective serotonin reuptake inhibitors appear to be less effective for the management of pelvic pain [440]. Fluoxetine can increase plasma levels of amitriptyline and induce toxicity, and therefore care must be exercised if the drugs are combined.

Anticonvulsants have been used in the management of pain for many years.

3. **Anticonvulsants**

Gabapentin and pregabalin have recently been introduced for pain management. There is evidence to show that both compounds are effective in chronic neuropathic pain [441,442]. Whereas
there is little evidence to support the use of anticonvulsants in the management of genitourinary pain, they should be considered if there is a suggestion of neuropathic pain or central sensitization [275,443-445].

N-methyl-D-aspartate (NMDA) antagonists. Ketamine is thought to act primarily at the NMDA receptor, though it may also have actions at sodium channels, as well as opioid (kappa and mu) receptors [446]. Ketamine has been shown in both human [447] and animal models [448] of neuropathic pain to reduce central sensitization and wind-up. Ketamine has been found to be useful in a number of chronic pain states including: peripheral neuropathies with allodynia, stump and phantom pain, central pain, as well as fibromyalgia [449-453] However it has become evident that ketamine should only be used with caution (or not at all) by an experienced practitioner trained in its use. Ketamine is a street drug of addiction and has recently been associated with disastrous bladder consequences, the so-called ketamine bladder. [454]

4. Opioids

There is now a general acceptance that opioids have a role in the management of chronic non-malignant pain [455]. While the use of opioids in urogenital pain is poorly defined, they should be considered for patients with BPS in whom all other treatments to reduce pain have failed. Opioid use does present very real risks and potential harms [284] and include overdose, addiction, and opioid diversion and prescribers have an obligation to assess risks and minimize harms. Unfortunately, not enough is known about the long-term benefits, risks, and side effects of opioid therapy, not only in IC/PS, but other chronic non-cancer pain conditions. More research is needed in this area. The following guidelines for the use of opioids in chronic/non-acute urogenital pain are suggested by the European Association of Urology [436].

1. All other reasonable treatments must have been tried and failed.
2. The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with another physician (preferably the patient's family doctor).
3. Where there is a history or suspicion of drug abuse, a psychiatrist or psychologist with an interest in pain management and drug addiction should be involved.
4. The patient should undergo a trial of opioids.
5. The dose required needs to be calculated by careful titration.
6. The patient should be made aware (and possibly give written consent):

I. that opioids are strong drugs and associated with addiction and dependency
II. the opioids will normally only be prescribed from one source
III. the drugs will be prescribed for fixed periods of time and a new prescription will not be available until the end of that period
IV. the patient will be subjected to spot urine and possibly blood checks to ensure that the drug is being taken as prescribed and that non-prescribed drugs are not being taken
V. inappropriate aggressive behaviour associated with demanding the drug will not be accepted
VI. hospital specialist review will normally occur at least once a year
VII. the patient may be requested to attend a psychiatric/psychology review
VIII. failure to comply with the above may result in the patient being referred to a drug dependency agency and the use of therapeutic, analgesic opioids being stopped.

- Morphine. There is no compelling evidence that one opiate is better than another. Morphine has, however, become the traditional gold standard. Morphine is the first-line drug, unless there are contraindications to morphine or special indications for another drug. The drug should be prescribed in a slow release/modified release form. Short-acting preparations are undesirable and should be avoided where possible. Parenteral dosing is undesirable and should be avoided where possible. In an acute situation, the daily morphine requirement may be calculated by titration of the drug with progressively increasing doses of 4-hourly rapid-release morphine. However, in most cases, starting with a low dose of slow-release morphine and confining the increments to occur at intervals of no less than 3 days to 1 week is adequate. Chronic non-cancer pain can be managed effectively in most patients with dosages at or below 200 mg/day of morphine or equivalent.

- A fentanyl patch can be used when oral absorption is restricted or when the patient suffers from nausea and vomiting. Patches are generally changed every 72 hours. The problem with the currently available patches is that the dosing increments between patches are large. Care needs to be exercised when increments in dose are undertaken. Fentanyl has contributed to numerous overdose deaths [456,457].

- Methadone is a strong analgesic which has a long track record [458]. While it may have a useful role in the management of urogenital pain, there is very little science to support this. Methadone has the
tendency to accumulate with repeated dosing and cause delayed respiratory arrest. Therefore, whereas it may be a very useful drug, it should only be prescribed by a practitioner familiar with its use as an analgesic. Methadone as an analgesic is usually prescribed 6 hourly as its analgesic action is relatively short-lived compared with the longer benefits seen from using the drug in drug addiction.

- **Meperidine** (Demerol) 300 mg intramuscular (i.m.) is about as effective as morphine 30 mg i.m. (conversion factor 0.1). Its oral bioavailability is, however, poor. Meperidine has a short duration of action, can accumulate with multiple dosing and is therefore not recommended for use in chronic, non-acute pain [459].

- **Oxycodone, hydromorphone and hydrocodone** are available as slow/modiﬁed-release preparations. They may be useful for opiate rotation if side effects or tolerance is a problem. They are powerful opioids and should be used with the same caution as morphine. 20 mg of oxycodone and 6 mg hydromorphone is equivalent to 30 mg of Morphine (1.5 and 5 X conversion factor). Oxycodone, hydromorphone and hydrocodone may have a higher abuse liability than morphine [460].

- **Codeine** is a less potent opioid than morphine and the other opioids discussed and could be useful in mild to moderate pain. 20 mg of Codeine is equivalent to 30 mg of morphine (conversion factor 0.15). Tramadol produces analgesia by two mechanisms: an opioid effect; and an enhancement of serotoninergic and adrenergic pathways [461,462]. It has fewer of the typical opioid side effects (notably, less respiratory depression, less constipation and less addiction potential) [463]. Morphine dose equivalences with tramadol has not been reliably established. Codeine and tramadol may have a lower abuse risk than more potent opioids [460,464].

**Opioid Recommendation:**

A stepped approach to opioid selection should be based on a patient’s clinical proﬁle and individual characteristics and should proceed in a stepwise fashion. First line therapy for mild to moderate pain would include codeine or tramadol while second line therapy for mild to moderate pain could include morphine, oxycodone or hydromorphone. First line therapy for severe pain would include these same agents, morphine, oxycodone or hydromorphone while second and third line therapy for severe pain could include fentanyl and methadone respectively. It is important to determine the optimal dose, i.e., a dose that will improve function or reduce pain intensity by at least 30% without causing major adverse effects or complications. It is recommended to start the opioid trial with a low dose and increase the dose in small quantities over several days or weeks carefully monitoring for effectiveness (or plateauing of response) and adverse effects or complications. Opioids produce a graded analgesic response: the patient experiences the greatest beneﬁts at lower doses and a plateauing of analgesic response and adverse effects at higher doses.

**Recommendation Pain Treatment**

BPS patients deserve to have their chronic pain treated. There are few well controlled long term pain therapy studies in this area, therefore most of our recommendations must come from studies in other non-cancer pain conditions. As discussed in the previous sections, management of symptoms of BPS, including the chronic pain must start with conservative therapies along with BPS condition-specific treatments. For those whose chronic pain is refractory to these therapies including standard analgesics, therapy for the chronic pain should normally start with a tricyclic and/or gabapentinoid (gabapentin or pregabalin), followed by addition of an opioid such as codeine, tramadol, morphine or oxycodone as a last resort. **Level of Evidence: 4** Recommendation: C

**XIII. SURGICAL THERAPY**

Bladder Pain Syndrome (BPS) is a chronic and debilitating disease. Major surgical options should be considered only when all conservative treatment has failed (Table 6) The patient should be informed of all aspects of surgery and understand consequences and potential side effects of surgical intervention. An experienced surgeon familiar with the particular surgical technique should perform the procedure.

1. HYDRODISTENTION

Bladder distension has been used for many years [465] not only as a diagnostic/ classification tool but also for treatment of BPS. In 1957 Franksson reported on a retrospective series of 33 patients, with symptom improvement in all, and lasting up to 1 year in 7 patients[466]. Reports from the seventies were contradictory. Using the Helmstein method [467] Dunn reported complete absence of symptoms in 16 of 25 patients[468], while Badenoch found no improvement in 44 of 56 patients[312]. More recent literature reports poor results with only a minority of patients reporting a small improvement in symptoms for a relatively short period of time[217,218,232,469]. Most studies are retrospective and uncontrolled.

Level of evidence 3; recommendation C

2. TRANSURETHRAL RESECTION

In his first papers Hunner described open resection of the bladder ulcer in the treatment of patients with IC[5]. He later abandoned this treatment due to operative morbidity and recurrence of symptoms. Results of transurethral resection were originally reported by Greenberg et al.[470] and Fall[471]. The retrospective results of this treatment in 116 patients with Hunner’s lesion from Fall’s Swedish clinic was later reported by Peeker et al.[472]. Hunner’s lesion was first recognized by bladder distension under general anesthesia. All lesions were then resected including at least half of the underlying muscular coat. Large areas of the bladder might be treated to resect all diseased tissue. Ninety-two of the 116 patients experienced amelioration of their symptoms. Average duration of symptom alleviation was 23 months ranging from 0-180 months. Up to 16 resections were performed if symptoms recurred. This is the only center having reported a large clinical series of patients with BPS treated in this manner. Shanberg and Malloy reported in 1987 on laser fulguration of 39 patients with BPS[473]. Nineteen of 39 had Hunner’s lesion. Of the 19 patients with Hunner’s lesion 17 reported good pain relief lasting between 6 and 18 months. In the 20 patients without Hunner’s lesion, reddened areas in the bladder were photoagulated with the Neodymium:Yag laser. Thirteen felt marked improvement of symptoms but time to symptom recurrence was not reported. Small bowel perforation in 2 patients was the most important complication in this series. This series was extended to 76 patients [474] where 21 of 27 patients with Hunner’s lesion (BPS ESSIC type 3X) experienced symptom improvement; 12 had relapse within 18 months. Of patients with BPS ESSIC type 1 or 2, 20 of 49 improved but 10 required further therapy within 1 year. Rofeim et al. [475] reported on Nd:YAG laser ablation of Hunner’s lesion in 24 patients with BPS type 3X. All had symptom improvement within days without complications. Pain, urgency, nocturia, and frequency were improved after 23 months, but relapse in 11 patients required up to four additional treatments.

Payne et al. reported on 14 patients with Hunners lesion treated by cystoscopic ablation. Eight became symptom free and 4 improved symptomatically more than 50%. Four had symptomatic recurrence with improvement after repeat ablation[476]. Intravesical, submucosal injection of triamcinolone has in uncontrolled studies been reported to have as good symptomatic effect as resection/fulguration[477].

Transurethral resection, coagulation, or laser ablation of Hunner’s lesions is a recommended treatment for patients with BPS type 3X.

Level of Evidence: 3 Grade of Recommendation: C

3. CYSTOLYSIS – PERIPHERAL DENERVATION

Hunner [5] simply dissected bladder from surrounding tissue. Initial results were encouraging, however after 3 years of follow-up, symptoms recurred. Worth and Turner-Warwick [478] attempted to do more formal cystolysis and were more successful with regard to symptoms. Worth [479] followed patients up to 7 years and found bladder areflexia to be a significant complication of this procedure. Patients had to use Credé technique or even be on intermittent self-catheterisation. Albers & Geyer [480] reported symptom recurrence after 4 years in most of the patients.

• Cystolysis – peripheral denervation is not indicated for BPS; Level of Evidence: 3 Grade of Recommendation: -A (not recommended)

4. SYMPATHETIC DENERVATION

Visceral pain is transmitted in most cases by the sympathetic nervous system. Gino Pieri [481] applied this principle to the bladder pathology and suggested resection of the superior hypogastric plexus (presacral nerves), paravertebral sympathetic chain, and gray rami from S1-3 ganglia (Level 4). This was repeated by Douglass [482] a few years later. Immediate results were very good; however Nesbit [483] showed that the long term results were short lived.

• Sympathetic denervation is not indicated for BPS; Level of Evidence: 4 Grade of Recommendation: -A (not recommended)

5. PARASYMPATHETIC DENERVATION

Based on the contribution of S2-S4 segments to bladder innervation, Moulder and Meirowsky [484] used S3 neurectomy in 3 patients with good long term follow-up. Larger series were reported by Miller [485] and Mason[486] but results after five years were not encouraging. To improve results selective dorsal sacral root neurectomy, unilateral or bilateral, was introduced by Bohm and Franksson[487]. The outcomes of this procedure were unclear.
• Parasympathetic denervation is not indicated for BPS;  
Level of Evidence: 4 Grade of Recommendation: -A (not recommended)

6. BOWEL SURGERY

a) Bladder augmentation-cystoplasty has been commonly used for refractory BPS for 50 years. First reports of ileocystoplasty from 1958 were very promising[488]. Later publications were less sanguine with good results varying from up to 100% [489,490] to 25%(312,491]. Cystoplasty is usually done with or without bladder resection.

Cystoplasty alone was reported as early as 1967 by Turner-Warwick and Ashken[492], advocating augmentation with removal of the diseased tissue. Several subsequent studies indicated that cystoplasty with subtrigonal cystectomy offers better results than without subtrigonal cystectomy[490,493-495]. These were all retrospective studies and conclusions should be taken with reservation. Cystoplasty with partial or total removal of the bladder requires bowel tissue substitution. Different bowel segments are used to enlarge the bladder. It is the general consensus that the intestine segment used for bladder augmentation should be detubularized[496]. Experiences with different bowel segments have been reported in numerous articles with level 4 evidence:

• Ileum [312,489,490,495,497-501]  
• Ileocecum [344,490,491,493,502,503]  
• Cecum [489,504]  
• Right colon [312,490,505]  
• Sigmoid colon [493,495,499,502]  
• Gastric segments [506,507]

There is no significant difference between different bowel segments with regard to outcome except for gastric tissue substitution which is associated with dysuria and persistent pain due to production of acids.

b) Cystoplasty with Supratrigonal Resection (i.e. trigone-sparing) has been reported in various studies. Von Garrelts[489] described excellent results in eight of 13 patients with a follow-up of 12-72 months. Bruce et. al [495] reported satisfactory relief of BPS symptoms by ileocystoplasty and colocystoplasty in eight patients. Dounis and Gow [508] reported improvement in pain and frequency in seven BPS patients after supratrigonal cystectomy with ileococcal augmentation. Kontturi et. al [493] used segments of colon and sigmoid colon in 12 cases with 100% symptom-free outcome in five patients augmented with sigmoid colon over 4.7 years of follow-up. Two of seven cases augmented with colon required ileal conduit and cystectomy. Linn et. al [509] followed six BPS patients for 30 months, and reported that all were symptom-free and voided spontaneously. The report by Nielsen et. al [491] was less favorable. Six out of eight patients had good results. Van Ophoven et. al [510] reported the long-term (mean 5 years) results of orthotopic substitution enteroplasty in 18 women with BPS, using ileocecal (n = 10) or ileal (n = 8) segments with only two failures. In the group [511] augmented with ileum, three patients required self-catheterization and one a suprapubic catheter. Peeker et. al [512] found that patients with end-stage ulcerative BPS had excellent results following ileocystoplasty but not so the patients with non-ulcer disease. A follow up on this paper was recently published[180] with the same conclusion for the patients with end stage BPS ESSIC type 3C, while both continent diversion and illocystoplasty were unrewarding in patients with type 2X BPS. Patients with low cystoscopic capacity (<200 ml) under general anaesthetic have achieved better results [7,25,513,514].

There is some weak evidence that cystoplasty with supratrigonal resection may benefit some selected patients with end stage ESSIC type 3C BPS.  
Level of Evidence: Level 3; Grade of Recommendation: C

c) Cystoplasty with Subtrigonal Cystectomy — orthotopic continent bladder augmentation (i.e. with trigone removal but preservation of the bladder neck) in the management of BPS has been reported less often[511,515-517]. Because of the need of ureteral reimplantation, it is associated with some risks of urine leakage, urethral stricture and reflux[516]. Linn et. al [509] had three failures in 17 patients and half of the patients with good symptomatic response required self catheterization. Nielsen et. al [491] had better results following orthotopic substitution with low bladder capacity (200 ml versus 525 ml, respectively). Orthotopic continent bladder augmentation, particularly when removing the trigone, may cause incomplete voiding requiring intermittent self-catheterization. Therefore patients considering such procedures should be advised accordingly and must be considered capable of performing, accepting and tolerating self catheterization. Nurse suggested that the decision on whether to due a subtrigonal or supratrigonal cystectomy be based on the results of trional biopsy, with the former procedure indicated in the patient with trigonal inflammation[518].

There is no compelling evidence that subtrigonal cystectomy with cystoplasty has any outcome advantage over supratrigonal cystectomy but it tends to be associated with more complications and poorer functional bladder rehabilitation. Level of evidence: 3; Grade of Recommendation: C

7. URINARY DIVERSION WITH OR WITHOUT TOTAL CYSTECTOMY AND URETHRECTOMY

This is the ultimate, final and most invasive option. It should be used as a last therapeutic resort in selected
patients. Techniques include simple or continent urinary diversion. Continent diversion may be preferable for cosmetic reasons in younger patients.

Simple urinary diversion with formation of an ileal conduit is the most common surgical treatment for BPS [519]. Initially, diversion can be done without cystectomy and only when bladder pain is persistent, cystectomy may be considered. Bladder defunctionalization alone produced symptom-relief in several reports. [7,25,312,520,521]

Often diversion is performed as a next step after unsuccessful bladder augmentation. To avoid further bowel resection, a bowel segment used for cystoplasty can often be converted to a conduit[522] In some patients chronic inflammatory changes have been seen in the cystoplasty pouch resembling interstitial cystitis[7,312,523,524], preventing one from using this technique. Similar bowel changes however have been described when cystoplasty is performed for pathology other than interstitial cystitis, suggesting that these pathologic findings are not a direct result of the exposure of bowel to BPB urine [525]. Relatively good responses to diversion without cystectomy have been reported in small series. [491,526]

Urinary diversion with and without cystectomy may be the ultimate option for refractory patients. Continent diversion may have better cosmetic and lifestyle outcome but recurrence of pain in the pouch is a real possibility. Level of Evidence: 3; Grade of Recommendation: C

XIV. CLINICAL SYMPTOM SCALES

Symptom scales have enabled patients to be categorized by symptom severity and have also served to follow results of treatment in patients with bladder pain syndrome. Their future development may enable a presumptive diagnosis of the syndrome but at this time that is not possible. A brief survey that reliably segregates BPS from other urologic disorders would make the ability to diagnose the syndrome reliable, inexpensive, and available to all healthcare providers. It would aid in epidemiologic studies as well. Currently such work sponsored by NIDDK is ongoing. www.mappnetwork.org

A process for development of a case definition for BPS has been developed by adapting the RAND/University of California, Los Angeles Appropriateness Method.[46] This involves a panel consisting of nine experts with experience in BPS and related diseases, literature review of case definitions of BPS, initial ratings of symptoms as indicators of the BPS diagnosis, and discussion and a second set of ratings to establish criteria for diagnosis through patient reports. Symptom questionnaire development, based on the results of the case definition exercise, and validation have been successful in establishing a population-based estimate for disease prevalence using both high specificity and high sensitivity models.[69] If this could be adapted for use in screening by primary care physicians, the potential benefits in early diagnosis of BPS are evident.

Questionnaires and symptom scales are currently utilized to measure treatment outcome and are especially valuable in clinical research studies as well as for guiding therapy for individual patients.

There are 3 published BPS symptom questionnaires: the University of Wisconsin IC Scale (Figure 11), the O'Leary-Sant IC Symptom Index (ICSI) and IC Problem Index (ICPI) (Figure 12), and the Pelvic Pain and Urgency/Frequency (PUF) Scale (Figure 13).

The University of Wisconsin IC Scale includes 7 BPS symptom items and has not been validated for identification or diagnosis of BPS. It captures severity of symptom expression [527,528]. Unlike the other two instruments, it addresses some quality-of-life issues, and this is an advantage when such issues are subject of investigation. Its most attractive aspects are its clinically apparent face validity and its ease of implementation.

The O’Leary-Sant indexes are validated questionnaires that were originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to BPS patients and asymptomatic controls[529,530]. The questionnaires center on 3 questions related to urgency/frequency and one on bladder-associated pain. It does not address generalized pelvic pain or symptomatology associated with sexual activity. This is not because these questions were not considered in the formulation of the questionnaire. Of 73 questions in the preliminary instrument covering domains of urinary symptoms, pain, sexual function, menstrual variability, and general health, only the four questions now in the instrument were needed to reliably and validly describe the illness experience of those with IC and distinguish these patients from those without the disorder[531].

The Pelvic Pain, Urgency, Frequency (PUF) questionnaire[201] was specifically designed to include questions that directly reflect a wide variety of the symptoms experienced by patients who are affected by this disorder. One-third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum.

The PUF is marred by the fact that patients were not included in its development. If used to monitor outcomes, question 4 regarding sexual activity may worsen the score as the outcome improves. These and other problems make its use highly dubious.[532]

A large study utilizing the PUF questionnaire has concluded that up to 23% of American females have BPS[201]. This makes one wary as to the utility and
face-validity of the PUF[533]. A total score of 10-14 = 74% likelihood of positive potassium test (PST); 15-19 = 76%; 20+ = 91%. To the extent that the PST is suspect, the reliability of PUF data comes into question.

Neither the PUF nor O’Leary Sant questionnaires have been shown to be of value in diagnosis of the individual patient[534]. In an interesting epidemiologic study in Finland, Leppilahti and colleagues randomly selected 2000 participants from the Finnish population registry and administered the O’Leary Sant IC symptom and problem index[64]. Women with symptom scores 7 or higher with no history of urinary tract infection in the preceding month were invited to undergo clinical examination. Of these 32 women, 21 underwent examination of whom 3 had probable interstitial cystitis and 4 had possible interstitial cystitis. Based on this specificity, a population prevalence in Finnish women of 230/100,000 probable interstitial cystitis and 530/100,000 possible interstitial cystitis was calculated. Thus, one can get some idea as to O’Leary Sant specificity. For probable BPS it would be about 14% using a parameter of 7 or greater on the symptom index.

The O’Leary-Sant and University of Wisconsin instrument correlate strongly in a large population of patients with BPS.[535] Clemons and co-workers administered the ICSI to 45 patients scheduled to undergo laparoscopy for pelvic pain. Seventeen were diagnosed with BPS based on the finding of glomerulations on bladder distention associated with urgency, frequency, or nocturia. A score of 5 on the ICSI had a 94% sensitivity and a 93% negative predictive value in this enriched population of patients with pelvic pain[536]. However, Clemens and colleagues have found a high degree of overlap in International Prostate Symptom Scores, the O’Leary Sant Symptom Index, and the Chronic Prostatitis Symptom Index in a random sample of over 1400 men and women with urologic symptoms, underscoring that we should be cautious in using these questionnaires as a basis for diagnosis in epidemiologic studies[537].

Rosenberg and Hazzard[62] surveyed 1218 consecutive patients presenting to their primary care office and found 7 (0.6%) who had a 7 ICSI score. Likely BPS was noted in 12.6% of patients on the PUF scale, a Figure 21 times higher, suggesting that either the PUF drastically overestimates BPS, or the ICSI lacks sensitivity. Based on the correlation of the potassium sensitivity test and the PUF questionnaire, Parsons[49] stated that 30.6% of 3rd year female medical students at his California institution had probable BPS. Sahinkanat and co-workers[202] in Turkey administered the PUF questionnaire to all 442 female textile workers in two local factories. Eighty-six per cent of those with a PUF score 7 or greater had an 86% positive rate of PST testing verses 9% positive in the group with PUF less than 7. They extrapolated that bladder epithelial permeability dysfunction was present in 32.8% of these unselected women. The ICSI estimate seems much more in line with current epidemiologic data.

While perhaps not ideally suited for epidemiologic studies, these questionnaires can reveal important

epidemiologic data. Porru and colleagues[538] compared University of Wisconsin scores including both urinary and non-urinary symptoms, for 30 BPS female patients and 30 female controls. While the IC group had significantly higher scores for the urinary symptoms, they did not appear to indiscriminately report higher scores than controls for different somatic and general complaints, as might be expected if this disease is a manifestation of a more generalized disorder. Diggs and colleagues[539] used the ICSI to investigate how interstitial cystitis patients interpret urgency. The ICSI question regarding: “the strong need to urinate with little or no warning” consistently underestimated the response to the International Continence Society definition of urgency: “the compelling urge to urinate that is difficult to postpone.

Treatment outcome studies have also used the Global Response Assessment (Figure 14); a balanced patient self-report on overall response to therapy, developed for NIDDK sponsored multi-center therapeutic trials[301]. The O’Leary Sant and University of Wisconsin questionnaires are responsive to change over time in patients with BPS and have been recommended as secondary endpoints in future clinical trials of the disorder. Propert and colleagues in the Interstitial Cystitis Clinical Trials Group determined that a 1.2 point change in the O’Leary Sant indexes and a 3.1 point change in Wisconsin IC inventory corresponded to a one-category change in the GRA. Individual symptoms were also responsive [540].

A self-report measure that reliably identifies moderate to severe bladder pain syndrome patients for inclusion into clinical trials was recently reported by Pfizer Inc. [532]. Whether it will have value in diagnosis of the syndrome or following patients’ clinical course remains to be seen. A quality of life scale for women with BPS has also been developed for use in clinical trials and reportedly can be used to examine the effects of psychosocial and treatment interventions on quality of life.[541]

Conclusions

The three commonly employed clinical symptom scales include the O’Leary Sant, the University of Wisconsin, and the Pelvic Pain, Urgency, Frequency scales. None of the questionnaires have the sensitivity or specificity to be used in the clinical diagnosis of patients. The O’Leary Sant and University of Wisconsin indexes have been validated as reliable instruments for following the course of the disease and results of treatment interventions. All have shown some value in assessing the severity of disease. The Global Response Assessment has become one of several primary endpoints used in judging the response to specific therapies.

XV. OUTCOME ASSESSMENT

1. THE PROBLEM

BPS/IC has been a difficult condition for which to assess therapeutic impact. There is a 50% inci-
dence of temporary remission unrelated to therapy, with a mean duration of 8 months [52]. A somewhat surprising finding from the Interstitial Cystitis Database was that although there was initial improvement in symptoms partially due to regression to the mean [542] and the intervention effect, there was no evidence of a long-term change in average symptom severity over the four year course of follow-up [98]. In a chronic, devastating condition with primarily subjective symptomatology, no known cause, and no cure, patients are desperate and often seem to respond to any new therapy. A skeptical view of outcomes is essential (Figure 15), as patients can be victims of unorthodox health care providers using unproven forms of therapy, some medical, some homeopathic, and some even surgical.

2. THE PLACEBO ISSUE

Where possible, the results of randomized controlled studies should be used for decision making. Placebo, double-blind studies are optimal in this disorder for which there is no generally effective standard therapy.

Placebo effects influence patient outcomes after any treatment which the clinician and patients believe is effective, including surgery. Placebo effects plus disease natural history and regression to the mean can result in high rates of good outcomes, which may be misattributed to specific treatment effects [98,543-545]. Unfortunately, few BPS treatments have been subjected to a placebo-controlled trial. This is not to say that what seems effective is not, but rather that a high index of skepticism is healthy, even in treatments tested in controlled trials [546].

While in many diseases an argument can be made against using a true placebo control as opposed to an orthodox treatment of approved or accepted value [547], a good case for true placebo comparison can readily be made for BPS. The vagaries of the natural history, the general lack of progression of symptom severity over time, and the fact that it is not life threatening, mean that there is little to lose and much to gain by subjecting new treatments to the vigorous scrutiny of placebo control. Many patients who volunteer for such trials have already run the gamut of accepted (though generally unproved) therapies. It has long been recognized in protocols that use subjective criteria for assessment that “improvement” may be expected in up to 35% of placebo-treated patients [548]. As the spontaneous remission rate (though temporary) for BPS is 11% [311] to 50% [52], combined with the placebo improvement it can be difficult to prove efficacy. Even in placebo controlled trials, it is reasonable to surmise that some degree of unblinding may occur as a result of somatic or psychological side effects of the active arm, impairing the validity of the trial results and giving the active arm a slight edge over placebo [549,550]. Failure to recognize unblinding can easily bias results of a study and has not been routinely measured in clinical trials [551]. When occurring late in a study after one would expect onset of a therapeutic effect, unblinding could be the result of side effect profile or drug efficacy. Early in the trial it reflects poor placebo or study design. The degree of blinding needs to be ascertained throughout the trial. This is of specific concern in BPS and any disorder where primary outcomes may be subject to patientspecific psychological and physiological factors.

The ethics and necessity of placebo-controlled trials have been questioned, especially in situations in which an effective treatment exists and also where delay in treatment has been shown to result in disease progression [552-554]. However, there are methodological concerns with equivalence and non-inferiority active agent comparison trials [555]. These include an inability to determine if the treatments are equally good or equally bad, and the possibility that successive non-inferiority trials can lead to a gradual decrease in treatment efficacy. Although the use of placebo-controlled trials raises ethical concerns when proven effective treatment exists for the condition under investigation, they are ethically justified, provided that stringent criteria for protecting research subjects are satisfied [556].

The value of placebo-controlled trials is aptly illustrated by the recent decisions by pharmaceutical manufacturers not to pursue FDA approval in the United States for seemingly promising intravesical therapies for BPS [557,558] after placebo-controlled trials failed to establish efficacy. These include low concentration hyaluronic acid (Bioniche, Canada), high concentration hyaluronic acid (SKK, Tokyo), and resiniferatoxin (ICOS, Bothell, Washington, USA). Nalmefene, an initially promising oral therapy in the 1990's [559] also failed phase 3 trials (IVAX, Miami). Placebo trials are impractical in surgery and it can be difficult to evaluate surgical reports. The many older medications currently used off-label might not meet success if tested in the stringent manner in which new molecular entities are tested. The expense of testing therapies currently used off-label often requires dependence on the largesse of government agencies like the National Institute of Health [301,395,560].
Figure 15: Selected reported treatment outcomes in uncontrolled studies in IC literature: Percentage of patients initially improved.
3. OUTCOME INTERPRETATION

As has been discussed with regard to rheumatologic disorders[561], the interpretation of measurements of physical functioning in clinical trials should consider the composition of the study sample, with attention to the stage of disease and the heterogeneity in disease duration. Patients with long-standing disease or compromised bladder capacity or central sensitization can be expected to be less responsive to treatments directed toward the bladder itself. Finally, when considering objective changes, the concept of statistical versus clinical significance is paramount. Investigators should, but rarely do, point out differences between statistical improvement and what they consider to be clinically significant improvement[562]. As Gertrude Stein reportedly stated, “A difference, to be a difference, must make a difference”. An increase in bladder capacity of 30cc may be statistically significant but clinically irrelevant. Number needed to treat and number needed to harm data[563] may be particularly important in BPS and have not typically been included in efficacy analysis.

4. IMMPACT RECOMMENDATIONS

The core outcome domains for chronic pain clinical trials have been published.[423,564] The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) recommendations indicate that core outcome domains should be considered in all clinical trials of the efficacy and effectiveness of treatments for chronic pain. These domains include:

1. Pain
2. Physical functioning
3. Emotional functioning
4. Participant ratings of improvement and satisfaction with treatment
5. Symptoms and adverse effects, participant disposition

CONCLUSIONS:

Currently for BPS/IC there are no accepted biologic disease markers that can be used for the assessment of response to therapy. The O’Leary Sant, University of Wisconsin, and Global Response Assessment are well-validated questionnaires to follow disease progression and response to therapy. The IMMPACT recommendations suggest that, as well as symptoms scores, any future study on a pain syndrome must involve more general assessments of psycho-physical functioning. There is limited experience in BPS/IC for the use of well-validated measures available for the study of chronic pain. Future NIDDK research initiatives may help to rectify this. http://www.mappnetwork.org

International recognition of an agreed upon definition and inclusion and exclusion criteria of BPS/IC will help future studies to fulfill the highest standards available, and placebo-controlled, double blind, randomized controlled trials, where possible, will provide the highest level of evidence to move the field forward.

LEVEL 2 GRADE C RECOMMENDATIONS

XVI. PRINCIPLES OF MANAGEMENT

The information currently available in the literature does not lend itself to easily formulating a diagnostic or treatment guideline. Different groups of “experts” would undoubtedly create different “best practices”.[565] The compromise approach devised by an experienced cross-section of urologists and gynecologists from around the world at the International Consultation on Continence 2004 meeting in Monaco[41] and subsequently modified at the 2008 meeting in Paris[1] has been reviewed and updated by the committee and allows for significant latitude to reflect varying individual practice patterns and to account for patient preference.

An underlying principle is that, where possible, decisions on the treatment of bladder pain syndrome should be evidence based[566]. Unfortunately, high level evidence of efficacy is lacking for many common treatments, either because such studies have not been done, or were done and failed to demonstrate efficacy.[343,567,568]

Another principle is that we should be guided by patient perceived and driven outcomes for bladder pain syndrome, which is, after all, diagnosed on the basis of symptoms after exclusion of confusable diseases. Many patients prefer noninvasive therapies[569], and it would seem reasonable to start with physical therapy and/or oral therapies if conservative non-medical interventions (i.e. education, diet, behavioral modification, stress reduction) fail to result in significant symptom amelioration. Use of surgical therapies should be approached with some caution. It has been reported that women with BPS have had significantly more pelvic surgeries than controls, and the majority were performed prior to diagnosis of BPS, possibly for pain related to undiagnosed BPS.[570,571]

1. HARMONIZATION

With representatives from Asia, Europe, and North America, the Consultation has attempted to create a document that is harmonious with guidelines developed around the world in the last several years, many since the last meeting of the Consultation. The Canadian Urological Association[572], the International Society for the Study of Bladder Pain Syndrome (ESSIC)[2,15], the European Association of Urology[342], the Japanese Urological Association[45], East Asian countries[11], and the American Urological Association[12] all have published...
consensus guidelines, many of which have been reviewed in a recent publication[565].

In the Japanese and Asian view, urinary frequency/urgency is the primary symptom, with overactive bladder (OAB) and hypersensitive bladder (HSB) listed as subgroups (with painful bladder syndrome (PBS) as its extreme form)[44]. (Figure 3)

In the European view as reflected in European Association of Urology and ESSIC guidelines, pain is the key symptom, with frequency being secondary to pain, while urgency basically represents a different pathology. American and Canadian guidelines are concordant with the European view. They emphasize pain, pressure, and discomfort perceived by the patient to be related to the bladder and associated with urinary frequency or urgency.

Pathologic afferent activity is a feature in overactive bladder as well as BPS, making the philosophy of the Asian guidelines conceptually attractive. But the knowledge gaps on lower urinary tract sensory functions are tremendous and from a neurophysiologic point of view it may be premature to link the conditions.

As a disorder based on symptoms, it is remarkable that we do not know if sensations described by the patient as pain, urge, or pressure are physiologically different or identical, if they represent various grades of the same pathology, or if this set of terms merely represents linguistically different ways of presenting the same problem. Do cultural differences play a part? Are Asian patients more reluctant to use the word pain to describe the same symptoms?

Cystoscopic and pathologic findings have a more important role in Asia and Europe than in North America, but nowhere do guidelines now recommend invasive procedures like endoscopy with or without biopsy as essential to make a diagnosis of BPS.

The latest algorithms from the European Association of Urology, American Urological Association, and East Asian nations are presented below and illustrate different approaches to a difficult problem. (Figures 16, 17, 18) Opportunities for future harmonization are apparent.

**XVII. RECOMMENDATIONS OF INTERNATIONAL CONSULTATION ON INCONTINENCE:**

### 1.HISTORY / INITIAL ASSESSMENT

Men or women with an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes should be evaluated for bladder pain syndrome[12] The initial assessment consists of a frequency/volume chart, focused physical exam, urinalysis, and urine culture. Cytology and cystoscopy are recommended if clinically indicated.

Patients with infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and/or hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms are they diagnosed with BPS.

### 2.INITIAL TREATMENT

Patient education and support, dietary manipulation, stress reduction, nonprescription analgesics, and pelvic floor relaxation techniques comprise the initial management of BPS. It is important at every stage to address the patient’s pain, and understand that at some point in the progression of treatment, referral to a pain specialty clinic may be desirable. When the conservative approach fails, or symptoms are severe and conservative management unlikely to succeed, oral medication, physical therapy, and/or intravesical treatment can be prescribed.

### 3.SECONDARY ASSESSMENT

If oral or intravesical therapy fails, or before beginning such therapy at the discretion of the clinician, it is reasonable to consider further evaluation which can include urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anesthesia. Laparoscopy may be indicated if there is a suspicion of gynecologic disease. Findings of bladder overactivity suggest a trial of antimuscarinic therapy. Findings of a Hunner’s lesion suggest therapy with transurethral fulguration or resection of the ulcer. Distention itself can have therapeutic benefit in up to one-third of patients, though benefits rarely persist for longer than a few months.

### 4.REFRACTORY BPS

Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. These might include neuromodulation, intradetrusor botulinum toxin, or cyclosporine. At any stage of the treatment algorithm, experimental pharmacologic protocols of promising new treatments are reasonable to consider if symptoms warrant and the risk-benefit ratio is acceptable.

The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urine stream. Augmentation (substitution) cystoplasty and urinary diversion with or without cystectomy have been used with good results in very well selected patients.

A treatment algorithm by the Consultation is presented in Figure 19.

**Figure 16:** European Association of Urology guidelines 2012/2013.

**Figure 17:** Management proposed by Japanese Urological Association and urologists in Taiwan and Korea, modified from Homma[573].
IC/BPS: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes.

The evidence supporting the use of Neuromodulation, Cyclophosphamide A, and BTX for IC/BPS is limited by many factors including study quality, small sample sizes, and lack of durable follow up. None of these therapies have been approved by the U.S. Food and Drug Administration for this indication. The panel believes that none of these interventions can be recommended for general use for this disorder, but rather should be limited to practitioners with experience managing this syndrome and willingness to provide long term care of these patients posts intervention.

Figure 18: Management Guideline of American Urological Association[12].
Figure 19: Algorithm for Diagnosis and Treatment: 2012 International Consultation on Incontinence.
It is the opinion of the committee that, because of the natural history of the disorder, it is best to cautiously progress through a variety of treatments. Whereas the shotgun approach, starting newly diagnosed patients on a variety of simultaneous medications, seems to have many adherents, employing one treatment at a time makes the natural history of the disease itself an ally in the treatment process. If a treatment has no efficacy, it should be stopped. It a treatment results in modest improvement, it should be continued and another treatment option employed in an attempt to further improve symptoms. The goal is to maximize quality of life and dispense with ineffective treatments in a somewhat controlled fashion. The patient and clinician must remember that “perfect is the enemy of good” and expectations should be realistic. One should encourage patients to maximize their activity and live as normal a life as possible, not becoming a prisoner of the condition. Although some activities or foods may aggravate symptoms, nothing has been shown to negatively affect the disease process itself. Therefore, patients should feel free to experiment and judge for themselves how to modify their lifestyle without the guilt that comes from feeling they have harmed themselves if symptoms flare. Dogmatic restriction and diet are to be avoided unless they are shown to improve symptoms in a particular patient.

Level 4 Grade C

XVIII. FUTURE DIRECTIONS IN RESEARCH

The committee believes that further research is needed in the following broad areas:

1. The recent American Urological Association guideline[12] points out numerous areas for which there was not enough information to allow an evidence basis for recommendations, and these areas require further study.

2. Pathology of BPS
3. Biomarker development
4. Immunology of BPS
5. Neurological aspects with particular attention to the relationship of BPS to overactive bladder
6. The relationship of bladder pain syndrome to chronic pelvic pain syndrome (nonbacterial prostatitis)

The majority of current treatments options are still targeting the bladder. However, as said in the AUA guideline, IC/BPS, which was originally considered to be a bladder disease, has now been recognized as a part of chronic pain syndromes. There is a growing body of literature demonstrating that different visceral pain syndromes, as well as pain syndromes in other body regions, and other systemic diseases often occur together in the same patient. Thus, the efforts to understand the pathophysiology and to design therapeutic modalities have recently shifted from an organ-based approach to a more global approach. Therefore, “phenotyping” of the disease conditions would be important to identify “bladder-related” and “non-bladder” (=outside the bladder) components that contribute to the symptoms for improving the treatment efficacy.

For this purpose, following issues require major research initiatives:

1. To improve symptom-based classification to identify the degree of bladder and non-bladder symptoms, for example, based on the responses to local treatment such as lidocaine intravesical application.

2. To identify bladder-specific pathology (urothelial changes, ulcer, hypervasculization, and the potential role of narrow band imaging[574], Neurometer[575] etc.

3. To identify bladder-specific biomarker (NGF or other neurotrophic factors, angiogenic growth factors, urothelial markers such as antiproliferative factor, cytokines/chemokines profile, uroplakin [antibody, splice variant])

4. To identify bladder-specific or systemic immunological process (cytokines/chemokines profile) Identification of these factors could also identify the difference in the disease process between IC/BPS and OAB (=LUTS with and without pain, respectively)

Finally, if we can identify the “bladder-related” and “non-bladder” (=outside the bladder) components that contribute to the symptoms, we should be able to develop the agent(s) to control bladder pain based on its pathology.

Major recommendations of the last Consultation for future directions in research on BPS still have pertinence today. They include:

A) Epidemiological study

i. Develop a reliable screening tool with adequate sensitivity and specificity to conduct epidemiologic research in the general population to study the incidence, prevalence and identify risk factors for the development of BPS.

ii. Establish patient databases in different regions and conduct longitudinal follow up to understand the natural history of the disease and to examine the differences in disease natural history among regions.

B) Sub-grouping/phenotyping patients.

Patients who have or develop additional pain syndromes, such as vulvodynia, temporomandibular disorder, irritable bowel syndrome, fibromyalgia and
chronic fatigue syndrome, or autoimmune diseases such as lupus erythematosus and Sjögren’s syndrome might have different pathophysiology, natural history and treatment response from those patients without co-morbidities. Sub-grouping patients not only allows us to develop better treatment strategy but also may answer the question: Is BPS an end-organ disease of the bladder or a systemic condition? However, to properly phenotype patients, it is necessary to develop an easy-to-use tool for non-specialists to identify those with co-morbidities. It is also important to validate the concept that categorizes all types of pelvic pain into one “chronic urological pelvic pain syndrome”, as some patients’ symptoms involve multiple pelvic organs, concurrently or sequentially along with other body systems.

C) Developing a simple, non-invasive diagnostic test for BPS.

This will most likely involve urinary markers. Urinary markers may help to sub-classify various types of BPS. This test will determine the diagnosis of BPS in the female population, as well as determine the subset of men currently diagnosed with non-bacterial chronic prostatitis/chronic pelvic pain syndrome who may actually have BPS.

D) Develop a practical multi-disciplinary care model.

In addition to physical morbidities (urinary frequency, pain), many BPS patients have associated psychological co-morbidities. These can often be managed by psychological intervention. BPS patients also need help from dietitians and physiotherapists. A practical multi-disciplinary care model, which includes physicians, dietitians, physiotherapists, pain specialists, psychologists, psychiatrists and patient support groups, should be developed and tested in various settings.

2. BLADDER PAIN SYNDROME (BPS)

a) Nomenclature

The scientific committee of the International Consultation voted to use the term “bladder pain syndrome” for the disorder that has been commonly referred to as interstitial cystitis (IC). The term painful bladder syndrome was dropped from the lexicon. The term IC implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. Painful Bladder Syndrome, as defined by the International Continence Society, is too restrictive for the clinical syndrome.

Properly defined, the term Bladder Pain Syndrome appears to fit in with the taxonomy of the International Association for the Study of Pain (IASP) (see below), and focuses on the actual symptom complex rather than what appears to be long-held misconception of the underlying pathology.

Bladder Pain Syndrome (XXIII-2) (per IASP)

Bladder pain syndrome is the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. There is no proven infection or other obvious local pathology. Bladder pain syndrome is often associated with negative cognitive, behavioral, sexual, or emotional consequences as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.

b) History / Initial Assessment

Males or females whose symptoms meet the requirements of the definition of bladder pain syndrome should be evaluated. The presence of commonly associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms of bladder pain syndrome also suggests the diagnosis. Abnormal gynecologic findings in women and well-characterized confusable diseases that may explain the symptoms must be ruled out.

The initial assessment consists of a frequency/volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology, cystoscopy, and urodynamometric evaluation are recommended if clinically indicated and/or the diagnosis is in doubt. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and microscopic or gross hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms, are they diagnosed with BPS. Grade of recommendation: C

c) Initial Treatment

- Patient education,
- dietary manipulation,
• nonprescription analgesics,
• stress reduction,
• pelvic floor relaxation techniques comprise
the initial treatment of BPS. In the patient with
findings suggesting pelvic floor dysfunction,
pelvic floor physical therapy with myofascial
trigger point release and intravaginal Thiele
massage is often an effective therapeutic
intervention. The treatment of pain needs to
be addressed directly, and in some instances
referral to an anesthesia/pain center can be
an appropriate early step in conjunction with
ongoing treatment of the syndrome.

When conservative therapy fails or symptoms are severe
and conservative management is unlikely to succeed,
• oral medication or
• intravesical treatment can be prescribed. It is
recommended to initiate a single form of ther-
apy and observe results, adding other modal-
ities or substituting other modalities as indicat-
ed by degree of response or lack of response
to treatment. Grade of recommendation: C

d) Secondary Assessment
If initial oral or intravesical therapy fails, or
before beginning such therapy based on clinician
judgment, it is reasonable to consider further eval-
uation which can include Urodynamics, pelvic im-
ing, and cystoscopy with bladder distention and
possible bladder biopsy under anesthesia.

• Findings of bladder overactivity suggest a trial
of antimuscarinic therapy.

• The presence of a Hunner’s lesion suggests ther-
apy with transurethral resection, fulguration of the
lesion, or direct steroid injection into the lesion.

• Distention itself can have therapeutic benefit
in 30-50% of patients, though benefits rarely
persist for longer than a few months. Grade
of recommendation: C

e) Refractory BPS
Those patients with persistent, unacceptable symp-
toms despite oral and/or intravesical therapy are
candidates for more aggressive modalities. Many of
these are best administered within the context of a
clinical trial if possible. These may include
• neuromodulation,
• intradetrusor botulinum toxin,
• oral cyclosporine A, or
• clinical trials of newly described pharmacologic
management techniques. At this point, most
patients will benefit from the expertise of an
anesthesia pain clinic.

The last step in treatment is usually some type of sur-
gical intervention aimed at increasing the functional
capacity of the bladder or diverting the urinary stream.

• Urinary diversion with or without cystectomy
has been used as a last resort with good re-
sults in selected patients.

• Augmentation or substitution cystoplasty
seems less effective and more prone to recur-
rence of chronic pain in small reported series.

Grade of recommendation: C

• Pain management is a primary consideration
at every step of algorithm

• Patient enrollment in appropriate research
trial is reasonable option at any point

• Evidence supporting neuromodulation, cyclo-
sporine A, and botulinum toxin for BPS indica-
tion is limited. These interventions are approp-
riate only for practitioners with experience
treating BPS and willing to provide long-term
care post-intervention.

Not all incontinence can be cured completely and even those who are ultimately successfully treated may have to live with incontinence for a time, for example, whilst they wait for surgery or for pelvic floor muscle training to yield its benefits. Still others – depending on their frailty, severity of incontinence and personal priorities – may not be candidates for treatment or may choose management over attempted cure. For all such people, the challenge is to discover how to deal with their incontinence so as to minimise its impact on their quality of life. This usually involves using some kind of incontinence product(s) to control or contain leakage of urine and/or faeces, and/or to manage urinary retention. In short, the possible role of incontinence products should be considered at each stage of patient assessment and treatment and, if treatment is not available, appropriate, acceptable or (fully) successful – subsequent management. Managing incontinence successfully with products is often referred to as contained incontinence, managed incontinence or social continence, in recognition of the substantial benefits it can bring to quality of life even though cure has not been achieved [1].

This chapter is aimed primarily at healthcare professionals seeking to make informed decisions as they choose – or help their patients to choose - between incontinence product categories and then select a specific product within their chosen category. We have also aimed to make this information accessible to the user, particularly in the summary and recommendation sections. The chapter includes a section for each of the major product categories, each section reviewing published data and – where possible - identifying evidence-based recommendations for product selection and use. Products designed to deal with skin and odour problems caused by incontinence are also addressed.

The sections on the major product categories are preceded by two others. The first provides overall guidelines for product selection, describing the key elements of patient assessment and suggesting a classification of people with incontinence into a number of broad groups based on gender, age (adult or child) and the nature and severity of their incontinence. A table is provided for each group summarising the user characteristics, priorities and contexts which commonly favour or discourage the use of each of the major product categories available to them. Following these overall guidelines and preceding the sections on the major product categories, a review is provided of the methodological challenges of conducting incontinence product evaluations and interpreting the results.

Much of the evidence base for product selection and effective use is patchy and so, where there is little published data to provide confident evidence-based advice on an issue commonly raised by patients and caregivers, an expert opinion is offered as the best advice available. The hope is that highlighting knowledge gaps in this way will help stimulate the research necessary to provide more robust evidence-based advice in the future.

To accompany this chapter, the International Consultation on Incontinence and the International Continence Society have collaborated to make the material more generally available via a new website hosted by the International Continence Society at http://www.continenceproductadvisor.org/. The hope is that this will help people with incontinence and their caregivers to make informed choices in selecting appropriate products, and provide them with accessible, evidence-based advice on how to use them effectively.

The literature search strategy to identify material for this chapter additional to that reviewed for the third consultation [2] was conducted as follows. MEDLINE and CINAHL databases were searched from 2008 – 2011 for English language publications. Detailed search strategies were developed for each electronic database searched. Consideration was given to variations in terms used and spellings of terms in different countries so that studies were not missed. Relevant abstracts were examined and then pertinent articles were retrieved and reviewed, and the reference lists searched for further studies.
For product categories associated with little or no research literature, analysis relied on expert opinion from clinical practice papers.

The following main search terms were used: incontinence AND device*, toilet* AND facilities, female, male, urinal*, commode*, bedpan*, urin* AND sheath, condom AND catheter*, incontinence OR absorbent pad*, urinary AND catheter* (in title), urinary AND leg bag* OR legbag* OR drainage bag, faecal OR fecal AND incontinence AND plug OR pouch OR bag OR device, OR manage* system, incontinence OR perineal AND dermatitis OR inflammation OR skin damage.

II. OVERALL GUIDELINES FOR SELECTING CONTINENCE PRODUCTS

Selecting suitable continence products is critical for the well-being and quality of life of patients and carers. The ability to contain and conceal incontinence enables individuals to protect their public identity as a “continent person” and avoid the stigma associated with incontinence [3]. Failure to do so can result in limited social and professional opportunities, place relationships in jeopardy and detrimentally affect emotional and mental well-being [4]. The ability to contain and conceal incontinence enables carers to feel confident that the person(s) they care for will not be embarrassed publicly. It reduces the level of care required in relation to maintaining hygiene, skin care and laundry for the person who is dependent upon continence products [5].

Fortunately there is a diverse range of different products to choose from. However, without comprehensive and current information on the products available, this plethora of choice can be overwhelming and confusing [5]. Furthermore, the range of products actually accessible to users can vary enormously between and within countries, depending on the funding available, healthcare policy and the logistics of supply [5].

The choice of appropriate products for an individual with incontinence is influenced by the resources and care available and patient / carer preference, as well as assessment of specific client characteristics and needs [6] [7].

The stigma associated with incontinence means that another measure by which the success of products is judged is their ability to conceal the problem [8]. Such concealment may involve compromises: for example, in order to prevent leakage from a product, those with a larger capacity than strictly necessary may be preferred but this can in itself introduce issues to do with discretion when the product is worn. The intimate and stigmatised nature of incontinence means that issues relating to self-image can affect some patients’ preferences. This may be especially marked in younger people for whom body-image may be particularly important and for whom disruption to normal social and interpersonal development may result in isolation or lack of access to normal experiences [9] [10].

1. PRODUCT CATEGORIES

The continence products considered in this chapter may be divided into those that are intended to assist with toileting and those to manage urinary retention and / or contain incontinence (urinary and / or faecal) (Figure II-1).

All toileting products can be useful for dealing with urine and / or faeces except for handheld urinals which are just for urine. Containment / control products are subdivided into three overlapping classes: those for urinary retention, urinary incontinence, and faecal incontinence. So, for example, someone with urinary retention is most likely to benefit from one of the products in the red ellipse, while someone with urinary incontinence will most likely benefit from one in the blue ellipse. A patient experiencing both problems will need two products (one from each ellipse) or one product from the intersection of the two ellipses.

2. IDENTIFYING THE NEEDS

The algorithms below (Figures II-2 and II-3) are designed to provide guidance for determining broadly which product(s) is likely to be of benefit to a particular patient. There are three main questions:

Figure II-1: Products for toileting (top) and for managing incontinence and / or urinary retention (bottom). CIC= Clean intermittent catheterisation; IDC= Indwelling catheter
Figure II-2: Algorithm to help identify the category(s) of products most likely to help a patient with urinary incontinence and / or urinary retention. (Y = Yes; N = No; U = unsatisfactory outcome considered and deemed unsuitable or tried and found not to work satisfactorily). * Consideration should be based on assessment of the patient’s physical characteristics, cognitive ability and personal preferences, as well as the nature of their incontinence. (CIC = Clean intermittent catheterisation; IDC = Indwelling catheter).
Figure II-3: Algorithm to help identify the category(s) of products most likely to help a patient with faecal incontinence. (Y = Yes; N = No; U = unsatisfactory i.e. considered and deemed inappropriate or tried and found not to work satisfactorily). * Consideration should be based on assessment of the patient’s physical characteristics, cognitive ability and personal preferences, as well as the nature of their incontinence.

- Is there urinary retention (with or without incontinence)?
- Are there problems with toilet access (e.g. the proximity or design of the toilet; mobility or urgency problems for the patient)?
- Is there urinary incontinence or faecal incontinence or both?
- Answers to these questions will determine which one (or both) of the algorithms is most appropriate for an individual and help identify the category(s) of products most likely to help.

3. PATIENT ASSESSMENT FACTORS

A careful patient assessment is an important part of the process of product selection and Table II-1 summarises the key elements to be considered.

The choice of appropriate products for an individual with incontinence is dependent upon the resources and care available. It must also be influenced by patient and carer preference as well as assessment of specific client characteristics and needs [6] [7].

Assessment of physical characteristics such as anthropometrics, level of independence, mobility and dexterity, mental acuity and the nature of the incontinence will determine which products may be appropriate. In addition to these factors, successful product choice and effective use involves other practical and psychosocial considerations. Product effectiveness depends upon the same factors as any assistive device intended to address a disability or impairment: patient participation in device selection [11] provision of adequate instructions for use [12] and the need for products to fulfil their function reliably and not be difficult to use [12] [9] [13].

While Table II-1 provides general guidance on patient assessment relating to product selection, later sections in the chapter provide further discussion on assessment issues specifically related to the various product categories.

In addition to selection of appropriate and effective products following patient assessment, education and training of users or carers in the correct use of the devices is of importance if product use is to be optimal. This may be a simple matter of instruction in the effective fitting and changing of absorbent products, or may involve more in-depth training in the ongoing care of, for example, a suprapubic catheter.
<table>
<thead>
<tr>
<th>Element</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nature of the continence problem</td>
<td>The frequency, volume and flow rate of the incontinence influences product suitability.</td>
</tr>
<tr>
<td>Gender</td>
<td>Males may consider and prefer sheaths as a more masculine option to pads. Females may be attracted to products that are more feminine in design and presentation. Some ‘unisex’ products such as absorbent pads have different designs that work better for men (or women).</td>
</tr>
<tr>
<td>Physical characteristics</td>
<td>Anthropometrics (e.g. height and waist, thigh, penile circumference) will influence the comfort and effectiveness of a product.</td>
</tr>
<tr>
<td>Mental acuity</td>
<td>Mental impairment can affect the person’s ability to manage the product. Products that resemble usual underwear (e.g. some absorbents) may be easiest to manage. Products which have health implications if used incorrectly (e.g. mechanical devices or catheter valves) should be avoided if mental impairment is likely to preclude correct and safe use.</td>
</tr>
<tr>
<td>Mobility</td>
<td>Impaired mobility may make some product choices impractical or require toilet or clothing modification to allow effective use of the product.</td>
</tr>
<tr>
<td>Dexterity</td>
<td>Problems with hand or finger movement can make it difficult to use some products (e.g. taps on leg bags, straps with buttons).</td>
</tr>
<tr>
<td>Eyesight</td>
<td>Impaired eyesight limits effective application and management of some products.</td>
</tr>
<tr>
<td>Leg abduction problems</td>
<td>Difficulty with abduction can make the use of some products impractical or ineffective.</td>
</tr>
<tr>
<td>Lifestyle and environments</td>
<td>Daily activities and environments can influence the choice of product and a mixture of products may provide optimum management. Different products may be most satisfactory for daytime and going out (when discreetness may be a priority) and night-time or staying in (when comfort may be a priority), for holidays (when laundry and/or large quantities of disposables may be a problem) or for use at work. The proximity and accessibility of a toilet in the various environments may be a key factor.</td>
</tr>
<tr>
<td>Independence / assistance</td>
<td>If a caregiver is required to apply or change the product then it may be important to involve them in the selection of the product and to establish their willingness and ability to use it.</td>
</tr>
<tr>
<td>Laundry facilities</td>
<td>Washable pads and bed linen may be very heavy when wet and take a long time to dry. It is important to check that the person doing the laundry has the ability and facilities to cope.</td>
</tr>
<tr>
<td>Disposal facilities</td>
<td>Ability to appropriately, safely and discreetly dispose of the selected products needs to be considered.</td>
</tr>
<tr>
<td>Storage facilities</td>
<td>Some products - notably, pads for heavy incontinence - can be bulky. Adequate space to store supplies between deliveries / purchases needs to be available.</td>
</tr>
<tr>
<td>Personal preferences</td>
<td>Different people like different products and where possible patients should be given a choice of products with which to experiment to determine the most satisfactory product.</td>
</tr>
<tr>
<td>Personal priorities</td>
<td>Everyone wants to avoid leakage but other factors such as discreetness may be more or less important to individuals.</td>
</tr>
</tbody>
</table>
Incontinence is often a long term condition and so monitoring and periodic reassessment is essential to maintain effective management with products.

4. MAIN USER GROUPS

Although needs, priorities and preferences vary between people with incontinence it is useful to divide patients into major user groups to help identify the category(s) of products most likely to benefit an individual. Seven primary groups are identified in this chapter:

• People with urinary retention.
• People who need help with toileting / toilet access.
• Females with light urinary incontinence.
• Males with light urinary incontinence.
• Females with moderate / heavy urinary incontinence.
• Males with moderate / heavy urinary incontinence.
• People with faecal incontinence.

An individual may belong to more than one group. Each group includes children and young people: the products available for them are broadly similar to those for adults.

5. CHOOSING BETWEEN PRODUCT CATEGORIES

• Figures II-4 to II-9 summarise the user characteristics, priorities and contexts which favour or discourage the use of each of the categories of products available for six of the seven user groups identified in section II.4. Assistance with choosing appropriate products for the first group (people with urinary retention) is given in the section on catheters (Table XII-1) as all the product options for these people are in the same category (catheters).

• The recommendations given in these charts are based on the evidence presented in the sections of the chapter dedicated to different product categories and they are intended to help identify which product category (categories) are most likely to help an individual. However, it should be remembered that the same product will not suit all people, even if they have very similar assessment outcomes on the factors summarised in Table II-1. Different people prefer different products and where possible patients should be given access to a range with which to experiment to determine the most satisfactory product(s) for them. Similarly, the balance of priorities varies between users; for example, some pad users will opt for a bulky and, therefore, less discreet product to achieve an acceptably low risk of leakage while others will see the balance differently. It should also be noted that a mix of products from different categories may provide the best solution; for example, needs may vary between day / night and home / away. Once a product category of interest has been identified the corresponding chapter section should be consulted for further help.

6. SUMMARY

In conclusion, continence products can play an important role in enhancing the quality of life and reducing the stigma of incontinence of those who: are awaiting treatment; are waiting for treatment to take effect; elect not to pursue cure options; are unable to be fully cured and are living with an ongoing bladder / bowel problem.

7. RECOMMENDATIONS

• Incontinence should be actively managed with products to minimise the impact of incontinence on quality of life (Grade of Recommendation C).
• Patients should be carefully assessed (and reassessed periodically) to select the most appropriate products (Grade of Recommendation C).

III. PRODUCT EVALUATION METHODOLOGY

This section aims to assist those planning clinical trials of products. There have been relatively few large clinical trials of continence products (with the exception of urinary catheters) and for most product categories research evidence to guide the selection of individual products / designs / features is limited and in some cases absent.

Measuring the performance of continence products is methodologically challenging. Manufacturers modify and change their products regularly - in terms of both materials and designs - and this limits the long-term validity of research results. There are also complex issues regarding research questions, study design, product representation, blinding and sample size [14] which are discussed below.

It is common for practitioners to be asked (by their employers or by companies) to do a small evaluation or trial – sometimes to ‘test out’ a new product and sometimes to help choose between competing brands for bulk-buying. Such trials should be approached with caution; they can be very demanding but their results may be of very limited value, even for local use. The methodological challenges identified below still apply but are compounded by small sample size and restricted product selection. These studies are likely to be helpful only for identifying gross product short-comings or benefits.

1. RESEARCH QUESTIONS

a) Comparisons

Part of the complexity of product evaluations stems from the sheer number and type of products available, meaning that many different comparisons could be made. Table III-1 illustrates the problem
Figure II-4: Products for people who need assistance with toileting.(Grade of recommendation in brackets)

Figure II-9: Products for people with faecal incontinence. (Grade of recommendation in brackets)
using a hierarchy of questions relating to absorbent products. So, in this example, once the decision is made to choose an absorbent product in response to question 1, successive further questions can be used to narrow down the choice to a specific product brand. Questions at any of these levels may form the basis for research projects.

**Table III-1: Levels of questions**

- Which product category (eg catheter, sheath, absorbent pad)?
- Which design of product design (eg pull-up or diaper design of pad)?
- Which material type (eg reusable or disposable)?
- Which features (eg with / without elastic gathers)?
- Which product brand?

In the field of absorbent products the practitioner and / or patient wishes to know whether to use an underpad or a bodyworn product, a reusable or a disposable, a diaper or an insert (if they select a bodyworn), a diaper with internal elastication (standing gathers) or without and, finally, which of the many diaper brands is likely to be most effective. Attempting to answer this final question is the most pertinent question for the practitioner (who may already have made decisions about questions 1-4, Table III-1) but is particularly problematic because of the high rate of product change. By the time the results of a clinical trial of product brands are known many of the test products will have been modified and the results will have limited value for product selection. However, these ‘single design’ studies do have value in demonstrating the range of performance within the group of product brands, and where objective measurements can be made (for example, of leakage performance) can allow for comparisons between groups of products. Single design studies are also helpful in promoting product improvement by revealing common problems experienced by patients and exposing particularly poor products or poor product features which are amenable to change by manufacturers.

Basic product designs, features and materials change much less frequently and attempting to answer questions 1-4 (Table III-1) is therefore likely to lead to more long-lasting results. Such studies have been attempted by many researchers, but these have frequently been confounded by problems with product representation.

**b) Product representation**

The single greatest (and most frequently overlooked) threat to the validity of clinical trials of products is the selection of the products entered into the study. Evaluations of a number of product variants of a similar design (eg different brands) have shown that patient ‘overall opinion’ scores can vary by as much as 70 percentage points between apparently similar products [15]. Accordingly, in an evaluation to compare different designs, the selection of one or more products to represent each design, is crucial. Studies that have purported to compare different designs or materials have often included a small number (most often just one) of arbitrarily selected product(s). Generalizing the results of such studies to whole product groups (eg reusable underpads, or disposable bodyworn) is meaningless and misleading. It is perfectly possible to select (either by accident or design) a particularly ‘good’ product from one group and a particularly ‘poor’ product from another. A well-designed study will therefore be seriously flawed if there is no clear process or pilot study to determine and justify the choice of particular products. Even with a systematic process of product selection (or preferably a pilot study) it is unwise to select a single product to represent a whole group of products and selection of a small group of products (eg three) is preferable. This allows for any ‘within group’ differences to be detected and helps to demonstrate the ‘representativeness’ of the products selected.

The most controlled method of testing different designs, materials or features of products is to make up experimental batches which differ only in the aspect of interest (eg the material or the feature) and a small number of studies have attempted this [15] [16]. However, experimentally made products are not usually identical to those available on the market which impairs the validity of such studies.

**2. RESEARCH DESIGN**

A randomized controlled trial is not possible for clinical trials of products in most categories simply because a ‘control’ product does not usually exist. Nor is there a ‘standard or reference’ product to act as a control and comparisons with ‘standard practice’ (ie the product currently in use) are prone to bias.

Although it is methodologically simpler (and more robust) to compare only two different product groups, it is more clinically relevant to compare several competing groups, using a multiple cross-over design, where there are valid comparisons. For example, there are four main design groups of disposable bodyworn pads for moderate / heavy incontinence (inserts, diapers, pull-ups and T-shaped). Evaluation of all four groups together is much faster (and therefore gives more long-lasting results) and more cost-effective than several serial studies. Cross-over trials are vulnerable to order effects and randomization of the order of testing should be carried out using Latin squares [17] to ensure balance.

It is important that clinical trials of single designs of products (which aim to enable selection of particular product brands) are comprehensive (ie cover all the available products) because otherwise manufacturers
can justifiably claim that although their product may be similar to one of those tested even subtle distinctions may lead to clinically important differences.

A further problem with research design is the blinding of products. Different products have different appearances and it is impossible to blind subjects or staff to the product in use. Products can be re-packaged to assist anonymising but this may have unwanted effects on the products and is expensive.

Previous product experience can also affect study results, particularly if a substantial proportion of subjects are currently using a product included in the study. It is therefore important to record which products are in current use in order to add this data to the model used in the analysis.

a) Sample size and study power

Studies that include more than two products (or two small groups of products) will need to be powered so that multiple comparisons can be made. As the number of products included in the study increases the number of possible comparisons of pairs of products rises. This requires a corresponding reduction in the significance level (e.g. by using the Bonferroni method) for each pair-wise comparison to retain the overall level of significance (usually p<0.05). Thus as the total number of pair-wise comparisons increases the likelihood of a type 2 error (accepting the null hypothesis when it is false) also increases.

Sample sizes therefore need to be calculated to allow for each pair-wise comparison. Sample size requirements rise rapidly if each subject does not test each product and the number of products entered into a study must therefore be limited by subject fatigue. As an example, a clinical trial of four product groups where the primary outcome variable will be binarised (e.g. satisfactory / unsatisfactory) will require a sample size of approximately 80 subjects with an alpha of < 0.05 and d (difference) of 20%.

b) Outcome variables

Studies of product performance have most frequently used self-report questionnaires at the end of the product test period to assess participant ratings of product performance. Diaries of product-related events such as leakage, laundry generation and product consumption are also commonly included. Subjects in some absorbent pad studies have been asked to identify and prioritise items of product performance [18] [19] [20] to inform questionnaires and Table III-2 shows the most common items of high priority to women with light urinary incontinence identified by Getliffe and colleagues [19].

Outcome variables in studies designed to compare catheterisation strategies and / or catheter materials or other design features commonly encompass measures of urinary tract infection, tissue trauma and recurrent catheter encrustation leading to blockage (see Section XII-2).

Questionnaire items vary depending on the products being tested and for product groups where few studies have been carried out it is particularly important to tailor questionnaires to patient needs by asking study subjects to prioritise items and to assess final questionnaires for content and face validity. One study [21] has measured the test re-test reliability of a questionnaire to assess sheath performance and found moderately good Kappa scores (around 0.7) when assessing the same sheath twice with four weeks between assessment periods.

Skin health, urinary tract infection, pain or discomfort are the main physical health consequences of containment products and skin health (which can be rated by self-report or by skin inspection) has sometimes been used as the primary outcome variable (e.g. [22]). Urinary tract infection is an important outcome for invasive devices such as catheters.

Although leakage performance is most frequently scored by the user, discomfort and skin health are also important aspects of product use.

rated as the top priority for users, good leakage performance is not adequate as a sole measure of patient satisfaction with performance. A single (or multiple) fatal flaw such as poor comfort, bulkiness, or poor fit may cause a product that performs well for leakage to be unacceptable to the patient. For this reason aggregate measures - which assumes that the overall performance of a product can be calculated using a weighted sum of the scores for specific aspects of performance (like comfort and freedom from leakage) - are ill-advised. Patient overall opinion or satisfaction with the product should therefore be used as the primary outcome variable [21].

There are no quality of life measurement tools specifically designed for clinical trials of products, but there is a need for such tools to measure the impact that good or bad product performance has on people’s lives. Existing incontinence-specific quality of life tools are designed to measure change after interventions to improve incontinence and include urinary symptoms. These tools are therefore likely to be insensitive to changes in quality of life brought about by products which are designed to contain incontinence rather than reduce or prevent it. The first stage in the development of a quality of life tool for absorbent product users has been reported by Getliffe et al. [19] and a similar tool for catheter users is known to be under development.

**3. SUMMARY AND RECOMMENDATIONS**

There is little published evidence on which to base summary and recommendations regarding methodology and so the following summary points / recommendations are all Level of Evidence 3 / Grade of Recommendation C.

- Evaluation of continence products is methodologically complex and many attempts at providing robust evidence for product selection have been hampered by methodological weaknesses.

- Product representation is critical to providing robust and generalisable data. Selection of products for inclusion in a study needs to be transparent and systematic and several products should preferably be included to represent a product group. In particular, care should be taken not to select a particularly good or a particularly poor product to represent a whole class of products.

- Multiple crossover designs are likely to be more efficient than randomised controlled trials for many products (eg pads) and therefore sample sizes estimation needs to take into account the multiple comparisons that will be made.

- Outcome variables should include patient (or carer) questionnaire including items that have been established as important to patient users.

- Diary data should be included to determine leakage performance, skin health, laundry and product consumption.

- Incidence of urinary tract infection should be included when testing invasive devices such as catheters, but "significant" UTI/bacteriuria needs to be carefully defined (see Section 12.2.8).

- The primary outcome variables should be patient overall opinion / satisfaction and patient preference.

- Health economics should be measured alongside product performance

**4. RESEARCH PRIORITIES**

- The development of Quality of Life tools for users of continence products.

### IV. HANDHELD URINALS

Handheld urinals are portable devices designed to allow a person to empty their bladder when access to a toilet is not possible or convenient, often due to limited mobility, hip abduction or flexibility. They can be especially helpful for those suffering from frequency and/or urgency.

An effective hand held urinal must enable its user to empty his / her bladder in comfort and be confident of no spillage. It should not require excessive physical effort on their part and should be easy to empty without spillage.

General guidelines on patient assessment for product selection are discussed in Section 2. Aspects of patient assessment particularly important for handheld urinals are user postures (in bed, on side of bed, back in chair, on edge of chair, standing/crouching/kneeling), leg abduction, approach of urinal (from front, side, behind, above), ability to initiate void, dexterity and strength to position and remove urinal, level and availability of assistance, user preference.

There has only been one clinical trial [23] of female urinals and there are no published trials of male urinals. However, much helpful guidance and expert opinion has been published [24] [25] [26] [27].

#### 1. FEMALE HANDHELD URINALS

Female handheld urinals come in a variety of shapes and sizes (Figure IV-1). Most are moulded in plastic but they may be made from metal or (for single use items) cardboard. Some are designed for use in particular postures, like standing, sitting or lying down – (see below). Some have handles to facilitate grip and positioning. Some are intended to empty into a drainage bag during or after use.

Although female handheld urinals are often described and discussed in general nursing articles on continence products they have only been the subject of one published (cross-over) evaluation. Fader
et al. [23] carried out a multi-centre study in which each of 37 community-based women (age range 33-89y; mean age 61y) was invited to evaluate all 13 products on the UK market in 1997. No product suited everybody but each was successful for at least some subjects. The key requirements for success were that the user should be able to position the urinal easily and feel confident that it would catch urine without spilling (Level of Evidence 2). Many products were successful when used in the standing / crouching position or when sitting on the edge of a chair / bed / wheelchair. Fewer worked well for users sitting in a chair / wheelchair. Only one worked even reasonably well when users were lying / semi-lying (Subaseal). In general, subjects with higher levels of dependency found fewer urinals to be suitable for their needs.

Recently the development of a powered urinal designed to pump urine into a reservoir has been described [28]. The aim of the device was to provide active removal of urine without leakage and without the need for gravity-assisted drainage. The urinal was tested by 80 women from six countries. Although evaluated as ‘good’ or ‘okay’ by more than three-quarters of the women, nearly half the women found the device ‘poor’ for weight and size. Problems with reliability of the device were also common and the authors concluded that the current device needed further refinement but may have potential as an alternative to conventional urinals. Although this device is not currently on the market, at least one other powered device is available. However, there are no published reports on efficacy.

2. MALE HANDHELD URINALS

Most handheld urinals for men are somewhat similar, involving a narrowed neck opening into which the penis is placed. Some products come with a detachable or integral non-spill adaptor containing a flutter valve to impede back-flow of urine from the urinal. There are no published trials of such products.

A review paper by Vickerman [27] makes recommendations for selecting suitable urinals for men. A flat bottom urinal may be more stable (and less likely to spill) for those using a urinal in bed. Urinals made from soft plastic (jug-style or with a funnel) may be easier to grip for those with poor manual dexterity. Urinals designed to be attached to a drainage bag (for emptying the urinal) may also be helpful to men living at home with limited support.

Vickerman also suggests that home-made devices (such as empty wide-mouthed containers with a handle and lid (for example, those used for clothes-washing liquid or conditioner) may be a practical (and cheap) option for some men. For those with a retracted penis female urinals may be easier to use than male products.

3. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

The literature [24] [25] [26] [27] suggests that successful use of urinals depends on many factors which are summarised below.

- Experimentation is often needed to find the optimum urinal for an individual. A ‘library’ of urinals (i.e. a collection of different types of urinals to be lent out to users for experimentation) has therefore been recommended [26] but rigorous cleaning methods are needed (see below).

- Clothing alterations can aid quick and easy use of a urinal. For men, extending the fly opening of trousers or replacing zips with Velcro can be helpful, as can boxer shorts. For women drop-front pants may be needed, particularly if mobility is limited.

- Disposable and reusable ‘travel’ hand-held urinals are available for both men and women. These urinals fold away to fit into a pocket and may therefore be more discreetly portable than conventional urinals.

- Some disposable urinals include superabsorbent polymer in their reservoirs which turns urine into a gel and help to prevent spillage. Sachets of superabsorbent polymer may also be added to reusable urinals.

- Use of a urinal is not always free from leakage and provision of absorbent chair or bedpads to protect bedding, clothes and furniture (particularly when testing out urinals) may be necessary.

- The limited range of urinal options in acute settings, where often only bedpans are available, has been criticised and the process of introducing hand-held urinals to hospital services has been described and recommended [29].

- When used by one individual in the home, urinals can be cleaned with soap and water between uses. But where urinals are shared (i.e. cleaned and used by others), or if a library of urinals is used then robust methods are necessary. Some urinals can be cleaned in a bedpan washer but cleaning methods vary with different designs and
materials and compliance with local infection control procedures will be needed.

4. RECOMMENDATIONS

- There is a wide range of female urinals and experimentation is likely to be necessary to identify the best one for an individual (dependent on their individual needs and abilities) (Grade of Recommendation C).

- A library of female urinals (used with robust cleaning methods) will help to facilitate experimentation (Grade of Recommendation C).

- Male urinals are less varied than female urinals, but may be supplemented by use of less conventional receptacles (e.g. jugs, home-made devices); experimentation will help to identify best options (Grade of Recommendation C).

- Section IV.3 addresses other more general recommendations regarding urinal use.

5. PRIORITIES FOR RESEARCH

- Further development of female urinals is encouraged, particularly for supine users and those unable to move to the edge of a chair.

- The range of male and travel urinals need to be evaluated to provide guidance for users and carers.

V. COMMODES AND BEDPANS

Toilets can be difficult to use by people with mobility problems and other disabilities. Toilet adaptations such as raised toilet seats, padded seats, and grab rails can be very helpful in enabling individuals to access the toilet easily and comfortably. Bottom wipers and bidets can also be useful. However, if access to the toilet is impossible, commodes and other toileting receptacles should be considered.

Commodes are devices that comprise a frame supporting a toilet seat with a pan (disposable or washable) beneath to receive urine and faeces. They are used independently of a toilet and may be static or mobile. Mostly, they are used by people with reduced mobility who find it difficult to access a conventional toilet. Bedpans are portable receptacles that may be used for passing urine or faeces while in bed or chair. Some female urinals (see section 4) may also be used to collect faeces.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding commodes and bedpans begin with appropriate indications for their use since Matsumoto and Inoue [30] reported that incontinent elderly persons or their caregivers misunderstand indications of commode use for incontinence. Other patient assessment elements include: a) physical characteristics of the person with incontinence (e.g. can an obese person fit on a commode and use its handrails?); b) mental acuity (e.g. will a person with dementia recognize a commode or bedpan as a device to be used for defecation?); c) need for supervision or foot supports whilst on the commode (what is the risk of falling?); d) mobility (e.g. does the person need a commode or bedpan?), ability to transfer and method of transfer to the commode (e.g. hoist, carer help, independent with transfer board), need for static or mobile commode (particularly when considering using commode over a toilet), postural stability and need for supportive commode, e) level of assistance needed and physical burden to caregiver involved; and f) personal preferences (e.g. comfort of bedpan type) including need for ‘non-commode-like’ appearance (e.g., particularly when used in own room, particularly the living room). Patient assessment findings need to be evaluated in terms of the safety and stability properties of a commode. The proximity of the area for waste disposal, storage facilities (i.e., the location / visibility of the commode in the household), the availability of privacy during defaecation, and length of time likely to remain on the commode (is there a need for a pressure-relieving commode cushion?), are additional factors to be considered.

Commodes (or better still toilets) are preferable to bedpans (which are relatively difficult to use and do not permit appropriate posture for passing urine/faeces). Bedpans are generally reserved for people who are confined to bed (e.g. post-operatively) and for whom safety (risk of falling) is an important assessment issue.

1. RESULTS

Fader [31] has reviewed the little work that has been done to evaluate existing commodes and bedpans and to identify the needs of users. An investigation of commode design by Nazarko [32] highlighted the problem of commodes providing poor trunk support for elderly and disabled people. Prolonged periods of sitting alone (for privacy) to enable defaecation resulted in a risk of falls. Nazarko worked with a manufacturer to produce a design specification for a commode. Consultation with patients indicated that many would prefer to use a toilet. As a consequence, attention was focused in designing a shower chair which could also be used as a commode or could be wheeled over a toilet.

An evaluation of the four main types of commodes (standard; with adjustable height; with removable / drop-down arm; with adjustable height and removable / drop-down arm combination) was published by the UK Medical Devices Agency [33] [34]. One third of the 150 commodes on the UK market at the time were found to have backwards instability, and most of them scored poorly for aesthetics and comfort. A discussion of the results of this evaluation and its application to nursing was subsequently published by Ballinger et al. [35].
The maintenance of hospital commodes can be a problem and Gillan [36] complained about the poor condition of commodes in wards for elderly people. Commode cleaning has also been found to be poor [47] and a recent audit by Bucior and Cochrane [37] showed visible traces of faecal contamination on cleaned commodes. The authors concluded that it was necessary for ward staff to have clearly defined roles and responsibilities for commode cleaning. New commodes have been designed to overcome such problems by being easier to clean (e.g. design-bugs-out commode www.designcouncil.org.uk/our-work/challenges/Health/Design-Bugs-Out/Case-studies/Commode).

Naylor & Mulley [38] investigated the use of commodes in community-dwelling patients and the attitude of carers and users towards them (115 subjects and 105 carers). The main reasons for commode use were impaired mobility, difficulty climbing stairs and urinary incontinence. Main concerns were lack of privacy and embarrassment about using the commode, unpleasant smells and the poor physical appearance of the commode. Carers tended to view them negatively, particularly with regard to cleaning. Where commodes were used for defecation in a living area the authors highlighted the problem of odour that lingered even after a commode had been emptied, and recommended the use of a chemical toilet.

Thorough cleaning of commodes or bedpans after every use is necessary for hygienic purposes and to eliminate odours. Naylor & Mulley [38] report that typically a caregiver rather than the commode user empties and cleans a commode. No recommendations for cleaning a home commode or bedpan were found in the published literature. In institutional settings, large sinks with spray hoses or special sanitizing equipment are available. The size and shape of a bedpan or commode receptacle may be difficult to fit under a standard sink basin in the home. Whether certain commode cleaning products reduce any residual odour more than others is not known. Toilet bowl cleaning products are suitable for cleaning a commode or bedpan; many contain bleach or antibacterial ingredients but their effect on reducing odour of commodes or bedpans has not been studied. Gel formulations are advertised by manufacturers as being better able to cling to hard-to-reach surfaces than liquid agents. Use of a deodorizer can be considered (Level of evidence 4).

Nelson and colleagues [39] surveyed 147 spinal cord injured patients concerning their satisfaction and safety with the shower chairs (used for bowel care) used in the home. They found that around a half of patients were dissatisfied with their chairs and concerns expressed related to lack of hand access to the perianal area, difficulty in turning and rolling the chair and problems with keeping the chair clean. One third of patients experienced chair related falls and nearly a quarter reported pressure ulcers. Two-thirds of subjects felt that their safety was compromised.

The same group of researchers evaluated three shower chairs using video-taping, photography and questionnaires and produced performance criteria for the design of an optimal shower chair [40]. Pressure mapping devices were used to measure seat pressures on three subjects who tested all three bowel / shower chairs to inform seat design [41].

These researchers [42] then set about designing a more advanced commode-shower chair. It had lockable, swing-away armrests and lever activated brakes to facilitate transfers. To prevent pressure ulcers a chair frame and padding combination was designed to facilitate a seating position that distributed body weight and reduced pressure on pressure points. Cupped edgeless footrests were designed to reduce the risk of heel ulcers. An adapted version of this chair is now commercially available in the USA.

Matsumoto and Inoue [30] examined whether use of a commode in the home might prevent or delay nursing home admission of elderly people who were incontinent. A five-year follow-up of multiple predictors of institutionalization in elderly people in a rural town in Japan showed that 40% of incontinent men and only 17% of incontinent women used a commode. Use of a commode was not associated with institutionalization. The authors suggested several possible reasons: misunderstanding of appropriate indications for a commode based on the type of incontinence; physical burden in assisting a care recipient to use a commode that seemed no different than for cleansing after an incontinence episode; and inadequate muscle strength of the elderly for using either a Japanese-style or Western commode.

Bedpans and other portable receptacles are not well described in the literature. Wells and Brink [43] describe three general shapes of bedpans: concave, cutaway, and shovel. The concave pan has a rounded triangle shape that slopes back to front and a curved seat. The cutaway has a rounded triangle shape with a flatter seat and rolled edges that allow for handgripping. The shovel shape, commonly called a “fracture pan” is a wedge or rectangle shape that has a flattened end that goes under the individual and a handle at the distal end. Generally bedpans are considered to be unsuitable for defecation for safety and acceptability reasons. However, for individuals with specific needs (e.g. frequency and urgency of defecation) a portable receptacle may be beneficial. Although many portable urinals are now available for both men and women, very few are recommended for defecation [44] and they have yet to be formally evaluated.

Privacy and dignity need to be given high priority when patients need to use a bedpan or commode, in particular in institutional settings. Care needs to be taken when transporting patients on a shower
chair to maintain dignity and avoid revealing the patient’s bottom.

Bottom wiping and cleaning can be difficult for people with disabilities, particularly manual dexterity problems, or caregivers. Simple moist wipes may be helpful and are widely available. Devices designed to assist with bottom wiping problems are on the market and portable bidets are also available, however there are no published trials of these products. Bedpans have other disadvantages including difficulty removing the bedpan from under an individual without spilling (particularly if the individual is obese), risk of spilling and odour when transporting the contents for disposal since none have lids, and lack of privacy during use.

2. SUMMARY

- There are major defects in most of the current designs of commodes, especially: poor aesthetics; poor trunk support; instability (i.e. a tendency to tip over easily); poor comfort; difficult to clean; poor pressure relief (Level of Evidence 3).
- If direct transfer to a toilet is impossible or unsafe a sani-chair / shower chair is usually preferable to a commode (Level of Evidence 3).
- The main concerns of users about commodes and bedpans are: lack of privacy; embarrassment over use; odour; poor aesthetics; poor perineal cleanliness; accessibility; and inadequate facilities for cleaning the devices in the home (Level of Evidence 2).
- Defecation on a bedpan or other portable receptacle presents problems of safety and unacceptability to users (Level of Evidence 2).

3. RECOMMENDATIONS

- If at all possible, access to a toilet should be made available for defecation (Grade of Recommendation C).
- If direct transfer to a toilet is impossible or unsafe, a sani-chair / shower chair should be offered in preference to a commode wherever possible (Grade of Recommendation C).
- If a commode is used, care should be taken to ensure good trunk support; that the chair is stable; and that methods of reducing noise and odour are offered (Grade of Recommendation C).
- With commodes and sani-chairs / shower chairs, the user’s bottom should never be visible to others and transportation to the toilet and use of the toilet or commode should be carried out with due regard to privacy and dignity (Grade of Recommendation C).
- Bedpans and other portable receptacles should be avoided for defecation purposes (Grade of Recommendation C).
- Patients vulnerable to pressure ulcers should not sit on a commode / sani-chair / shower chair for prolonged periods (Grade of Recommendation C).
- The person should be given a direct method of calling for assistance when left on the toilet / commode / sani-chair / shower chair (Grade of Recommendation C).
- Cleaning of bedpans and commodes should be carried out after each use following local infection control policies (in institutional settings) (Grade of Recommendation C).
- There are no evidence-based published guidelines regarding frequency of cleaning or type of cleaning product. However, thorough cleaning after bowel evacuation (to avoid odour and maintain aesthetics) is important, together with rinsing after urine has been passed. Cleaning needs may vary according to personal hygiene standards and offensiveness of urine/faecal smells (Grade of Recommendation C).

4. PRIORITIES FOR RESEARCH

- Studies are needed to determine how to make toilets accessible to as many users as possible. These may lead to improved designs for toilets and associated equipment and / or strategies for toileting.
- Studies are needed to determine which commode / sani-chair / shower chair designs best meet performance and safety requirements.
- Development of better commodes designed to overcome the limitations identified

VI. ABSORBENT PRODUCTS

1. INTRODUCTION

Absorbent products (commonly known as pads) are available in a wide range of sizes and absorbencies encompassing light through to very heavy incontinence. Most pads are bodyworn but some are used on the bed or chair (underpads, see Section 6.2); in this section the term ‘pad’ refers to bodyworn absorbent products. Broadly speaking, absorbent products can be divided into two main sub-groups: those suitable for light incontinence (usually smaller products) and those suitable for moderate-heavy incontinence (usually larger products). Manufacturers generally indicate the severity of incontinence that each product is designed to accommodate, but see the discussion in Section VI.4. Although absorbent pads are most commonly used for urinary incontinence they are also used by individuals for both faecal and urinary / faecal incontinence; however, there have been no published studies which specifically address this issue.

Incidental findings from evaluations of products indicate that absorption capacity alone does not
determine whether a user will choose to use a product. Some users may have frequent, low flow-rate loss of small volumes of urine (“dribble”), whilst others may be dry for days but then have a higher volume, higher flow-rate incontinence incident (“gush” or “flooding”. Both may prefer to use pads for light incontinence. Mobile and independent community-dwelling women of all levels of incontinence are reported to generally prefer small pads and are often willing to change them frequently rather than use larger products and change them less often [45]. Conversely, dependent, immobile individuals may prefer the security of larger products despite relatively low urine volumes due to their dependence on others for pad changing.

More recently studies have focused on the use of pads by men. Teunissen and Lagro-Jansson [46] interviewed 56 men with UI of which only nine used absorbent pads. They concluded that men use pads less frequently than women, have little knowledge about purpose-built pads, are more likely to construct their own pads out of absorbent materials such as towels and are less satisfied with pads than women. Furthermore there are indications that men may prefer other devices such as urinary sheaths [47] (see Section VII Sheaths).

Studies that have collected and weighed used pads to measure urine volume have found overlap between the quantities contained by pads from different sub-groups of users; thus in a study of insert pads for moderate-heavy incontinence used by older people in residential care around 15% of insert pads for moderate-heavy incontinence contained less than 100g of urine [48] and in a study of older women with light incontinence living in the community about 10% of insert pads for light incontinence were found to contain more than 100g of urine [49].

It might be speculated that the number of pads used per day might be a good measure of degree of urinary incontinence, but this has not been found to be the case in nursing home residents in Norway [50]. Pads were collected and weighed from residents in six homes, but a poor correlation was found between the number of pads used and the mass of leaked urine measured over 48 hours. The authors concluded that this was due to pad changes being carried out at routine times by healthcare assistants.

It is possible that a proportion of patients are simply provided with inappropriate products that exceed or fall short of the absorption capacity they require. One study investigated this issue [51] and found that patients were more satisfied with their products once their urine loss had been determined by pad weighing and appropriately absorbent products were provided. But many of these patients were using inadequate products to start with (such as pads comprising tissue paper) and firm conclusions could not be drawn. In practice, it is probably hard to justify the need for pad weighing to determine which absorbents should be provided and if there is doubt about which group a patient falls into then the patient should be offered small pads for light incontinence in the first instance and the size of pad titrated upwards as necessary.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding absorbent pads are frequency / severity of leakage, day / night incontinence, gender (some products are designed for, or are better for, men / women than others), ability to change pad independently / need for carer, pad changing position (standing / lying), laundry / drying facilities, individual priorities (e.g. need for discreetness), personal preference for design / materials (washable / disposable), lifestyle (at home / travel / work etc).

Aspects of absorbent pad performance have been identified and prioritised (during interviews) by men and women taking part in a series of clinical trials of such products [19]. There was considerable consistency across patient groups (light / heavy, men / women) with the ability of a product to hold urine without leakage being the top priority, and the following aspects also being considered to be of high priority: discreetness, containment of smell, ability to stay in place, comfort when wet and ability to keep skin dry.

2. ABSORBENT PRODUCT CATEGORIES

Absorbent products may be classified into two broad categories - disposable (single-use) and washable (reusable) - with each category dividing into two sub-categories: bodyworn products (worn on the person) or underpads (placed under the person). Within each sub-category are different design groups such as diapers and pull-ups which are subdivided by size (to fit users of different sizes) and / or absorbency (to cater for different severities of incontinence). Some designs are further subdivided into those intended for men, women or children. This classification is shown in Table VI-1.

- **Bodyworn** absorbent products can be divided into four main design groups:

- **Inserts** (sometimes called liners or, in the case of small pads, shields) are held in place by close-fitting underwear or stretch mesh briefs (Figure VI-1). Some patients experience problems with keeping pads in place using the commonly supplied net pants. As a result, many use more robust stretch pants purchased privately (e.g. cotton / Lycra, etc). Many disposable inserts (Figure VI-2 and Fig VI-3) have an adhesive strip on the back to help secure them and may have an indicator that changes colour when the pad is wet to signal the need for a change. They may have longitudinal, elasticated standing gathers of hydrophobic material intended to impede lateral leakage of urine and faeces. They
are sometimes rectangular but are more usually shaped to fit the body more snugly. Elastication at the legs may also be used to enhance fit. Washable inserts (Figure VI-4) are usually more simply designed than disposable inserts, with no elasticity and are either shaped or a simple rectangle. Inserts are made in a wide range of sizes suitable for light through to very heavy urinary incontinence. For light faecal incontinence, the liner may be a small cotton gauze dressing placed against the anus and held in place by the cheeks of the buttocks (Figure VI-5).

- **Diapers** (sometimes called all-in-ones or briefs) are adult-size versions of babies’ diapers. Disposable diapers (Figures VI-6) usually have elasticated waist and legs and self-adhesive tabs (usually resealable), and often a wetness indicator and standing gathers. More recently modified diapers have been introduced that fasten round the waist before the front is pulled into position and secured, to enable users to apply the diaper whilst standing (Figure VI-7). Washable diapers are usually elasticated at the waist and legs and are fixed with Velcro or press-studs (Figure VI-8). Diapers are intended for moderate to very-heavy incontinence.

- **Pull-ups** are similar in construction to trainer pants for toddlers. The absorbent material is built into a pull-up pant and is either limited to the crotch area or distributed throughout the pants (Figures VI-9 to VI-11). Disposable pull-ups (Figure VI-9) are usually elasticated throughout the pants to give a close fit. Both disposable and washable pull-ups have versions for different levels of incontinence. Washable pull-ups for light incontinence are often known as pants with integral pad (Figure VI-11).

Some people use less conventional or homemade systems either instead of or as well as the designs described above. In particular, terry-towelling squares may be used by those with heavy incontinence. These may be formed into briefs by folding into different configurations and fastening with pins and covered with plastic pants as a waterproof barrier. It is known that such pants may also be worn over more conventional designs in an attempt to reduce leakage and / or odour.

“Body” garments (like vests which have a crotch section which opens and closes with snap fasteners, much like those manufactured for babies) may be helpful to hold pads in place well and may reduce the rustling noise from plastic backing materials.

- **Male pouches** (sometimes called shields, guards or leaves) are for lightly incontinent men and are designed to fit around the penis and sometimes the scrotum too (Figures VI-12 and VI-13). All are worn with close-fitting underwear or stretch mesh briefs. An adhesive strip is often provided on the disposable versions to help hold them in place.

- **Underpad** absorbent products are usually simple rectangles of different sizes to be used on the bed or chair (Figure VI-14). Washable underpads (Figure VI-15) may have a high friction backing or have ‘wings’ for tucking beneath the mattress of single beds to help keep them in place. Underpads vary widely in absorbency with less absorbent products being used as ‘back-up’ with bodyworn absorbents and more absorbent products being used as sole protection on the bed at night.

3. ABSORBENT PRODUCT MATERIALS

Absorbent products – disposable or washable – usually comprise three main layers: an absorbent core sandwiched between a water-proof backing and a water-permeable coverstock (or topsheet) next to the wearer’s skin.

The main component in disposable absorbent cores is invariably some kind of fluffed wood pulp fibres, but most also contain some powdered superabsorber (sometimes referred to as SAP (superabsorbent polymer) or AGM (absorbent gelling material)), which is often concentrated in the crotch region. Superabsorbers hold much more urine – weight for weight – than fluff pulp and retain it far more tenaciously under pressure. They are usually based on cross-linked salts of polycrylic acid whose chemistry can be varied according to the balance of properties such as absorption capacity and absorption speed desired. Some thermoplastic fibres are also sometimes included in absorbent cores to reduce core break up and the collapse of the structure when wet. It is increasingly common for absorbent cores to comprise two or more layers, each designed to perform a different function. For example, an upper layer might comprise low absorbency fibres engineered to receive and distribute urine efficiently and maintain a dry layer next to the skin, while lower layers provide absorption capacity. Some disposable products have ‘breathable’ plastic backings designed to reduce skin occlusion.

Washable absorbent cores are usually made from a needlefelt or knitted fabric comprising rayon and / or polyester fibres. A variety of polymers are used for the water-proofing. In general, the thicker, stiffer materials are more durable (the durability of the plastic backing often determines the lifetime of the product) but less comfortable. Topsheets are usually made from either cotton – which is hydrophilic and intended to have good dry comfort – or polyester – which is hydrophobic and intended to have good wet comfort.

Concern for the environment and also for controlling costs has led to an increase in the number of washable products available on the market. An important consideration in the comparison of washable and disposable designs is the relative environmental cost, particularly disposal (landfill) costs of disposable designs and energy costs associated with laundering the washables. A recent report on baby diapers concluded that there was no significant difference in environmental impact between three diaper systems (disposables, home and commercial laundered washables) although the types of impacts did vary [52].

4. ABSORBENT PRODUCT CAPACITY AND USER REQUIREMENTS

Pads come in a range of absorbencies to cater for users with different levels of urinary incontinence and, understandably, purchasers wish to know how much urine available pads will hold. But there is no simple answer: a pad does not have a volume of urine below which it is guaranteed not to leak; rather, the probability of success decreases as the volume of the urine increases. However, for higher absorbency pads the performance falls away more slowly with increasing urine volume than it does for lower absorbency products.

This is a complex concept to communicate in sales literature and product packaging and so companies commonly quote a simple absorption capacity figure. Some use the volume of fluid a pad will hold in a laboratory test - usually international standard ISO 11948-1[53] - but this figure can be very misleading. Although it has been show to correlate well with the leakage performance of pads for some groups of users (see Section VI.7.2), the volume of urine which a pad will hold when tested with ISO 11948-1 is enormous compared with how much it will hold in real use. For this reason, some companies prefer to quote a “working capacity”, which might be calculated as some proportion (companies vary in the proportion they use) of the capacity in the laboratory. However, this is still misleading as it implies that the pad will not leak until the working capacity is exceeded. A simple, valid and widely accepted solution to this problem has yet to be devised.

It is equally difficult to determine the needs of users in terms of the volume of urine they need their pads to hold. Not only can different users leak widely differing volumes from each other but also a given user may leak widely differing volumes on different occasions. This means that, like pad performance, users’ needs cannot be easily quantified. However, a number of studies have been published on work with pad users described as being lightly incontinent of urine in which the median and 90th percentile urine volumes in used pads have been of the order of 15ml and 100ml, respectively [54]. Similarly, a number of studies of pad users described as having moderate-heavy urinary incontinence have yielded corresponding figures of about 250ml and 600ml [54]. Accordingly, in this chapter the material is divided – somewhat simplistically – into that which relates to light incontinence and that which relates to moderate-heavy.

But the published work also makes it clear that some products work better for users whose inconti-
nence is towards the lighter or the heavier end of the spectrum within each of these two groups and so, where necessary in the text and tables that follow, these distinctions are made by dividing light incontinence into “light LIGHT” and “heavy LIGHT”; and moderate-heavy incontinence into “light HEAVY” and heavy HEAVY”.

5. ABSORBENT PRODUCTS FOR WOMEN WITH LIGHT URINARY INCONTINENCE

There are four main product designs for women with light incontinence (Table VI-2). In addition menstrual pads are known to be frequently used for light urinary incontinence. The disposable pull-up group are relatively expensive, single-use items and are seldom used for light incontinence except as ‘emergency’ items. Underpads are not commonly used for light incontinence. (Figure VI-16)

Aspects of assessment that are particularly important regarding pads for women with light incontinence include frequency / severity of leakage, day / night incontinence individual priorities (e.g. need for discreetness), personal preference for washables / disposables, lifestyle (home / travel / work).

a) Quality of data

A small number of robust comparative evaluations of absorbent pads for lightly incontinent women have been published and there has been a Cochrane review [55]. A recent study has compared the most common designs: disposable inserts, menstrual pads, washable inserts and washable pants with integral pad. One study has compared a range of disposable inserts and menstrual pads and there have been comprehensive single group studies of disposable inserts and washable pants with integral pads. A further study has compared specially made experimental products that have differed from one another in carefully controlled ways enabling more specific questions about product materials and design to be addressed.

b) Results

Using a crossover design, Fader et al [54] compared disposable inserts, menstrual pads, washable pants with integral pad, and washable inserts. Three products were selected (based on previous study results) to represent each design and each product was tested for one week (three weeks for each design block, total 12 weeks). Order was randomised. Product performance was characterised using a validated questionnaire to evaluate pad performance (leakage, discreetness etc) with a five point scale (very good – very poor) at the end of each week of product testing. A pad change and leakage diary was used to record severity of leakage from pads (three-point scale: a lot, a little, or no leakage), and numbers of laundry items and pads used were recorded to estimate costs. Skin health changes were recorded weekly. At a final interview preferences were ranked (with and without costs), acceptability of the design recorded (highly acceptable – totally unacceptable) and overall opinion marked on a visual analogue scale (VAS) of 0-100 points (worst design – best design). This VAS score was used to estimate cost-effectiveness.

Eighty-five women (mean age 60) completed the study and 8691 used pads were weighed. The disposable insert was significantly better than the other designs on most variables except for discreetness. For leakage prevention, overall acceptability and preference, disposable inserts were found to be significantly better than menstrual pads, which were better than washable pants with integral pad, which were better than washable inserts. There was no clear benefit for skin health using either washable or disposable designs. Most women preferred the disposable insert pad but some preferred the other cheaper designs (6/85 preferred menstrual pads; 37/85 preferred disposable inserts).

Figure VI-16: Designs of pads for women with light urinary incontinence. For definitions of light LIGHT and heavy LIGHT, see Section VI.4. (Grade of recommendation in brackets)
13/85 preferred washable pants), both of which were >50% cheaper to use than disposable inserts. Washable inserts were significantly worse than the other designs (72/85 found them unacceptable). Overall there were generally more practical problems with washables, particularly when away from the home (**Level of Evidence 1**).

The authors concluded that allowing women to choose their preferred design of absorbent product (or combination of different designs for different circumstances) would be more cost-effective and provide better patient satisfaction than provision of disposable insert pads (the most expensive product) alone.

Clarke-O’Neill et al. [18] compared the range (12 products) of disposable inserts for lightly incontinent women available in the UK in 2000. Products were tested by 60 community-based women aged 50 years or older who currently used products similar to those to be evaluated. Products were evaluated using a pad performance questionnaire and a pad leakage diary. As a group, the products performed well in terms of their ability to hold urine without leakage. However, the ‘overall opinion’ scores of the testers showed large differences between products with 88% of subjects scoring the most successful insert as Good or OK compared with 51% for the least successful product (p<0.001) (**Level of Evidence 2**).

A similar study by the same research group [56] compared all 10 washable pants with integral pad for lightly incontinent women available in the UK in 1999. Seventy-two community-based women who usually used absorbent products for light incontinence tested each product for one week each. Leakage performance was found to be disappointing with 69% (CI: 59-78) of the best performing product not leaking at all with 10g of urine, compared to 40% (CI: 29-51) for the least successful product. Again subjects’ ‘overall opinion’ scores showed wide differences between products with the best performing product scoring 85% Good or OK compared with 34% for the least successful product (**Level of Evidence 2**).

Baker and Norton [57] evaluated six small disposable inserts and two menstrual pads (available in the USA in 1991) with 65 community dwelling women. The products were rated using an evaluation questionnaire and daily diary of pad use. The two menstrual pads (which were the least expensive pads in the study) scored significantly higher than many of the incontinence products although neither was the most popular pad. The authors concluded that women should try a ‘maxi’ menstrual pad first and then move onto a higher capacity (incontinence) pad if this was inadequate. However, this study was carried out more than 10 years ago and products have changed considerably since then (**Level of Evidence 2**).

Thornburn et al. [16] studied ‘wet comfort’ using small disposable pads that had been experimentally made using different combinations of materials in an attempt to reduce ‘wetback’ (the tendency of pads to allow urine to escape back on to the wearer’s skin). Twenty women tested the pads. Whenever differences in wet comfort, absorbency or overall performance were found they were in the expected order but differences were small and few reached statistical significance. The clinical value of including technically superior materials was not strongly supported. However, this was a small study and may have had insufficient power to detect significant differences (**Level of Evidence 2**).

More recently Erekson and colleagues [58] measured the wet-back performance of a range of 10 different branded products. This was a laboratory experiment involving two patients (of different BMIs) sitting on pre-wetted pads. Results showed that neither size nor price of the pads had any effect on the measured product performance. However it is difficult to determine how much such measurements reflect clinical performance.

c) Summary

There is robust evidence that disposable inserts are more effective in terms of leakage and more acceptable than menstrual pads, washable pants and washable inserts (**Level of Evidence 1**). Menstrual pads are cheaper and washable pants cheaper still (on a per-use basis) and are acceptable to many, particularly those with lighter incontinence and particularly when used at home. Washable inserts are not acceptable to most women. The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in **Figure VI.16**.

d) Recommendations

- Disposable inserts are recommended as the most effective and preferred absorbent product for women with light incontinence (**Grade of Recommendation B**).
- Menstrual pads or washable pants may be sufficient for some patients with very light incontinence and are cheaper (**Grade of Recommendation B**).
- Washable inserts are not recommended (**Grade of Recommendation B**).
- Combinations of designs for different situations (e.g. disposable inserts for going out, washable pants with integral pad for staying at home) are likely to provide optimum management in terms of patient needs and cost-effectiveness, and product advice and provision (where purchased by institutions / services) should reflect this (**Grade of Recommendation B**).
- See also the general recommendations relating to pad selection in Section VI.11 and to washable pads in Section VI.12.
e) Research priorities

• Because the performance of washables is generally poor (particularly for leakage) compared to disposables, the development of better washable products is a priority.

• The use of combinations of designs for different situations needs to be evaluated.

6. ABSORBENT PRODUCTS FOR MEN WITH LIGHT URINARY INCONTINENCE

There are five main product designs for men with light urinary incontinence (Table VI-4). However, disposable and washable insert pads are often unappealing to men as they are frequently marketed specifically at women and bear a strong resemblance to menstrual pads. Anatomical differences are also likely to mean that they are less effective for men. Pouch, shield and leaf products (Figures VI-11 and VI-12) are designed to be more suitable for men by containing the penis or penis and scrotum.

Aspects of assessment that are particularly important regarding pads for men with light incontinence include frequency / severity of leakage, day / night incontinence, retraction of penis, individual priorities (e.g. need for discreetness), personal preference for washables / disposables, and lifestyle (home / travel / work).

Only one study has been published which has evaluated absorbent products for men with light urinary incontinence (59). It compared the four main absorbent designs of products available in the UK in 2003: disposable insert pads, pouches and leafs and washable pants with integral pad. All six leaf products (five disposable and one washable) and all six pouches (all disposable) on the UK market in 2003 were evaluated, together with a selected disposable insert pad and a selected washable pant with integral pouch (chosen to represent their respective designs). Seventy men with light urinary incontinence completed the 14 week study and filled out product performance questionnaires at the end of testing each product for a week. Products were supplied in random order within their design group and the design group order was also randomised. Pad leakage diaries were used to record product performance and used pad weight. At the end of testing each design a design performance questionnaire was completed. ‘Overall opinion’ was used as the primary outcome variable. Results showed that the pouch design performed significantly worse than the leaf and the insert design. The most common problems with the pouch were staying in place and difficulties re-inserting the penis in the pouch once the pouch was wet. The leaf designs had the best leakage scores, but one product was significantly better than the other leafs (Tena). The disposable insert was also effective for leakage prevention and was substantially cheaper than the leaf designs.

The washable leaf was the least successful of the leaf designs. The washable pants with integral pad received polarised overall opinion scores (loved or hated) and scored well for staying in place but poorly for leakage (Level of evidence 2). The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Figure VI-17.

a) Recommendations

• Disposable leafs are recommended as the most acceptable and effective design for men with light incontinence, but some men prefer other designs which should be considered as alternatives (Grade of Recommendation B).

• Simple insert pads are cheaper and may be acceptable to some men (Grade of Recommendation B).

• Washable pants with integral pad are likely to be most suitable for men with very light incontinence who have difficulties keeping an insert or pouch in place (Grade of Recommendation B).

• See also the general recommendations relating to pad selection in Section VI.11 and to washable pads in Section VI.12.

b) Research priorities

Because the performance of washables was generally poor (particularly for leakage) compared to disposables, the development of better washable products is a priority.

7. ABSORBENT PRODUCTS FOR MEN AND WOMEN WITH MODERATE-HEAVY URINARY INCONTINENCE

There are at least 12 absorbent product designs for men and women with moderate-heavy urinary incontinence (Table VI-5). The most commonly used products are disposable bodyworn inserts and diapers (Figures VI-3 and VI-6). More recently, modified diapers (T-shaped diapers, Figure VI-7) have been introduced which can be applied by the wearer whilst standing. Pull-ups are also a relatively new innovation and comprise an absorbent pad integrated into a disposable elasticated pant (Figure VI-9). Washable counterparts to most disposable bodyworn designs are available but they have a much smaller market, where they are available. They are made from a variety of natural and synthetic materials. Disposable and washable bedpads are used on the bed at night with or without the support of a bodyworn product. Disposable and washable chairpads are used either without a bodyworn product (in which case the individual must sit directly on the pad with no underpants on) or in combination with bodyworn products to protect chairs from any leakage from the bodyworn. Both practices place an underpad on display and mark the individual as being incontinent and are therefore to be discouraged.

Aspects of assessment that are particularly important regarding absorbent pads for moderate / heavy UI are frequency / severity of leakage, day / night incontinence, gender (some products are better for men/women than others), ability to change pad independently / need for carer, pad changing position (standing / lying), laundry / drying facilities, individual priorities (e.g. need for discreetness), personal preference for design / materials (washable / disposable) and lifestyle (at home / travel / work etc).

a) Quality of data

There have been two recent clinical trials comparing the main designs of disposable bodyworn pads (one also included washable designs) which are included in a Cochrane review [55]. There have been no trials of underpads for the last 15 years. There have also been a large number of comparative studies of absorbent products for moderate-heavy incontinence but most are more than 10 years old and evaluated products that are no longer available. Furthermore, changes in materials and design features mean that it is impossible to generalise any particular findings to products of today. Brink [60] identified 30 studies of absorbent products published between 1965-1990. Some robust multi-centre international studies have examined the correlation between laboratory testing and the leakage performance of products clinically.

b) Results

1. EVALUATIONS COMPARING DIFFERENT DESIGNS OF DISPOSABLE AND / OR WASHABLE BODYWORN ABSORBENT PRODUCTS FOR URINARY INCONTINENCE

Fader et al. [54] carried out two clinical trials of absorbent products for moderate-heavy incontinence; one involving subjects in the community and the other subjects in nursing homes. In the community-based trial 85 moderate / heavily incontinent adults (urinary or urinary / faecal) living in their own homes (49 men and 36 women) were enrolled, and tested three (or two) products from each of five design categories (total of 14 test products): disposable inserts (with mesh pants); disposable diapers; disposable pull-ups; disposable T-shape diapers; and washable diapers. All products were provided in a daytime and a (mostly more absorbent) night-time variant. Products were selected based on having similar scores for absor-bency across the designs (Rothwell scores, [53] see below) and performance data from pilot studies. In the nursing-home-based trial 100 moderate / heavily incontinent adults (urinary or urinary / faecal) living in a total of 10 nursing homes (27 men and 73 women) evaluated one product from each of the four disposable design categories above. Products were selected on the basis of product performance from the community-based trial and, again, day and nighttime variants were provided.

Product performance was characterised using validated questionnaires which asked the participants (in the community-based trial) or carers (in the nursing home based trial) to evaluate various aspects of pad performance (leakage, ease of putting on, discreetness etc) using a five point scale (very good – very poor) at the end of the week (or two weeks for the nursing-home-based trial) of product testing. In addition, participants / carers were asked to save individual used pads in bags for weighing and to indicate the severity of any leakage from them on a three-point scale (none, a little, a lot). These data were used to determine differences in leakage performance. Numbers of laundry items and pads used were recorded to estimate costs, and skin health changes were recorded by the participant or by the researchers. At the end of testing participants were interviewed and ranked their preferences (with and without costs), stated the acceptability of the design (highly acceptable – totally unacceptable) and recorded their overall opinion on a visual analogues scale (VAS) of 0-100 points (worst design – best design). A pad changing experiment was conducted with 12 women from the nursing home based trial to determine any differences between product designs. Under idealised conditions the different designs were applied (by the same carers) in random order for each patient and the speed of pad changing was timed using a stop-watch.

Findings from the community-based and nursing home trials were broadly similar. The leakage performance for the disposable inserts was worse than the other designs for day and night and disposable pull-ups were preferred over inserts for the daytime. The new T-shape diaper was not better overall than the traditional disposable diaper. But there were important differences in performance and preference findings between men and women from both trials.

and the men (in the community) had more severe urinary incontinence than the women - mean daytime urine mass in a pad 375 g for men and 215g for women (difference148g, CI: 80, 218).

Pull-ups (the most expensive design) were better overall than the other designs for women during the day and for community-dwelling women during the night too. Although disposable diapers were better for leakage than disposable inserts (the cheapest), women did not prefer them, but for men (in the nursing homes and the community) the diapers were better both overall and for leakage and were the most cost-effective design. No firm conclusions could be drawn about the performance of designs for faecal incontinence and there was no firm evidence that there were differences in skin health problems between designs (Level of Evidence 1).

In the nursing home trial the carers found pull-ups and inserts significantly easier to apply (in the standing position) and significantly quicker in the pad change experiment (mean time 35.2 and 37.9 seconds for inserts and pull-ups respectively and 53.2 and 62 seconds for diapers and T-shaped diapers respectively) and ability to stand was associated with preference for pull-ups or inserts. Despite being designed for ease of changing the T-shape diaper was not found to be easier or quicker to change than the diaper.

The washable products (used in the community-based trial) gave diverse results. Two of the products were made from cotton terry-towelling (one a simple square, folded and pinned in a diaper shape; the other a shaped diaper-like design, both worn with plastic pants) while the third product had a felt absorbent core, with an integral plastic backing and was fixed by poppers. This third product performed significantly worse for leakage than the other two washables and was therefore excluded from the final data analysis. The terry-towelling washables were better for leakage at night than the disposable designs, but were less popular overall for daytime use than the disposable designs. Three quarters of the women (27/36) found them unacceptable, but nearly two thirds of men (31/49) found them highly acceptable at night. Findings from the community-based trial showed that there were many practical problems dealing with washable products particularly when out of the house, but that they were more acceptable at home.

Macaulay et al, [20] carried out a pilot study of 19 washable products with 14 community dwelling subjects. The products included a mixture of washable insert and brief designs and two disposable body-worn products. Product performances varied widely: the most popular was rated as good (for overall performance) by 78% of testers, while the least popular scored 22%. Although most of the washable products performed poorly for leakage, one washable product made of cotton towelling (used with plastic pants), scored better than both the other washable and disposable products (Level of Evidence 3).

Eight older trials have compared disposable with washable bodyworn products for moderate-heavy incontinence [61] [62] [63] [64] [65] [66] [67] [68]. The trials varied in size and design from a large controlled trial with 276 subjects [61] to a small trial of eleven subjects [64]. In addition some trials have compared disposable and washable bedpads and body-worns. Brown [22] [69] undertook a large trial of this kind. The fact that no systematic method of product selection was used for these studies limits the utility of the results since particularly good or poor products may have been selected to represent the disposable or washable groups.

Skin condition was used as an outcome measure in five of the above trials. However, only three used an experimental design and statistical methods of analysis. Beber [61] and Grant [62] both reported that they did not find statistically significant differences between their washable and disposable products in terms of an adverse change in skin condition. But Hu et al. [70] reported a statistically significant improvement in the skin condition of their disposable product users as compared to their users of washable products (See Section XIV).

Other parameters frequently investigated in these studies were staff preference, product leakage and laundry. Overall, the disposables in the studies were considered to have performed better than the washable products in terms of preventing leakage (often measured by quantity of laundry) and staff preference.

Four studies attempted to measure costs [63] [62] [71] and [69]. Of these, three used statistical methods of analysis. Hu et al. [71] and Brown [69] reported that although there were no statistically significantly differences in terms of per-day product costs of washable and disposable products, the laundry costs associated with the disposable product (ie for laundering soiled bed linen and clothes) were significantly lower than those associated with the washable product (ie for laundering the products as well as soiled bed linen and clothes). Brown [69] found no significant differences between daily costs of the washable and disposable products. However, statistically significant differences were found between the groups in terms of incontinence-related laundry, with the disposable group producing less laundry than the washable group. Grant [62] reported that the cost of washable products was significantly lower than that of disposables, but laundry costs were not taken into account.

2. DISPOSABLE ABSORBENT PRODUCTS FOR URINARY INCONTINENCE: STUDIES OF SINGLE DESIGNS, LABORATORY TESTS AND STUDIES OF MATERIALS

Clancy and Malone-Lee [15] compared versions of the same pad experimentally engineered to have differ-
ent combinations of fluff pulp and topsheet materials. Forty-five heavily incontinent older adults participated. The main valuable finding from this study was that pants were more likely to leak if they were not held in place by pants (p<0.0001) and that, if there was any leakage from a pad, this tended to be less severe if the supplied mesh pants were worn than if normal pants were worn (p<0.05) (Level of Evidence 2). The mesh pants probably held pads more firmly to the body.

There have been two single design group studies of bodyworn products for moderate-heavy incontinence [72] [73], both carried out in nursing homes. A study of shaped insert pads involved 228 subjects from 33 nursing / residential homes who tested 20 ranges of shaped insert pads involved 228 subjects from 33 nursing / residential homes who tested 20 ranges of insert pads (74 products in total). A similar study of diapers involved 192 subjects from 37 nursing / residential homes who tested a total of 36 products. These studies showed the wide range of product performance that can exist within single product groups. For example, the least successful diaper (based on ‘overall opinion’) was found to be unacceptable to 100% of the test subjects while the most successful was unacceptable to only 6% (Level of Evidence 2).

In addition, there have been a number of studies on the impact of wet pads on skin health and these are reviewed in Section XIV.

Because clinical evaluations are expensive and time-consuming, laboratory evaluation procedures are in widespread use. Few have been clinically validated but there is a clinically-validated International Standard (ISO 11948-1) relating to the leakage performance of disposable bodyworn pads for moderate-heavily incontinent adults in institutions [53]. It describes a simple method for measuring the absorption capacity of pads in the laboratory that was shown to correlate well with the leakage performance of 18 different products evaluated in an international multi-centre clinical study involving 112 heavily incontinent adults [74]. The strength of the correlation between technical and clinical data data depended on the exact parameters being compared, but typically r=0.9 (Level of Evidence 2). This laboratory test (the Rothwell method) is now in common use in the UK, Sweden and other countries and provides a basis for selecting similar products with which to make direct comparisons (for cost purposes) or to select promising pads for inclusion in clinical trials.

The ability of ISO 11948-1 to predict the leakage performance of more recent bodyworn pads (138 diapers and inserts) for heavy incontinence was investigated by Cottenden et al. [75]. Correlations were poorer than in the original 1993 study (r<0.87 compared with r<0.95) but still strong enough to make the method useful. For a given Rothwell capacity, the leakage performance of diapers was far superior to inserts, but no evidence was found for any other design feature of the test products (inserts and diapers) having a significant impact on their leakage performance (Level of Evidence 2). The repeatability and reproducibility of the ISO 11948-1 was investigated by Cottenden and co-workers [76] in three laboratories (UK, Spain and Sweden). Repeatability (precision between repeats in the same laboratory) was found to be very good with the co-efficient of variation for five repeats rarely exceeding 5%. However, the reproducibility (precision between laboratories) was poorer, revealing systematic differences: results from the Swedish and Spanish laboratories typically exceeded those from the English laboratory by 13% and 8%, respectively. Efforts to identify the source(s) of this poor reproducibility have so far been unsuccessful but it seems likely that minor variations in interpretation of the standard when constructing the apparatus and / or executing the test are to blame (Level of Evidence 2).

c) Summary

Results from these studies indicate that there is no single best design (i.e one design that is significantly better than all other designs for all users) (Level of Evidence 1).

There is evidence that different designs are better for men and women, and that men leak substantially higher volumes of urine than women (Level of Evidence 1).

Of the disposable designs, the more expensive pull-up and T-shaped diaper designs are not better overall than the cheaper diaper for men, indicating that the diaper is the most cost-effective design for men. For women pull-ups are better overall than the other designs (except for night-use in those living in nursing homes), but they are expensive (Level of Evidence 1).

Unlike men, women in the community do not favour diapers over insert pads and of these cheaper designs, inserts may be preferred for women. There is also evidence that the leakage performance of inserts is worse than other designs, but that they leak significantly less if they are held in place by mesh pants than by ordinary pants, and using no pants at all is associated with significantly more leakage than if either kind of pant is worn (Level of Evidence 3).

There is evidence that pads containing superabsorber leak less, are more comfortable, and keep the skin drier than those without (Level of Evidence 2).

The leakage performance of inserts and diapers for heavy incontinence can be predicted with reasonable precision using an international standard laboratory tests (Level of evidence 2).

This test has been shown to have very good repeatability and adequate reproducibility (Level of Evidence 2).

Washable products are very varied in design and materials, and also in performance. There is evidence that terry-towelling products (used with plastic pants) have good leakage performance, however they have limited acceptability - confined mainly to some men at night. There is no firm evidence regarding the perfor-
mance of different designs for faecal incontinence and no firm evidence that any particular design or type of material (washable or disposable) is better or worse for skin health.

The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Figure VI-18.

d) Recommendations

- Gender should be considered when products are prescribed / purchased for users. As men often have substantially higher incontinent urine volumes than women, men may require more products and / or more absorbent products than women (Grade of Recommendation B).

- Gender should also be considered when products are prescribed / purchased for users because men and women are likely to prefer different designs. Men generally prefer disposable diapers to inserts (Grade of Recommendation B).

- Women generally prefer disposable pull-ups to other designs, but these are expensive. Disposable inserts are a cost-effective alternative (Grade of Recommendation B).

- Caution is recommended if washable designs are being considered. Heavy bulk confines their use mainly to the night-time (where they may be particularly useful for users who lie on their side). They are unacceptable for most people during the daytime and for most women at any time and for this reason a blanket policy of health services providing washables alone is not recommended. If washables are being considered refer to points below (Grade of Recommendation B).

- Freedom from leakage: Where possible, international standard laboratory tests should be used to rank the likely leakage performance of different pads for heavy and light incontinence (Grade of Recommendation B). In general, diapers should be selected in preference to inserts to minimise leakage (Grade of Recommendation B).

- Carer application: When products are applied by a carer to a patient who can stand for pad changing, disposable inserts or pull-ups are easier and quicker to change than diapers or T-shaped diapers. If the patient is lying down (e.g. at night) pull-ups should be avoided (Grade of Recommendation B).

- Combinations of designs for different situations (e.g. disposable inserts for staying in, disposable pull-ups for going out, washable diapers at night) are likely to provide optimum management in terms of patient needs and cost-effectiveness (Grade of Recommendation B).

- See also the general recommendations relating to pad selection in Section VI.12 and recommendations specific to washable pads in Section VI.13.

e) Research priorities

- Comparison of absorbent products (disposable and washable) when used by carer-dependent users in the community.

- Development of more effective and aesthetically acceptable washable products, particularly for night-time use and for women.

- Development of more effective and acceptable disposable designs specifically for men.

8. DISPOSABLE UNDERPADS

There have been no published studies examining the use of underpads during the last 15 years. This probably reflects the recognition of their limited role in long-term management of incontinence. Disposable underpads on chairs declare their user to be incontinent and require clothes to be pulled up (or absent) which is unacceptable for dignity. In the bed disposable underpads easily become displaced, folded and creased under the patient which inhibits their performance and comfort, and may potentially be a threat to skin health. Large disposable underpads with wings to tuck into the bed may have a role as bed protection ‘back-up’ to bodyworn pads. The main role of disposable underpads should be confined to temporary bed or chair protection such as during clinical procedures (e.g. enemas) or when using a urinal.

Published trials comparing different disposable underpads are few [77] [78] [22] and it is not possible to draw firm conclusions from them on the effectiveness of different product design features and materials. Some useful work has been done to highlight the risks of infection from disposable underpads and to validate clinically some laboratory tests to assist with product selection by predicting pad leakage performance.

Bedpads are generally supplied as non-sterile items and Bradbury [79] has drawn attention to the risk of infection, particularly from products containing recycled paper. Leigh and Petch [80] and Sprott et al. [81] have conducted microbiological tests on a range of products. Both studies identified low levels of bacterial contamination but concluded that the risk to patients was minimal unless they were immunocompromised in some way. More recently, Stansfield and Caudle [82] reported an outbreak of wound colonization on a surgical orthopaedic hospital ward which they attributed to the use of disposable underpads containing virgin wood pulp.

Due to the paucity of published clinical data many technical tests have been devised to evaluate products in the laboratory. The only tests with published clinical validations are described by Cottenden et al. [74] who subjected six different bedpads to a variety of laboratory tests and to a multi-centre clinical evaluation in which 95 incontinent subjects tested each product in turn for a week, in random order.
Figure VI-18: Designs of pads for adults with moderate-heavy urinary incontinence. For definitions of light HEAVY and heavy HEAVY, see Section VI.4. (Grade of recommendation in brackets)
A combination of two laboratory tests (one to measure the absorption capacity and the other the absorption time of bedpads) gave a strong correlation with the percentage of subjects finding the leakage performance of a product acceptable when used as their sole protection \((r = 0.94)\) and predicted the acceptability scores of all six products accurate to within ± eight percentage points. A different absorption capacity test produced a strong correlation for the leakage performance of bedpads used as back-up to body worn products \((r = 0.96)\) and predicted the acceptability scores of all six products to within ± five percentage points.

**a) Summary**

No robust data are available on the effectiveness of current disposable bedpads or of their various design features or constituent materials. There is a risk of infection from bedpads made from recycled paper for immunocompromised users (Level of evidence 2). The leakage performance of bedpads (used alone or as back up to body worn pads) can be predicted with reasonable precision using clinically validated laboratory tests (Level of Evidence 2).

**b) Recommendations**

- Disposable underpads should not be used for long-term management of incontinence, but have a useful role as temporary protection for chairs and beds during clinical procedures (Grade of Recommendation C).
- Immunocompromised people should not use bedpads made from recycled paper because of the risk of infection (Grade of Recommendation B).
- Where possible, clinically-validated laboratory tests should be used to rank the likely leakage performance of different products (Grade of Recommendation B).

**c) Research priorities**

Disposable underpads have a limited role in continence management but are known to be widely used. An exploration of patient views regarding their use may help demonstrate their limitations.

**9. WASHABLE UNDERPADS**

Aspects of assessment that are particularly important regarding washable underpads are patient acceptability and preference, particularly with regard to willingness to be naked below the waist (if sole use intended) and availability of laundry and drying facilities.

Cottenden [83] has reviewed comparative evaluations of different washable bedpads up to about 1990. Leiby and Shanahan [84] have since published a study. Some evaluations have found significant differences between products relating, for example, to leakage performance and impact on skin health but none of the products evaluated is still available in the variant tested. In addition, compared products always differed from one another in many respects making it impossible to draw reliable generic conclusions relating to the products now available. However, the choice of topsheet material and the presence or absence of features like tuck-in flaps and integral water-proofing appear to be, primarily, matters of personal preference.

In institutional settings washable bedpads are commonly used by multiple patients and questions are often asked about the risk of cross-infection. Cottenden et al. [85] assessed the risk by determining the microbial content of 145 bedpads of five different designs after a night’s use by incontinent adults, followed by laundering using a standard foul wash procedure which included heat disinfection at 71°C for three minutes. Laundering destroyed all known pathogenic organisms, although some commensal flora were isolated in small numbers. It was concluded that foul wash laundry had left bedpads safe for multiple patient reuse with no demonstrable risk of cross-infection.

**a) Summary**

The literature contains insufficient robust data on which to base guidelines for choosing between washable bedpads. Choice of topsheet material and the presence/absence of design features like tuck-in flaps and integral/separate water-proof backing appear to be, primarily, matters of personal preference (Level of evidence 3). Provided an approved foul wash procedure is used, the risk of cross-infection between different users of a bedpads is very low (Level of Evidence 2).

**b) Recommendations**

- If considering using washable underpads for sole use (ie without a body worn product) the patient will need to be naked below the waist. Patient consultation and approval will therefore be needed (Grade of Recommendation C).
- Personal preferences of users with regard to topsheet material, tuck-in flaps and integral waterproof backing should be considered in making product selections (Grade of Recommendation C).
- Provided an adequate foul laundry wash cycle is used, the risk of cross-infection between successive users of washable bedpads is low and not a contra-indication for their use (Grade of Recommendation B).

**c) Research priorities**

- Comparison of washable underpads with body worn products when used at night.

**10. ABSORBENT PADS FOR CHILDREN WITH URINARY AND / OR FAECAL INCONTINENCE**

Most children are expected to achieve daytime dryness by the age of three [86]. However, some children take longer to become dry and some (e.g.
children with learning and physical disabilities) may never reach this goal. These children usually require absorbent products to contain leakage.

Aspects of assessment that are particularly important regarding bodyworn products for children are presence of faecal incontinence, day / night incontinence, level of independence with toileting, and use of aids (e.g. callipers).

To date there has been only one study of absorbent products for children and this has compared the diaper design with the newer pull-up design [87]. Sixty-one children with physical and / or learning disabilities tested five diaper products and five pull-up products, each testing each product for one week. The children were randomised to receive either the pull-up or diaper group first and individual products were tested in random order within each design arm. Parents completed a product performance questionnaire and a pad leakage diary to record wet weights and severity of leakage. Parents were asked to state their preference for a design for day and night use.

Findings indicated that generally, the diaper products performed similarly to each other and so did the pull-up products, although there were some statistically significant differences between products within each of the two design groups. Overall diapers were preferred for night-time use by the majority of parents. By contrast, 40% of parents preferred pull-ups for daytime use and these were found to be particularly appropriate for older children and those who were attempting independent toileting, provided they did not have faecal incontinence and did not wear callipers or adapted footwear. Diapers were more suitable for children who were dependent on carers and / or had faecal incontinence, and wore callipers or adapted footwear. The authors recommended that both diapers and pull-ups should be supplied for children, with pull-ups (which are about 50% more expensive than diapers) being provided for selected children during the daytime.

**a) Summary and recommendations**

Diapers and pull-ups meet different needs of children and both should be made available to children with disabilities, dependent on assessment (Level of Evidence 3 / Grade of Recommendation C).

**b) Research priorities**

Comparison of washable and disposable bodyworn products.

11. **PADS FOR FAECAL INCONTINENCE**

Most absorbent products are designed for urinary incontinence. No studies comparing available absorbent products for faecal incontinence were found. Bliss et al. [88] reported preliminary findings of a survey of the use and evaluation and suggested modifications of absorbent products for faecal incontinence by 188 community-living persons with the problem. Forty-five percent of persons used an absorbent product for FI. Ninety-eight percent of those with UI and FI used the same type of product for both. Suggested improvements in product designs included having better odour control, fit, and ability to stay in place; a clearer distinction between the front and back of a pantiliner or pad; adding wings for greater absorbency; and making them flushable, cooler feeling, wider and longer in the rear and more absorbent but less bulky. For mild faecal incontinence, especially when faeces remain between the buttocks without soiling underwear, persons have used a small disposable gauze surgical dressing placed between the buttocks. This product was more acceptable than a pantiliner or pad to some men [88] (Level of Evidence 2).

**a) Recommendations**

- A disposable gauze dressing that can be placed between the buttocks maybe acceptable for men with light faecal incontinence (Level of Recommendation C).

**b) Research priorities**

- Better designs of products are needed for light and moderate FI (with and without UI).

12. **GENERAL RECOMMENDATIONS ON PAD SELECTION**

- **Individuality**: No study has ever identified one product that worked best for all testers: needs and priorities vary. Accordingly, users are advised to try a variety of products when possible (Grade of Recommendation B).

- **Brand differences**: The individual product brands within a design group often exhibit a wide range of performance and acceptability for individuals, and it cannot therefore be assumed that pads of different brands but broadly similar design will be equally acceptable or effective (Grade of Recommendation B).

- **Combinations of designs**: Absorbent products vary greatly in price and performance and suitability for individual needs. Users may therefore find combinations of designs preferable and cost-effective. For example, women might use pull-ups (expensive, but discreet and good for leakage) for going out, and inserts (cheap, less good for leakage) for staying at home. Men might use disposable diapers for daytime, and washable terry-towelling products for night-time (Grade of Recommendation B).

- **Freedom from leakage**: In general, pads containing superabsorber should be selected in preference to those without (Grade of Recommendation B). Nobody wants their pad to leak but compromises have to be made: the pad needed to contain a person’s most severe accident may be substantially more bulky and expensive than is needed most of the time. Some users choose to
tolerate a higher risk of pad leakage in exchange for being able to use cheaper, smaller (more discrete) pads. The balance of priorities for a given user should be investigated in making product selections (Grade of Recommendation C).

- **Comfort and skin health:** In general, pads containing superabsorber should be selected in preference to those without (Grade of Recommendation B). Shaped pads should usually be selected in preference to unshaped (Grade of Recommendation C).

- **Staying in place:** No product is effective if it slips from position. Inserts should be used with pants, preferably mesh pants (Grade of Recommendation B). Robust, stretch (e.g. cotton / lycra) pants may also help to provide a snug fit and minimise leakage. Shaped pads are preferable to rectangular (Grade of Recommendation C).

- **Ease of putting on and taking off:** The ease of putting pads on and taking them off should be considered, especially for caregivers and for incontinent users with reduced mobility or dexterity (Grade of Recommendation C).

- **Aesthetics and discretion:** A possible preference for small, more discrete pads (even if they are more likely to leak) should be considered, especially for those wishing to wear close fitting clothing (Grade of Recommendation C). The possibility of plastic backing materials rustling noisily should be considered (Grade of Recommendation C).

- **Independence and lifestyle:** The ability of a user to change his / her own pad should be considered (Grade of Recommendation C): those able to change their own pad can often manage with a smaller (less absorbent) one than those reliant on a caregiver. Users who travel should consider in their choice of product(s) the practicalities of carrying a supply of pads, disposing of used ones, and dealing with laundry (Grade of Recommendation C).

- **Costs:** Cost issues should be approached with caution (Grade of Recommendation C). Expensive pads do not necessarily work better than cheaper ones. Cheaper pads do not necessarily save money. If pads leak more they may have to be changed more frequently and / or lead to higher laundry costs. More pad changes will mean increased caregiver workload. However, more absorbent pads will not necessarily reduce pad consumption rates: pads are often changed according to ward or personal routine.

13. RECOMMENDATIONS RELATING TO WASHABLE PADS

- **Laundry issues:** Access to good, reliable washing and drying facilities should be checked before washable products are introduced (Grade of Recommendation B). Laundry – especially of bedpads – can be heavy work, beyond the capability of frail incontinent people or their caregivers. The number of washable products needed per user depends on laundry turn-around times. Drying times for washables can be long and expensive, especially for bodyworns for heavy incontinence and for bedpads.

- **Personal preferences:** Personal preferences (of both users and caregivers) with regard to choosing between washable and disposable products should be taken into account carefully (Grade of Recommendation C). Some users prefer the chore of laundering washables to anxiety over whether their next consignment of disposables will be delivered on time. Washables generally require less storage space than disposables. Discreet disposal of disposables can be a challenge. The possibility of using a mix of disposable and washable products should be considered (Grade of Recommendation C). Some users who choose disposables when at home prefer washables when travelling because of the space that disposables occupy in luggage and the possible inconvenience of disposal. Others use washables at home and disposables when away as they see the balance of disadvantages and advantages differently.

- **Personalisation of products:** In institutions, the chore of personalizing washable products and sorting them after each laundry cycle should be considered before they are introduced (Grade of Recommendation C). Washable bodyworns are often personalised to particular users. In institutions this means marking products with users’ names and sorting them after laundry, an extra task for caregivers. Washable bedpads are not usually personalised.

- **Staining:** Washable products should not usually be used by those with faecal incontinence – beyond occasional light smearing – because of staining (Grade of Recommendation C). Skin sprays and ointments may stain washables too.

- **Costs:** Cost comparisons between washable and disposable products should be made with caution (Grade of Recommendation C). Key factors are: local arrangements (mostly laundry and transport costs); the durability of the products (which depends on how carefully they are used and the criteria for deciding when they should be replaced); the costs of ordering, transporting and disposing of disposables; and product purchase costs. Much of the cost of washables is encountered with the initial capital outlay for stock. This also represents a commitment to use the products for an extended period and so expensive mistakes can be made if it transpires that a better product was / has become available. It will usually be wise to experiment with samples of a variety of alternative products before committing to major purchases.
VII. SHEATHS

Close-fitting penile sheaths (sometimes called condom catheters, uridomes or external catheters) are commonly used male incontinence devices and they are used in combination with a urine drainage bag. They are suitable for males who are experiencing moderate to heavy urine loss, or have limited mobility and are experiencing frequency and urgency and may even be considered in combination with intermittent catheterisation (IC) for males who are leaking urine as a consequence of bladder emptying problems. Sheaths may not be suitable for males who are experiencing confusion, considered psychologically vulnerable or have decreased sensation through spinal cord injury [89], [90], [91]).

There is strong opinion expressed in the literature that suggests assessment, selection and use of penile sheaths and the accompanying urine drainage systems needs to be undertaken with the guidance, education and monitoring of health professionals who have a knowledge of continence products. Failure to do so, according to this expert opinion ([90], [92], [91]), may result in serious penile trauma, impaired penile skin integrity and leakage of urine.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important in relation to sheaths include: physical, mental, cultural, gender and socio-economic factors. This incorporates assessment of the cognitive and dexterous ability of the male or carer to apply the sheath and empty the drainage bag, the integrity of the penile skin, length and circumference of the penis and whether it is retracted, or retracts on sitting or bending down, history of latex or adhesive allergy and, most importantly, recognition that the assessment from the health professional needs to be ongoing. It is also important to assess factors known to encourage or discourage sheath usage. Expert opinion ([93], [90], [94]) suggests factors that encourage usage include: level of reimbursement, cultural expectation, resonance with masculine image, and ability to keep urine off the skin when the skin integrity is at risk because of incontinence. Factors which they suggest discourage usage include: ignorance of product efficacy by professionals and consumers and embarrassment between carer and client.

An effective sheath is one that stays securely in place for an acceptable period of time, is leak-free, comfortable to wear, easy to apply and remove, avoids skin damage and channels the urine effectively into a urine drainage bag.

1. PRODUCT CATEGORIES AND FEATURES

Sheaths come with a variety of features (Figure VII-1) of which the following are the most important to consider in making selections:

- Material: sheaths may be made from latex, silicone rubber or other synthetic polymers. Some men will be allergic to latex.
- Size: most sheaths are supplied in a range of lengths and sizes. Most companies supply them with diameters in the range of about 20 – 40 mm, in 5-10 mm increments.
- Adhesive: the adhesive may be integral to the sheath (one-piece systems) or come as a separate strip or spray (two-piece systems). Some men will be allergic to some adhesives.
- Applicator: some sheaths come with an applicator intended to help users and carers to put the sheath on.
- Anti-kinking / twisting features: some sheaths come with features intended to improve drainage by reducing kinking and twisting at the distal end, near the connection to the drainage bag tube.
- Anti-blow-off features: some sheaths come with features intended to reduce the likelihood of the sheath blowing off at high urine flow rates, for example, at the beginning of a void (eg the distal end of the sheath may be thickened and bulbous to stop the internal walls sticking to one another between voids).
- Connection to the drainage bag: some sheaths come with features intended to increase the ease and security of connection to the drainage tube (eg a push ring or ridge at the end of the outlet tubing).
- Retracted penis features: with or without specific features intended to accommodate a retracted penis (eg a shorter sheath or a wider adhesive seal).
- Durability: some sheaths are intended for use over a limited time period (eg 24 h) while other (generally, more robust) designs are intended for extended wear.
- Transparency: some sheaths are transparent allowing for observation of the condition of the skin along the shaft and glans of the penis.

2. QUALITY OF DATA

Some controlled comparative evaluations of different sheaths have been performed; one extensive market survey to identify the needs and priorities of sheath users; and two studies comparing sheaths with other product categories (versus indwelling urethral catheter, and versus absorbent pads). Other studies report on the problems encountered by various groups of sheath users.

3. RESULTS

Although many men use sheaths successfully, problems have been reported in the literature. In a study on an unspecified number of spinal cord injured men, Goli [95] found that 15% experienced side effects or complications when using sheaths. These were irritative, allergic or compressive in
nature. Jayachandran et al. [96] reported similar experiences with six incontinent men of widely varying aetiology and highlighted the importance of ensuring that the sheath does not become twisted near the distal end to avoid stagnation of urine and the risk of UTI. They also stressed the importance of good genital hygiene to avoid problems with infections. In a study of 94 men on medical / surgical wards, Hirsh et al. [97] found that none of the 79 who were judged as co-operative and able to manage their sheaths properly developed UTI (mean period of use, 21.2 days). By contrast, eight of 15 patients who tended to tug and kink the drainage tube attached to their sheath developed UTI within a mean of 9.6 days. In a retrospective study, Johnson et al. [98] compared the frequency of UTI in users (mean period of use, 35 months) and non-users of sheaths amongst 64 elderly men on an extended care unit. He found that 63% of users but only 14% of non-users developed UTI. No difference was found between men who did and did not tug and kink their tubing. Ouslander et al. [99] reported that 40% of 30 nursing home sheath users (mean period of use, 35.9 months) developed at least one UTI. The need for proper fitting of the sheath and regular monitoring of the skin integrity of the penile shaft, glans penis and prepuce of males who are regular sheath users has been highlighted in two articles that report a combined total of eight cases of fibropithelial polyps of the glans penis and prepuce of which six had a history of long term sheath use [92] [100].

A trial to compare sheaths and indwelling catheters in terms of infection, risk and patient satisfaction has been reported by Saint et al [101]. This was a prospective, randomised, unblinded, controlled trial which compared one type of sheath drainage with one type of indwelling urethral catheter using a small group of participants (N=75) across several locations in one hospital. There are important limitations of the study, including the low numbers drawn from a specific population, and the lack of comment on the changing / care routines associated with the sheaths and catheters. After making adjustments for age, mental score, history of UTI and history of catheterisation the conclusions of the study were that for males without dementia the use of sheaths has the potential to reduce infection compared to indwelling catheters and is more acceptable to patients in terms of comfort and pain. For males with dementia no significant difference in infection rates was found.

There has also been a cross-over trial [47] comparing sheaths with absorbent pads when used by men with moderate to severe UI (N=61). Products were used for two weeks each and the Kings Health...
Questionnaire was used as the primary outcome measure. Scores for the sheath system were significantly better than for the pads on most domains and the number of men preferring sheaths was significantly higher than for pads.

Nichols and Balis [102] reported the results of a survey undertaken for marketing purposes of an international cohort of 216 men who had used sheaths for at least three years, and their carers. Their responses to 19 brands of sheath were gathered using a questionnaire in the form of a Likert scale. It was found that catheter security (presumed to mean staying in place and freedom from leakage) was the most important issue for both wearers and carers, followed by comfort and ease of application and removal.

There have been a number of comparative evaluations of different sheaths. Peifer and Hanover [103] reported on an evaluation in which 20 men compared a new branded sheath system that consisted of three ed parts: a tubular sheath impervious to urine with a drainage tube connection at one end and a ring at the other; an undergarment with a frontal opening through which the penis is extended; and a ring-like collar which is used to keep the sheath and penis in the correct position, with the variety of external sheaths they had previously been using. The participants were a convenience sample identified through pharmacy medication files. In all, 32 men were approached and 20 consented, all experienced users of urinary sheaths. A questionnaire was developed to test the participants pre and post intervention. The new sheath – which was used for a week - proved more popular with the participants: it was judged to provide superior security (13/20 experienced increased dryness by day; 10/20 by night), and considered easier to apply (19/20) and remove (20/20).

In a multi-centre study involving 35 men (age range 22-87y; mean age, 54y; 34 living in their own homes), the UK Medical Devices Agency [104] compared four latex sheaths: two with integral adhesive; and two in which the adhesive was supplied as a separate strip. They found the products with integral adhesive to be more successful in both overall performance and ease of application. Fader et al. [21] conducted a multi-centre study to compare all six sheaths with integral adhesive on the UK market in 1998. Five were made from latex, one from silicone rubber. Four were supplied with an applicator, two without. Fifty-eight men (age range 26-88y; mean age 53y) were given the opportunity to try each sheath in turn for one week. The silicone rubber sheath was found to be significantly better than four of the other sheaths in overall performance (p<0.01). The ease with which a sheath could be put on was found to be the best predictor of overall performance. Surprisingly, sheaths with an applicator were found to be unacceptable to a significantly higher proportion of subjects than sheaths without an applicator (p=0.0001). Subjects found that the silicone sheath fell off / blew off significantly less frequently than two of the other products (p<0.01).

Pemberton et al [94] report a randomised prospective open crossover design trial to test user preference for an established one-piece silicone rubber self-adhesive sheath with a new one-piece silicone rubber self-adhesive sheath in a study sponsored by the distributor of both products. To be included the males had to be currently using at least one, one-piece urinary sheath, per day. Fifty three males from seven centres participated in the trial and were each given 10 sheaths of each product. Data from the 44 participants who had evaluated at least three of each product were analysed. No reason was given for why nine males did not complete the trial. The data shows that there were some problems with both products, however, it is difficult to understand why the new product was preferred, as the report does not mention any differences in the features of the two products.

Watson & Kuhn [105] describe a crossover study with six male participants that found the choice of leg bags may influence the performance of penile sheaths. Goldyn, Buck and Chenelly [106] conducted an exploratory study on 10 patients in an extended care hospital to consider the efficacy of a brand name external sheath and a hospital constructed sheath. The brand name sheath was found to be more secure and the preferred nursing choice but it was recognised that the hospital-constructed sheath was useful for patients with fragile skin and limited mobility. A study by Saint et al. [107] provided further evidence (although low level) to support the importance of security and comfort to sheath users. Using questionnaires, they interviewed a convenience sample of 104 older men (response rate = 90%) and surveyed 99 nurses (response rate = 92%) about the relative merits and problems of sheaths and indwelling catheters. The study population was drawn from a university-affiliated Veterans Affairs Medical Centre in the USA. The patients using the sheaths were more likely to believe their product was comfortable (p = 0.04) and less likely to believe it was restrictive (p = 0.002) or painful (p = 0.008) than those using an indwelling catheter. This viewpoint was supported by the nurses surveyed, the majority of whom (no numbers given) believed that sheaths were more comfortable and less restrictive than indwelling urinary catheters for male users, but required more care time because they fell off or leaked.

4. SUMMARY

For incontinent males, sheath drainage can provide a good alternative to pads. However, the increased risk for complications such as local skin breakdown, bacteriuria and infection – especially in the frail confused elderly male – should be borne in mind (Level of Evidence 2). Also, there is the risk of urinary retention if the condom twists or the external band is
too tight, leading to poor drainage to the urine bag (Level of Evidence 3). Sheaths with integral adhesive are more popular with users and easier to apply than those with separate adhesive strip (Level of Evidence 2/3). Secure fixation and the ease with which a sheath can be put on are the best indicators of its overall performance (Level of Evidence 2). Sheath applicators are often ineffective and unpopular (Level of Evidence 2). There can be considerable differences in performance between products with somewhat similar designs (Level of Evidence 2).

5. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

• Prior to applying the sheath, ensure any remaining adhesive or barrier cream is removed from the penis and that it is thoroughly washed with soap and water and thoroughly dried.

• Trim long pubic hairs to prevent them being caught up in the adhesive.

• Protective skin wipes can be used to protect the skin, but make sure the skin has dried properly before applying the sheath.

• Leave a gap at the end of the sheath between the glans penis and the drainage tube to avoid trauma to the glans / prepuce. However, make sure the gap is not too large such as to cause kinking or twisting of the sheath [108].

• After the sheath has been applied, snip any reinforced ring or unrolled section of sheath sitting at the bottom of the shaft of the penis.

• Penile sheath removal should not be rushed and is made easier by gently rolling it off while bathing the penis in warm soapy water.

6. RECOMMENDATIONS

• Since there can be considerable differences in performance between products of similar design, men should be given the opportunity to experiment with different products before making a final selection (Grade of Recommendation B).

• The key performance characteristics which should be considered in selecting products are: security (ie ability to keep a leak-proof seal and channel urine to the drainage bag without leakage) and ease of putting the sheath on and taking it off (Grade of Recommendation B).

• In general, sheaths with integral adhesive (one-piece systems) should be selected rather than those in which the adhesive is supplied separately (two-piece systems) (Grade of Recommendation C).

• It should not be assumed that a sheath applicator will make sheath application easier: often it does not (Grade of Recommendation B).

• Potential sheath users should be asked if they have an allergy history and regular users should be routinely checked as their latex allergy status can change over time and with continued use. (Some health settings are moving to reduce or eliminate latex usage whenever possible and some manufacturers have moved to offer non-latex sheaths) (Grade of Recommendation C).

• Sheath users should be monitored for skin health, tissue damage and UTI (Grade of Recommendation C).

• When possible the external sheath rather than indwelling urethral catheter should be the urinary collection device of choice. (Grade of recommendation B).

7. PRIORITIES FOR RESEARCH

• Although products are continually being developed, changed, withdrawn and released, comparison studies that are controlled and use multiple sites to achieve larger numbers are recommended to further evaluate the effectiveness of the variety of sheaths available.

• More comparative studies of the risks of complications between the use of sheaths, pads and catheters are required.

• Since leg bag features may influence the performance of the sheath, further evaluation of design features claimed to reduce twisting and kinking at the drainage bag connection site and increase ease and security of connection to drainage bags is required.

• Well designed studies to generate and validate procedures to help identify the type of sheath most likely to suit an individual are needed.

8. URINE DRAINAGE BAGS AND ACCESSORIES

Urinary drainage bags are attached to an indwelling catheter or penile sheath to collect and store urine. Features of effective drainage bag systems include ease of operation of all components (connectors, taps, and support devices), comfort and discreetness.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding urine drainage bags are patient / carer dexterity [90] [109], and eyesight. Both are necessary to manage the urinary drainage bag system, including using the outlet tap to empty the drainage bag. It is also important to assess the patient’s preferred and usual mode of dress [90] [109]; for example, a male whose preferred mode of dress is shorts will want a drainage system that is not visible and allows easy access for emptying.

1. PRODUCT CATEGORIES AND FEATURES

Urine drainage bags fall into two major categories:
leg / body worn bags for day-time usage; and large capacity body-free bags for night-time use (night drainage bag) which are suspended from a stand or bed hook.

Leg / body worn bags come with a variety of features of which the following are the most important to consider in making selections:

- **Volume:** most bags have a volume in the range of 350-750 ml, but some are bigger.
- **Material:** most bags are made from transparent PVC (polyvinyl chloride) but PVDF (polyvinylidene fluoride, less noise from rustling), polyethylene or rubber / latex may be used.
- **Sterility:** bags may or may not be supplied sterile.
- **Wear position:** bags may be designed for wearing over the knee, across or down the thigh, or against the abdomen.
- **Attachment / suspension system:** most leg bags are attached to the leg with straps, which are usually made from latex or a (usually elasticated) fabric. A variety of hooks, loops, buttons / button holes and Velcro may be used to secure straps and to attach bags to straps. Some bags are designed to be suspended around the waist. Some straps and suspension devices can be bought separately from bags, but they are generally not suitable for use with all bags (Figure VIII-1).
- **Connecting tube:** bags come with a variety of connecting tube lengths (eg the length required for wearing a bag on the calf will be greater than that for the thigh). With some products the tube can be cut to the preferred length.
- **Drainage tap:** Drainable bags come with a variety of drainage tap designs (Figure VIII-2).
- **Sampling port:** bags may or may not have a sampling port in the drainage tubing for taking urine specimens.
- **Comfort features:** some bags come with features intended to increase comfort – most commonly, a fabric backing against the skin to reduce sweating.
- **Discretion features:** some bags come with features intended to increase discretion – most commonly, internal welds between the front and back faces to reduce bulging and / or sounds caused by a large volume of liquid moving about as the user mobilises.
- **Anti-kinking / twisting features:** some bags come with features intended to improve drainage by reducing kinking and twisting in the connecting tube.
- **Infection reduction features:** some bags come with features intended to reduce the risk of infection for the self-carer and cross-infection between bag users by carers. Such features may include: a non-return flap valve, designed to help reduce reflux of urine up the tubing when the bag is moved by users or carers, a sampling port and / or a tap with an outlet sleeve which allows the overnight bag to be connected to the body worn bag. This linkage provides a mechanism to maintain a closed catheter drainage system designed to minimise the risk of cross-infection by reducing the handling of the catheter. Having connected the night bag to the leg bag sleeve, the leg bag tap is opened and urine flows freely from the sheath or catheter through the leg bag into the night drainage bag. Pre-sealed drainage systems to prevent breaking the closed system are also available, and these could be beneficial in reducing time to bacteriuria [110].

Night drainage bags are usually held on a suspension system away from the body. They may be connected directly to the catheter or sheath or they may be connected to the drainage tap of the leg / body worn bag to avoid the need for repeated connections and disconnections with the catheter or sheath (Figure VIII-3) ie a closed-link system. They usually have a capacity of 2000-4000 ml and come with a variety of design features many of which are similar to those for leg / body worn bags. Night drainage bags are available as non-drainable bags (NDB) i.e. without a tap for single use as well as with a variety of drainage tap designs for emptying and reuse. Glass bottles are also available for high volume or overnight urine drainage. It has been suggested that current standard drainage tubing / bag designs evacuate the bladder sub-optimally, leading to retention of residual urine. Outflow obstruction can be caused by the development of air-locks in the dependent curls of tubing. A new drainage tubing design which incorporates a coiled downward-spiral-shaped configuration has been reported to eliminate air-lock obstruction [111] in experimental and clinical studies. However the importance of this in relation to infection requires further study.

2. QUALITY OF DATA

Several controlled comparative evaluations of urine drainage bags and suspension systems have been performed, as well as a small number of studies addressing infection and cross-infection issues There are also two case-controlled studies which have investigated the purple urinary bag syndrome.

3. RESULTS

a) Evaluations of urine drainage bags

A randomized cross-over design compared use of a standard latex drainage bag with a cloth covered bag in 42 men with post prostatectomy incontinence [112]. Each bag was tested for about 4-5 days, and complete data were provided by 30 individuals. People with known latex allergy were excluded. Measures included adapted questionnaires for Leg Bag Evaluation and Skin Health. A statistically significant preference was found for the
cloth covered bag with a main effect (F= 36.614, df = 1.28, p<0.01) as well as an effect related to the order provided (F= 8.398, df = 1.28, p<0.01). That is, those who used the cloth bag first had a stronger preference for it than those allocated to the latex bag first. The cloth backed bag seemed to have several positive features, including comfort under the bag and cloth straps, flexible adjustable tubing, and taps that did not cause urine spillage on fingers. But these bags had a tendency to slip down and pull on the catheter. Two persons using the latex bags had minor skin irritation, one a rash related to the straps pulling on hairs on the leg and the other minor redness and swelling which resolved within 24 hours.
Kennedy et al. [113] tested the performance of ten different drainage bags in a simulation study involving 40 subjects (mostly health-care staff) which focused particularly on taps. Significant differences (p<0.05) were found between many pairs of bags with regard to each of the performance aspects studied: ease of tap opening and closing, ability to empty the bag without urine wetting fingers; and how easy the tap mechanism was to understand. Taps comprising caps or bungs were found to be particularly fiddly and messy to use.

In a study which focused primarily on the cross-infection risks associated with leg bags, Wilson and Coates [114] evaluated four leg bags. Each of ten long-term catheterised patients was invited to try each bag for a week in turn. The authors concluded that no one bag suited every patient; rather, each was liked by some users. The popularity (or otherwise) of many features was a matter of personal preference. Adverse comments mostly related to the tap (difficult to operate, opened accidentally, causing leakage) and the straps.

The UK Medical Devices Agency [115] evaluated all 14 sterile 500 ml leg bags on the UK market in 1995 in a multi-centre study involving 83 test subjects (58 men, 25 women). About half (44) lived in their own homes and almost all the rest in nursing / residential homes. Subjects were divided into pairs matched for sex, mobility, manual dexterity and dependency and each pair was offered each of the 14 bags (seven each) to try for a week in turn. Preferences varied but the main concerns of users consistently focused on taps (many subjects found many taps difficult to operate), straps (discomfort was common) and the minimisation of leakage (through faults in bags and / or connectors; onto the fingers when emptying; or by the tap accidentally opening in use). The most popular bags tended to perform well in these three respects.

In a multi-centre study involving 34 men (age range 27-84y; mean age 55y; all sheath users) Fader et al. [116] evaluated all seven non-sterile 500-700 ml leg bags on the UK market in 1997. Twenty-five of the men lived in their own homes and the rest in residential/nursing homes or long stay wards. Conclusions were substantially similar to those for the earlier MDA study.

Some international standards have been developed which provide general advice on bag performance and test methods [53]. These standards can be useful to laboratories asked to advise on bulk buying choices.

b) Urine drainage bag suspension systems

Little research has been undertaken on urinary drainage bag suspensions apart from a study by Thelwell et al. [117]. Thelwell et al. conducted a cross-over study using 52 subjects (20 men, 32 women). This study compared four suspension systems for fastening leg bags with the leg straps they had used prior to the study. Each subject evaluated each product for a week in turn and recorded findings on a weekly questionnaire. Again, difficulty of application, comfort, discreteness and cost were key issues. However, there is suggestion in the literature that urinary drainage bag suspensions have an important role to play not only in the comfort and security of the wearer but in the prevention of urinary tract infection regardless of whether the drainage system is connected to a sheath or an indwelling catheter.

Munnings and Cawood [118] report the findings of a pilot study designed to evaluate the use of a belly bag of 1,000ml capacity and worn 24 hours a day, thus eliminating the need to use two separate bags and reducing the number of times the closed system is broken. Twenty-nine patients from a variety of areas from within an acute care setting who were using continuous catheter drainage systems were invited to participate, with 27 of the participants completing the study. All agreed to wear and then compare the belly bag with their previous leg and night drainage bag system. Worn around the waist, the belly bag is not positioned below the bladder: the manufacturers claim that the pressure of the bladder muscles is sufficient to ensure that urine flows through the catheter from the bladder into the bag. The residual pressure of the bladder is reported to be around 10-25cm H2O, while the manufacturer asserts that a pressure of only 6cm H2O is necessary to ensure the urine drains into the bag. Following education of how to use the drainage bag, users were given a questionnaire designed to facilitate comparison between the previous drainage system used and the belly bag. This was followed up with a telephone call. All agreed the belly bag was an improvement over their previous system of leg and overnight drainage bags, and found it more convenient, comfortable and less likely to cause pain with movement.

It has been suggested that current standard drainage tubing / bag designs evacuate the bladder sub-optimally, leading to retention of residual urine. Outflow obstruction can be caused by the development of air-locks in the dependent curls of tubing. A new drainage tubing design which incorporates a coiled downward spiral shaped configuration has been reported to eliminate air-lock obstruction [119] in experimental and clinical studies. However the importance of this in relation to infection requires further study.

There is opinion in the literature that positioning standard drainage bags below the bladder in a
manner that averts kinking will prevent reflux of urine, and associated infection [120], [121], [122]. When doing so care must be taken not to increase traction or friction [109]. This can be achieved with the use of supports specially designed to divert accidental pulling on the catheter or sheath. When using these support systems allowance should be made for penile erection and tumescence [109].

The drainage system for indwelling catheters should be positioned off the floor to reduce the risk of cross infection [120], [121], [122]. Some sterile and unsterile leg bags come with a variety of tubing lengths or tubing that can be cut according to the needs of the individual, and leg straps that can be adjusted to allow positioning of the bag on the thigh or calf. Night bags - even if the tubing can be cut - rely on uniform stands or hangers to ensure that they are off the floor. Roe et al [123] raised the issue of poorly designed support systems for night bags. Expert opinion suggests that this still remains an issue.

c) Infection and cross-infection issues for management of urine drainage systems for indwelling catheters.

Usage of urinary catheters and their drainage systems increases the risk of urinary tract infection and cross infection (See Section XII.2.h). There is evidence to suggest that catheter associated infections are reduced with the use of closed urinary drainage systems. A randomised controlled trial was reported by Platt et al [124]. This trial compared the incidence of infection (measured as $10^5$ cfu/ml in catheter urine or drainage bag urine) between patients who were catheterised using sealed junction catheters (i.e. catheters pre-connected to a drainage bag using a sealed junction), and those catheterised using unsealed junction catheters (i.e. unconnected catheters and drainage bags), in a hospital setting with a median period of catheterisation of three days. For subjects not taking antibiotics, sealed junctions showed less infection than unsealed ($p<0.01$). For subjects taking antibiotics there was no difference in infection rates between sealed junctions and unsealed junctions. The infection rate appeared to be consistently lower in the subjects taking antibiotics than the ones not taking antibiotic but no statistical significance tests of this effect were reported.

Maintaining a ‘closed’ system has since become an important tenet for avoidance of urine infection both particularly in acute care but also in long-term care. This has led to the introduction of products designed to maintain a ‘closed’ system. In the UK the ‘link’ system is advocated whereby legbags are designed with a connector to attach to a night drainage bag, thereby obviating the need to disconnect the legbag from the catheter in order to connect a night bag. Use of non-drainable (single-use) night bags is also recommended in the UK (RCN 2008) presumably to reduce the cost of using a new (and more expensive) drainable night-time bag every night and also to avoid the practice of cleaning and re-attaching drainable night-time bags. However it should be noted that this ‘link’ system is not completely ‘closed’ (because the night bags are still disconnected and reconnected every night – albeit at the legbag tap rather than at the catheter) and the legbag may still be disconnected at the catheter junction for other purposes such as bladder instillations.

If a ‘link’ system is not in use then whenever a legbag needs to be changed to a nightbag the bag will need to be disconnected at the catheter junction. The bag (leg or night) may then be replaced (or more commonly) will be cleaned and reused. As yet there have been no studies to compare the use of the ‘link’ system with a conventional disconnection system.

The number of days that a legbag may be safely (or acceptably) left in place before it is replaced is unknown. There is little research to support the common practice of changing drainage bags every five to seven days (or any other particular change regime). The practice appears to be based upon expert opinion, anecdotal evidence and manufacturers’ recommendations. The five to seven day practice seems to be challenged by a study by Rogers et al. (1996) [125], of biofilm progression, which showed that it took only four days for colonization in the bladder model to extend all the way to the drainage bag (Royal College of Nursing, 2008).

A prospective study of catheter use in the US, of 43 long-term catheter users, indicated that drainage bags were changed less often than either commonly reported, or Rogers et al. suggest. In that study, drainage bags were replaced an average of every 23.5 (95% CI 21.1-25.9) days, during their six months’ participation in the study [126].

Of interest is the study outlined by Keerasunptonpong et al. [127] which was a randomized controlled study that compared the incidence of catheter-related urinary tract infections in a group of 79 hospitalised patients whose catheter bag was changed every three days with that for a group of 74 patients who had their bag changed at the time of the catheter change or if the bag became faulty. A urine sample for culture was obtained for each participant every seven days, on the day the catheter was removed or on the day the participant was suspected of having an infection. The findings suggest that urinary drainage bags could be left for longer than three days but the authors were reluctant to define how long as the sample size was considered too small to rule out a false-negative result. They recommended additional study.
Single use drainage bags, including non-drainable urine bags (NDB), were recommended in England’s Royal College of Nursing Catheter Guidelines (2008) for all sites of care (hospital based and community living patients). Only one study was found of this product. Hardyck and Perrinovich (1998) [128] described a retrospective home care trial of a NDB in 63 elderly patients, comparing with the same persons who had used a typical drainable bag (DB) in the previous months. The non-drainable bag was replaced when full, but no information was given about the capacity of the bags, the mean number of bags used per day or how often they were replaced. Fewer UTIs (and hospitalizations) were reported with the NDB, 71 (2) versus 1395 (27) in the DB. Unfortunately the methodology was flawed in several ways. Counts of UTIs were reported though the timeframes were vastly different, with a mean of 44.4 months for DB prior to the intervention period and a mean of 8.8 months for NDB. UTI diagnosis was determined by mailed questionnaires to 82 home care patients and information from nurses, physicians, and patients as well as chart information reviewed by the physicians. Comprehensiveness or completeness of the chart data extraction was not described. Additional analysis comparing matched timeframes of 16 months for a subsample of 15 (and 5 more within 2 months either direction) indicated that the mean number of UTI related hospitalizations in the NDB group was significantly higher: 12.1 (SD 8.87) as compared with 2.8 (SD 4.74) in the DB group (Wilcoxon rank test p<0.005). The matched pairs were selected based on whether the NBD was used for at least a month and chart data were available. Given questions on the methodology, it seems that a well designed randomized trial is needed, but no such study was found.

There is no evidence to support the practice of adding in situ antiseptic agents to drainage bags to reduce catheter-associated infection. A paper by Thompson et al. [129] which was primarily looking at the effectiveness of hydrogen peroxide instilled into closed drainage bags in reducing infection in drainage bags and in catheters also raises the question of whether catheters are infected primarily via drainage bags or vice versa. This prospective randomised study in a hospital setting involved daily sampling for bacteriuria (See Section XII.2.h for further discussion of outcome measures for catheter-associated infection) in catheters (>=10^5 cfu/ml) and drainage bags (>= 10^3 cfu/ml) and identifying the infecting bacteria species. In a sample size of 688, infection was found in 68 catheters and 78 bags. Although bag contamination was 8% in the H_2O_2 group and 16% in the control group (p<0.001) there was no significant difference in catheter bacteriuria (11% and 9%, respectively). One of the reasons given in the paper for questioning whether the drainage bag is the main source of catheter infection was that 77% of the bags in this study were contaminated later than the catheters.

Best practice guidelines to prevent infections associated with short term indwelling urethral catheters are available. The most recent of these, the EPIC 2 guidelines, were revised in 2005 and reported by Pratt et al. [122]. Designed to prevent short term, indwelling urethral catheter associated infection in NHS Hospitals in England, the guidelines are based upon a series of systematic reviews that include the best available evidence (experimental and non-experimental research as well as expert opinion). These guidelines recommend a closed catheter system where drainage bags are changed according to the manufacturer’s recommendations (5-7 days) or the patient’s clinical need. The guidelines also recommend that antiseptic or antimicrobial solutions are not added to urinary drainage bags.

Recommendations for acute care settings were issued by the Society for Healthcare Epidemiology of America (SHEA) in 2008[130] addressing system wide infrastructure preventive activities. These include use of written guidelines, complete documentation, surveillance for catheter-associated UTI (CAUTI), education and training of personnel related to catheter insertion and management, and appropriate insertion technique. The authors noted that decreasing catheter use and duration are central to preventing bacteriuria and CAUTI. Suggestions were given for organization-wide strategies, such as reminder systems for review of catheter continuation, automatic stop order processes, ward rounds to enhance communication and review, catheter related protocols like post operative duration, and systems for data reporting. Guidelines from SHEA for preventing infection in long-term care facilities were updated also in 2008 [131].

d) Long-term management of urine drainage systems and reuse of components

The quandary for health professionals involved in the education and support of clients, who are self-managing and often financing their long term indwelling catheter drainage systems while living at home, is that they are aware that many of them are leaving the bags on for much longer than the manufacturers recommend and are often washing the bags out with a variety of solutions and reattaching the bags directly to the indwelling catheter. The reuse of drainage bags is often not a matter of choice but necessity in developing countries. In a survey of 28 continent nurses who were members of ICS, a majority (68%) said they advised their community dwelling patients to reuse drainage bags [132]. A number of reasons were given, such as cost of bags, evaluation of risk in the patient, policies, guidelines, and ability to do the procedure. While advice varied, most suggested a solution of water mixed with vinegar, household bleach, or dishwashing detergent.

There is a paucity of studies that have explored long-term self-management of urinary catheter drainage systems in a community setting. Moreover,
practices may vary considerably in parts of the world where catheter supplies are not routinely provided by prescription, as in the UK, or in developing nations where supplies are scarce. More research in this area is needed to provide guidance to clinicians. Implications involve cost, aesthetics, and environmental waste, particularly when single use non-drainable bags are used.

Madigan & Neff [133] undertook a literature review (50 studies) that explored the complications and long term management of long term indwelling catheters used for urinary retention and incontinence. Their recommendation in relation to management of drainage bags was that closed drainage systems were preferred best practice. However, they also indicated that leg and bed bags may be used for up to four weeks if the system is broken daily to allow daily bag decontamination with a dilute (1:10) bleach solution. This recommendation appears to be based on the following two trials, one of which involved 54 participants sampled from an acute care rehabilitation centre and one involving 14 community dwelling participants.

Dille et al [134] report a randomised group parallel study with a pre-test and multiple post-tests utilised to determine the safety of a four week re-use of vinyl leg and bed bags compared to the usual practice of one week when de-contaminated daily with a procedure that utilised dilute bleach (sodium hypochlorite, 1:10 bleach to water). This study was based on previous research in which daily decontamination of drainage bags was done as compared with replacing with new sterile bags each day [135]. Set in an acute rehabilitation unit, 54 participants (18 female and 36 males) completed the four week data collection period. Randomised by the flip of a coin, 28 participants were in the experimental group and 26 in the control group. All participants had an indwelling catheter and were using a leg bag during the day and a bed bag at night. Both groups received identical daily bag decontamination and weekly bag and urine cultures. A standard of 0 to 100 cfu/mL was used to measure bag decontamination effectiveness and the urine cultures were processed by the Associated Regional and University Pathologists Inc. No significant differences were found between groups and the authors concluded that it is safe and cost effective to reuse vinyl bags for four weeks as opposed to the previous practice of one week, if the protocol for daily decontamination described is used. This study does not compare the practice of washing out the drainage bags with the chlorine solution either weekly or for a period of four weeks with a closed urinary catheter system to determine if that would result in fewer UTI’s.

Rooney [136] reported a study of 14 people with neurogenic bladders living at home. They changed from using daily sterile leg bags to non-sterile leg bags which were washed out after use each day with a dilute chlorine solution. Nine participants were on Foley catheter drainage and five were using sheaths. Bedside urine collection bags were used by all participants at night and there was no change made to the standard practice of rinsing the overnight bag with water each morning and recapping the drainage tubing. While the steps of the procedure were described, no information was given on who did the decontaminating, i.e., patients/care givers or both. The study ran for three months including a preliminary baseline phase of one month. No comment was made on whether the non sterile bags were changed. There were no symptomatic UTI infections during the study and urine samples with bacteriuria (>105 cfu/ml) did not increase. However, the sample was very small and no statistical tests were applied to the results.

e) Urinary drainage bag features intended to reduce the risk of cross infection

The cross-infection risks of leg bags (particularly via the tap or sampling port) have been studied by Glenister [137] and by Wilson and Coates [114]. In her study, Glenister [137] concluded that designs in which the tap and outlet spouts were most widely separated were most effective at preventing contamination of the hands with urine. Wilson and Coates [114] studied sampling ports and contamination of leg bag spouts. They suggested that the night connector tubing attached to the taps on the four leg bags in their study made decontamination difficult.

A small comparative study of two sets of closed system bags with a double non-return valve and two sets of bags with a single non-return valve - all inoculated with Escherichia Coli and using simulated laboratory conditions in two separate microbiological laboratories blinded to each other - found that the colonisation of a simulated bladder was significantly delayed when the double non-return valve was used [138].

f) Purple urine bag syndrome

There are occasional reports in the literature of purple discoloration in urine drainage bags – termed, purple urine bag syndrome (PUBS) – and there is considerable debate and diversity of opinion over the cause and significance of the phenomenon. Two case controlled studies were found. Tsunura et al. (2008) [139] compared five persons with PUBS to 10 without it. Urine sugar, serum amino acids, and leukocytes were similar, but the PUBS group differed in having a high alkaline urine in combination with bacteriuria. An earlier study had showed similar results with a high urinary pH. Mantani et al. [140] conducted a case controlled study on 26 patients in three long-term wards. Fourteen (two men and 12 women) had exhibited PUBS while 12 (four men and eight women) had not. The clinical, microbiological and bacteriological backgrounds of the subjects in the two groups were compared to identify possible causes of PUBS. The findings of both studies suggest that urine that is alkaline and has a high
bacterial yield are most likely to exhibit PUBS. There is no evidence to suggest detrimental effects on patients’ health or functioning of the drainage system. However, the smell can be very distressing.

Studies which have compared leg bags and catheter valves are reviewed in Section 12.

4. SUMMARY

Taken together, published studies agree that the main factors to consider in selecting leg bags are the ease of tap operation, the comfort of suspension systems and the minimisation of leakage (Level of Evidence 2). Bags in which the tap and outlet spout are widely separated are most likely to be effective at preventing contamination of the hands with urine and cross-infection (Level of Evidence 3). There is high level evidence from studies – predominantly in acute care settings - to support the use of closed urinary drainage systems (Level of Evidence 2).

5. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

 Provision of clearly presented information based on the best evidence available is needed for clinicians, carers and patients as many aspects of caring for a urinary drainage bag system are supported by scant or conflicting evidence or by custom.

There is agreement that the hands must be cleansed and clean non-sterile gloves put on prior to caring for the urinary drainage bag system and that, on completion of handling the system, the gloves must be discarded and the hands cleansed again [141], [122].

There is also mention of confusion arising for clinician, patient and carer because of the many different designs of urinary drainage bag taps, and the regularity with which such features are changed [142]. Manufacturers should ensure that the instructions and accompanying literature that they develop for their urinary drainage bag systems are clearly presented and easily understood [142] in a format which is convenient to retain and refer to.

6. RECOMMENDATIONS

In making urinary drainage bag selections particular attention should be focused on: the ability of the user to operate the tap; comfort (especially of the straps); freedom from leakage (especially from the welds and the tap); and discretion (especially visibility beneath clothing) (Grade of Recommendation B).

The patient’s individual needs and personal preferences should determine the use of leg / suspension / attachments and position of where the bag is worn (Grade of Recommendation C).

Maintain closed urinary drainage system for indwelling urinary catheterisation where the system is only broken to change the sterile bag according to manufacturer’s recommendation or in a shorter period of time if clinically indicated. (Grade of recommendation A).

7. PRIORITIES FOR RESEARCH

Jones, et al [141] identify many of the issues concerning the handling of urinary drainage bag systems that require further research, including the issue that has already been discussed above, of how long a closed urinary drainage system can be left unbroken before the urinary drainage bag is changed. Jones et al [141] also suggest research is needed into:

- How often and how drainage bags should be emptied?
- If a closed urinary drainage bag link system is used, does the night bag that is connected to the leg bag need to be sterile or can it be a reusable one?
- If a reusable night urinary drainage bag can be used, how should it be cared for when not in use?
- What is a reasonable method to dry reusable bags after they have been washed?
- Establishing whether the incidence of UTI is increased in hospital, community or residential aged care settings when urinary drainage bags in closed drainage systems are changed at different intervals (eg the time of catheter change rather than weekly).
- Determining whether the incidence of UTI is increased in hospital, community or residential aged care settings when urinary drainage bags in closed drainage systems are changed at different intervals (eg the time of catheter change rather than weekly).
- Determining which method of cleaning non-sterile urinary drainage systems is most effective and acceptable to patients.

IX. BODYWORN URINALS

1. FEMALE BODYWORN URINALS

Pieper [143] has reviewed the many attempts to design bodyworn urine collection devices for women. The major challenge is in achieving a comfortable and aesthetically acceptable leak-proof seal with the body. Various designs have sought to achieve this by holding a collection device over the urethral meatus with the help of suction, straps, adhesive or close-fitting underwear. While none have found widespread success and usage, they are available commercially in some countries.

2. MALE BODYWORN URINALS AND DRIBBLE CONTAINERS

The urine collection devices most commonly used by men are sheaths (see Section VIII) but a variety of other products such as pubic pressure urinals are available. They comprise a ring-shaped opening or cone-shaped component which is worn around the
Figure IX-1: A variety of pubic pressure bodyworn urinals for men.

Figure IX-2: A dribble pouch

penis (and held firmly against the pubis by means of a belt and straps) and channels urine to an integral collection bag (Figure IX-1). Such devices are not widely used but they can be effective for individuals whose penis is too retracted for a sheath to be suitable. There are no published evaluations of these products.

They should be fitted by a specialist: a good fit is crucial for comfort and to avoid leakage. It is also important that the wearer / carer understands how to use the device and the importance of skin care. The wearer / carer will need good manual dexterity to manage the device. Several urinals will be needed to use in rotation, allowing each to be properly washed and dried between periods of use.

Dribble pouches are also available for light incontinence (Figure IX-2) but there are no published evaluations of these products.

3. PRIORITIES FOR RESEARCH

There is a need for leak-free, comfortable and aesthetically acceptable body-worn urine collection devices for women and improved (in these respects) products for men.

X. MECHANICAL DEVICES FOR WOMEN WITH URINARY INCONTINENCE

Female mechanical devices are designed to prevent urinary leakage in different ways and fall into three main categories: those that are applied over the urethra at the external meatus; those that are placed within the urethra (intraurethral devices) and those that are inserted into the vagina (intravaginal devices). Both designs of urethral device are intended to occlude the urethra and the intravaginal devices are intended to provide some support to the bladder neck and possibly some compression to the urethra. These devices are also known as occlusive devices and are primarily used by women with
stress incontinence. There is a recently updated Cochrane review of these devices [144].

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding mechanical devices are high levels of motivation and acceptability of the concept of use, good cognition and good manual dexterity. They should probably be avoided by those with skin sensitivity or if avoidance of urinary tract infection is a priority.

1. DEVICES THAT OCCLUDE AT THE EXTERNAL MEATUS

Urethral occlusion devices have been developed to block urinary leakage at the external urethral meatus (Figure X-1). Several devices have utilized either adhesive or mild suction to achieve occlusion. In addition to the simple barrier effect, compression of the wall of the distal urethra has been hypothesized to contribute to continence.

Miniguard (Uromed Inc., but no longer available) is an angularly shaped foam device which utilizes an adhesive hydrogel to adhere to the peri-meatal area. The device is single use, removed prior to voiding, and disposable. FemAssist (InsightTM Medical Corp., but no longer available) is a hat-shaped silicone device, which adheres by applying an adhesive gel to the edge of the device, squeezing the central dome and creating a vacuum. The device is then placed over the urethral meatus and, upon release, the meatal mucosa is drawn up into the device and the urethral lumen is occluded. It may be worn for up to four hours or until voiding, after which the device is washed in hot soapy water and reapplied. The device was reusable for one week. CapSure (CR Bard Inc., no longer available) was applied and retained by suction. A petroleum based lubricant is applied prior to device use. The device is removed for voiding and re-utilized for up to two weeks.

a) Quality of data and results

Miniguard: Eckford et al. [145] studied the efficacy of a single application of this device during a one hour pad test and reported that 25% of patients were continent, 50% were improved, but 25% had worse incontinence. Brubaker et al. [146] enrolled 411 women to their study; 390 used the device, and 346 completed the study. Results showed significant improvement in symptoms. The incontinence impact scores significantly decreased from a mean of 41.0 (out of 300 – high scores worse) to a mean of 10.5 at 17 weeks. Twelve hour pad test showed mean urine loss decreased significantly from 15.8 to 6.9 ml and incontinence episodes from 14.2 episodes per week to 4.9 episodes at week 17. Symptoms of vulvar irritation or lower urinary tract discomfort occurred in a small percentage of subjects but it was generally transient, and only three women discontinued using the device for this reason. There were no statistically significant differences in the proportion of subjects reporting urinary tract infection during device use compared to beforehand. The authors concluded that the device was safe and effective (Level of Evidence 3).

Fem Assist: Versi et al. [147] studied 155 women with stress or mixed incontinence, of whom 133 attempted to use FemAssist and 96 enrolled in a four-week study. Their mean pad test loss fell from 27 g to 9.4 g (p<0.001) and 49% were dry. Symptomatic cure was more likely in those with mild incontinence. Of the nine women who had a positive pad test (>2 g) without the device, five were dry (<2 g) with the device (p<0.05). VAS scores showed a significant improvement for the symptom of stress incontinence (p<0.05). QoL scores improved significantly by 38% (p<0.05) for the IIQ and 29% (p<0.01) for UDI (Level of Evidence 3).

Moore et al. [148] reported on 57/100 recruited women who completed a one-month trial. Reduction of incontinence was statistically significant on pad testing, which revealed that 47% of the patients became continent and 33% had more than 50% benefit compared to baseline, while 9% had worse leakage. Those with severe baseline leakage were as likely to respond as those with mild or moderate pad test loss. Women with stress, urgency or mixed incontinence appeared to respond equally well. Dropouts included 13% who were unwilling to utilize the device (Level of Evidence 3).

Tincello et al. [149] in a 3-month prospective study involving 27 women with urodynamic stress incontinence found the median (range) loss with and without the device was 4.9 (0–65) ml and 21 (1–94) ml respectively (p<0.01); and 20 patients were
less wet when using the device. Discomfort was greater among the women with a greater loss. The acceptability correlated negatively with discomfort ($r = -0.53$) and negatively with embarrassment ($r = -0.39$); 15 patients (56%) reported that they would use the device in the long-term (Level of Evidence 3). Tincello et al. [150] later reported on 41 women = -0.39); 15 patients (56%) reported that they would acceptability correlated negatively with discomfort ($r = -0.53$) and negatively with embarrassment ($r = -0.39$); 15 patients (56%) reported that they would use the device in the long-term (Level of Evidence 3). Tincello et al. [150] later reported on 41 women recruited to use the device over a three month period, but 10 declined to participate, six withdrew before two weeks, 10 failed to attend two week follow-up and 11 did not attend three month follow-up. Only two completed the study. There was no difference in pad test or voiding diary grades. The authors concluded that the device had low acceptability and was ineffective, and could not be recommended for non-surgical management of stress incontinence (Level of Evidence 3).

**CapSure:** Bellin et al. [151] reported on 88/100 completers after 12 weeks, with 82% elimination of leakage on pad test, 91% continent on provocative stress test (single cough assessment of leakage), and 48% dry and 40% improved on urinary diaries. Pad test leakage decreased from 6.67 g (range 0.55-25.95 g) to 0.19 g (range 0-2.5 g) by week 12. Five patients withdrew secondary to vaginal irritation and three due to poor device fit (Level of Evidence 3).

Shinopulos et al. [152] carried out a multi-centre study enrolling 100 women with stress incontinence who wore the device for 12 weeks. Eighty-four women completed the study. Mean pad weights reduced from 6.7 g at baseline to 0.19 g by week 12. Complications affected seven patients, including urethral / vaginal swelling and vulval abrasion, but none of the affected patients withdrew from the study. The IQOL tool showed significant mean improvement from 62.3 to 90.4.

**b) Summary**

External urethral occlusive devices were found to be of varying efficacy, with minimal morbidity. Efficacy of the combined studies reveals a continence rate of approximately 50% dry and two-thirds of patients improved, but this data is from open studies (typically pre-test / post-test with no control group) and there have been no randomised controlled trials. Devices achieve occlusion either by blocking at the meatus or compressing the distal urethral lumen and adherence to the peri-meatal area is essential to success. However, the method and degree of adherence is also the determining factor for the type and severity of local irritation. Patient selection based on motivation, appropriate anatomy, and manual dexterity, in combination with efficacy and morbidity will determine overall satisfaction. There is no data which compares one extra-urethral device to another, or to other categories of products. Cost comparisons for disposable versus short-term reusable devices are not available. Efficacy for different grades of incontinence has not been established. The objective degree of continence improvement in the clinical laboratory (pad and stress tests) is greater than in community use (diaries). The devices tested in these studies are no longer available and there are no external urethral devices currently on the market.

**c) Recommendations**

Although these devices have proved effective for some women (limited mainly to those with high motivation, manual dexterity and cognitive function), it appears that they have failed to find popularity with users and clinicians. They are no longer commercially available and so no recommendation on their use can be made.

**d) Priorities for research**

Further research on the development and role of devices which block urinary leakage at the external urinary meatus, with a focus on improving patient acceptability is recommended. One half of patients utilizing these devices in monitored studies were dry and two-thirds of the patients were improved with minimal morbidity. These devices may have a future role in the algorithm of conservative treatment based on patient acceptance, availability and cost, especially in those patients with mild or moderate stress incontinence, for occasional or intermittent use and/or for those who prefer to avoid pads or surgery.

### 2. INTRAURETHRAL DEVICES

Urethral inserts are silicone cylinders that are self-inserted or removed at the patient’s discretion. They are intended for day-time use, especially during vigorous physical exercise. While some women manage exercise incontinence by limiting fluid intake before or during exercise, by choosing sports that allow frequent bathroom access, or wearing absorbent pads, 20% to 40% of women cope with leakage by ceasing exercise [153]. These devices have external retainers or flanges to prevent intravesical migration and proximal balloons to hold the device in place. They act by causing occlusion either in the urethra itself or at the external urethral meatus [154]. *(Figure X-2)*

The FemSoft (Rochester Medical Corporation) is the only urethral insert currently distributed. It has a soft, compressible, mineral oil-filled silicone layer with an insertion probe. Before insertion, the fluid distends the proximal end of the cylinder, as the user pushes the device (guided by the insertion probe) into the urethra, fluid transfers automatically to the distal end, allowing the device to pass through the urethra. Once in place, fluid flows back to the proximal end to hold the device in place. None of these devices are recommended for reuse after removal. The FemSoft Insert is currently packaged in a box of 28 inserts and each box is priced at $49.95. The Viva [155], Reliance and other intra-urethral devices mentioned in this sub-section, are not currently marketed.
The objective efficacy measurements utilized were the one-hour pad test, voiding diary and quality of life questionnaires. There have been no randomized control trials.

Nielsen et al. [155] [156] and Peschers [157] studied the Viva device. Peschers et al. screened 53 patients with USI and 21 patients accepted treatment with the two sphere device. During a four month study, the investigators analyzed subjective improvement and performed pad-weight and cough tests. The authors reported that 67% of patients had improvement in symptoms. Nielsen et al. [155] studied forty women who tested two variants of the device (with one or two spheres) each for two weeks in a cross-over study. They then continued with what they judged to be the better plug in period three (two months). Only 45% (18/40) completed this period but almost all (17/18) were reported to be subjectively and objectively continent or improved. Six women developed urinary tract infections and two of these had retained a plug in the bladder.

Staskin [158] reported on a four month study of 135 of 215 patients who utilized a disposable balloon tipped urethral insert made from thermoplastic elastomer, inflated with an applicator on insertion and deflated by pulling a string at the meatal plate for removal during voiding (Reliance, Uromed Corp., but no longer available). Eighty subjects discontinued the device prematurely, mostly because of discomfort and inability or unwillingness to use the device. Miller et al [159] and Sand et al [160] then reported on 63 of the 135 patients from the above cohort who utilized the device for one year.

The Reliance device provided 72% complete dryness with 17% improvement on diary, and 80% complete dryness and 15% improvement on pad weight testing in the study by Staskin et al. [158], and 79% complete dryness and 16% significant improvement on objective pad weight studies consistent with the improvement in subjective diaries (p<0.0001) for Miller et al. [159]. In the Miller study the patients reported improved comfort and ease of use over time. Sensation of device presence decreased from 35% at week one to 7% at 12 months. The volume of urine lost during exercise decreased from a median of 20g (range 4.9-80.2g) without the insert to 2.6g (1.3-6.8g) when the insert was worn (p=0.03). On a 5-point scale, in which 1 represented very comfortable and 5 very uncomfortable, subjects rated the mean comfort for the sessions performed with the insert in place as 2.1.

Treatment for positive urine cultures was undertaken in 20% of symptomatic and 11% of asymptomatic patients, 39% of patients had positive cultures which were not treated and 30% had negative cultures at all monthly intervals for the four month study. The main reason for drop-out was discomfort [158]. One or more episodes of gross haematuria (24%), cystoscopic findings of mucosal irritation at four or at 12 months (9%) and asymptomatic bacteruria (30%) on monthly cultures were also documented [159].

Robinson et al. [161] carried out a small randomised controlled trial comparing the NEAT device (intra-urethral device with expandable tip) with the Reliance device. Twenty-four women (mean age 51 years) entered the study and there were eight withdrawals. Devices were randomly allocated and tested for four months. Improvement was reported for 6/8 women (NEAT) and 5/8 women (Reliance) when compared to baseline. There were no significant differences in the number of women improved, in mean reduction in urine loss, or in leakage scores between the two groups.

Boos et al. [162] reported in an abstract, a randomized prospective parallel group trial comparing the Reliance intra-urethral insert with the FemAssist external meatal occlusive device. Assessments at baseline, one month, and three months included subjective efficacy, seven day diary, and pad test (1 hour). Fifty-three females were randomized to the FemAssist and 49 to the Reliance device. There were some initial problems with sizing the Reliance. Once this was corrected, 40.8% (20) of women were subjectively dry and the remainder improved on completing the trial. Of women using the FemAssist, 28.3% [15] were dry, 60.4% [32] were improved, 9.4% [5] were no better and only one subject was made worse with device use. Problems experienced were few and minor with no serious adverse events. The conclusion was that both devices are efficacious, the FemAssist was more comfortable, but required a greater degree of user skill to achieve control of leakage (Level of Evidence 2).
Recent studies have investigated the efficacy of the FemSoft which is the only intra-urethral device which is currently available. Dunn et al. [153] measured pad weights during four standardized aerobics sessions during which six subjects were randomly assigned to exercise twice with the insert and twice without it. The medians of the averaged pad weights for the two different types of sessions were compared. Median urine loss during standardized exercise sessions decreased from 20g (range, 4.9 to 80.2g) without the device to 2.6g (range, 1.3 to 6.8g) with the device (p=0.03). Five women used the device at home during unsupervised exercise; one subject had urinary tract infection. At the end of three months, satisfaction and comfort were rated high on a 5-point scale. The conclusion was that the FemSoft urethral device is an effective, safe, and comfortable treatment for exercise incontinence in women (Level of Evidence 3).

Results from a prospective three-year study, (FDA post-approval device safety data submitted by Rochester Medical Corporation, 2002 unpublished), for evaluation of the long term effect of the device involved 41 subjects. Of the group, nine women were 65 years or older (22%, 9/41); 80% were post-menopausal with 24 women (59%) being on hormone replacement. Thirty-eight, (93%) used absorbent products to contain urine leakage prior to enrolment. A total of 66 follow-up visits took place with an average participation period of 4.2 years. Seven patients withdrew in the third year, three due to non-study related health problems and one because of dissatisfaction due to urge symptoms. Two were lost to follow up. There was a significant difference in the rates of incontinence at the three-year follow-up between users and non-users of the device: 0.83 versus 2.64 episodes per day, according to voiding diaries. The difference in urine loss during pad weighing tests was also significant. There were 24 reported adverse events in the 41 subjects enrolled. None of these events required medical intervention except for antibiotic prescription in cases of urinary tract infection. The 24 events included: bacteriuria (11); symptomatic UTI (3); urinary symptoms (3); device performance problems (2); irritation (2); and migration (1).

In 33 women a total of 38 cystoscopies were performed at three years. Only one patient was reported to have an abnormal finding, but this was due to mucosal irritation produced by an indwelling Foley catheter during one hospitalization for a problem unrelated to the device. Patient satisfaction had not changed over the follow-up time interval. The Quality of Life questionnaire (I-QoL) scores at three years were compared to those at 12 months and there was improvement from the baseline of 60.6 to 74.0. No safety concerns concerning urethral integrity were identified after the three years of continuous use. The incidence of urinary tract infections, given the high number of insertions and removals, was considered low risk (Level of Evidence 3).

b) Summary

Intraurethral devices have demonstrated high efficacy, but have been associated with urinary tract infection, hematuria and discomfort. Bacteriuria, without symptomatic infection, was similar to extraurethral device use, which approaches screening urinalysis data [146] or may be similar to the rates seen with self catheterization. Device migration into the bladder, which requires endoscopic removal is the most serious reported problem. Long-term results are limited. Patient and clinician acceptance of this form of therapy has also been limited and there is currently only one intraurethral device on the market. High cost is also a factor that probably precludes more widespread application but ‘occasional’ use, for example during exercise may be helpful and affordable for some patients. Good hand dexterity is necessary to use the device (Level of Evidence 3).

c) Recommendations

Intraurethral occlusive devices may be considered for women with stress incontinence but they are invasive devices with high cost and have had limited evaluation. They may be most appropriate for intermittent and occasional use (such as during vigorous exercise) (Grade of Recommendation C).

d) Priorities for research

It is important that new devices - particularly invasive ones - are evaluated by randomized trials and comparing to control approved devices. Long-term follow-up results are needed to demonstrate the effects of such devices on the urethra and / or bladder and will determine the real value and safety of devices that initially have been adopted enthusiastically. Further development and study of the use of intraurethral devices for the treatment of urinary incontinence is recommended. In particular assessment of their cost-effectiveness and effects on quality of life, when used intermittently or for particular activities, is recommended.

3. INTRAVAGINAL DEVICES

Support of the bladder neck to correct urinary stress incontinence has been achieved, with varying success, utilizing traditional tampons, pessaries and contraceptive diaphragms, and intravaginal devices specifically designed to support the bladder neck.

a) Quality of data and results

1. TAMpons / PEssaries

Nygaard [163] performed a prospective, randomized, single blind, and laboratory based study testing 18 patients (age 33-73) with three 40 minute standardized aerobics sessions, utilizing a Hodge pessary, a super tampon, or no device. Urine loss was determined by a change in the weight of the pad worn while exercising. Statistical analysis of the log of urine loss revealed that women lost
significantly less urine when exercising with either the pessary or the tampon than when exercising with no device. Continence rates were 6/14 cured and 2/14 improved with tampons, 4/10 improved with a diaphragm (Level of Evidence 2).

2. Diaphragms / Pessaries

Realini et al, [164] analyzed the benefit for one week, in 10 selected patients of a coil-type diaphragm ring, which was softer than a pessary, utilizing diaries and a two hour pad test. They also gave an overall subjective evaluation of their experience. Urodynamic findings were essentially unchanged by wearing diaphragm rings. Four of the 10 women experienced clinically significant improvement in the amount of urine lost during pad tests, number of leaks per week, and overall assessment response (Level of Evidence 3).

Suarez et al. [165] included urodynamic testing in his evaluation of a contraceptive diaphragm in 12 patients. Complete resolution of SUI was achieved in eleven of twelve patients (91%) but two of them withdrew from the study because of associated discomfort from the diaphragm, therefore, complete resolution of SUI was achieved in 9/12 patients (75%) (Level of Evidence 3).

Bhatia et al. [166] reported on the urodynamic effects of the Hodge pessary on 30 women aged 29 to 71 with a history of UI. With the pessary, 24 of the 30 patients became continent when tested in supine position with a full bladder, three of the 24 patients lost urine with coughing in the standing position and demonstrated a positive cough profile despite the presence of the vaginal pessary. Uroflowmetry data show that the vaginal pessary did not produce any obstruction to the free flow of urine and suggested this is a modality to predict the outcome for bladder neck support surgery.

Richter et al (2010) [167] compared use of a pessary (ring or dish) with behavioural therapy (pelvic floor muscle training plus strategies for active use of muscles to prevent stress and urgency incontinence), compared with combined treatment in a randomized controlled trial of 446 women with stress incontinence. Outcomes were measured at 3, 6 and 12 months. There were small differences between groups at 3 months with slightly better results in terms of bothersome incontinence symptoms for the behavioural therapy group than the pessary group. Combined treatment was not significantly better than behavioural therapy alone and difference between groups were not sustained at 12 months.

The long-term discontinuation rates of ring pessaries (including the Introl device – see below) was investigated by Sarma et al (2009) [168]. A retrospective review of the notes of 273 women was carried out and found a surprisingly high rate of complications (93 (56%) of the 167 women who were successfully using a pessary at 4 weeks subsequently developed problems such as bleeding, extrusion, discharge and pain). The majority of women discontinued use of the pessary over time. It is therefore important that further studies of pessary use should include long-term follow-up results. Gorti et al (2009) [169] surveyed clinicians about use and follow-up of pessary placement and concluded that patients should be followed up at 6-12 monthly intervals.

3. Intra-vaginal devices designed specifically to support the bladder neck

Included in this category are:

1. Removable reusable intra-vaginal ring, composed of silastic, and constructed with two prongs which are placed behind the symphysis to support the bladder neck (Introl, no current distributor).

2. Single-use disposable devices: (i) A clam-type device composed of polyurethane foam, which is folded up upon its long axis and placed into the sagittal plane in the vagina, and when moistened, its dimensions expand by 30% and create a supportive cushion under the urethrovesical junction (originally called the Conveen Continence Guard, now known as Contrelle Activgard); (ii) A version of the expanding polyurethane design, with similarities to a tampon, (Conveen Continence Tampon, Coloplast, Denmark (no longer available) (Figure X-3); (iii) An expanding polyvinyl alcohol sponge (Ladycon, Home Care Engros, Norway); (iv) A simple surgical foam cylinder with draw-string e.g. Rocket stress incontinence device (Rocket Medical PLC)

Figure X-3: A female intravaginal occlusive device.
4. REUSABLE INTRA-VAGINAL RING (INTROL)

A pilot laboratory study was carried out by Biswas [170], the developer of the device, employed a straining cystogram. Eighty-six percent of the patients were continent with the device in place on cystogram. Following this study, the number of device sizes was increased from eight to 25. Evaluation studies followed examining efficacy, safety and satisfaction. Davila [171] initially demonstrated that 83% of patients were dry on pad weight test. Later [171] the researchers enrolled seventy women (53 completed) aged 24-76, 29 with stress, and 24 with mixed incontinence in a one month study. A statistically significant reduction in incontinence was noted on pad testing (stress mean 46.6-16.6g; mixed, mean 31.9-6.8 g) and in bladder diary (stress, mean 28.6-7.8 losses per week; mixed, mean 30.2-15 losses per week). QoL scores (I-QoL) improved in both groups. With the device in place, urodynamic testing indicated normalization of urethral function without evidence of outflow obstruction. Subjects found the device comfortable, easy to use and convenient. Side effects included five urinary tract infections and 23 cases of vaginal soreness or mild irritation (Level of Evidence 3).

Moore et al. [148] detailed problems with both sizing and efficacy. Of the 80 recruits, four could not be fitted, and 11 did not satisfy all entry criteria. Of the 65 participants, 39 (60%) withdrew; 20 for distorted vaginal anatomy which made fitting difficult, five for lack of efficacy, four for constipation, and ten for unrelated patient events. In the remaining 26 patients, pad test weights decreased from a baseline median of 19g to 2g (p<0.001), 62% were continent, and 15% were >50% improved, and wished no further therapy. Moore et al. commented that the device was difficult to fit in women who have had multiple vaginal surgeries or were oestrogen deficient. Long-term follow-up showed that 18 of 26 (from the original 65) continued to use the device at six months (interim dropouts being due to concurrent illness in half, the remainder had declining efficacy). Of these, 78% continued to wear the device for a minimum follow-up of two years (Level of Evidence 3).

In a separate study of patients with mixed incontinence by Moore et al. [148], five of 21 recruits never wore the device home, leaving 16 participants. A further two did not reach week four, because of poor efficacy or inability to fit the device. In the 14 who reached week four, the median number of leaks/day declined from 4.3 to 1.0 (p=0.002). Median pad weight loss fell from 53g to 7g. (p=0.012). Cystometry showed an increase in maximum bladder capacity (p=0.05) and a modest reduction in severity of detrusor overactivity, with no evidence of outflow obstruction. Three women discontinued because of poor efficacy or a poorly fitting device, leaving 11 of 16 participants (69%) at week eight, when median pad weight decreased to 2 g (Level of Evidence 3).

Kondo, et al. [172] found no urinary flow obstruction with the device in place. Urine loss decreased from 20.6 to 4.8 g per hour (p<0.001) on the 60-minute pad weight test. Twenty two patients (29%), reported complete continence, and 39 (51%) had decreased severity of incontinence by more than 50%. Minor adverse effects occurred in 26% of the patients. According to the global usefulness rating which was employed, 62 patients (81%) had some or maximum benefit (Level of Evidence 3).

5. REUSABLE INTRAVAGINAL HOLLOW TAMпон (CONTIFORM)

The Contiform intravaginal device was first tested in 2003 and although significant benefit was shown only 20% of participants were completely dry on 24 hour pad test [173]. In 2007 Allen et al [174] enrolled 65 women to test the device and fitted 52 devices. 37 women completed the protocol (4 weeks testing). Urine loss on pad testing was significantly reduced from a median of 6.6g to 2.2g and there were significant improvements on the Incontinence Impact Questionnaire and Urinary Distress Inventory. Seven patients were unable to insert the device and two were shown to have residual urine over 100ml, but overall the authors concluded that the device was well tolerated.

6. DISPOSABLE INTRA-VAGINAL DEVICES

Thyssen et al. [175] tested the Continence Guard in 26 women with stress incontinence before and after one month’s use: four women discontinued the treatment because of discomfort or difficulties in using the device 9 (41%) were subjectively cured of incontinence, 10 (45%) improved while three (14%) claimed unchanged incontinence. With the device in place all had decreased leakage at the 24-hour pad weighing test and unchanged urodynamic tests. No vaginal or urinary infections were found (Level of Evidence 3).

Thyssen et al. [176] reported on 19/22 women with stress incontinence, subjectively and objectively cured or improved in a short-term study, and who then continued the treatment with the device for one year. All 19 completed the study, 13 (68%) were subjectively dry, (26%) were improved and one (5%) reported unchanged incontinence. All but one had decreased leakage at the 24h pad test, and 67% a greater than 50% decrease. Subjectively cure was 41%, and 36% were dry on 24 hour pad test. Overall reduced leakage was statistically significant (p<0.0005) No significant changes were found in the other urodynamic measurements, specifically, urinary flow rate.

Sander et al. [177] found subjective cure in 11/55 women (20%) and improvement in 27/55 (49%) was reported. Results of the 24-hour pad test and mean leakage and episodes in the voiding diary significantly decreased. After three months, 58% of the 55 patients desired to continue device usage. There was a highly significant improvement in QoL scores using the IIQ, as well as two additional
incontinence-related quality of life questionnaires. Responses to the SF-36 general health questionnaire showed no significant changes.

Hahnet et al. [178] reported on 121 women, in a four-week study. Patients dropped out because of vaginal irritation (25%), other product-related reasons (6%), lack of time (6%), or failure to complete a user questionnaire. Of the remaining 90 (mean age 47.5), 85 performed a 24 hour pad test, which showed that baseline leakage of 42 ml/24h decreased to 14 ml/24h (p <0.001). Of these, 39 (46%) were continent. The device was considered unpleasant by 8%, and caused some local discomfort in 62% on direct questioning: 75% of these wished to continue using the device. The authors noted that older women (age 56-65) tolerated the device and appeared more motivated to continue. Coexistent atrophic vaginitis and the use of topical oestrogen was not discussed.

Thyssen et al. [179] reported on 94 women recruited in a cross-over study, which compared two versions of the same device; the Conveen Continence Guard (CCG) and the Contrelle Continence Tampon CCT. 62 women (66%) completed the study with withdrawals mainly due to discomfort or for unknown reasons. Both devices reduced leakage significantly but the CCT was significantly better than the CCG. Few side-effects were reported. Thirty-two women continued the treatment for one year or more with 63% preferring the “tampon” type design for its ease of use.

The report on the polyvinyl sponge by Glavind [180] was an acute laboratory study of only six women utilizing a pad test measurement during 30 minutes of aerobic exercise. Without the vaginal sponge the patients had a mean loss of 7g (range 2-18g) during exercise. With the vaginal sponge in situ there was no leakage.

Two papers have been published recently on the Tipi device (ConTIPi Ltd. Israel) [181] [182]. This device has a resin core with support ‘poles’ covered with a soft nylon mesh that stretches between the arms of the poles to act as a suburethral sling. Ziv et al. [183] recruited 60 women with severe stress incontinence to test the product. A seven day ‘control’ period was followed by a 28 day device usage period. There was no control arm or comparison product. Pre-weighed pads were used during the test period and the primary end point was the percentage of women achieving at least a 70% reduction in pad weight gain from the control period to the last 14 days of usage. Ten women withdrew from the study during the test period, four for device-related reasons. Using intention to treat analysis 85% of women achieved at least 70% reduction in pad weight gain. The most common adverse events reported were mild and included genital tract discomfort, pain and spotting with blood; the only report of a moderate event was of candidiasis. The authors conclude that the device is easy to use, well-tolerated and effective.

Farage et al (2011) used a similar evaluation design with 57 women who had at least seven episodes of SUI per week. After a baseline period the women identified the best TIPI among a selection of three device sizes. The fitting period was followed by 14 days of device usage for up to 12 hours daily. The results of the 57 intention to treat population shows that 75% of the patients had at least a 60% reduction in SUI episodes, the subjective perspective of patients with regard to the severity of their incontinence improved and the results show also an improvement in the quality of life (statistically significant for: feeling frustrated, impact on social activities and impact on recreational activities). The authors stated that the device is safety in daily use and a nonsurgical alternative in the therapy for SUI.

b) Summary

Support of the bladder neck resulting in improved continence is possible with intravaginal devices without evidence that they cause significant lower urinary tract obstruction or morbidity, but the evidence is limited (Level of Evidence 3).

Studies performed in the acute setting, regardless of the device type, demonstrate better performance than diary based studies performed over time. Efficacy appears to be higher in patients with minimal to moderate urinary leakage.

Relatively high drop-out rates in monitored studies, during which patient support is provided, indicates the need for proper patient selection and patient and provider education, but may also indicate limitations in product efficacy, difficulties in application or other factors such as discomfort (Level of Evidence 3).

c) Recommendations

Intra-vaginal support devices may be considered as a treatment option when managing women with stress urinary incontinence, dependent upon the availability of product, patient ability to manage the product (particularly manual dexterity) patient acceptance, and cost (Grade of Recommendation C).

d) Priorities for research

Long-term results are not available and studies comparing these therapies to other forms of conservative therapy or surgery are needed.

4. OVERVIEW OF MECHANICAL DEVICES FOR WOMEN

a) Overall summary

The recently updated Cochrane review of mechanical devices for urinary incontinence in women [144] review found seven trials that met their criteria and concluded that the role of such devices is questionable. The authors state that there are indications...
that using mechanical devices might be better than no treatment but that the evidence was weak and that there was insufficient evidence to recommend any specific device or to show that mechanical devices are better than other forms of treatment.

In this section we have attempted to review all available evidence including many trials that did not meet Cochrane criteria. Most trials were open pre-test post-test trials with no comparators and the strength of this evidence is relatively weak. Although most trials showed positive effects on symptoms, this was often combined with relatively high drop-out rates and unwanted effects, such as discomfort, skin irritation or urinary tract infection.

Although many products have appeared on the commercial market, few have stood the test of time and are currently marketed – there are no external urethral devices available and there is only one intra-urethral device. There are at least two intra-vaginal devices available on the market and these may have potential to be more acceptable to women because of their similarities to familiar tampons. The relative lack of market success for these products may indicate low efficacy and unwanted effects, but may also reflect their relatively high cost compared to pads which are the main alternative.

b) Overall recommendations

It is possible that some of the mechanical devices currently marketed are effective and acceptable to a minority of women and, given that they are relatively non-invasive (with the exception of intra-urethral devices), they may be suggested to patients for consideration and testing, particularly for short-term or occasional use.

c) Overall priorities for research

The substantial withdrawal rate and the frequency of unwanted events indicates that there is a need to establish efficacy of these devices (compared to no treatment) over longer time periods (more than a year), with careful identification of unwanted effects.

There is also a need to compare devices with simple, cheap devices. The Cochrane review recommends an intravaginal tampon as a suitable comparator.

There are indications that the devices may best be used occasionally or intermittently for specific activities and there is a need for this type of use to be tested, possibly compared to the most common alternative - an absorbent pad.

As these devices aim to prevent urine leakage there is also potential for testing their efficacy compared to other treatments such as pelvic-floor exercises or surgery.

XI. MECHANICAL DEVICES FOR MEN WITH URINARY INCONTINENCE

Male mechanical devices aim to prevent urine leakage by compressing the penis. A variety of designs are available but occlusion is usually achieved with either a clamp or a peri-penile strap (Figure XI-1). Such devices have the potential advantages of low cost and simplicity compared with a sheath and drainage bag. However there is potential for tissue damage and these devices should be used with caution.

Careful assessment is necessary for use of these devices because there is potential for damage to the penis from ischaemia (restriction of blood to the penis). Such devices should be fitted by a trained health professional and subject to regular review. Use should be limited to men who are assessed as being cognitively intact, are aware of bladder filling, have normal genital sensation and intact penile skin, have sufficient manual dexterity to open and close the device (Moore 2004) and are motivated and willing to use such a device.

Figure XI-1: A penile clamp.

1. QUALITY OF DATA

The use of penile compression devices is described only rarely in the literature [184] [185] and is usually referred to as a last resort where other forms of management have failed or been judged inappropriate. There has only been one published evaluation [186].

2. RESULTS

Moore et al. [186] evaluated three different devices (Timms C3 penile compression device; Cunningham clamp; and U-Tex male adjustable tension band) in a cross-over study in which twelve men with stress urinary incontinence following radical prostatectomy tried each device in turn. Each of the devices significantly (p<0.05) reduced mean urine loss (measured using a 4h pad tests) compared with baseline measurements. There was some objective or subjective improvement in continence for
each of the 12 men with at least one of the devices, although none completely eliminated urine loss when applied at a comfortable pressure.

Ten of the 12 men rated the Cunningham clamp positively; two, the C3; and none, the U-Tex. However, the C3 and U-Tex allowed good cavernosal artery blood flow while the Cunningham clamp significantly reduced it. Overall Moore et al. concluded that, used correctly, the Cunningham clamp can be an effective method of controlling urinary incontinence (although it should be noted that complete control i.e. no leakage, was not achieved) in men with stress urinary incontinence who are cognitively intact and aware of bladder filling, and have normal genital sensation, intact penile skin and sufficient manual dexterity to open and close the device.

Expert opinion and anecdote suggest that penile clamps may be more successful when used for short periods, for example when undertaking activities such as swimming or jogging. Such activities may not only exacerbate incontinence but also preclude the use of bulky and/or absorbent products.

3. SUMMARY

Male mechanical devices can partially control urinary leakage (but not eliminate it at comfortable levels of use) but are likely to lead to reduced cavernosal artery blood flow and therefore care must be taken to ensure regular removal or release (Level of Evidence 2).

4. RECOMMENDATIONS

- Male mechanical devices may be considered for selected men with stress urinary incontinence who are cognitively intact and aware of bladder filling, and have normal genital sensation, intact penile skin and sufficient manual dexterity to open and close the device (B).

- The devices should be fitted by a trained healthcare professional and reviewed regularly (Grade of Recommendation C).

- The devices may be considered for short-term use when undertaking sport or other activities, as an adjunct to management with other products (Grade of Recommendation C).

5. PRIORITIES FOR RESEARCH

- There is a need for mechanical devices for men which are discreet, easy to use and which prevent leakage without risk of tissue damage.

XII. CATHETERS

Urinary catheters can provide an effective way of draining the bladder in either the short-term or long-term, by intermittent or indwelling catheterisation, where alternative strategies are unsuitable or unsatisfactory. However, indwelling catheters are rarely completely trouble-free and the risk of catheter-related complications is high, with substantial detrimental impact on patients, carers and healthcare services. It is generally agreed that catheter use should be avoided wherever possible and only adopted for those for whom alternative strategies are unsuitable or unsatisfactory, after careful assessment of the patient and their particular problem [187].

This section examines the characteristics of urinary catheters, and provides a critical review of existing evidence to guide decision-making on choice of catheters, equipment and management strategies to minimise associated risks. Specific issues relating to short-term catheterisation are addressed, but the main focus of the section is on long-term management of bladder dysfunction, by intermittent catheterisation (least invasive) or indwelling catheterisation (most invasive). An overview of factors influencing choices of catheterisation strategy is provided in Table XII-1. Detailed discussion of key issues is provided under the following headings: user characteristics, catheter characteristics, associated risks/problems, catheter management.

The bulk of research evidence on catheter use relates to short-term catheterisation. In particular there are numerous trials which focus on catheter-associated urinary tract infection since this is well recognised as a major source of healthcare associated infection. The quality of data is very variable and many studies are limited by being underpowered and by other design issues, including poorly defined outcome criteria and highly selected study populations. Much less research has addressed intermittent or long-term indwelling catheter-related issues and guidance to healthcare practitioners remains largely based on expert opinion. Some of the difficulties in conducting research on use of continence products are discussed in Section III. Further discussion related specifically to catheters is provided within the following sections.

1. INTERMITTENT CATHETERISATION

Intermittent catheterisation (IC) is the act of passing a catheter into the bladder to drain urine via the urethra, or a catheterisable channel such as a Mitrofanoff diversion. The urine can be drained into a toilet, urinal, plastic bag, or other reservoir. The catheter is removed immediately after drainage. This technique avoids many of the problems associated with indwelling catheters. Intermittent catheterisation may be carried out using a sterile technique in some care settings, but clean intermittent catheterisation (CIC) or clean intermittent self-catheterisation CISC [188] is widely accepted as a safe technique for people who are self-caring in their own homes. Since some studies do not distinguish between CIC and CISC, the term CIC has been adopted to cover both throughout the following section. CIC provides much greater convenience than urethral catheterisation, without unacceptable
Table XII -1: Catheter choices. Catheters should only be considered where there is no satisfactory, non-invasive alternative to manage bladder drainage. *(Grade of recommendation in brackets)*

 increases in infection rate, and has become a method of choice for management of bladder drainage for neurogenic and non-neurogenic bladder dysfunctions where urinary retention is a significant symptom and not easily remedied by other relatively simple means, eg TURP for prostatic obstruction. CIC can be taught to people of all ages, including the very elderly and children as young as four years old, with parental supervision [189] [190]. CIC can also be taught to carers, where this is an acceptable procedure to both patient and carer.

a) Quality of data

The majority of research evidence on intermittent catheterisation relates to catheter-associated urinary tract infection (CAUTI) and catheter materials and coatings. The most frequent complication of CIC is urinary tract infection (UTI) but it is unclear which catheter types, techniques or strategies, affect its incidence. There is wide variation in practice and important cost implications for using different catheters, techniques or strategies. Two relevant Cochrane reviews were identified: ‘long-term bladder management by intermittent catheters in adults and children’ [191]; and ‘urinary catheter policies for long-term bladder drainage’ [192]. The objective of the first review was to examine which intermittent catheter types, techniques or strategies, affect the incidence of UTI. Fourteen trials were included but sample sizes were small and attrition of participants was problematic. Definitions of outcome variables and follow-up periods differed, making it difficult to draw clinically useful conclusions. Several of the trials were more than 10 years old and were typically less rigorous in design and analysis. The authors concluded there is insufficient evidence to state that incidence of UTI is affected by use of sterile or clean technique, coated or uncoated catheters, single (sterile) or multiple use (clean) catheters, self-catheterisation or catheterisation by others, or by any other strategy. The objectives of the second review [193] were to determine if certain catheter policies are better than others in terms of effectiveness, complications, quality of life and economics. Comparisons included type of catheterisation (intermittent, indwelling urethral and indwelling supra-pubic) and antibiotic prophylaxis. Seven trials were included but all were small and confidence intervals were wide. There was limited evidence which indicated that prophylactic antibiotic therapy was associated with reduced episodes of bacteriuria (asymptomatic and symptomatic) in subjects using intermittent catheterisation. In both reviews, the trials which met the inclusion criteria were limited by small sample sizes and methodological weaknesses. A third review on ‘catheter policies for management of long-term voiding problems in patients with neurogenic bladder’ [194], which aimed to assess the effects of different types of urinary catheter (IC): in managing the neurogenic bladder, found there were no trials that met the inclusion criteria. Other research in this area is dominated by retrospective reviews of bladder management outcomes of patient cohorts. Long-term follow-up studies are almost exclusively of patient groups with neurogenic bladder disorders. Small scale, comparative studies of new products are common and are often industry-sponsored. Quality of life issues are vitally important for continence product users but studies are often limited by outcome measures predominantly based on user satisfaction, in the absence of clear criteria. Few studies have directly compared CIC with other methods of bladder drainage.

b) User characteristics:

CIC is a commonly recommended procedure for people with incomplete bladder emptying not satisfactorily managed by other methods. CIC can be appropriate for post-void residual urine volumes of 100ml or more in:

- Patients with neurological disorders that result in urinary retention problems, including failure to empty the bladder, incomplete emptying, detrusor sphincter dyssynergia.
- Patients with difficulty emptying the bladder after surgical procedures, if outflow obstruction occurs either in the short or long-term.
- Patients who accumulate a build up of residual urine caused by detrusor overactivity and inadequate bladder emptying.
- Acute urinary retention (most commonly in men).
- Management of urethral stricture.
- Emptying the bladder following continent urinary diversions such as a Mitrofanoff diversion.

CIC may be a practical option for patients who are:

- Sufficiently motivated to manage their bladder drainage by this technique.
- Sufficiently dexterous to perform the technique. An appropriate level of manual dexterity is essential but generally if people can write and feed themselves they have sufficient dexterity [195].
- Sufficiently cognitively aware to adhere to a regime and empty the bladder at appropriate time intervals to prevent bladder over-distension and preserve upper urinary tract function.
- Unable to perform the technique themselves but willing to accept the procedure from a caregiver.

Most men require some form of lubrication to aid catheterisation, which can be on the catheter surface or instilled into the urethra [196] (Level of Evidence 3). For those with preserved urethral sensation, a local anaesthetic gel may be needed. Many female patients also use a catheter lubricant / anaesthetic gel although some choose not to. In developing
countries, where resources are limited (or sometimes through patient choice), patients sometimes use plain water as lubricant [197] (Level of evidence 4). Some may benefit from adaptive equipment. An occupational therapist reported [198] on how a specially constructed penile trough (to hold the penis in a fixed position) allowed catheterisation with just one hand in a person with multiple brain injuries.

Regular bladder drainage is important to avoid potential damage to the upper urinary tract from urine reflux and raised intravesical pressure from build up of residual urine. Patients require individualised care plans to help identify appropriate catheterisation frequency, based on discussion of voiding dysfunction and impact on quality of life, frequency-volume charts, functional bladder capacity, and ultrasound bladder scans for residual urine. Some people need to catheterise several times per day, others less frequently. Catheterising frequently enough to avoid residual urine greater than 500ml is a general rule for adults but further guidance is also provided by urodynamic findings, detrusor pressures on filling, presence of reflux, and renal function. Disabilities such as blindness, lack of perineal sensation, tremor, mental disability and paraplegia do not necessarily preclude individuals from mastering the technique if they have sufficient manual dexterity [195]. Learning the technique may require more sessions for people with physical disability, such as MS, and cognitive impairment can contribute to less adherence over time [199]. Lack of motivation is the most common reason for failure, often linked to difficulty managing the technique or adhering to the required regime.

Children at school need a multi-professional assessment which may include a continence advisor, paediatric community nurse or school nurse, the child’s consultant, the child and parents. With adequate training, suitable facilities and supportive teaching staff many children are able to carry out CIC themselves either on a toilet or from a wheelchair. CIC has been shown to be a viable therapeutic option for children with a large post-void residual urine volume in the absence of any neurological abnormality [200]. Intermittent catheterisation has also been shown to be an effective technique for elderly patients with post-void residuals more than 50% of the bladder capacity, resistant to other treatment [201]. In a group of 21 patients (mean age 76.5 years), 12 mastered the technique of CIC, with the remainder catheterised by their partners or nurses. Urinary continence was restored, urgency, frequency and nocturia decreased and UTI rate diminished, resulting in improved quality of life.

In a study in a 110-bed hospital, a bladder scanner was introduced to decrease unnecessary catheterizations using either a straight catheter (in-out) or an indwelling catheter [202]. Staff members were educated on the use of the new scanner in conjunction with an algorithm to guide decisions on treatment.

Fourteen per cent (11) of the 79 scans resulted in catheterization, and there was an 80% decrease in catheterizations in 47 persons unable to void, based on clinical observation during a one month period. Most of those who required catheterization were surgical patients. There were three in-out catheterisations and eight indwelling catheters were inserted, more were female (73%), and over age 75 (p=0.035).

Advantages of intermittent over indwelling catheterisation include:

- Greater opportunity for individuals for self-care and independence.
- Reduced risk of common indwelling catheter-associated complications.
- Better protection of the upper urinary tract from reflux.
- Reduced need for equipment and appliances e.g. drainage bags.
- Greater freedom for expression of sexuality.
- Potential for improved continence between.

c) Catheter characteristics

Types and characteristics of catheters used in intermittent catheterisation vary considerably so evaluation and selection of products is complex [191]. Plain uncoated catheters, typically clear plastic polyvinyl chloride (PVC), are packed singly in sterile packaging. As per industry standards, all disposable catheters are intended for one time use, but PVC catheters are frequently cleaned and reused by individual users because of cost or concern about environmental issues. Recently, to address environmental concerns related to single use catheters, a new PVC-free catheter was created and evaluated by 173 persons in comparison to the standard PVC one [203]. Both catheters had a hydrophilic coating. No significant differences were found. Some health care professionals make a distinction between ‘single-use’ (i.e disposed of after insertion) and ‘single patient use’ (cleaned and re-used by the same patient for a limited period of time, such as one week). Where products are used in ways which differ from manufacturers’ guidance, both patients and health care professionals should recognise their personal, professional / legal responsibilities. In some countries, including the US, there are very clear governmental directives that catheters identified as single-use devices should not be re-used in any setting. US patients should be provided with an adequate number of catheters to use a sterile catheter for each catheterisation, and patients and carers must be informed that catheters are identified for single use only. However, not everyone in the US using IC has the federal insurance program (Medicare), which began paying for single use catheters on April 1, 2008 at the rate of up to 200/month [204] [205]. In one US study of 34 IC users [206], many said they
did not have adequate insurance reimbursement for single use catheters, and 35% cleaned and reused catheters.

Most uncoated intermittent catheters are used with separate lubricant, although this is a matter of personal choice. Cleansing for re-use (where this occurs) varies from being washed with soap and water, boiled, soaked in disinfectants, or microwaved. Cleaned catheters are air dried and then stored in a convenient container (often plastic containers / Zip loc bags or paper bags). Metal catheters made from silver or stainless steel can be sterilized by heat or chemicals and may be used repeatedly for longer periods than other reusable materials.

Coated catheters are single use only (they are not currently suitable to be cleaned and reused) and are designed to improve catheter lubrication, ease of insertion and convenience. Coated catheters may reduce urethral trauma and CAUTI although good quality research evidence remains limited. The most common coatings are hydrophilic (which require the addition of water to the catheter to form a lubricious layer) or pre-lubricated (whereby the catheter is supplied pre-packed with a coating of water soluble gel). There are also several pre-lubricated products with an integrated collection bag (all-in-one) which gives flexibility for the user and are efficient for hospital use. Not all CIC users like this type of bag; thus trying several types of catheters for various activities, such as when home or when away, can help in decisions about what is best for the person [206].

Intermittent catheters range in size from 6-20 Ch, with most common sizes being 10-12 for females and 12-16 for males (Figure XII -1). Intermittent catheters are generally around 40cm long (male length) and are more rigid than indwelling catheters to aid insertion. A variety of aids to assist catheterisation are available (Figure XII -2).

Some women find a stiffer catheter easier to handle and some designs are slightly curved and made only in female length (around 18cm) to accommodate their requirements. A new compact catheter of 7cm was as effective in 23 of 24 women in removing residual urine as 20cm catheters [207]. Some manufacturers produce conveniently packaged ‘catheter-sets’ where the catheter is already attached to a urine containment pouch inside the pack and a non-touch, clean technique is facilitated by holding the catheter inside the bag and gradually advancing it from the bag during insertion. Catheter designs may include a protective tip to help reduce the transfer of bacteria from the distal region of the urethra further into the bladder. Patients should have the opportunity to try different catheters and choose which best suits their needs and lifestyle. Different catheters / packs may be appropriate at different times e.g. when added convenience for quick and efficient use and disposal is important, such as going to work or on holiday.

An effective intermittent catheter should have the following characteristics:

• Smooth for comfort, but sufficiently firm for easy insertion and maintenance of lumen patency.
• Minimal friction on insertion or removal.
• Smooth edges to catheter eyes to avoid tissue trauma on frequent catheterisation.
• Shaped for easy passage through urethral contours.
• Easy to hold and manipulate for those with limited dexterity.
• Easy to identify correct end for insertion and for drainage, for those with visual impairment.

Although there is an increasing range of intermittent catheter types on the market - including many pre-lubricated products with integrated collection bags - the quality of evidence for clinical benefit is poor. De Ridder et al [208] conducted a prospective, randomised, parallel, comparative trial of a hydrophilic coated catheter with an uncoated PVC catheter with
123 male spinal cord injured (SCI) patients. Only 57 completed the 12 month study but fewer patients with the coated catheter experienced one or more symptomatic UTIs (p=0.02). There was no difference in haematuria, leukocyturia and bacteriuria. However a recent Cochrane Review [191], concluded that overall current research evidence is weak, most studies are underpowered and conclusions are limited by serious design issues. A recent review indicated that hydrophilic catheters are beneficial for men with SCI, in relation to safety (preventing urethral damage and associated complications) and quality of life (comfort) [47]. However research is limited in women, MS, and spina bifida. An earlier literature review [209] also indicated the wide variety of materials and techniques used for intermittent catheterisation. It concluded that there was no one best technique or material and that choice of both depend greatly on the patient’s individual anatomic, social and economic status.

d) Associated risks / problems

Urinary tract infection is well-recognised as the most frequent complication of intermittent catheterisation [191]. The accumulation of urine in the bladder provides a reservoir for infection, but it has also been proposed that the increased intravesical pressure reduces the vascular supply to the bladder tissue rendering it more susceptible to bacterial invasion [210]. A post-void residual urine volume of 150ml has been demonstrated to be an independent risk factor for the development of UTI, in stroke patients [211] (Level of Evidence 2). In Wyndaele’s review of complications of intermittent catheterisation (82 studies), prostatitis was identified as a risk in men but epididymitis and urethritis were relatively rare [209]. Trauma from catheterisation, measured by haematuria, was noted to occur regularly but lasting effects were more limited. The prevalence of urethral strictures and false passages increased with longer use of CIC but the review concluded that the most important preventative measures are good education of all involved in CIC, good patient compliance, use of an appropriate catheter material, good catheterisation technique and the avoidance of bladder over-filling. Similar findings were reported by Campbell [212] in a follow up of children with spina bifida who had used intermittent catheterisation with uncoated PVC catheters for at least five years. The incidence of urethritis, false passage, or epididymitis was very low whilst adherence to the protocol was excellent. However, Ku et al [213] found a higher incidence of epididymitis in their cohort review of 140 male, SCI patients followed over 16 years.

A study of medical and social complications of US data in 24,762 persons with SCI [214] who were evaluated every five years for 30 years, has been published (see section XII.1.g below for report on bladder management changes over time). Bladder management comparisons were done for indwelling (IC), CIC, condom, and spontaneous voiding. While there was some variation at different time points, medical complications were higher in persons with indwelling catheters, for pressure ulcers and days in the hospital, and kidney stones, though infrequent, were higher at times. Psychosocial outcomes also did not favour IC users, and each measure (satisfaction with life, perceived health status, and participation in society) was lower than the other groups, though not significantly so. The authors said that better understanding of psychosocial issues could be attained though prospective studies, as other factors than bladder management might affect quality of life.

1. Urinary tract infection

It is difficult to know the prevalence of UTI associated with intermittent catheterisation as reports vary widely and definitions of UTI are inconsistent, sometimes based on bacteriuria alone (asymptomatic) and sometimes on symptomatic UTI (with or without clearly defined criteria). In a study of 41 European centres serving children with spina bifida, although most centres had established protocols for diagnosis and treatment of UTI, no consensus was identified for common protocols [215]. Other variations found included methods of evaluation, catheterisation techniques, frequency of urinalysis / culture, administration or not of prophylactic antibiotics, and the patient group studied (including gender, functional ability, behavioural and personal hygiene factors).

In a prospective study of 128 SCI patients, where the incidence of UTI was calculated as the number of episodes per 100 person-days, the overall incidence of UTI was 0.68. The rate for males using CIC was 0.41, compared to 2.72 for those using an indwelling catheter [216]. Biering-Sorensen et al. [217] studied 77 SCI patients on CIC after five years and found that 81% had been treated for at least one UTI, 22% had two-three UTIs/year and 12% had four or more per year. The technique of intermittent catheterisation used does not seem to be a risk factor and despite different catheterisation techniques used, the number of episodes of clinically significant nosocomial urinary infections and the mean species turnover remains similar [218] (Level of Evidence 2).

In the Cochrane review cited above [191], the primary outcome measure was catheter-associated infection (definition of infection as used in the trial reports). Fourteen trials met the inclusion criteria but too little data could be entered into a metaanalysis to produce meaningful data summaries. Based on the available data, the authors concluded that there appeared to be no clear difference between various methods of catheterisation (sterile catheterisation techniques, clean catheterisation with a single-use sterile catheter, or clean catheterisation with a clean reused catheter). Whilst the outcomes of this review raise questions over efficacy and cost-effectiveness of expensive coated catheters it is clear that further
robust research is needed. All sample sizes in the trials were small and only two included statistical power calculations, although they were unable to achieve their predicted sample sizes. Most studies suffered from high attrition rates and several reports were more than 10 years old. The challenges of obtaining sound data in this clinical area continue to hinder the accumulation of evidence to help guide healthcare practitioners. A common difficulty is in the establishment of robust outcome measures. UTI remains the most clinically important primary outcome variable but bacteriuria/positive urine culture is not clinically relevant unless accompanied by symptoms. Symptoms themselves may present in vague and imprecise ways, especially in elderly and/or SCI patients where symptoms can be masked or unclear.

Since the Cochrane review two further studies have compared hydrophilic versus plastic IC catheters and examined the effect on UTI [219]. In a community study of patients with spinal cord injury (45 participants completed) Cardenas and Hoffman found no differences in the incidence of symptomatic UTI between the groups, although the number of antibiotic treated UTIs was significantly smaller in those using hydrophilic catheters. Regression analysis showed that women were more likely to have UTIs than men and it is noteworthy that there were twice the number of women in the control (plastic catheter) group compared to the hydrophilic group (N=11 versus N=5).

Cardenas and other co-workers also carried out a randomized trial of hydrophilic or plastic IC catheters in SCI patients in hospital. This study demonstrated benefit from the hydrophilic catheter during initial early rehabilitation with a delay in the first symptomatic UTI [220]. Fifteen North American SCI centres took part, and 224 patients were randomized to the catheter type within 10 days of beginning IC, and were followed either in the hospital or rehabilitation then, when discharged to the community, for up to 3 months more, for a total of up to 6 months. This delay in first UTI resulted in a daily risk reduction of 33% and during the initial institutional time the UTI rate decreased by 21% (p<0.05) in the hydrophilic group. However, no differences were found between the two groups in the incidence of UTI over the whole study period.

A Cochrane review on urinary catheter policies for long-term bladder drainage [221] reported limited evidence that prophylactic antibiotic therapy was associated with reduced episodes of bacteriuria (asymptomatic and symptomatic) but all trials were small and confidence intervals were wide. The authors caution that possible benefits from prophylaxis must be balanced against possible adverse effects such as the development of antibiotic resistant bacteria.

In order to improve rigorous clinical evaluation of current and innovative products for CIC, more epidemiological data on user populations and characteristics of catheter use is needed. A recent Canadian national survey of intermittent catheterisation practices following SCI [222], reported on 912 responses to a 36-item self-report postal questionnaire. Fifty five per cent of respondents used intermittent catheterisation regularly, with users forming a significantly younger group than non-users (p<0.001). The majority of users (73%) used a clean technique. The remaining 27% reported using a sterile technique. Uncoated catheters were used most commonly; 74% only used uncoated catheters; 15% used hydrophilic coated catheters; and 11% reported using both types. These notable differences may be partially related to patient education, costs to patients and health insurance funding constraints. The majority of uncoated catheter users used their catheter only once (53%) but a further 30% used their catheter more than nine times. The mean frequency of self-reported CAUTIs in the past 12 months (symptomatic but not necessarily confirmed by laboratory evidence) was 2.6, with females experiences significantly more infections than males (p=0.003). Although the use of hydrophilic coated catheters was associated with a lower rate of CAUTI (2.46 versus 2.62 for those using uncoated catheters), this difference was not reported as statistically significant. However UTI rates are multi-factorial and are unlikely to be fully accounted for by the variables investigated. A significant relationship between number of catheterisations per day and CAUTI rates was identified, with those who catheterised only once a day having the highest rate of infections (p=0.03). This is consistent with previous suggestions that increasing the time that colonised urine is present in the bladder is associated with increased infection rates [208]. It is interesting to note that, while extra fluid intake was positively related to reduced rate of CAUTI (p<0.001), catheter re-use, catheter disinfection and antibiotic prophylaxis were not significantly associated with CAUTI rate. Clearly there are potential limitations in this study as with any which employs self-report methodology. These include self-selection of respondents, accuracy of recall and quality of information provided, but the large number of respondents and the degree of internal consistency reported by the researchers provide credibility to these results.

Several studies have sought to determine whether the antibacterial effects of cranberry extract will reduce or eliminate bacteriuria and pyuria in patients using intermittent catheterisation, particularly in SCI populations [223] [224]. In a randomised, double-blind, placebo-controlled study of 48 SCI patients living in the community and using intermittent catheterisation or external urine collection device, participants ingested 2g concentrated cranberry extract in capsule form or placebo daily for 6 months [224]. There were no differences between groups with respect to number of urine specimens with bacterial counts >10^4 cfu/ml, types and numbers of different bacterial species, numbers of urinary leukocytes, urinary pH, or episodes of symptomatic infection.

1715
2. TISSUE TRAUMA, STRICTURES AND OTHER COMPLICATIONS

Long-term follow-up studies have examined other complications associated with intermittent catheterisation and found urethral trauma to be common [225] [226]. Urethral bleeding is frequent in new patients and has been noted to continue to occur in up to 30% on a long-term basis [226] [227], however risks of tissue trauma may be reduced with newer catheter products which are designed to reduce friction. Consequently the outcomes of older studies need to be considered with caution. The withdrawal frictional force was compared between two hydrophilic coated catheters and one uncoated catheter in a prospective, randomised, participant-blinded, crossover trial by Stensballe et al [228]. Forty participants completed the study and it was interesting to note that while one coated catheter (SpeediCath) exerted a lower mean withdrawal force than the other catheters, the second coated catheter (LoFric) exerted a significantly higher mean friction force than both the other catheters. Both hydrophilic coated catheters were associated with less microscopic haematuria than the uncoated catheter. Similarly, there was a lower incidence of microscopic haematuria reported in two of the coated catheter groups compared to uncoated catheters in trials included in the Cochrane review [191]; 0.31 versus 0.65 [229]; 6/14 (43%) v 11/14 (78%) [230]. Trauma of the urethra, especially in men, can cause false passages. Treatment for false passages in SCI patients by six weeks indwelling catheter use and five days antibiotics, has been reported to be effective [231] (Level of Evidence 3). The false passages had disappeared on cystoscopy and CIC could be restarted.

It has been claimed that the long term risk of urethral stricture formation may be less when hydrophilic coated catheters are used [232]. The degree of urethral inflammation, measured by urethral cytology in two groups using CIC (one using ordinary PVC catheters with lubricant; the other using hydrophilic coated catheters), showed significantly less urethral inflammation in the hydrophilic coated catheter group. Although this data suggests some benefit in using hydrophilic coated catheters to minimise stricture formation in the long-term comparative studies are limited. One recent follow-up study of 31 females with spina bifida, using CIC for a median of 15 years, examined risk of urethral lesions. There were few problems reported (only on 20 occasions in a total of 459 patient-years), despite long-treatment periods and use of non-coated PVC catheters [233].

The relative importance and cost-effectiveness of hydrophilic catheter coatings has not been adequately addressed in large scale studies to date. Hedlund et al. [234] in their review of 28 CIC studies, called for a prospective, randomized, long-term, multi-centre study to address clinical benefit and cost effectiveness. Data on patient characteristics should include age; gender; diagnosis of bladder dysfunction; reason for CIC; physical and mental disability; manual dexterity; and previous treatments. Effect parameters should include number of catheterisations; urinary tract infection (symptomatic or asymptomatic); early and long-term urethral complications; patient satisfaction, preferences; and drop-out rates. Robust studies of this nature are still awaited.

3. OTHER COMPLICATIONS

Formation of bladder stones has been found to be associated with long-term use of CIC in a number of studies [235] (Level of Evidence 2). Barroso et al. [236] reported an increased risk of developing bladder calculi in children performing CIC based on the records of 403 children. Stones were diagnosed in 28 patients. The incidence was slightly higher in those with a Mitrofanoff conduit but was not influenced by bladder augmentation (Level of Evidence 3). A retrospective study of 140 SCI patients, followed up from 1987 to 2003, identified 27.9% of patients diagnosed with epididymo-orchiditis. This problem was more common in patients using CIC compared to indwelling catheterisation (42.2% v 8.3%, P= 0.03). Multivariate analysis showed CIC to be an independent risk factor for epididymo-orchiditis, with SCI patients in this study subject to a 7-fold higher risk (OD 6.96; 95%CI, 1.26-38.53) [213]. While the risk of cancer in long-term indwelling catheter users is known, (see section 12.2.10 below) squamous cell cancer in persons with intermittent catheters has been reported also in at least eight cases. A number of factors may be involved including leukoplakia, bacteriuria, trauma from the catheter and squamous metaplasia, a premalignant change [237].

e) Catheter management

1. EDUCATION, SUPPORT AND QUALITY OF LIFE (QoL)

Good education of all involved in CIC, good patient compliance, use of an appropriate catheter material, and good catheterisation technique have been identified as the most important measures to prevent adverse complications [209]. Factors affecting adherence to self-catheterisation procedures have been explored, addressing both initial mastery of technique and both short-term adherence and long-term adherence [238] [239]. Time taken to build confidence is variable and may range from days to years [239]. General determinants of adherence related to knowledge, complexity of the procedure, misconceptions, fears, shame, motivation, quality and continuity of professional care.

CIC may affect both sexuality and sexual activity [240] and sensitive support and teaching are needed. An emotionally negative response can occur, which requires individualized teaching in a relaxed, supportive environment [240]. Adequate information combined with thorough teaching and good
communication can help new CIC users gain initial acceptance and adherence to the procedure [239]. Some women are not able to locate the urinary meatus, and they may not be comfortable in learning and thus require additional coaching, encouragement, practice and support [241] [206] [240]. Other anatomical issues need to be considered as well, such as redundant prepuce in some males, false urethral passages, and bladder spasms [242]. In addition, lack of adequate bathroom accessibility, especially in public places, can be a major barrier to adherence [242] [206].

Integration of the CIC regime into everyday life was a recognised difficulty and for younger patients, in particular, availability of materials, physical impairments and resistance to 'sickness role' were factors which could also compromise adherence. Qualitative research studies using a grounded theory approach have identified similar factors influencing variations in quality of life (see also section XII.4). These include sex; lifestyle; frequency of duration of carrying out CIC; technical difficulties; type of catheter; comorbidities; and individual predispositions [241].

In the large scale Canadian survey above [222] 71% reported that CAUTIs had negatively impacted on their QoL score (a 10-point scale). Several significant variables associated with CAUTI and QoL were determined. Interestingly, time lost from social activities was more strongly associated with compromised QoL than actual number of infections or days lost from work. In another study in 41 persons with SCI, treatment success correlated positively with the Qualiveen QoL measure. Success criteria involved clinical symptoms of continence, lack of autonomic dysregulation (dysreflexia), and urodynamic testing for adequate bladder storage capacity (> 360 mL) and detrusor pressure (< 40cm water) [243].

Twenty two teenagers and young adults with myelomeningocele were interviewed about psychosocial factors related to CIC [244]. Deciding when to disclose CIC use was important in relation to peer support and friendships, and many wished they had done so at an earlier age, with the help of an adult. In fact everyone in a group needed to appreciate the need to avoid gossip. Those not in wheelchairs found it harder to convince others of their need to use CIC. In healthcare settings, many wanted to perform self-catheterisation instead of staff doing it. Information about sexual function was desired by many.

An Internet based qualitative study in the US aimed at discovering issues and problems in long-term CIC users [206] found key concerns related to use of bathrooms that were dirty and inaccessible and a lack of knowledge of options in supplies and/or insurance coverage. Other themes involved knowing the body, practising intermittent catheterization, hassles, and adjustment in making intermittent catheterization a part of life. Experienced CIC users explained how they made adjustments to include CIC in daily life by paying attention to their routines.

More education may be provided to catheter users through the Internet in the future. In a study using 18 articles written for persons with spinal cord injury (based on suggestions from patients and rehabilitation nurses), consumers were satisfied with the information and scored this approach as 8.02 on a 1-10 scale with 10 as being most satisfied [245]. Information was available in English and Spanish. Utilization during the 13 month study, scored as "hits" on the website, was far more frequent in the Spanish language materials (n=811, 70% ) than "hits" for the English materials (n=351, 30%). Examples of article content in both languages included cranberry juice and UTIs, cleaning the drainage bag, types of urinary management and only in English, latex allergies and catheter use, autonomic dysreflexia, and sexuality.

2. Catheter cleaning for re-use

Where catheters are cleaned for re-use they may continue to be used many times, up to weeks or even months. However, health professionals and users need to recognise their personal responsibilities and liabilities in supporting this approach since manufacturers' guidance will normally relate to single use only (see also Section XII.1.c). Questions over how long the same catheter may be safely re-used require further examination, and may be particularly important in developing countries, where access to new supplies may be limited [246]. Methods of cleaning or re-sterilising include soaking in a variety of antiseptic solutions or boiling water or microwave sterilisation. In a study which compared three home cleaning methods used by patients performing CIC, all of the following were found to be effective: 0.6% hydrogen peroxide; bleach in a 1:4 solution with tap water; and betadine in a 1:2 solution with tap water [247]. None of the cleaned catheters showed detectable bacterial growth for 48 hours after the cleaning procedure was performed (Level of evidence 4). Lavallee et al. [248] also compared the effectiveness of hydrogen peroxide, vinegar, dishwashing detergent, and tap water alone to clean catheters contaminated with Pseudomonas aeruginosa and Escherichia coli. They also examined the effect of immediate rinsing and drying before cleaning. Results indicated that rinsing and drying immediately after use was the most effective at reducing bacteria to near zero (Level of evidence 4). Microwave sterilization has been advocated by some, but has not been adequately evaluated. A study by Sherbodny, et al. [249] showed that even where standardized instructions (both verbal and written) were provided, microwave sterilization techniques by patients performing CIC varied considerably. Many patients surveyed did not follow the study instructions recommending sterilizing used catheters on a daily basis, cleaning with soap
and water and air drying before inserting into a microwave oven on a paper towel. Microwaving on a high setting for six minutes on a rotation table was recommended together with a heat sink – a cup of water in a microwave-safe container placed in the microwave to absorb extra heat. Catheter melting was reported by 63% and was significantly associated with the absence of a rotation table. If microwaving is to be accepted as an appropriate sterilization method then users must be provided with a standardised, evidence-based, protocol to follow. A recent study reported the development of titanium dioxide-coated catheters for CIC which were easily sterilized under certain light sources and were shown to be safe in experimental studies [250]. Preliminary clinical analysis with 18 volunteers was also promising.

**f) Comparisons between intermittent and indwelling catheterisation**

A systematic review of risk factors for UTI in adults with SCI reported evidence of fewer infections in patients using intermittent catheterisation compared to indwelling catheterisation [251]. Twenty two studies met the inclusion criteria for evaluation but the authors noted that many had important methodological deficiencies. Intermittent catheterisation has also been shown to be associated with fewer UTIs compared to indwelling catheterisation in elderly patients after surgical repair of hip fractures [252] and in a comparative study of patients at a hospital department of urology [253].

**g) Catheter use over time in persons with SCI**

Bladder management methods in 24,762 patients were tracked for over 30 years, using the US National Spinal Cord Injury Database, yielding the results summarised in Table XII-3 [168]. Surveys were completed every five years to evaluate catheter use at discharge from rehabilitation. In addition, continued use in the same individuals was evaluated 30 years later in follow up data with 12,984 to determine changes in use over time.

At discharge from rehabilitation, condom catheter use decreased gradually (35% in 1972 to 1.5% in 2001) while clean intermittent catheterization increased from 13% in 1972, peaked in 1991 at 56%, and fell slightly to 50% in 2001. Indwelling catheter use initially decreased during this time (33% in 1972 to 17% in 1991) but increased somewhat to 23% in 2001. In follow up data, the great majority of those originally using an indwelling catheter stayed with it, i.e., 71% after 30 years. However, most persons using CIC or condom drainage did not continue to use them, and only 20% and 35%, respectively, did so after 30 years. This indicates that despite CIC being the bladder drainage method of choice, individuals with SCI might use indwelling catheters if not able to manage CIC (Level of Evidence 3).

Patel et al. [254] examined the outcomes of different forms of urinary drainage for men with acute urinary retention. After a short period of indwelling urinary catheterisation patients were taught to use CIC (34 men). Patients who failed this were re-catheterised and taught to manage a valve or failing this a leg bag (16 men) and then discharged home. The CIC group had a higher rate of spontaneous voiding (56% v 25%) and a lower incidence of UTI (32% v 75%). At TURP 20% in the CIC group had a UTI compared to 69% in the indwelling catheter group. Patients using CIC preferred it and had fewer complications. The authors concluded that CIC was well accepted by those patients who were able to manage the technique, resulted in fewer UTIs and should be considered in patients presenting with acute retention.

In a recent 2-week prospective study of intermittent catheterisation versus indwelling urethral catheterisation in older female patients in a rehabilitation setting, 81 females >65 years with post-voiding residual volume persistently >300 ml were randomized to one of two groups [255]. Both groups demonstrated similar success in regaining bladder function and similar rates of bacteriuria. The authors concluded that intermittent catheterisation was justified in managing this patient group, particularly since indwelling catheters were deemed to hinder rehabilitation and adversely affected quality of life.

An RCT of 72 women post-urogynecological surgery (stress UI or pelvic organ prolapse) compared intermittent catheterization (CIC) with supra-pubic catheterization (SPC) [256]. The length of hospital stay was decreased significantly (Mann-Whitney p=0.003) with CIC (median 5 days, range 2-19) as compared with SPC (median 6 days, range 2-15). The days of catheterization also decreased significantly (Mann-Whitney p=0.01) with CIC (mean 4, SD 26, median 2) as compared with SPC (mean 5, SD 36, median 4), but the differences were viewed as limited clinically. Post-op UTIs were higher in the CIC group (13 versus nine in the SPC group), but not significantly (Fisher’s exact p=0.44). Of note, the CIC group had the opportunity to void much sooner than the SPC group because the latter were on straight drainage for 48 hours post-operatively as hospital policy, and this may have had an impact on the results and clinical relevance.

In a prospective RCT of CIC versus supra-pubic catheterisation (SPC) for post-operative bladder care following hysterectomy in 40 women there was no significant difference in the length of bladder care between the two groups [257]. Bacteriuria was higher in the CIC group at days 3 and 5 (p=0.05 and 0.004, respectively) although it is unclear whether there was evidence of symptomatic infection. However, there was a higher incidence of symptoms / problems arising from the SPC site, of which 23% were shown to have a positive wound swab. The authors concluded that despite a higher rate of bacteriuria, the high incidence of site problems with SPC could be avoided by CIC. The technique of CIC was seen to be more acceptable to patients (p=0.009); allowing fewer disturbances at night (p=0.006); greater freedom to lead a normal life during the day (p=0.000); and less anxiety / embarrassment (p=0.005) compared to SPC. However, in a study of 43 persons with tetraplegia who were on artificial ventilation comparing IC and SPC, SPC users had significantly fewer urological complications and better quality of life, as measured by the ICIQ-SF (3 items), but not significantly better [258].

h) Summary

CIC is the preferred method of urinary drainage in patients with neurogenic bladder dysfunction and others with problems of bladder emptying who are
capable of performing the procedure and who find it acceptable. It can be taught to patients of all ages who have sufficient manual dexterity and motivation to manage the technique. Urinary tract infection is the most frequent complication and the most important preventative measures for all complications are good education of all involved in CIC management, good patient compliance and support, use of an appropriate catheter material and good catheterisation technique. Difficulties in carrying out the procedure such as physical and technical difficulties, embarrassment, time involved and lack of appropriate public facilities may deter users from adhering to the regime. Hydrophilic-coated catheters confer benefits in terms of comfort and minimised tissue trauma compared to non-coated catheters (Level of evidence 2/3) but evidence of benefit in relation to urinary tract infection is less clear.

The available data on intermittent catheterisation does not provide convincing evidence that any specific technique (sterile or clean), catheter type (coated or uncoated); method (single use or multiple use), person (self or other), or strategy is better than any other for all clinical settings. This reflects lack of reliable evidence rather than evidence of no difference. Currently clinicians will need to base decisions about which technique and type of catheter to use on clinical judgment, in conjunction with patients. Differential costs of catheters / techniques may also inform decision making.

In particular, CIC has been shown to have benefits over indwelling catheterisation in the following ways:

- Avoidance of common problems associated with LTC use such as catheter leakage and / or practical management of drainage systems
- Avoidance of complications linked to bacterial biofilm formation, including catheter encrustation and blockage. Strong evidence for reduced risk of CAUTI is less clear.
- Maintenance of some level of bladder capacity and muscle tone by allowing the bladder to fill periodically, compared to free drainage by indwelling catheter.
- Less urethral inflammation (measured by cytology) than urethral indwelling catheterisation (Level of evidence 2/3).
- Lower incidence of bladder calculi than indwelling catheterisation (Level of evidence 2/3).

2. INDWELLING CATHETERISATION

Indwelling catheters (Figure XII-3) may be used in the short-term to manage an acute need for controlled bladder drainage or as part of a long-term management strategy (Table XII-1).

Catheters may be inserted into the bladder urethrally (UC) or suprapubically (SPC) through an incision in the abdominal wall. The continued requirement for indwelling catheterization should be reviewed at regular intervals and the catheter removed promptly if no longer necessary, since catheter use is associated with a number of risks. The major complication associated with short-term, indwelling catheters used in acute care, is nosocomial (healthcare acquired) catheter-associated urinary tract infection (CAUTI), which can lead to life-threatening bacteraemia in vulnerable groups and may also contribute to reservoirs of antibiotic resistant microorganisms [187] [122] [259]. Long-term catheters (LTC) are also associated with increased risk of CAUTI and a further range of problems including: recurrent blockage due to encrustation by mineral deposits; meatal tissue damage - often caused by excessive weight from heavy drainage bags; frequent bladder spasm with potential expulsion of the catheter; formation of bladder calculi; and potential for long-term neoplastic changes in the bladder (although further long-term studies are needed to establish this risk).

Although for some patients an LTC catheter can provide satisfactory management of bladder problems and greater independence, others experience pain and discomfort with a catheter in situ and / or, are distressed by the impact of a catheter on their body image and sexuality. Intermittent catheterisation (See Section XII.1) is less invasive and is generally associated with fewer risks.

a) Quality of Data

Nine Cochrane reviews relating to short and long-term indwelling catheter use were identified. Five reviews on short-term (<14 days or other temporary
short-term use as defined by trialists) catheter issues included: types of urethral catheters for management of short-term voiding problems in hospitalised adults [260]; policies for bladder management[192]; the role of prophylactic antibiotics [221]; use of alpha blockers for acute retention prior to a trial without a catheter [261] and policies for removal of short-term indwelling catheters [262]. The objective of the first review [260] was to determine the effect of type of indwelling urethral catheter on the risk of UTI. Twenty-three trials - comparing different types of standard catheters or a standard catheter with an antiseptic catheter (silver alloy or impregnated with silver oxide), or an antibiotic impregnated catheter (either minocycline and rifampicin, or nitrofurazone) - met the criteria. The reviewers concluded that currently available evidence suggests that silver alloy catheters prevent asymptomatic bacteriuria in the short-term catheterised patient, although trials are generally of poor quality (Level of evidence 2/3). They also recommended that further economic evaluation is required to confirm that reduction of infection compensates for the increased cost of the silver alloy catheters. Catheters impregnated with antibiotics were also beneficial in reducing bacteriuria in hospitalised adults catheterised for less than a week but data were too few for those catheterised longer. However, it is important to note that although bacteriuria is a commonly used outcome measure in CAUTI studies there is much debate over the clinical utility of this measure. Many studies fail to distinguish between asymptomatic bacteriuria and symptomatic infection. This is discussed further in Section XII.2.h.3.

The second review [192] included 14 trials which reported on comparisons between SPC and UC for short term (up to 14 days). Higher relative risks scores were found for UC related to more bacteriuria (RR 2.60; 95% CI 2.12 to 3.18), more frequent re-catheterization (RR 4.12; 95% CI 2.94 to 7.56) and increased discomfort (RR 2.98; 95% CI 2.31 to 3.85) (Level of Evidence 1). The third review [221] included six parallel group RCTs and reported weak evidence that antibiotic prophylaxis reduced the rate of symptomatic UTI in female surgical patients, compared to antibiotics given when clinically indicated. The review of policies for catheter removal [262] reported suggestive, but inconclusive, evidence of benefit from midnight removal of the catheter (larger volumes at first void) and shorter hospital stay after early rather than delayed removal.

In the fifth Cochrane review [261] use of alpha blockers prior to a trial without a catheter for acute retention was evaluated. This treatment is believed to relax smooth muscle in the prostate which would improve urine flow and decrease the need for recatheterisation. Five clinical trials were involved, in four trials ranging from 24-72 hours prior to catheter removal in most persons (up to eight days in one trial).

In the other study, the drug was given for eight days. Results overall were mixed, with two trials favouring the treatment and two favouring placebo, and thus there was limited but positive evidence that this was helpful. There were some side effects, such as hypotension and headache, but this was similar in the placebo groups. Further research was suggested.

Of the four Cochrane reviews relating to long-term catheter use, a review of 400 articles for comparative methods of using catheters for neurogenic bladder management, updated in 2011 [194] failed to find any trial that met the inclusion criteria. A second review [263] to compare types of indwelling catheter for long-term use (defined as >30 days) found only three trials which met the inclusion criteria. One trial compared antiseptic impregnated catheters with standard catheters and two compared different types of standard catheter. The authors reported ‘an astonishing lack of evidence for this clinically highly relevant problem’. Since the included studies were very small and showed methodological weakness, the authors concluded that the available evidence was insufficient as a reliable basis for practice and catheter choice remains largely based on clinical experience. In the third Cochrane review on ‘urinary catheter policies for long-term bladder drainage’ [264], seven trials met the inclusion criteria. All were small, with wide confidence intervals. No appropriate trials addressed comparisons between: indwelling UC and SPC; UC and intermittent catheterisation; or SPC and intermittent catheterisation. Evidence pertaining to whether antibiotic prophylaxis is better than antibiotics given when clinically indicated, was insufficient as a basis for clinical practice.

A fourth new Cochrane review for long-term catheter care involved washout policies for the management of long-term catheters in adults [265] which examined five trials, four of which were poorly reported or designed. Two crossovers compared group differences not sequential treatments in individuals, and two parallel groups provided limited value. One trial with a strong methodology had a small sample size. No differences were found in three studies in which solutions were compared: saline, acidic, and antibiotic. Unfortunately, there was not enough evidence overall to conclude that washouts were of benefit. Larger size samples in full randomized trials are needed.

There was little research to judge the value of catheter clamping prior to removal, and one (non-Cochrane) systematic review [266] of postoperative clamping in three clinical trials in 224 surgical patients (mostly women) was inconclusive. In two studies, clamping in comparison with free drainage was not effective in reducing UTI (not defined) or retention post removal. Time to first void decreased in one study. Recatheterisation and length of stay were measured in one study each, and were not different between groups. More recently in a trial in Sweden, 113 persons <50 years with short term
catheters post hip fracture were randomized to clamping or free drainage [267]. The primary outcome was the time to normal voiding, with a median of 6 hours (Q14–Q38) in the group with clamping and four hours (Q13–Q37.25) in the group with free drainage. This difference was not significant, nor were groups different related to recatheterization or length of hospital stay.

Overall long-term catheter care practices remain poorly supported by research evidence. This is at least partially due to difficulties in conducting trials in long-term catheterised populations for a variety of reasons, many of which have been discussed in earlier sections (See Sections XII, XII.1 and XII.1.d).

The impact of long-term catheters on users’ quality of life (QoL) is a very important issue which has not been studied adequately. No Cochrane reviews have dealt with this topic directly, although several reviews have included issues with an impact on QoL such as catheter related complications and comfort. One RCT addressed education needs of catheter users. Other studies include a small number of prospective cohort studies, with the remainder being retrospective studies and case series reports, providing evidence at Level 3. Much relevant research uses qualitative research methodologies, aimed at understanding the nature of long-term catheter-related issues and patient concerns. Measures of QoL used commonly rely on a single question of quality of life or satisfaction on a 3- or 10-point scale. Validated QoL instruments, such as SF 36 are not only infrequently used, but are likely to lack sensitivity for the specific issues which concern catheter users. There is one device-specific measure for long-term catheter users [268], recently validated in two small samples for internal consistency reliability and content validity (expert review) [269]. Factor analysis yielded three subscales related to management, interpersonal, and psychosocial issues. Work in this area is continuing.

b) Prevalence of indwelling catheters use

1. Decreasing acute care use

Short-term catheterisation is common in acute care settings, with up to 25% of patients receiving a catheter during their hospital stay [270] [187]. Recently a change in the US, whereby CAUTI will not be reimbursed during hospital stays [271], has triggered a number of studies designed to reduce the use and duration of indwelling catheters in acute care, and subsequently the number of associated infections. A popular approach is a “bundle” in which several evidence-based strategies are grouped and implemented in a system-wide approach. Analysis of cause and effect are incorporated into the bundled activities, and checklists are often used to address the issues in methods (procedures), people, environment, and equipment [272].

In one study [273], in a community hospital’s 22 bed intensive care unit (ICU), a bundled approach was used to decrease catheter use with a checklist, a decision algorithm and criteria based guidelines. A fishbone diagram helped the nurses to identify the (historical) reasons for extended catheter device days (duration of use) and to plan the intervention. The device days decreased significantly from 4.72 (SD 7.67) in 124 persons to 2.98 (SD 3.17) in 83 persons, p=0.38, t=-2.10, df 176, n=83). Similar results were found in an inner city ICU with 21 beds [274] with duration of catheter use decreasing from 312 days/month to 239 days/month. CAUTI events decreased as well, from 4.7/month in the 11 previous months, to zero during the six months’ intervention. Also, a multidisciplinary team was successful in using a bundled approach and decreased catheter use by 56% and the duration of device days by 71% [275]. In a hospital in Brazil [276], the CAUTI rate went from 10 to 3.3/1000 catheter days after an intervention that bundled several activities in the previous year. Settings in rehabilitation [277] [278] and in an emergency department [279] have also been able to decrease catheter use and CAUTI by effective surveillance and an interdisciplinary approach.

Requiring documentation for the reason for catheter placement is critical to reducing unnecessary use. In one study with emergency room physicians [280] education and guidelines for placement contributed to an increase in appropriate indications for catheter use (72.6% to 82.2% post intervention), and unnecessary catheterizations decreased significantly from16.4% to 13% (p=0.018). Inappropriate catheter use (30%) in a hospital study in Italy with 461 patients [281] was linked with older age, not having had surgery, conscious state, comorbidities, the length of time the catheter had been used, and the hospital ward. In the only randomized (and patient blinded) trial related to interventions to decrease catheter use in acute care [282], automatic stop orders for inappropriate catheter indications were successful in decreasing catheter duration in 392 patients. For those randomized to stop orders, catheter duration was lower at 3.7 days, compared with 5.0 in usual care (mean difference -1.3; 95% CI=-2.1, -0.6). Likewise, inappropriate catheterizations were lower in the stop orders group at 2.2 versus 3.9 in usual care (mean difference -1.7; 95% CI=-2.2,-1.2). CAUTI and recatheterisation rates did not differ.

Simple approaches such as checklists and stop reminders have also been effective in decreasing catheter use. In one study testing a checklist [283] catheter duration decreased significantly in five acute care hospital units from 402 to 380 pre/post intervention (p=0.047), and CAUTI went down from 2.88 to 1.46/1000 catheter days (NS). Compliance with the checklist varied from 50-100% but provider surveys indicated most viewed the checklists as relevant, easy to use, and were satisfied with them. An educational intervention on issues related to infec-
tions and notification of the continued catheter presence [284] also successfully decreased catheter use and the CAUTI rate. A simple chart reminder sticker related to removing the catheter when not needed [285], resulted in a significant increase in appropriate indications and a decrease in CAUTI in a hospital setting.

In a study of an educational strategy to use reminders with or without structured education, Gokula and colleagues (2007) [286] reported a 14% reduction in the number of inappropriately catheterized elderly patients in emergency departments, following a staff education program and the use of an indications checklist attached to each catheter kit. The intervention also enhanced documentation about catheter use. In another study, the total duration of catheter use and number of days of inappropriate catheter use was significantly less for patients randomized to an intervention that required staff in three hospitals in Canada to remove the patient’s catheter if six criteria for appropriate catheterization were not met [282]. Saint and colleagues (2005) [287] reported a similar outcome from a simple reminder to assist hospital staff to remember which patients had catheters. Using a pretest-posttest design, two of the four wards were assigned to the intervention group, and two served as controls. The researchers found that of 5,678 patients, the average duration of catheter use decreased by 7.6% in the intervention group and increased by 15.1% in the control group (p=0.007). Similarly, Voss (2009) [288] reported a reduction from 33% catheter use to 15.3% (p=0.0006) in acute care older patients after the implementation of a protocol designed to enhance clinicians awareness of the appropriate use of catheters and the parameters for catheter removal.

A systematic review of reminders and stop orders for catheter use in acute care settings [289] indicated a benefit in the rate of CAUTI, which was reduced by 52% (p=0.001), duration of use decreased by 37%, and 2.61 fewer catheter days’ use in treatment versus control groups. Stop orders were more effective than reminders.

Empowering nurses to remove catheters when not indicated was also successful in a quality improvement project [290]. Daily prevalence of catheter use decreased from 24% to 17%. However, in an anonymous survey of 164 nurses [291] 54% said they were not comfortable removing a catheter without a physician’s order, but 74% remind the physician daily of the presence of the catheter.

2. PREVALENCE OF CATHETERS AND CAUTI

Despite the increase in research in preventing CAUTI, many hospitals do not have systems in place for prevention. Based on a large survey to 600 non-governmental hospitals and 119 VA hospitals in the US [292], only about 1/3 of the respondents stated that they use antimicrobial catheters or bladder scanners, and surveillance data were not tracked for catheter placement by 56%, nor duration of use by 74%. Catheter reminders were used by only 10%.

The prevalence of LTC use in home care or community care settings varies widely and can be more difficult to determine. A large scale survey of 4010 older people (>65 years) receiving home care in 11 European countries, found a mean prevalence of LTC use of 5.4%, ranging from 0% in the Netherlands to 23% in Italy [228]. In another large study of 1004 frail older women living in the community the reported LTC prevalence rate was 38.1% [229]. Duration of use can be for many years. In a US sample of 43 community dwelling long-term catheter users, who each provided data over a six months’ period, mean use was 11.7 years (ranging in months from 1-589; median 8.8 years). Twenty persons had used it over 10 years [126].

There is evidence that older patients aged 65 years or more are often catheterised inappropriately [293] [294] [295]. Gokula et al. [294] surveyed a 10% random sample of patient charts from 2845 elderly patients who received an indwelling catheter during hospital admission in one year. Less than half the selected charts recorded an appropriate indication for catheterisation. An explicit reason for catheter insertion was documented in only 13% of charts and there was no written order for catheterisation in 33% of the charts. Only 18% had documented care plans for catheter removal. Expert opinion and experience suggests that even when there is an appropriate clinical reason for initial catheterisation, patients may remain catheterised unnecessarily if medical and nursing staff fail to review ongoing need (Level of Evidence 3). Problems of inappropriate catheter use may be compounded when patients are transferred from one clinical setting to another without adequate information on why the person was catheterised [296]. Wald et al [297] reported that 32% of patients catheterised during treatment for hip fracture in their study were discharged to nursing homes with the catheter still in place.

The prevalence of catheterized patients in nursing homes is generally higher than in people living at home and has been reported to be around 9% in the UK [298], but there may be considerable variation between homes [299]. In nursing homes in the US, it has been estimated that between 7-10% of the residents have an LTC [300], although figures vary from state to state. More recent data from analysis of a US National Nursing Home Survey [301] and a point prevalence study of nursing home-associated infections in the Department of Veterans Affairs nursing home care units [302] demonstrated similar prevalence. Tsan et al. [302] reported a prevalence of 10.7% for indwelling urethral catheters and 2.46% for suprapubic catheters amongst a nursing home population of 11,475 in 133 care home units.
There is some evidence of decreasing rates of urinary catheterisation in some places. A retrospective cohort study of the use of urine collection devices in skilled nursing facilities (SNFs) in five US states examined the characteristics of 57,302 patients who remained in an SNF for one year in 2003 [303]. The prevalence of indwelling catheterisation was 12.6% at admission and 4.5% at annual assessment (p<0.001). Paraplegia, quadriplegia, multiple sclerosis and comatose state were strongly associated with LTC use. Male residents were more likely to use a catheter at every assessment, as were obese patients; individuals with diabetes mellitus, renal failure, skin conditions, deep vein thrombosis, aphasia or end-stage disease; and those taking multiple medications.

A qualitative study of catheter use in 14 UK care homes (skilled nursing) [304] found that catheter use was higher in homes which were task-centred rather than patient-centred, and / or where patients were inappropriately given residential care when skilled nursing was actually needed. In contrast, the homes with lower rates of catheter use (6% or < versus 9% or >) were more proactive related to catheter removal (many of which had been “inherited from the hospital”), and they actively promoted toileting and mobility. Both groups had similar staffing and believed their approaches enhanced patient dignity.

Duration of catheter use in home settings varies widely, with a median of 3-4 years and some individuals using them over 20 years [305] [306]. Management regimes for continence problems in older people continue to demonstrate a predominance of containment strategies, using pads and catheters [307] and consequently unwarranted use of LTCs for incontinence continues in many places despite known catheter-associated risks.

In view of the considerable cost, and morbidity and mortality associated with the use of catheters, health services should consider adopting similar successful strategies, incorporate such information into their policies and ensure that education on catheters forms part of staff’s continuing education.

c) User characteristics

Short-term catheterisation (usually defined as up to 14 days) is most commonly used:

• During surgical procedures and post-operative care.
• For accurate monitoring of urine output in acute illness.
• Instillation of medication directly into the bladder.
• For relief of acute or chronic urinary retention.

Long-term indwelling catheters - routinely changed and replaced, often over many months or years - may be required to aid those who have difficulty emptying their bladder due to obstruction or neurological disorders, where intermittent catheterisation is not a satisfactory option. LTCs may also be used to provide supportive care for those with severe incontinence who cannot manage otherwise, are terminally ill, or need treatment to heal skin lesions or surgical wounds affected by the presence of urine.

Long-term catheterisation is most commonly used to help manage:

• Bladder outlet obstruction (BOO), where patients are unsuitable for - or waiting for - surgical relief.
• Chronic retention, often as a result of neurological injury or disease (where intermittent catheterisation is not possible).
• Debilitated, paralysed or comatose patients (in presence of skin breakdown and infected pressure ulcers).

Intractable urinary incontinence where catheterisation enhances the patient’s quality of life (as a last resort when alternative non-invasive approaches are unsatisfactory or unsuccessful).

d) Routes of catheter insertion

For some patients the insertion of an indwelling catheter suprapubically (SPC) into the bladder, through the abdominal wall, offers advantages over the urethral route (UC). SPC may be necessary following urethral or pelvic trauma but also offers advantages in acute and long-term care. In frail elderly men, and / or those prone to infection e.g. diabetes mellitus, SPC can be preferable to a urethral insertion to avoid urethritis, orchidoejpididymitis and prostatitis [107]. Strategies to support the SPC may be required (e.g anchoring to the abdominal wall with a BioDerm tube holder) to prevent traction and potential displacement of the catheter or balloon [308].

Advantages of SPC compared to UC are:

• Avoidance of risk of urethra trauma to men and women during catheter insertion and withdrawal.
• Avoidance of risk of urethral destruction / necrosis from pressure caused by the weight of poorly supported catheter bags, expulsion of the catheter (particularly in neurologically impaired women), or sitting on the catheter in wheelchair bound women.
• Ease of access to entry site in patients with reduced mobility, who are wheelchair bound, have restricted hip mobility, or experience urethral pain.
• Facilitation of post-surgical trial of voiding (by temporarily clamping the drainage tubing).
• Greater freedom for expression of sexuality, although this may be counteracted by perceptions of altered body image.
• Reduced risk of contamination where faecal incontinence is a problem.
SPC insertion is generally contra-indicated in patients with haematuria of unknown origin, bladder tumour, or small contracted or fibrotic bladders which may have resulted from long-term urethral catheterisation on free drainage. In obese or immobile patients the traditional SPC stoma site may become concealed by an apron of excess anterior abdominal wall fatty tissue which can lead to sub-optimal care by both patient and carer. SPC is an effective and well-tolerated method of bladder management for many SCI patients [309] [310] [311]. In Sheriff et al’s study [309] the general level of satisfaction with SPC was very high with 70% of patients awarding a satisfaction score of 9/10 and 95% awarding 7/10 or more. It is of interest to note that in 18% of cases, an SPC was inserted following the request of the patient, having heard about this form of bladder management from others. A review of current literature on SPC in the neuropathic bladder, by Feifer & Corcos [311] identified some notable differences between early studies and more recent reports. Problems and complications of SPC identified in earlier studies of SCI patients were less common in the more recent investigations, in which patients were managed with anti-cholinergics, frequent catheter changes and volume maintenance procedures.

Recent studies demonstrated similar morbidity profiles to clean intermittent catheterisation. In one retrospective study from 2010 [312] comparing 85 persons with neurogenic bladder prior to SPC use, and after a mean of 65.3 (± 48.0) months with SPC, anti-cholinergic medicine and bladder clamping (with a valve) did not seem to be needed to preserve detrusor compliance nor renal function. Bladder capacity did decrease significantly, though, and renal function deteriorated in three persons, two of whom were on anticholinergics and none used clamping. Complications were reported by 62.6%, including recurrent blockage (19.2%), surgery for bladder stones (12.1%), and CAUTI (28%). 3.6% had septicaemia or were hospitalized for CAUTI. In another retrospective study of 179 men with SCI comparing indwelling urethral catheters (UC) and suprapubic catheters (SP) [313] complication rates were similar for UTIs, recurrent bladder/renal calculi and cancer. However, those with UC had higher urethral and scrotal complications and SP users suffered from leakage from the urethra and/or SP tube site. Individualizing care management was suggested.

Although SPC has gained wide acceptance for bladder drainage and many regard SPC insertion as a simple procedure, it is not without risks. The initial insertion of the SPC requires a minor surgical procedure which presents a potential risk of injury to adjacent structures to the bladder, especially the small and large intestines with resultant peritonitis [314] [309]. Other complications of initial SPC insertion include misplacement [315] [316] [317], displacement to the peritoneal cavity and sepsis, [318] and incisional hernia [319] [320]. There are a number of SPC techniques for insertion described in the literature and training models have been developed to facilitate teaching [321]. Some modern catheter insertion kits employ the initial introduction of a guide wire into the bladder, to facilitate accurate positioning of the catheter introducer. However, where patients are at high risk of bowel injury (eg previous abdominal surgery or small fibrotic bladders which do not expand well at cystoscopy), some authorities recommend introduction of the SPC by percutaneous technique using intraoperative ultrasonography combined with flexible cystoscopy [322] [323]. In low risk patients nurse specialists may undertake first insertion of an SPC, according to agreed policy and protocols [324]. Subsequent SPC changes can be competently managed by skilled nurses [325].

e) Catheter characteristics

An effective indwelling catheter should have the following design characteristics:

• Retained in the bladder effectively, yet easily removable without trauma to tissue.

• Soft ‘tip’ within the bladder to avoid pressure damage to the mucosa.

• Effective drainage while minimising risk of bladder mucosa being ‘sucked’ into drainage channel.

• Conforms to shape of urethra.

Despite some notable efforts to improve catheter design, the original Foley design has changed very little over the years and remains the most common. However traditional drainage systems may fail to drain the bladder to completion, due to potential outflow obstruction caused by air-locks within the curled, redundant drainage tubing segments. A novel, spiral-shaped, drainage tubing design has recently been reported which appears to optimize flow and minimize residual urine [119]. Adding more eyeholes has been suggested to reduce residual urine [326] and in a case report, leakage [327]. Further evidence of efficacy is awaited.

f) Catheter materials

An ideal catheter material requires the following properties:

• Soft for comfort.

• Causing minimal tissue reaction or friction.

• Sufficiently firm for easy insertion and maintenance of lumen patency in situ.

• Elastic recoil so that an inflated balloon can deflate to almost its original size.

• Resistant to colonisation by micro-organisms and to encrustation by mineral deposits.

Catheters are made of a variety of materials includ-
ing polyvinyl chloride (PVC) or other plastic, latex rubber with or without a coating, silicone or metal. Plastic catheters are relatively cheap to manufacture, have a thin wall and relatively large lumen, and are designed for short-term use (in situ up to 14 days). Latex catheters are restricted to short-term indwelling use (and commonly avoided where possible) because of potential discomfort due to high surface friction, vulnerability to rapid encrustation by mineral deposits from the urine and the implication of latex allergic reactions in the development of urethritis and urethral stricture [328] [329] [330] [331] [332] [333] or anaphylaxis [334].

Attempts to minimise friction during catheterisation and to reduce tissue reactions have led to the coating of latex catheters with tightly bonded materials designed to provide a smoother, less irritant surface which also minimizes absorption of water by the latex (and subsequent changes in internal and external catheter diameters). Polytetrafluoroethylene (PTFE or teflon) coated latex catheters are sometimes used for medium-term use (catheter can remain in situ up to 28 days) but the materials known to cause least friction and tissue reaction are silicone elastomer and hydrophilic polymer-coated catheters, or all-silicone catheters [335] (Table XII-4). These materials are therefore recommended for long-term use (e.g. expected to remain in situ for 14 days or more, and changed regularly for a new catheter as part of a long-term strategy of care). LTC materials are also less vulnerable to rapid colonisation by bacteria and encrusting by mineral deposits than short-term catheter materials. There is evidence that silver-alloy coated catheters can help to reduce risks of CAUTI in the short-term (where bacteriuria is used as the outcome measure) (See Section XII.3.a), but no currently available material or surface coating is completely immune to microbial colonisation.

Inflation of silicone catheters with water can sometimes lead to water loss from the balloon over time, [336] with an associated risk of the catheter falling out [337]. Consequently some manufacturers recommend filling the balloon with a 10% aqueous glycerine solution, or to fill the balloon with the full 10mL, knowing that 1/4 to 1/2 could be lost over time [336].

Most catheter materials are suitable for either UC or SPC, however not all UC catheters are also licensed for SPC. Suprapubic catheter removal is sometimes associated with trauma of tracts or stoma site where overgranulation has occurred, with bleeding and patient discomfort [338] [325]. This can be a particular problem with catheter materials such as all-silicone, which are prone to hysteresis, leading to balloon cuffing on deflation. This problem may also occur with hydrophilic coated catheters but is less common [339] [340]. Management of this and other catheter-related problems is considered below in Section XII.2.k.

The main finding of a recent Cochrane Review of types of indwelling urinary catheters for long-term bladder drainage in adults [263] was a remarkable lack of evidence for this clinically, highly relevant problem. Despite consideration of 11,000 abstracts and 74 full papers, only three trials met the inclusion criteria. Since these were very small and showed methodological weakness, the authors concluded that there was insufficient evidence to provide a reliable basis for clinical decision-making and catheter choice remains largely based on clinical experience.

### g) Catheter size – catheter gauge, length and balloon size

Indwelling catheters are formed either by building up layers through dipping and coating on a shaped ‘former’ or by a process of extrusion of a single material. Catheter size is measured in Charrière (Ch) – also called French gauge (Fr) - which refers to the circumference of the catheter shaft in millimetres. Internal diameter varies depending on the manufacturing method, with the extrusion process resulting in a catheter with relatively thinner

The urinary tract is recognised as the commonest associated urinary tract infection (CAUTI). Approximately 30cm long. Paediatric catheters are usually ap... - Meatal tissue damage caused by bladder spasm - Loon within the urethra can result in severe trauma. - Balloons are also associated with increased risk of meatal tissue damage caused by bladder spasm and possible expulsion of the catheter with a fully inflated balloon. The most common sizes of SPC catheters for adults are also 12-16Ch. Some SPC kits provide a specific catheter in the kit and therefore dictate the sizes available; others allow the insertion of a range of Foley catheters. Since the catheter is inserted into the bladder via an artificial stoma it is possible that slightly larger sizes may be better tolerated than for UC although there is no research evidence to support this. The standard male length catheter (41-45cm) is available to males and females but a shorter female length (25cm) can be more comfortable and discrete for some women. The female length catheter should not be used for males as inflation of the balloon within the urethra can result in severe trauma. In one case series report [344] six boys, aged < 1 month to 16 years suffered damage to the bulb or prostatic urethra due to inflation within the urethra. Three required suprapubic catheters, and all healed without further complications. Insertion to the bifurcation of the catheter – that is, until only the inflation and drainage ports were visible - was advised to prevent this. Paediatric catheters are usually approximately 30cm long.

h) LTC-associated risks / problems: catheter-associated urinary tract infection (CAUTI)

The urinary tract is recognised as the commonest site for nosocomial infection in hospitals and nurs... - Indwelling catheters rapidly become colonised by micro-organisms which form a strongly adherent biofilm on catheter and drainage equipment surfaces. Biofilm formation begins with deposition of a conditioning layer of proteins, electrolytes and other organic molecules from the urine which may alter the microenvironment that may impair activity of the antimicrobial agent [356]. The close proximity of cells within a biofilm can facilitate plasmid exchange and the spread of antimicrobial resistance [355]. 1. Antibiotic use Hospitalized patients are likely to be on antibiotics for other causes than an indwelling catheter, which also might be present. In one study in an acute care setting, [360] catheterized patients on antibiotics...
The researchers’ model predicted that decreasing CAUTI in hospitals with high rates (75th percentile or >) could reduce antibiotic use by 2.1% and 0.4% for fluoroquinolone.

2. PREVALENCE OF CAUTI

The majority of research on the risks of CAUTI has been conducted in acute care settings where catheters usually remain in place for less than 14 days and many patients’ health is already compromised by co-morbidities [362]. A series of reports from the International Nosocomial Infection Control Consortium (INICC) provided rates of CAUTI in intensive care unit (ICU), using the methodology of the US National Nosocomial Infections Surveillance system. The rates per 1000 catheter days were: Brazil 9.6 [363] and Peru 5.1 [364]. Overall, in 13 limited resource countries implementing INICC infection control guidelines for education and surveillance (Argentina, Brazil, Colombia, Costa Rica, Cuba, El Salvador, India, Macedonia, Mexico, Morocco, Philippines, Peru, and Turkey) the CAUTI rates dropped from 8.2 to 6.9 per 1000 catheter days [365]. A later report in ICUs in Cyprus, Greece gave a rate of 2.8/1000 catheter days [366]. From the U.S. National Healthcare Safety Network (NHSN) [367] from January 2006 through December 2008, the pooled mean CAUTI rate in ICUs ranged from 3.1 to 7.4 /1000 catheter days, depending on the type of specialty unit. Surveillance was suggested for a minimum of three months, based on a pilot study describing the protocol and surveillance tool used in six hospitals caring for elderly people in Scotland [368].

Less is known about the prevalence of CAUTI in long-term and home care settings or about the potential for reduction of CAUTI and improved cost benefits in the LTC population [352]. Encouragingly, in a recent U.S. study in North Carolina home health and hospice populations, [369] the CAUTI rates have decreased over 11 years of surveillance. The rate of catheter-associated UTI decreased in home health from 4.2/1000 catheter days in 1998 to 0 in 2008, and in hospice patients from 2.35/1000 catheter days in 1999 to 0 in 2008. Infection control specialists trained the persons collecting data, and presumably the rates reflect symptomatic CAUTI. However, in a hospital study of U.S. Veterans with spinal cord injury and disorder, [348] the rate was higher (8.9/1000 catheter days), reflecting greater risk. In a similar population of 100 inpatient and outpatient veterans with chronic catheters, candiduria was present in 17%, and all but one had an indwelling catheter. This was of concern due to the likelihood of recurrence of this microorganism [370].

In the multi-national survey of 4010 older people (>65 years) receiving home care in 11 European countries, the risk of a UTI was found to be 6.5 times greater for catheterised individuals than for non-catheterised [371]. Prevalence of a UTI amongst for a shorter period of time (< 5 days) were more likely to develop CAUTI than those taking antibiotics longer, and the former should be evaluated for this risk. In a prevalence study in France of antibiotics used to treat hospital acquired infections, [361] urinary tract infection had the highest association with antibiotics use, in particular with fluoroquinolone.
1004 frail older women living in the community was 21% in catheterized women compared to 10% in non-catheterized subjects (p>0.001) [372]. Furthermore, catheterised subjects were more likely to die within a year (RR1.44; 95% CI 1.01-2.07). Tsan et al’s point prevalence survey [302] of Nursing Home acquired infections found 13.2% of 11,475 residents had an indwelling urinary catheter. Of those, 13% of residents with a UC and 9.5% of those with a SPC had a UTI. In catheterised SCI populations the overall rate of urinary tract infection has been quoted as about 2.5 episodes per patient per year [373]. Although randomized trials are lacking there is some evidence of reduced rates of bacteriuria and CAUTI with SPC, condom catheters and intermittent catheterisation compared to UC [373] [374] [302].

Bacteriuria resulting from CAUTI invariably represents a serious complication which may occur in approximately 4% of catheterised patients with bacteriuria in acute care settings [375] [376] [377]. In their review, Saint et al. [375] statistically pooled results from several prospective studies on short-term indwelling catheterization (in which the definition of bacteriuria varied between studies, ranging from >103 cfu/ml to >105 cfu/ml) and estimated (Level of Evidence 2) that:

- 26% of patients (not receiving systemic antibiotics) with a short-term, standard non-coated indwelling catheter in situ for between two and 10 days will develop bacteriuria.
- 72% of patients developing bacteriuria will remain asymptomatic and not require treatment.
- 24% of those developing bacteriuria will develop a symptomatic UTI without bacteraemia.
- 4% with bacteriuria will develop bacteraemia.

This data is interesting since it provides supporting evidence that bacteriuria remains asymptomatic in a majority of catheterised patients. However, it can be difficult to generalize such data from acute care contexts to other practice settings. Unfortunately, few epidemiological studies or comparative catheter evaluations are conducted on long-term catheterised patients in community settings.

3. Outcome measures and criteria for CAUTI

Interpretation of the literature on CAUTI is often confused by the range of definitions and outcome measures used. In this chapter, the terms symptomatic infection and asymptomatic bacteriuria have been employed to distinguish as clearly as possible between symptomatic and asymptomatic conditions. However many studies make little or no distinction between these states, referring to both as infection. This can be particularly confusing when attempting to interpret results in terms of the magnitude of infection-related problems, clinical importance and implications for services and individuals.

Bacteriuria is commonly used as a surrogate outcome measure for the clinically more important outcomes of symptomatic UTI. Although symptomatic infection is far less common than asymptomatic bacteriuria, the frequency of catheter use produces considerable overall morbidity and mortality [378] for patients and high costs to healthcare services [377], often including unnecessary antibiotic drug therapy which may then become a major source of antibiotic resistant pathogens. Asymptomatic bacteriuria can lead on to symptomatic infection, but not necessarily. Questions about the significance of long-term asymptomatic bacteriuria in its own right (e.g. effects of chronic tissue inflammation) are currently unanswered.

In non-catheterised patients the criterion for ‘significant’ bacteriuria is commonly accepted to be >105 cfu/ml but since growth of micro-organisms in catheterised patients is rapid, many authorities consider >102 or 103 cfu/ml in a urine sample collected from the sampling port of the catheter, to be indicative [187] [342] [110]. Most definitions of symptomatic UTI [379] are based on those used for non-catheterised patients and include significant bacteriuria. For catheterised patients, these include presence of pyuria (>10wbc/mm3) plus one or more clinical signs and symptoms for which no other aetiology is apparent: fever, suprapubic or flank discomfort, bladder spasm haematuria, changes in mental state, or malaise / lethargy. Pyuria alone is not diagnostic of UTI. [110]. For SCI patients signs and symptoms may also include increasing spasticity and / or worsening autonomic dysreflexia (usually manifested by increase in blood pressure, headache, sweating above the SCI lesion, flushing below the SCI lesion) [380] or a “sense of unease” [110]. Elderly persons may have atypical or generalized symptoms [284]. In a study of the validity, accuracy and predictive value of UTI signs and symptoms in person with SCI using intermittent catheters, [381] cloudy urine had the highest accuracy (83.1%) and leukocytes in the urine was the most sensitive (82.8%). Fever was the most specific (99%) but least sensitive (6.9%) symptom. Moreover, patients might be better at identifying when they do not have UTI, as positive predictive value was 32.6% and negative predictive value was 82.8%.

However, commonly used criteria for symptomatic urinary infection have been questioned by Tambyah and Maki [362] in a prospective study of 1497 newly catheterised patients. No significant difference in reported symptoms of pain, urgency, dysuria and fever was found between patients with a catheter-associated infection and those without, nor was there statistical evidence that peripheral leukocytosis was predictive of infection (p=0.14) (Level of Evidence 2). The criterion for bacteriuria (catheter-associated infection) in this study was >= 108 colony forming units (cfu/ml urine). This finding raises further questions over the selection of the most appropri-
ate outcome measures in studies of CAUTI. Indeed concerns have also been raised over current UTI criteria for non-catheterised populations, particularly for elderly groups, including nursing home residents. Consensus criteria (e.g. Loeb criteria 2001) have been found to be limited in terms of sensitivity, specificity and predictive value by Juthani-Mehta et al. [382] and these authors have called for clearer identification and evaluation of evidence-based clinical criteria associated with laboratory evidence of UTI. A further complication to difficulties in confirming ‘best criteria’ for UTI and CAUTI is the variation in the clinical and scientific definitions required for specific populations, for research purposes or to meet stipulations for reimbursement from governments and medical agencies. Asymptomatic bacteriuria might be treated inappropriately, as described in a study in which 32% were treated (53 of 164 episodes of bacteriuria) [383] further confounding the definitions of CAUTI that include treatment with antibiotics. It is important that efforts to resolve these issues are progressed as quickly as possible to provide greater clarity in the interpretation of existing research, the design of new studies and the application of clinically important findings.

4. REDUCING THE RISK OF CAUTI

Risk factors which are independently predictive of increased risk for CAUTI have been identified in a number of large prospective studies of short-term catheterised patients [187] (Table XII-5). There is evidence that females have a substantially higher risk than males (relative risk: RR 2.5-3.7), and 1.3-2.2, \( p=0.001 \) in an ICU setting [384]. But the greatest risk is associated with prolonged catheterisation > six days (RR 5.1-6.8). A recent retrospective cohort study of 35,904 undergoing major surgery reported that 86% of patients had a perioperative indwelling catheter [385]. Multivariate analysis showed that postoperative catheterisation for longer than two days was associated with increased risk of UTI.

Use of a preconnected drainage bag may be of value in preventing CAUTI in acute care settings. A prospective study in the UK of 205 patients in three medical wards over two periods, each of about six months’ surveillance, [386] compared use of preconnected bags with the usual bags. The CAUTI rate was 41% lower in the group with the preconnected bags, with rates of 37.8/1000 catheter days for the usual bags, compared with 22.4/1000 catheter days in the intervention group (RR 0.59 (0.35–0.99) 0.04.

In Japan, a prospective observational study in five hospitals evaluated risks in persons with catheters 3> days, using a Cox proportional hazards model [387]. Risks were significantly associated with two practices in this study of 555 inpatients, not using a pre-connected closed system (RR 2.35, 95% CI 1.20–4.60, \( p=0.013 \)) and the lack of daily cleaning of the perineum (RR 2.49, 95% CI 1.32–4.69, \( p=0.005 \).

Although there is some evidence to suggest there may be a reduced risk of CAUTI when SPC is employed compared to UC, the data is limited, studies are often small and most catheterisations are for post-operative care in acute care settings. One large scale point prevalence study of nursing home acquired infections in >11,000 residents [302] reported that 9.5% of residents with a SPC had a UTI compared to 13% of those with a UC. These data just fail to demonstrate a statistically significant difference between UC and SPC (one-sided, Fisher’s exact test; \( p=0.066 \)). A review of five published RCTs comparing SPC with urethral catheters

following colorectal surgery [388] reported that sample sizes were small, catheters were used short-term and there was no apparent difference in the duration of catheterisation between the two techniques. Significant UTI was defined in different papers as bacteriuria with either $>10^4$ or $10^5$ organisms or cfu/ml. Frequency of UTI was less in the SPC group in three of the studies, with no significant difference in the other two. The SPC groups reported less pain and discomfort than the urethral groups and SPC was preferred by those patients who experienced both. The authors concluded that the results favoured SPC over urethral catheterisation as UTIs are reduced, particularly in females, and the ability to attempt normal voiding is facilitated, particularly in males (Level of Evidence 2).

Much of the recent research on reduction of risk of CAUTI has centered on the development of catheters with antimicrobial surfaces, such as silver. Silver ions are bactericidal [389], non-toxic to humans when applied topically, and have been used successfully in other areas of infection control such as burn wounds. Silver is also purported to have broad spectrum activity against Gram-positive, Gram-negative, aerobic and anaerobic organisms. Early silver-coatings incorporated silver oxide into the external surface of the catheter material only, but efficacy against CAUTI was limited [390]. Subsequently, silver-alloy coatings were developed to provide an integral coating on both internal and external surfaces and promote a slow release of silver ions. Other developments have been directed towards impregnation of catheter materials with antibiotic or antiseptic agents such as nitrofurazone [391] [392] [393] [394]; minocycline and rifampicin [395]; chlorhexidine, silver sulfadiazine, triclosan [396] and others. Although a large number of studies (both laboratory models and clinical studies) have attempted to examine the potential benefits of antimicrobial catheters, most have used bacteriuria - rather than symptomatic UTI - as a surrogate endpoint. Most reports were either prospective crossover studies [397] or prospective surveillance of outcomes associated with introduction of new catheter types, in comparison with historical or baseline outcomes associated with previously used catheter types [398] [399] [400]. Almost all have examined short-term catheter use in acute care settings.

A recent Cochrane review [260], designed to determine the effect of type of indwelling urethral catheter on the risk of UTI, examined 23 trials, comparing different types of standard catheters or a standard catheter with an antiseptic catheter (silver alloy or impregnated with silver oxide); or an antibiotic impregnated catheter (either minocycline and rifampicin, or nitrofurazone). The reviewers commented that trials were generally of poor quality but concluded that current evidence suggests silver alloy catheters prevent asymptomatic bacteriuria in the short-term catheterised patient (Level of Evidence 1). They recommended that further economic evaluation is necessary to confirm the extent to which reduction of clinically important infection compensates for the increased cost of the silver alloy catheters. Catheters impregnated with antibiotics were also found to be beneficial in reducing bacteriuria in hospitalised adults catheterised for less than a week, but data were too few for patients catheterised longer.

An earlier systematic review of antimicrobial urinary catheters to prevent CAUTI in hospitalized patients [401] identified 12 randomised or quasi-randomised trials of silver-alloy coated (n=9) or nitrofurazone-coated catheters (n=3) compared to standard silicone or latex catheters. Pre-post study designs were excluded. No study addressed symptomatic UTI and therefore analysis was based on bacteriuria. Although all studies indicated some benefit in prevention or delay of onset of bacteriuria the effect size varied substantially between studies. Variations were related to catheter type, patient characteristics, control group bacteriuria rate and year of publication (i.e prevailing clinical conditions at the time of the study). Post enrolment exclusions, absence of intention to treat analysis, highly selected study samples and lack of data on clinically meaningful end-points, all limited the ability to draw definitive conclusions on efficacy. The authors concluded that, according to fair-quality evidence, antimicrobial catheters can prevent bacteriuria in hospitalized patients during short-term catheterisation (Level of Evidence 1), but trial results are highly context dependent. The relevance of results to other institutions or patient groups depends on the similarities between settings with respect to a range of variables, including: background bacteriuria rate, baseline catheter type, local catheter use and maintenance practices, patient groups and patterns of antimicrobial usage. The authors cautioned that older data may lack current relevance, particularly where background rates of bacteriuria have changed notably in the intervening period. Although there is evidence that antimicrobial-coated catheters prevent bacteriuria during short-term catheterisation, there is a lack of corresponding data to demonstrate clinical benefit [402]. Further well-designed and adequately powered randomised trials, with clinically relevant endpoints are needed to clarify comparative clinical utility and economic value.

In contrast to the majority of trials of silver-coated latex catheters Srinivasan et al [403] found no significant reduction in bacteriuria with silver-impregnated, silicone catheters despite similar performances in vitro. However, outcomes may have been affected by notable differences in the study groups in this prospective, cross-over study. The authors drew attention to the fact that not all silver products are the same and clinical trials of new products remain critically important. Any potential advantages of silver alloy catheters (or other antimicrobial catheters)
for LTC patients remain uncertain, although clinical experience suggests some benefits for individuals with frequent symptomatic infections. It is not known whether argyria (deposition of silver in the skin) may be a potential problem for long-term care patients or whether silver-resistant mutants may be selected by repeated exposure [404] [405].

A common concern over the use of antimicrobial impregnated catheters is that elution of sub-inhibitory levels of the antimicrobial agent into the urine may induce resistance in resident organisms with prolonged catheter use [406]. Antiseptic agents are generally considered more likely to confer resistance to surface colonization than antibiotics and not to select for infection with antimicrobial drug resistant bacteria. Alternative approaches to inhibiting biofilm development include development of catheter surfaces which reduce protein absorption [407]; inflation of the balloon with a biocide solution, such triclosan, which then diffuses throughout the catheter material and into the surrounding area [408] [409]; or efforts to disrupt matrix or glyocalyx components with agents such as heparin [410], and colonization with a competing benign organism. Bacterial interference with E. coli 83972 was attempted in 13 CIC users with SCI, [411] [110], and eight were successfully colonized in 13 three-day attempts. Monthly urine cultures (until colonization was lost in the urine) indicated a reduction in asymptomatic UTI rate per year, 0.77 per patient year as compared with 2.27 per patient year prior to the study.

Relatively few studies have examined the cost benefits of different catheters. Those that have tend to rely heavily on assumptions that a certain proportion of patients with bacteriuria will develop the clinically important outcomes of symptomatic UTI or bacteraemia. The focus of economic studies generally falls on acute care settings and, as discussed earlier, it can be difficult to generalise results from one practice setting to another. Practitioners and/or institutions who are considering introducing a new product (e.g. catheter type) for a majority of their patients on the basis of claims of improved cost-effectiveness from clinical research studies, are advised to look carefully at the similarities and differences between their own local practice (and patient groups) compared to that described in the research. Economic studies are frequently required to make assumptions about certain data (e.g. increased length of hospital stay for CAUTI) which is then applied to an economic model. (\cite{Cross ref to economics chapter}. Such assumptions may or may not be applicable in local settings.

Numerous trials of oral antibiotics, antimicrobial bladder washes, drainage bag solutions and topical disinfectants all lead to the common conclusion that bacteriuria and UTI may be suppressed temporarily at best, but resistant organisms are highly likely to emerge [357]. The application of devices to secure catheters in place, to prevent a ‘to and fro’ pistoning effect that could favour invasion of catheter tracts by microorganisms, has been shown to reduce the incidence of catheter-related blood stream infection in central venous catheters. Only one prospective, randomised trial has examined a similar device for urinary catheters (StatLock) [380]. Although the study in 118 SCI patients failed to achieve statistically significant results the authors reported a clinically important reduction in the rate of symptomatic UTI of 45% and called for further larger scale trials. They also noted the polymicrobial nature of infections including the presence of a Candida species in more than 20% of infections.

5. Treating CAUTI: antibiotic use

Some studies have suggested that methenamine hippurate may have a beneficial effect in preventing bacteriuria in patients requiring short-term catheterisation during and post-surgery. However, a Cochrane review [393] designed to address this issue concluded there is not enough reliable evidence to conclusively support its use for urinary prophylaxis and identified a range of methodological limitations in existing studies. Caution is needed in translating research on reducing CAUTIs in short-term catheters to LTCs but treatment of asymptomatic bacteriuria is not recommended in either for either group. Urine cultures should be obtained before initiating treatment to permit selection of specific therapy for the infecting organism and the extensive use of broad spectrum therapy should be avoided [412].

Studies of LTC patients can be difficult given the relatively high proportion of disabled or elderly patients, many of whom are very frail. However, routine use of prophylactic antibiotics in LTC patients is not supported by research evidence and has been shown to favour the emergence of resistant organisms [110]. In a double-blind, cross-over study of 34 elderly nursing home patients with urethral catheters [413] subjects were randomised to receive antibiotic prophylaxis (200mg/day norfloxacin) or placebo for three months, followed by cross-over. Urine cultures were obtained once monthly. Episodes of UTI, catheter-related complications (obstruction, encrustation, leakage, suprapubic pain, inflammation of meatus, haematuria and side effects of treatment were monitored weekly. Symptomatic UTI was defined as bacteriuria >10^5 cfu/ml and (i) a temp>38.5°C for two days in the absence of other clinical sources of infection or (ii) flank pain or unexplained mental disturbance or abdominal discomfort. Only 23 patients completed the study and although norfloxacin failed to reduce asymptomatic bacteriuria, there was a significant reduction in symptomatic UTIs (1 v 12, p<0.02) and a decrease in catheter-associated complications of obstruction and leakage (p<0.05). Of the 11 patients who did not complete the study, six died (of non-infectious causes), one died of septic shock and four were withdrawn. However, norfloxacin
treatment was also strongly associated with the acquisition of gram-positive norfloxacins resistant flora (RR 4.66, 95% CI 2.47-8.80), and there was a rapid recolonisation by norfloxacinsensitive, gram-negative bacteria on cessation of treatment. Overall the study concluded that norfloxacinas failed to prevent bacteriuria in long-term catheterised patients and favoured the emergence of quinolone-resistant organisms, although there were some clinically observable benefits in some patients.

Similarly there is little strong evidence of benefit in prophylactic antibiotics prior to re-catheterisation and it is not routinely recommended [110]. One RCT in which 70 residents in a long-term care home were allocated to a treatment group (1gm IV meropenem given 30 minutes before re-catheterisation) or control group (no antibiotics) showed no significant differences in urine cultures at 3, 7, 14 or 28 days [414].

When catheterised patients are prescribed a course of antibiotics for symptomatic infection a common question from healthcare practitioners is whether the catheter should be changed to a new one prior to starting antibiotics. There are concerns that this may allow time for a new biofilm to become established on the catheter within a few hours (and provide a source of re-infection) before the antibiotics have taken effect. In contrast, the 2009 International Clinical Practice Guidelines from the Infectious Diseases Society of America suggest a catheter change if the catheter had been in place for at least two weeks and was still needed. The rationale was that this would facilitate resolution of symptoms and decrease risk of bacteriuria and CAUTI [110]. There is little research to guide practice but in one RCT of 54 nursing home residents managed by long-term catheterisation, subjects were randomised to undergo catheter replacement, or no catheter replacement, before antibiotic intervention for clinical diagnosis of UTI [216]. Clinical outcomes (reduction in polymicrobial counts, time to achieve afebrile status and clinical status at 72 hours) were significantly better among subjects randomised to catheter change immediately before institution of antibiotics (Level of Evidence 2). Replacement of the catheter, in patients suspected of having a UTI, prior to collecting a urine sample for culture and sensitivity testing has also been shown to reduce the number of pathogens identified, the number of antimicrobials prescribed and laboratory costs [415]. There is evidence that certain bacterial strains may be particularly difficult to eradicate. In a prospective study of infection in catheterised nursing home patients a single genotype of P.mirabilis was shown to persist in the urinary tract despite many changes of catheter, periods of non-catheterisation and antibiotic therapy [416].

Cranberry juice has long been advocated as a treatment for urinary tract infection and there is some evidence of decreased symptomatic infections in some study populations, but not in catheterised persons [417]. However current evidence to date is limited to non-catheterised patients and caution needs to be applied in extrapolating results to catheterised patients.

i) LTC-associated risks and problems: recurrent catheter blockage

Recurrent catheter encrustation by mineral deposits, leading to catheter blockage occurs in up to 50% of LTC users, with resultant increased costs to services and patients [418] [419] [420] [421]. Heavy encrustation on external surfaces of the catheter tip and balloon can also cause painful tissue trauma on catheter removal. The major components of encrustation are calcium phosphates and magnesium ammonium phosphate (struvite) (Figures XII-7 and XII-8) which precipitate from the urine, most commonly under alkaline conditions.

The precipitation of different ionic species (ie Ca++, Mg++, and phosphates) is influenced by their ionic concentrations in the urine. In addition, the urinary pH at which different ions precipitate from the urine varies, not only for different ions, but also between individuals and at different times [422] [423]. These factors contribute, at least in part, to individual variability in terms of susceptibility to catheter encrustation and time to blockage. Catheterised patients can usually be classified into ‘blockers’ or ‘non-blockers’ [418] [424] where ‘blockers’ are those individuals who experience recurrent catheter blockage within a few days to a few weeks. Early recognition of recurrent ‘blockers’ facilitates proactive care through appropriate catheter change regimes [424]. Urine from recurrent blockers tends to have a very narrow ‘safety margin’ between ‘voided’ urinary pH and the pH at which crystallisation (or nucleation) occurs. This margin is much wider in non-blockers [425]. Precipitates occur most commonly under alkaline conditions caused by the presence of urea-splitting micro-organisms such as Proteus mirabilis, in the catheter biofilm [426] [424] [427] [425].

1. Reducing catheter encrustation — catheter materials

The majority of research on catheter encrustation comprises experimental, laboratory-based studies addressing current and/or potential catheter material surface properties in relation to bacterial adhesion and encrustation. Encrustation may sometimes take place in the absence of infection [428] and is influenced by catheter surface properties, including roughness and irregularity, hydrophobicity and wetability, charge, polymer chemistry and coatings. None of the currently available long-term catheter materials is resistant to biofilm formation and encrustation. In a series of laboratory studies of 18 types of catheter materials, using a model of the catheterised bladder, none resisted biofilm formation by a clinical strain of P.mirabilis [429] [430]. Relative times to catheter blockage were: silver-coated latex 17.7h; hydrogel-coated latex 34h; silicone-coated latex 38h;
all-silicone 47h. However, the authors note that the internal diameter of the coated latex catheters was much smaller than for the silicone catheters (1.5mm compared to 2.5mm).

This finding was confirmed [409] in tests with five types of catheters (pure silicone, silicone-coated latex, hydrogel-coated latex, hydrogel/silver-coated latex, and nitrofurazone silicone) colonized with P. mirabilis 108 cfu/mL and a urine pH of 8.5 All had heavy encrustation by 18 h. and were blocked within 40h. There are implications for coated catheters, such as silver, because the bacteria can continue to grow even when attached to the crystalline biofilm, which shields them from the silver. To keep the pH from rising, antimicrobials need to get into the urine.

Targeting P. mirabilis infection for treatment as soon as it is introduced into the urinary tract may be beneficial in preventing recurrent encrustation and blockage [431]. While this organism, which is harboured in the intestines, may not cause problems in the urinary tract of a healthy person, it has many characteristics that negatively impact the bladder of a catheterized person who has an already inflammatory process taking place. These include: four adhesins that help make it stick to the bladder and catheter, a protective capsule, several secretions that promote extraction of host nutrients, quick migration capacity, and a powerful urease [431]. The ability of P.mirabilis to evade the host’s immune response make it a very difficult organism to treat. For example, a structure in the membrane called LPS contributes to virulence and can cause hypotension, fever, DIC and shock. Another component (migration factor Cmf) improves swarming [432].

Although it is not possible to examine the effects of polymer surface properties on microbial adhesion and formation of catheter encrustation in detail here, recent studies have shown that strongly electron donating surfaces are less prone to adherence by P.mirabilis than more hydrophobic materials [433]. Some copolymer, polyurethane blends are associated with less microbial adherence and improved resistance to encrustation in an artificial bladder model [434]. The effect of iontophoresis produced by passing an electric current through silver electrodes attached to catheters has also been shown to inhibit bacterial growth [435]. Another potentially promising innovation is the use of the anti-septic agent triclosan in the catheter balloon [408] [436] [437]. In laboratory models of the catheterised bladder infected with P.mirabilis, silicone and latex-based catheters, with balloons inflated with triclosan, drained freely for seven days compared to 24h for controls inflated with water. Triclosan became impregnated throughout the silicone catheter material and strongly inhibited the formation of the crystalline biofilm. However, latex-based catheters required a higher concentration of triclosan (>1mg/ml) than silicone catheters to produce similar inhibitory effects on P. mirabilis. Diffusion through the latex balloon occurred but the latex-based catheter did not become impregnated with triclosan throughout. The potential benefits of triclosan in catheter balloons now needs to be tested in clinical trials but it is also important to note that not all microbial species responsible for CAUTIs are sensitive to this biocide and emergence of resistant strains is a common concern [437].

2. Reducing catheter encrustation – interventions

A number of studies have employed in vitro models of the catheterised bladder to examine the influence of urinary composition on bacteria growth and encrustation, and the ability of acidic irrigations to reduce encrustation build up. There is good evidence from laboratory studies that increased fluid consumption (leading to lower concentration of encrustation components) increases the time to catheter
blockage [438]. Increasing citrate concentration in fluid intake and urinary output (e.g. through drinking orange juice or other fruit juices such as lemon or lime) has also been shown to increase time to catheter blockage (see below). Cranberry juice has frequently been advocated to reduce UTIs, microbial adherence and biofilm development but an in vitro study by Morris and Stickler [439] drinking cranberry juice did not produce urine which was inhibitory to the development of P. mirabilis biofilms and catheter blockage, although increased fluid intake was beneficial. Although some studies have claimed drinking cranberry juice can decrease urinary pH in healthy volunteers [440], this is unlikely to be accomplished in catheterised patients, in the presence of continued ammonia production by the action of urease-producing micro-organisms [441].

Urease inhibitors, including acethydroxamic acid (1.0mg/ml) and fluorofamide (1.0microg/ml), have been shown to restrict the increase in urinary pH of P. mirabilis infected urine from 9.1 to 7.6, in a simple physical model of the catheterised bladder [430]. Significant reductions in precipitation of calcium and magnesium salts were also noted but the impact of possible side-effects remains unclear, and therefore clinical potential is uncertain. Clinical studies on the prevention or management of catheter encrustation are extremely limited and only two relevant studies addressing the use of urease-inhibitors were identified. One early clinical study [442] examined oral administration of a urease inhibitor (acethydroxamic acid) to five patients who required frequent catheter changes (>1 every 2 weeks) due to encrustation and blockage. The dose was based on body weight (e.g. 250mg three times daily for patients between 50-70kg). The degree of encrustation decreased significantly during therapy (p<0.05) and the authors reported minimal adverse side effects experienced by patients, but acknowledged the potential for more severe side effects to occur. A subsequent double-blind, RCT of acethydroxamic acid in the palliative treatment of infection-induced urinary calculi, demonstrated lowered urinary pH in urine infected with P. mirabilis but the side effects were unacceptable to patients [443] (Level of Evidence 1).

An alternative approach to reducing catheter encrustation, aimed at increasing the ‘safety margin’ between urinary pH and the nucleation pH (pHn) (i.e. the pH at which crystals of calcium and magnesium are formed in the urine) warrants further clinical investigation. In laboratory studies using models of the catheterised bladder, the pHn of the urine was shown to increase when urine concentration was decreased and also by addition of citrate to the urine [438]. In models supplied with urine containing citrate at 1.5mg/ml or above, catheter drained freely for the seven day experimental period. Drinking 500ml pure orange juice per day can achieve concentrations of citrate of up to 1.2mg/ml urine [423] and further clinical evaluation of the effects of increasing a patient's fluid intake with citrate containing drinks is awaited. Viable cell counts of P. mirabilis in the model suggest that results were unlikely to be due to direct effects of citrate on the growth of metabolism of P. mirabilis in the catheter biofilm, but rather on the process of mineral crystallization.

Recent research provides more evidence. In a recent randomized six week crossover trial of citrated drinks in 24 persons with catheter blockage [444], it was demonstrated that the pHn could be significantly increased. The highest level of change was with lemon juice, with a “safety margin” of 0.84 (95% CI 0.63, 1.04), followed by fluid intake 0.57 (95% CI 0.37, 0.78), and potassium citrate 0.41 (95% CI 0.20, 0.61). Overall, the safety margin for the drinks was significant (p<0.001) when controlling for the three groups. Each participant, who had experienced at least three blockages within four weeks previously, received all three drinks. Baseline 24 hour urines were obtained after each week, allowing for a washout period between the one week drink consumption for each arm of the study. The lemon juice concentration was 60mL/1 litre of water, potassium citrate was 6 g/1 litre, and the fluid intake was also 1 litre additional. Participants were instructed to consume the drinks each day in addition to their usual fluid intake and they tracked their intake and output during the study. This study provides additional evidence that optimal and consistent levels of fluid intake could minimize catheter blockage or increase the interval between changes, in persons with persistent encrustation and blockage.

The reduction of encrustation and corresponding extension of ‘catheter life’ by regular instillation of an acidic catheter maintenance solution into the catheter has been advocated by some researchers, particularly where frequent catheter changes for recurrent blockage are difficult and / or unacceptable to patients. Solution G (Suby G) and Solution R (Table XII-5) have been shown to be effective in in vitro models of the catheterised bladder [445] [446] [447] and in vitro models of struvite stone chemolysis [448]. In response to concerns over potential damage to the bladder mucosa from acidic catheter maintenance solutions, Getliffe et al. [446] advocate the use of small volumes of solution so that less enters the bladder. Under controlled laboratory conditions smaller volumes of acidic solutions (Suby G) (50ml), retained in the catheter for 15 minutes, were shown to be as effective as the commonly available commercial standard of 100ml. Getliffe et al. also showed that two sequential washouts with 50ml were more effective than a single washout.

There is relatively little clinical evidence to draw on in this area and outcomes remain to be tested in well-controlled clinical trials. Most clinical studies are small-scale and descriptive although both Getliffe [424] and Kunin et al. [418] compared groups of ‘blockers’ and non-blockers’ to identify
characteristics of recurrent 'blockers'. One small-scale, comparative trial of Suby G, Solution R and saline catheter 'washouts' in 14 older female patients [449] reported a higher incidence of red-cells in the retrieved washout fluid with Suby G compared to saline (mean incidence of 28% and 14%, respectively. However, increased shedding of uroepithelial cells was present in the retrieved washout from all three solutions suggesting this was at least partially related to the physical process of administration. This issue was previously raised by Elliot et al. [450] who also demonstrated increased uroepithelial shedding following washouts with up to 60ml saline 0.9%; chlorhexidine 0.02% or noxythiollin 2.5%.

A more recent RCT with 73 community dwelling individuals, which aimed to compare weekly catheter flushes with saline or an acidic solution, with no flushes, reported the mean time until catheter removal was very similar between groups. Importantly, there was no evidence of detrimental effects, such as increased risk of symptomatic infection, from breaking the closed system in order to apply catheter flushes. Urinary pH did not change over the study time; at baseline the mean was 6.3 (SD 1.04), range 5-8.5. However the study was underpowered and subjects were only followed for a maximum of eight weeks, or until the catheter was changed three times, or a symptomatic UTI developed. There were considerable difficulties with recruitment of patients and target numbers fell short within each group (Level of Evidence 2) [358]. A sample of 400 per group, 1200 in total, was estimated posthoc, as giving sufficient power for future research in this area [451]. Other clinical studies have focused on chemolysis of infection stones (principally composed of struvite). Stronger acidic solutions such as Solution R have been shown to dissolve fragments of struvite renal calculi following lithotripsy [452] but potential benefits may be outweighed by the greater risk of inflammatory tissue reactions when used as a catheter maintenance solution. Renacidin solution is approved for kidney stone disintegration in the US but although it may be effective for recurrent catheter blockers, there is no published research evidence of its use in this group.

Overall, methodological issues make it difficult to draw robust conclusions on the effectiveness of acidic solutions in managing catheter blockage. It is unlikely that any currently available strategies will completely prevent catheter encrustation and a more practical aim is to extend catheter life to a period which is acceptable to users and manageable by healthcare professionals. Early detection of impending blockage by determination of usual length of catheter-life [424] or by application of a sensor device designed to detect early stages of P. mirabilis biofilm formation [453] are likely to remain the mainstays of management.

**j) LTC-associated risks and problems: urethral trauma, bladder calculi and bladder cancer**

### 1. Urethral trauma

Urethral trauma and discomfort can occur during catheterisation but may be minimised by using a sterile lubricant or anaesthetic gel [454], however clinical practice remains variable. More studies have considered the use of lubricants for male catheterisation but few have considered the procedure for women or for supra-pubic catheterisation [455]. A recent randomised, double-blind study with 62 alert, cooperative females requiring urethral catheterisation, demonstrated that the group receiving lignocaine gel had a significantly lower median procedural pain score compared to the group receiving a water-based lubricating gel [456]. It is not clear whether cleaning the urinary meatus prior to insertion is needed, based on two small trials (Level of Evidence II). In one study, 0.05% chlorhexidine gluconate or sterile water was tested in a home care sample (N=20), with four urine specimens cultured over two weeks. No difference was found, and no one developed a symptomatic CAUTI [457]. In the other study of 60 women receiving outpatient gynaecological surgery, [458] povidone-iodine was compared with water. No significant differences in bacteriuria or symptomatic CAUTI were found in comparing urine samples just prior to insertion and 24 hours later.

### 2. Bladder calculi

Most long-term follow up studies of LTC use have addressed SCI populations. Indwelling catheters (UC and SPC) have been significantly associated with increased risk of bladder calculi formation in SCI patients, compared to intermittent catheterisation [460] [235]. In a retrospective cohort study of 457 patients, controlled for variable follow up times by regression analysis, both UC and SPC were significantly associated with increased risk of bladder calculi formation compared to intermittent catheterisation IC (hazard ratio 10.5; p<0.0005 and 12.8; p<0.0005) respectively [461]. This increased risk was independent of age, sex, level and degree of injury but calculi were no more likely to form with SPC than UC (hazard ratio 1.2, p=0.6). Another case series of SPC in 118 patients with neurogenic bladders [462] found common complications were bladder calculi (25%), (particularly associated with high urinary pH) and urethral leakage (10%). Bladder calculi-free rates at five and 10 years were 77% and 64% respectively, falling to 50% at 20 years.

Where SPC has been compared to CIC the main difference appears to be in a lower incidence of bladder calculi in the CIC group. A prospective comparison of long-term outcomes between 34 quadriplegic patients managed by SPC (mean period 8.6 years) and 27 paraplegic patients managed with CIC (mean period 9.9 years) reported no significant
difference between groups in respect of symptomatic UTI, renal stone, degree of bother and overall satisfaction [310] but there was a significantly increased incidence of bladder stones in the SPC group. However a recent review of current literature [311] (56 studies), concluded there were variations between older and more recent studies. More recent studies showed morbidity profiles to be similar for SPC and CIC, where patients were managed by anticholinergic medications, frequent catheter changes and volume maintenance procedures. A dedicated catheter clinic established to aid the management of patients having problems with LTC, reported the majority of patients were elderly with chronic disabilities. A significant proportion of those with catheter encrustation and blockage (45% of 147 patients) were shown to have formed bladder calculi [463].

3. BLADDER CANCER

A number of retrospective, cohort reports of SCI patients have linked bladder cancer with long-term indwelling catheterisation [464] [465] [466]. The reported incidence of squamous cell and transitional cell carcinoma associated with chronic indwelling catheterisation varies widely between studies but Groah et al. [466] in their follow-up of 3670 subjects, calculated that patients with SCI and an indwelling catheter were 25 times more likely to develop bladder cancer than the general population (Level of Evidence 3). For SCI patients without an indwelling catheter, the risk of bladder cancer was 15 times that of the general population. Since SCI patients are already at increased risk of developing bladder cancer compared to non-SCI groups, the influence of an indwelling catheter on bladder cancer requires further clarification, including the potential relationship between duration of catheterisation and cancer development. Bladder calculi have been identified as an independent risk factor for bladder cancer by some authors [464].

Most reports have grouped UC and SPC together as indwelling catheters but a small number of case study reports have drawn attention to long-term risks of carcinoma within the cystostomy tract with SPC, with or without further extension into the bladder [467] [468] [469]. However, in a retrospective analysis of screening biopsies for bladder malignancy in 36 patients with SPC for more than 12 years, Hamid et al. [470] found no tumours in the screened group although histological findings were frequently abnormal (Level of Evidence 2). These authors raise concerns over the interpretation of screening cystoscopy and biopsy in this population and note the importance of the distinguishing between histological changes and confirmed cancers when interpreting study results. Recently published guidance on management and prevention of catheter-associated urinary tract infection, based on an extensive survey of the literature, includes a recommendation that patients with urethral catheters in place for 10 years or more should be screened annually for bladder cancer [471] (Grade of Recommendation C).

k) Catheter management strategies

Although guidelines and protocols for catheter-care practices are abundant, relatively few practices are supported by research evidence and even fewer by evidence from randomized controlled trials. For example, in the ‘Guidelines for prevention of healthcare associated infections in primary and community care’ commissioned by the UK’s National Institute for Clinical Excellence [472], of 29 recommendations relating to urinary catheterisation only six were Grade A (directly based on Level 1 evidence); with one each at Grades B and C. The remaining 21 were all grade D, being based on evidence from expert groups or clinical opinion.

1. GUIDELINES

In 2009, the U.S. Healthcare Infection Control Practices Advisory Committee issued through the Centers for Disease Control and Prevention (CDC) updated Guideline for Prevention of Catheter Associated Urinary Tract Infections [342]. This guideline, which updated the 1982 Guideline, expanded information about catheter related issues, including intermittent, condom, suprapubic, and chronically catheterised long-term users. The recommendations made by this committee for preventing catheter-associated urinary tract infections, based on systematic review of the best available evidence, address the following issues:

- who should receive an indwelling urinary catheter
- catheter insertion
- catheter maintenance
- quality improvement programs to achieve appropriate placement, care, and removal of catheters
- administrative infrastructure required
- surveillance strategies

This new guideline recommended selected practices at grade B based on level of evidence of 1 or 2. Therefore, many topics were judged as “no recommendation/unresolved issue” due to a lack of evidence.

2. QUALITY INDICATORS AND REGULATOR INITIATIVES

It is well established that guidelines alone do not change practice. Further efforts should be directed to disseminating evidence-based guidelines about catheter care through education and the use of quality indicators and regulatory initiatives.

Regulation that is accompanied by the use of evidence based quality indicators has a powerful influence on the quality of care. Quality indicators are defined as quantitative measures reflecting a professional
care standard which are used as guides to monitor and evaluate the quality of important patient care and support service activities. The ACOVE (Assessing Care of Vulnerable Elders) suite of quality indicators has been designed to measure the quality of care for vulnerable elders [473]. It incorporates one quality indicator to guide measurement of the quality of care related to catheter use.

"IF a VE has clinically significant urinary retention, and a long-term (> 1 month) urethral catheter is placed, THEN there should be documentation of justification for its use, BECAUSE treatment of certain underlying causes(s) of urinary retention (e.g., treatment of constipation or bladder outlet obstruction) may carry less risk than long-term urinary catheterization" [473].

Another attempt to ensure the appropriate use of catheters is the use of assessment protocols. For example, regulation for long-term care settings in the USA mandates that all newly admitted Medicare/Medicaid funded residents receive an assessment using a standardized form called the Minimum Data Set (MDS). A further level of assessment is triggered when/if a resident is newly incontinent and the Resident Assessment Instrument Minimum Data Set is completed (RAI-MDS). This assessment information in turn, acts as a prompt for staff to design an individualized care plan based on direct contact with residents, appropriate staff, and through use of observation, interviews and record reviews. The MDS and RAI are now used in a number of other countries, including Canada and Iceland, and other countries have developed their own assessment instruments. Ideally, these assessment instruments should prompt staff to enquire about whether the residents’ catheter is medically warranted, and to identify catheter related problems, and care plans should contain information about an individualized catheter care plan (including the frequency of catheter changes and ongoing maintenance). This assessment process is strengthened in the USA by its link to quality indicators. Specifically, long-term care facilities are required to use information from the residents’ comprehensive assessment to provide assurances that:

- Catheters are used for only medically valid reasons;
- Catheters are removed as soon as clinically warranted;
- Efforts are applied to restore or improve bladder function as much as possible; and
- Efforts are made to prevent infection while the catheter is inserted (U.S Dept of Health and Human Services, 2004).

It remains to be seen if these measures will reduce catheter rates in long-term care, and how they will impact day-to-day catheter use and catheter care.

However, similar regulatory approaches should be considered by government and health agencies in other countries.

3. Catheter change procedures and catheter comfort

Indwelling catheters can cause substantial patient discomfort but although anecdotal information on the discomfort experienced by many catheterised patients is readily available, there is a general lack of published evidence from research studies. Further investigation and guidance to practitioners is needed. Catheter-related pain or discomfort can occur as the catheter is passed, in situ and on removal. Local anaesthetic lubricant gels are commonly used to aid the insertion of indwelling catheters in males and protect the sensitive urothelium from trauma [474]. Similar use of anaesthetic gels is generally recommended for females although the procedure may be less consistent in some places and where only small amounts of lubricant are applied to the catheter tip this may be insufficient to coat the urethra adequately. There is little research evidence to underpin clinical practice in this area although the NICE guidelines on infection control [472] recommend: ‘an appropriate lubricant from a single-use container should be used during catheterisation to minimise trauma and infection’. The choice of lubricating gel is usually left to practitioners but not all gels containing anaesthetic agents (eg lidocaine) are suitable for both urethral and suprapubic use. One prospective, randomized, double-blind, controlled trial of plain lubricant versus lidocaine gel prior to female catheterisation in an accident and emergency department found no significant differences in pain ratings, based on lubricant type or catheter size amongst 100 women recruited to the trial [475]. Anaesthetic gels may be contraindicated in patients with damaged or bleeding urethral membranes and should be used with caution in those with cardiac conditions, hepatic insufficiency and epilepsy [476]. Lubricants which contain chlorhexidine have been reported to trigger anaphylaxis in a small number of patients during catheter insertion and consequently a careful history is required to screen for sensitivities [477] [96].

In a study with 45 infants (2-24 months) who needed urethral catheterization, random assignment was made to either a topical lubricant (control), topical and intrarethral lubricants, or topical and intraurethral lidocaines [478]. Infants with the lidocaine had less distress, but the lidocaine did not eliminate the distress totally.

Catheterization in males can be difficult at times, and different approaches can be used, including a Coude catheter, various guide wires or filiform catheters, and other techniques performed by urologists. Research in this area is needed to compare different practices and associated risks [479].

Catheters can be painful when in situ. In one study at a US Veterans Affairs Medical Centre, 42% of
catheterised patients reported it was uncomfortable, with 48% complaining it was painful, and 61% stated it restricted their activities of daily living [107]. In one small sample of 43 community dwelling persons with long-term catheters, pain was reported by 24 (54%) [126]. Causes of pain were bladder spasms, position of the catheter, or related to catheter changes. Three had pain all the time, but 21 of 24 persons had it intermittently. If bladder spasm is the cause of pain when a catheter is in situ a low dose of an anticholinergic medication can help [480]. Other helpful approaches include treating constipation if present, ensuring that the catheter is the smallest size to provide adequate drainage, and ensuring that the drainage bag is well supported to prevent dragging on the catheter. Attention to the catheter position is needed to prevent kinks or twists in tubing and ensure that the catheter straps are not blocking urine flow [481]. Blockage in urine flow can cause bladder distension resulting in increases in hydrostatic pressure and bleeding points which open the way to bacteria, already present, to cause a symptomatic infection [210].

Bladder discomfort related to an indwelling catheter can exacerbate post-operative pain by mimicking overactive bladder syndrome that is resistant to conventional opioid therapy. Sub-lingual oxybutinin has been shown to be an effective treatment for pain after radical retropubic prostatectomy, with significant reduction in other pain relief requirements [482]. Cuffing of the catheter material on balloon deflation (see below) and/or encrustation of the catheter by mineral deposits may cause pain during catheter removal. Encrustation is discussed further in Section 12.2.9 and management of these problems is also discussed below.

4. EDUCATION OF HEALTHCARE PROVIDERS

Educational approaches should ensure that all healthcare practitioners have the necessary knowledge and skills to care for individuals with a catheter. Some research however, points to gaps in healthcare practitioners’ knowledge about what catheter to select, and how to minimize and manage ongoing problems[483]. Mody and colleagues (2010) [484] assessed nursing home healthcare workers’ knowledge and awareness of recommended catheter care practices, and found significant discrepancies between their knowledge and research-based recommendations. Respondents were drawn from seven community-based nursing homes in the USA and included nurses and nurse aides.

Twin surveys were sent to healthcare providers in Minnesota to determine their level of knowledge about catheter use. The physicians (N=635) reflected awareness of the indications for catheter use, and about 1/3 said they remove them sooner. However, about 30% were unsure about how to prevent UTI [485]. Nurses (N=370) were aware of catheter indications, but some were likely to approve of catheter use in the ICU (for whatever reason) and of the value of silver coatings on catheters [485]. Both studies had low response rates, of 9% and 4% physicians and nurses, respectively. Another survey to 333 persons, (70% RNs and 27% unlicensed assistants) indicated that there was a need for more education related to catheters [486]. Incorrect practices involved not securing the catheter (75%) and not knowing when to replace the catheter (74%). The response rate was 54%, and about half of those surveyed had less than two years work experience.

An audit of education given to nursing students in Greece indicated that there was a need to upgrade teaching methods [487]. Proficiency was impaired by a lack of attention to preparing the patient (including emotional and practical aspects), old textbooks, outworn traditions, little or no instruction on troubleshooting and a lack of sophisticated methods for teaching (e.g. DVDs showing the procedure).

An audit of adherence to standards of nursing care in one UK Trust related to catheter practices in patients’ homes [488]. All nurses surveyed (N=25) indicated they would change the catheter every 12 weeks unless there was a reason to do this more often; no data were provided on the percentage with 12 week changes. Though a closed system was advocated by all nurses, washouts were performed by 75% and sampling ports for urine samples were used by 28%, and the rest used a clean drainage bag. A similar audit was conducted in a hospital setting [489]. Continuing catheter care was well documented at 98%, but 11% were missing details on insertion.

5. CATHETER CHANGE FREQUENCY

Protocols on indwelling catheter change frequency vary widely from monthly to up to three months if the catheter is trouble-free. In the absence of clear supporting evidence this remains an area of controversy amongst clinicians with advocates of early change believing this to reduce the incidence of complications while others argue that frequent changes increase the risk of infection, trauma and long-term histological changes. However, very sparse evidence suggests that CAUTI might be less when the catheter is changed every 4-6 weeks, rather than only when it blocks, or with planned changes of every two weeks [490].

SPC changes can be competently managed by skilled nurses [325], often in the patient’s own home, but the new catheter should be inserted as quickly as possible whilst the track is still easy to follow. A delay of only a few minutes can result in partial obliteration of the tract [491]. It is also possible to insert the new catheter too far through the bladder so it enters the urethra with resultant trauma when attempts to inflate the balloon are made. Careful observation of the length of catheter external to the abdomen and the angle of protrusion prior to catheter change can
help to ensure correct positioning of the new catheter [492]. Dressings around the stoma site are not normally required unless there is excessive discharge, causing staining and / or sticking to clothing.

While nurses do not usually order catheter insertions, and there may be times when delay in a clinically appropriate catheterisation is harmful to certain patients. A new protocol and algorithm was thus developed by nurses, physicians and other key stakeholders in an orthopaedic unit of a large urban hospital to facilitate catheter insertion in certain defined situations [493]. Indications, such as spinal column injury, and contraindications were depicted in a diagram to identify when to stop, consider the issues (e.g., neutropenia), and when to insert the catheter.

Urinary catheter ‘deflation cuff’ formation can be a problem in both SPC and UC, causing difficulty in removal and great discomfort to patients. Evidence suggests deflation cuff formation can be a particular problem for all-silicone SPCs. A retrospective study of 113 patients cared for by community nurses showed that 30% of nurses had experienced problems changing catheters in the previous 12 months [494]. In vitro studies have confirmed increased retention force and resistance to withdrawal caused by cuff formation and although cuffs can form with other catheter materials (eg hydrogel coated-latex) the retention force is less than with all-silicone material [339]. It has been suggested that slow deflation may enhance the probability of the silicone balloon returning to its pre-inflation shape [340]. Alternatively, reinsertion of 0.5-1ml water is sufficient to fill the catheter inflation lumen and eliminate the balloon cuff. Subsequent use of lubrication with gentle removal of the catheter has been well-tolerated by patients and produced virtually no trauma.

6. Personal hygiene and infection control

Meatal cleansing by simple washing with soap and water during routine bathing or showering is recommended (Level of Evidence 1) [495] [496]. No consistent reduction in bacteriuria has been demonstrated by any other meatal cleansing regimes, using povidone-iodine solution or cream, chlorhexidine, polymicrobial creams, 1% silver sulfadiazine or antiseptic lubricating gels, compared to routine bathing or showering [374] [122]. Effective handwashing by healthcare professionals, carers and patients, before and after handling catheters and drainage equipment is generally accepted to be the most important component of any infection control strategy. Healthcare professionals and formal carers should also wear gloves. Catheters and drainage equipment are commonly supported in position by tapes, Velcro and other securing devices (eg CathSecure, StatLock)

More securement devices are now on the market providing choices for long-term users, in particular. Consideration should be given to usual activity, clothing, size of the person (e.g. thighs) and the weight of the bag it would support. All, but especially those using adhesives, need to be comfortable, easy to use, and gentle to the skin [497]. These securement devices are designed to control post-operative bleeding, maintain surgical anastomoses in the lower urinary tract, and prevent urethral erosion or trauma and accidental dislodgement from traction [498]. The importance of these in reducing risks of CAUTI and the mechanism involved are not well-established [380] (See also section XII.2.h).

7. Urine collection — catheter valves

Urine may drain continuously from the bladder into a drainage bag attached to the catheter (See Section XIII) or intermittently via a catheter valve. The valve is a small device connected to the catheter outlet in place of a bag. Closure and opening the valve allows bladder filling and intermittent drainage rather than continuous drainage into a bag. Valves are available in a variety of designs (Figure XII-9) ranging from simple inexpensive types used for up to a week, to more expensive, complex, forms which last longer and which may permit one handed action. However, valves are not available or licensed in all countries.

Figure XII-9: Example catheter valves.

Most valve designs can be attached to a drainage bag at night to allow free drainage while the patient sleeps. A valve can provide a discreet alternative to conventional urine drainage bags and may offer improved maintenance of bladder tone and capacity for appropriate patients. A spigot is not a suitable alternative to a valve since it must be removed from the catheter to allow drainage thereby breaking the ‘closed system’. Patients must be able to manipulate the valve mechanism and empty the bladder regularly to avoid overfilling, with accompanying risks of back pressure on the upper urinary tract. Valves are generally inappropriate for patients with poor manual dexterity, poor bladder capacity, detrusor overactivity, ureteric reflux, renal impairment or cognitive impairment. There is relatively little research-based literature on catheter valves with much of the evidence supporting beneficial effects derived from the level of expert opinion. Concerns
over possible increased risk of infection associated with valves have not been realised although there is a paucity of research in this area. A lack of knowledge on valves may interfere with their use in appropriate situations; therefore, a full assessment is required to determine whether the person is a good candidate for a catheter valve using a systematic process, such as an algorithm [499].

The flushing mechanism resulting from bladder filling and emptying may be expected to contribute to reduction in problems of encrustation and blockage. One study was found that provides new evidence as to how a catheter valve might do this [500]. The laboratory study involved four experiments with a bladder model and artificial urine cultured with Proteus mirabilis. Manual valves were opened every two or four hours with continuous drainage at night, followed by experiments with automatic valves timed to open for five minutes every two to four hours around the clock for seven days. All experiments were compared with continuous drainage of urine. Analysis of variance showed that all models controlled by valves during the daytime (12 h) took significantly more time to block (62.6 versus 35.9 h, p=0.039) than 24 hour continuous drainage. Experiments were done with automatic valves which ran 24 hours day every two or four hours, and time to blockade extended to 119.8 h versus. 50.7 h, and 159.8 hours. 44.7 h, respectively.

There is stronger evidence of benefits in terms of patient comfort and independence since this is a common finding in most studies. Five studies comparing a catheter valve with standard drainage (leg bag) were identified: three were cross-over designs, with 28, 16 and 18 subjects respectively [501] [502] [503] (Level of Evidence 3); two randomized their sample of 100 subjects to either catheter valve or standard drainage [504] [505] (Level of Evidence 2). None of the studies identified any significant difference in urinary tract infection and a majority found a high level of preference or acceptability of catheter valves (>72%). There were no differences in reported incidence of bladder spasms or discomfort; however, there was a higher incidence of nocturnal frequency and episodes of bypassing with valves. It was suggested that a combination of a valve during the day and free drainage at night through an open valve connected to a drainage bag could be an appropriate management strategy.

Several studies have evaluated a single valve design [506] [507] but only one has compared a broad range of valve designs [508]. Fader et al undertook a comparative evaluation of the seven catheter valves available on the UK market in 1996. Each valve type was tested for one week by between 19 and 36 subjects, followed by completion of a product evaluation questionnaire. Performance scores (and costs) varied widely between products but critical characteristics were: being easy to manipulate, leak-free, and inconspicuous. The authors concluded that prescribers need to be aware of the strengths and limitations of different valves for appropriate product selection (Level of Evidence 3). A more recent development concerns the design of a prototype, novel, automatic valve system for LTC patients [509] which may be helpful for patients who lack sufficient dexterity to manage a manual valve. In summary:

- Catheter valves provide a well-accepted system of bladder emptying for suitable patients who are able to manipulate the valve mechanism and empty the bladder regularly to avoid over-filling (Level of Evidence 2).
- There is no evidence of increased risk of urinary tract infection with valves compared to conventional drainage systems (Level of Evidence 2).
- Valves may promote maintenance of bladder tone and capacity (Level of evidence 4).

8. MAINTAINING EFFECTIVE CATHETER DRAINAGE

Use of urinary catheters is rarely completely trouble-free. Catheter drainage can be compromised by a variety of factors from simple causes such as kinked tubing or the position of the drainage bag, to bladder spasm, pressure of a constipated bowel on the adjacent urethra, suction of bladder mucosa into the catheter eye, or blockage by blood clots, mucous or encrustations formed by deposits of mineral salts. The algorithms in Figures XII -10 to XII-12 combine current evidence-based knowledge and expert opinion to provide some guidance on troubleshooting common problems.

9. RECURRENT CATHETER ENCRUSTATION AND BLOCKAGE

Factors affecting persistent catheter encrustation leading to recurrent blockade have been discussed earlier in section XII.2.i. The day to day management of recurrent catheter encrustation and blockage is largely a nursing responsibility but there are few options available. Maintenance of dilute urine by a suitably high level of fluid intake has been shown to reduce encrustation in laboratory studies [438] and increased urinary citrate concentration produced by drinking orange juice or other fruit juices may also be beneficial [438]. However the amounts required may be relatively high and clinical studies are needed to assess benefits and possible detrimental side effects e.g on bowel behaviour. Use of a catheter valve in suitable patients may also help reduce build up of encrustation by facilitating periodic flushing but clinical evidence is currently unavailable. In a majority of patients a characteristic pattern of ‘catheter life’ can be identified with careful record-keeping of three or more catheter episodes [424] [418] [510]. This may allow pro-active strategies of care designed to change the catheter before likely blockade. However, very frequent catheter changes can be unsuccessful or
Figure XII-10: Troubleshooting long-term catheter problems: urine does not drain (N = No; Y = Yes). (Always have a spare catheter available)
Unacceptable for some patients, as well as being costly in terms of health service resources [420]. In a study of planned catheter changes [511], based on observation of the intervals for three changes, urinary pH, and visual encrustation, unplanned changes decreased significantly from 46 the year prior (n=39) to 30 during the 12 months post intervention (n=21, p<0.01). The major impact on quality of life related to catheter problems decreased from 39% to 5%, though satisfaction with care management did not change much.

An alternative strategy is the regular prophylactic instillation or irrigation of the catheter with an acidic ‘catheter maintenance’ solution to dissolve mineral deposits. In older literature the term ‘bladder washout’ appears but as the aim is to wash the catheter, rather than the bladder, ‘catheter maintenance solution’ is a more appropriate term. A range of commercially available catheter-maintenance solutions is indicated in Table 12-6, although these are not necessarily available in all countries. Support for irrigations is strongly divided between those claiming benefit for specific patients who experience very frequent blockage and those who consider any break to the closed system to increase risks of infection. Research evidence is primarily derived from laboratory models of the catheterised bladder. The few clinical studies which have addressed this issue have been limited by methodological deficits and small sample size.
THE INFLATION BALLOON DOES NOT DEFLATE

PROBLEM

Blocked deflation channel?

Faulty valve or syringe:

? constipation, present - may cause pressure on the inflation channel

consult local policy for further advice or seek medical help

ACTION

- try to remove or dislodge debris blocking the deflation channel by gently 'milking' the catheter along its length
- try to remove or dislodge debris by inserting a few drops of sterile water into the inflation channel (no more than 1-2ml) with a sterile syringe

- try a different syringe, withdraw water very slowly or leave syringe in place, the water may seep out over a period of time
- insert the needle of a sterile 10ml syringe into the balloon drainage channel just above the inflation valve. If the valve is faulty the water may be withdrawn gently via the syringe

- try to relieve constipation

- do not cut the catheter
  - it may recoil inside the urethra

- do not cut the inflation valve off
  - if the balloon does not deflate it will no longer be possible to try alternative simple methods

- do not attempt to burst the balloon by over-inflating it
  - a cystoscopy will be required to remove fragments!
  - remaining fragments may result in formation of calculi

Record problem, actions and outcome.
Record catheter details, lot number etc and report to manufacturer

Figure XII-12: Troubleshooting long-term catheter problems: the inflation balloon does not deflate.
Levels of evidence relating to catheter-associated risks and complications

- All currently available catheter materials are subject to bacterial biofilm formation (Level of Evidence 1).

- Silver alloy coated catheters are associated with a statistically significant reduction in incidence of asymptomatic bacteriuria in short-term catheterised, hospitalized adults (studies of varying quality included) (Level of Evidence 1). There is less robust data to show that silver-alloy catheters reduce symptomatic infection (Level of evidence 4). Silver oxide coated catheters are not associated with a statistically significant reduction in bacteriuria (Level of Evidence 2).

- Antimicrobial catheters can prevent bacteriuria in hospitalized patients during short-term catheterization (<14days) (Level of Evidence 1). Trial results are highly context dependent and the effectiveness of specific antimicrobial preparations may be limited to specific groups of microorganisms. Potential toxicity and / or antimicrobial resistance is unknown (Level of Evidence 2).

- There is little evidence to guide the precise timing of antibiotic cover (when required) for catheter change. One study has shown that clinical outcomes (i.e. reduction in polymicrobial counts in urine, time to achieve afebrile status and clinical status at 72 hours) are significantly better among subjects randomised to catheter change immediately before institution of antibiotics (Level of Evidence 2).

- A majority of health services have clear policies on the use of antibiotics, designed to limit unnecessary use. Current evidence does not support routine use of antibiotic cover during catheter changes unless the patient’s condition renders them particularly at risk (Level of evidence 4).

- Meatal cleansing by simple washing with soap and water (i.e. not with antimicrobial agents) during routine bathing or showering is recommended (Level of Evidence 1).

- Recurrent urinary catheter blockage caused by encrustation occurs in 40-50% of all long-term catheterised patients (Level of Evidence 2). In the majority a characteristic pattern of ‘catheter life’ can be identified (Level of Evidence 3).

- Evidence from in vitro models of the catheterised bladder indicates that acidic ‘catheter maintenance’

### Table XII-6: Catheter maintenance solutions

<table>
<thead>
<tr>
<th>Solution</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Suby G or Solution G&lt;sup&gt;1&lt;/sup&gt;</td>
<td>3.23% citric acid solution, pH 4, containing magnesium oxide to minimise tissue irritation, aimed at reducing encrustation. Used where routine catheter maintenance is required to reduce build up of encrustations.</td>
</tr>
<tr>
<td>Solution R&lt;sup&gt;1&lt;/sup&gt;</td>
<td>6% citric acid solution, pH 2, containing magnesium carbonate, aimed at dissolving encrustations. A stronger acid than Suby G and therefore not recommended for frequent, regular use.</td>
</tr>
<tr>
<td>Renacidin&lt;sup&gt;R2&lt;/sup&gt;</td>
<td>A citric acid solution, pH 3.5-4.2, containing glucono-delta-lactone to minimise tissue irritation and magnesium carbonate, aimed at reducing encrustation.</td>
</tr>
<tr>
<td>Mandelic acid 1%&lt;sup&gt;1&lt;/sup&gt;</td>
<td>An acidic solution, pH 2, aimed at inhibiting the growth of urease-producers. A stronger acid which is not commonly used to reduce catheter encrustations</td>
</tr>
<tr>
<td>Saline 0.9%&lt;sup&gt;1,3&lt;/sup&gt;</td>
<td>A neutral solution, pH 7, recommended for flushing of debris and small blood clots. Neutral pH solutions will not dissolve catheter encrustations.</td>
</tr>
<tr>
<td>Chlorhexidine 0.02%&lt;sup&gt;1&lt;/sup&gt;</td>
<td>An antiseptic solution aimed at preventing or reducing bacterial growth, in particular E. coli and Klebsiella species (but will not prevent biofilm formation on long-term catheters)</td>
</tr>
</tbody>
</table>

<sup>1</sup> Available in the UK pre-packed in a sterile delivery devices designed for instillation into a urinary catheter.

<sup>R2</sup> Renacidin<sup>R</sup> is approved in the USA for kidney stone disintegration only. Although it may be effective in certain situations for persistent catheter blockers, there are no supporting studies.

- Saline is widely available

---

1745
solutions may have a role in dissolving encrustations in persistent blockers (Level of Evidence 2). There is insufficient evidence from RCTs to assign an in vivo level of evidence.

- Suprapubic catheterisation (SPC) is an appropriate alternative to urethral catheterisation for many patients following appropriate risk assessment (Level of Evidence 1).

- There is some evidence for a reduction in catheter-associated infection in SPC use during short-term catheterisation (Level of Evidence 2), compared to urethral catheter insertion. However, there is no corresponding evidence for long-term catheterisation.

- Patient comfort, quality of life and satisfaction with SPC is generally good compared to urethral catheters (Level of Evidence 1).

- Catheter valves provide a well-accepted system of bladder emptying for suitable patients who are able to manipulate the valve mechanism and empty the bladder regularly to avoid overfilling (Level of Evidence 2).

- There is no evidence of increased risk of urinary tract infection with valves compared to conventional drainage systems (Level of Evidence 2).

m) Urinary catheters versus other care strategies

Very few studies have compared urinary catheterisation with other strategies to manage urinary incontinence, not least because of the difficulties in recruiting to and conducting robust trials. For male patients who do not have problems with retention of urine external urine collection systems are an option (See Sections VII, VIII and IX). One recent prospective, randomized, unblinded, controlled trial on men >40 years in a US Veterans Affairs Medical Centre reported that the use of condom catheters was less likely to be associated with bacteriuria, symptomatic UTI or death than the use of indwelling catheters [101]. Patients reported that condom catheters were more comfortable (P=0.02) and less painful (P=0.02) than indwelling catheters.

A small number of studies have attempted to examine preferences for different urinary incontinence treatments in long-term care. In a descriptive, comparative study of preferences for treatments for frail older adults, residents in long-term care facilities were interviewed and groups likely to serve as proxy decision makers were surveyed (family members of residents and nursing staff) [512]. Forced choice comparisons of continence treatments were measured. Although there was wide variation within and between groups, most preferred non-invasive strategies (diapers and prompted voiding) to invasive strategies including indwelling catheterisation. Older adults stated they would choose a treatment based, in part, on feeling dry, being natural, not causing embarrassment, being easy, and not resulting in dependence. Similar results, showing urinary catheterisation as the least favoured choice, were found in a study of 117 medical inpatients aged 80 years or over, their physicians, nurses and family members [513].

3. CATHETER-RELATED QUALITY OF LIFE

Use of a LTC is often a last choice for bladder management when other options such as CIC, for males a sheath (condom) catheter, or other voiding treatments like Credé procedure, are either unsatisfactory or no longer practical. Catheter users must deal with a variety of problems that disrupt their daily activities and negatively affect QoL, such as CAUTI, blockage, leakage and catheter dislodgment. In addition, the visibility of a catheter or drainage bag can contribute to shame or stigma, and urine odour can be embarrassing. A catheter can also be a reminder of vulnerability associated with illness / mortality and a symbol of a loss in control of bodily function. Yet catheter users also acknowledge catheter-associated benefits of freedom from wetness, convenience, and utility in promoting urine drainage. While this section focuses on long-term catheter use, even short-term catheters can have a detrimental impact on QoL. For instance in a study of short term catheter use prior to surgery for acute urinary retention, leaking, blocking, urgency, and pain at the penis or during erection were all reported [514].

Studies of QoL issues commonly utilise qualitative research methodologies, such as phenomenology or grounded theory approaches (see also Section XII.1.e). In-depth interviews with catheter-users and carers provide important insights into aspects of ‘living with a catheter’ and contribute research based evidence to support development of effective care strategies. Measurement of QoL and the impact of factors which may affect it is complex. Most validated QoL instruments fall into one of two groups: i) generic measures designed to encompass domains including physical, mental and social wellbeing; ii) disease specific measures designed to measure change in QoL resulting from treatment. For those people whose urinary symptoms are managed by products or devices, including catheter users, it is particularly difficult to assess the impact of the product on QoL. This is partially because changes are more likely to be related to improved management of ongoing symptoms rather than actual change in symptoms, and partially because QoL is also dependent on the underlying disease process.

Much of the literature on LTC use involves people with neurogenic bladder, particularly those with spinal cord injury (SCI) or multiple sclerosis (MS). Thus, QoL in catheter users must be considered from a perspective of how the disease and the device affect the individual’s life. For instance, in one postal survey of 230 people with SCI, the factors
which had most impact on QoL were social activities and accomplishments, including employment, attending school, and other activities. There was no association between QoL and different bladder drainage methods [515]. A particular problem for people with spinal cord injury or disease is autonomic dysreflexia (AD), an autonomic nervous system syndrome causing symptoms which include severe hypertension, headache and sweating. A blocked urinary catheter can be a common cause. AD can be a serious problem requiring emergency medical attention, but lack of knowledge and awareness of the risks by some health care providers can cause high levels of anxiety for SCI patients [516] [305] (Level of Evidence 3).

There is currently one instrument measuring quality of life in people with indwelling urinary catheters [269] though this measure was validated in two small samples. Further development and validation are ongoing in the US and in the UK (Level of Evidence 3).

The published literature addressing QoL in catheter-users is small, and is commonly limited to reports addressing levels of satisfaction with a device. Studies which include a broader perspective of QoL are discussed below under the following headings: changes in bladder management, embarrassment, sexuality, catheter-related pain, catheter adjustment, and self-management.

a) Changes in Bladder Management

Changes in bladder management are often made to promote QoL but there are trade-offs that require weighing up the pros and cons of various methods. People sometimes switch from CIC to an indwelling catheter - despite the inherent problems with an indwelling catheter - because quality of life might be improved. In particular, women with cervical spinal cord injury (SCI) may need an indwelling catheter because of difficulties in transferring to the toilet, limited hand dexterity, or dependence on caregivers [517]. Moreover, many people have used different bladder drainage methods over time. In one study, of 30 long-term catheter users, 80% of the sample had used another form, and 33% had used two or three different types [518]. In another small study with a sample of 11, 100% had used another method, and 27% had used two or three other types [306]. Reasons for non-compliance with CIC in relation to QoL or satisfaction have been addressed in Section XII.1.e and in some studies comparing drainage methods (Level of Evidence 3).

Two studies provided additional evidence of how changes in bladder drainage methods are made to improve their quality of life. In a retrospective study assessing compliance with bladder management, 50 new spinal cord injury (SCI) patient records were reviewed after admission, discharge, and follow up from 1994-1997 [517]. Of 38 patients on IC at hospital discharge, 20 (52%) were back to UC at follow up. Six of 10 females on IC had resumed UC. Reasons for not continuing with IC were: the need to depend on caregivers, poor hand functioning, spasticity, incontinence (despite anticholinergic drugs), and for females with cervical injury, toileting inconvenience (Level of Evidence 3). In contrast, a retrospective chart review and follow up questionnaire was used with 236 SCI injured people (at least 10 years post injury) between 1956-1990 [519]. An 85% response rate was achieved in the sample, with 82% males who had tetraplegia (47%) or paraplegia (53%). Although 46% changed their bladder management method over time and 26% considered the method a problem, in 58% of those who had tetraplegia, the use of CIC went up from 11% at discharge to 36%. Suprapubic tapping decreased from 57% to 31% and Crede increased from 5% to 19%. CIC alone, or with other methods, was the most common method (Level of Evidence 2).

b) Embarrassment

Embarrassment and a sense of lack of bladder control are two major catheter-related issues that are ongoing problems for many people. In one study at a US Veterans Affairs Medical Centre, 30% of catheterised patients surveyed found the indwelling catheter embarrassing, and 61% stated it restricted their activities of daily living [107]. The catheter is placed in a position in the body normally considered ‘private’, yet health care providers frequently need access to the site to provide care. Also, the force of urine flow is something that catheter users must deal with on a daily basis. In a qualitative phenomenological study of 14 people with long-term catheters, people told stories of how getting wet in public was embarrassing and how the force of the urine was like water that had built up pressure [516]. They used the metaphor of “flowing water” to describe the force of urine flow, the weight of the drainage bag, and the sound of urine sloshing around in the bag.

Living with the catheter was described in one qualitative study [305] as a swing back and forth between stigma, when it contributed to embarrassment or shame, and acceptance when it was working right and did not cause problems. The catheter became a source of embarrassment during catheter changes, bag emptying, and when it leaked or spilled in public. Individuals used planning and great care when going out (e.g. mapping out the toilets) to prevent urine accidents. They were bothered also by their lack of bodily control, the monotonous care, and how it was a reminder of their condition and mortality (Level of Evidence 3).

Catheter related embarrassment is a common experience stemming from exposure to the opposite sex, the visibility of the urine bag, and unpredictability of urine accidents [520] [521] [305]. Breeches in privacy were identified in two qualitative studies of the lived experience of catheter use [522]
To care providers, catheters may seem commonplace, but male / female sensitivities may occur during catheter care, particularly catheter changes, including men who are embarrassed by a female care provider [520]. Embarrassment can be minimized by providing privacy during catheter changes and same sex care providers when possible [522] [305] [523]. Acknowledging the embarrassment that exists if the nurse is of the opposite sex paradoxically may diminish the vulnerability [305]. Humour is often used by care providers, catheter users, and caregivers, and a professional approach by the health care provider may help the catheter user accept the situation [522] [305] [523] (Level of Evidence 3).

A few studies have examined QoL issues related to practical aspects of living with the catheter, such as managing the drainage bag (See Section VIII). While most people who are self-caring cope with the management of their catheter drainage system, many find them restrictive and report a negative impact on QoL. In a small pilot study based on a postal questionnaire to LTC catheter users (n=59) [525] almost 25% of respondents stated that wearing a bag had a major negative affect on everyday living. Concealment of the bag was one of the most important concerns raised (89%). Keeping the urine drainage bag covered and its visibility minimized can help reduce embarrassment and the stigma related to using a catheter. The visibility of the bag can be considered demeaning and it exemplifies a loss of bladder control [305] [523]. Moreover, if a bag is unreliable, and springs a leak for instance, it contributes to vulnerability. Even using a catheter for a short time can be an assault to one's dignity. In a study in post-operative short-term catheter use, people complained about feeling “on display” and objectified [522] (Level of Evidence 3).

c) Sexuality

In a study of experiences of 25 men with prostate cancer, many of whom were treated with a urinary catheter, subjects reported the catheter contributed to feelings of shame, excess hospital visits for complications, and with other treatments for cancer, an end to sexual activity [526]. Men viewed healthcare professionals as having responsibility for medical decisions and they alone felt responsible for the catheter, micturition, and sexual life (Level of Evidence 3).

Issues related to sexuality were dominant in several other studies. Using a catheter compounded changes in sexual life caused by illness or injury [521] [524]. In one study, catheter users complained that care providers did not provide enough information about sexuality and how to adapt to a catheter [524]. Despite some care provider’s reluctance to address these issues, sexual health should be a part of assessments [527], and information about sexual activity should be provided proactively, while recognizing that some catheter users will wish to engage in sexual intercourse and others will not (Level of Evidence 3-4).

In a study of 20 men in Nigeria with prostate-related obstruction, who used an indwelling catheter from 1-36 months, [528], negative changes in self-esteem and sexuality (manhood) were reported. However, family and friends were instrumental in providing support and encouragement, including financial help and transportation to the hospital. The underlying disease may also impact on sexuality. For instance, a urinary catheter complicates sexual activity in people with spinal cord injury (SCI). Moreover, men may have changes in sexual performance related to ejaculation, erectile function, and arousal [529]. For females with SCI, experimenting with positions, lubrication, and preventing stacuity may be helpful in sexual activity [529] (Level of Evidence 2). For people with SCI, sex-related autonomic dysreflexia (AD) occurs most often in people who suffer from AD during bladder or bowel care [530] (Level of Evidence 2). Autonomic dysreflexia is an autonomic nervous system syndrome that occurs in people with spinal cord injury or disease. Symptoms include severe hypertension and excruciating headache as well as sweating and goosebumps. It can be a serious problem—even life-threatening—requiring emergency medical attention, yet it is sometimes ignored or disregarded by health care providers [516]. A blocked catheter is also a frequent cause of AD. In a qualitative study [524], several people complained that care providers did not know much about AD and often dismissed their anxiety and concerns (Level of Evidence 3).

Promoting sexual health for persons with catheters [531] requires awareness of self (especially in relation to sexuality), training for health care providers, open communication, and advocacy for and validation of patients’ experiences.

d) Catheter-related Pain

Pain related to catheter use is not always recognized although anecdotal information suggests that many people find a urethral catheter uncomfortable (see also Section XII.2 k.3 on catheter comfort and catheter change procedures). In Saint et al’s study [107] 90% of catheterised patients surveyed reported they found the indwelling catheter uncomfortable or painful, and in a study of 43 community dwelling persons [126] 54% reported catheter-associated pain, and in a sample of 20 men who used a catheter for prostate obstruction, 35% had pain [528]. Sometimes women complained about the pain because of sitting on the catheter or sores in the vaginal area [516], however it is unclear whether sores or skin irritation are related to latex sensitivity, friction, or wetness or a combination. Bladder spasms, CAUTIs, blockage, and dislodgement can all contribute to catheter-associated pain, as well as insertion and removal procedures [532] [523] [516].
e) Adjustment to a Catheter

Adjusting to living with a catheter may take a considerable time. In Roe’s study [533] participants reported it had taken them up to a year. Similar lengths of time are commonly reported in anecdotal evidence. An educational booklet for catheter wearers has been shown to significantly improve knowledge and acceptance of the catheter [534]. Though the implications for this type of intervention are positive (Level of Evidence 1-2), the sample was small (n=45) and the study has not been replicated. The core category identified in a study using a grounded theory approach to examine older people’s experiences of living with a LTC was ‘all about acceptance’. Two further categories defined as ‘at ease’ and ‘unease’ reflected the extremes of their experience and these were mediated by ‘interaction with others’ [535]. The presence of a catheter can affect the individual’s view of their own body and such shifts in body image can cause some people to exclude themselves socially. New catheter users (both urethral and suprapubic) may resist the “intrusion of the catheter” prior to acknowledging the need for it [536]. Qualitative studies have shown that although some people felt ill prepared for a catheter, and even viewed it as distasteful, most learned to accept the device over time [536] [523]. Catheter-users have described their changed perceptions of the body and of how they learned to pay attention to urine flow to prevent catheter related problems. Though most acknowledged feeling vulnerable because of disruptions caused by the catheter, they noted also that keeping urine flowing was critical to their wellbeing [537] (Level of Evidence 3).

Health care providers need to provide proactive support and education about the catheter and its care, particularly since some catheter users are uncomfortable in asking for help or support. Male / female sensitivities can interfere; for example, a woman might be disinclined to talk about her catheter with her son [536] [523] (Level of Evidence 3).

Guiding and supporting an individual’s adjustment to living with a catheter involves promoting dignity, supporting the changed body image so that the catheter becomes a part of self (and almost not noticed), and learning self-management and self-care, and in planning for active life in the community. It is essential that catheter users know how to select suitable equipment. Simple advice such as not using a coloured catheter in the summer when white clothing would allow it to show can be very helpful. Knowing where toilets are and planning for outings (rehearsing) can prevent urine accidents [516] (Level of Evidence 3). Ambulatory females who use a belly bag need to face the toilet when emptying the bag. Since this position is associated with male toileting rather than female it can sometimes cause embarrassment. Some women may prefer to use a unisex toilet where possible.

While adjustment takes time, emotional distress with the catheter can swing back into the picture at any time if problems develop. Depending on whether the device is working well or not, people can move back and forth between acceptance and estrangement from the catheter [305] when the problem in the background emerges and brings the issue once again to the foreground [538] (Level of Evidence 3). Learning to live with a catheter involves recognizing that the benefits can outweigh the problems [524], watching for signs of problems, and adjusting to the interpersonal and sexual changes [536] (Level of Evidence 3).

f) Self-management

Self-monitoring, a component of self-management, involves awareness of what to notice and related measurements or observations [539]. Self-monitoring urine flow was found to be helpful in preventing or minimizing catheter-related problems in a pilot study with 11 community-based individuals over a six months’ time [306]. In this study, a 3-day urinary diary of intake and output was combined with an educational program, individualized to the interests of participants. Most participants said they learned to pay attention to urine flow, through observing continuous drainage into the drainage bag, increased awareness of the urine colour, position of the catheter, and by monitoring the consistency of their fluid intake [306]. Health care providers can help catheter users to learn to manage their catheter themselves, (i.e. self-care) by identifying where they are in the process of learning self-care and by working with them [536] (Level of Evidence 3).

g) Summary

Most published studies of patients with indwelling catheters have focussed on short-term catheters (< 14 days) in hospitalised patients and relatively few have compared different modes of catheterisation (urethral, suprapubic, intermittent). The main subject of research on catheter use has been the risk of catheter-associated infection and the surrogate outcome measure of bacteriuria (asymptomatic) is commonly employed. However, there are important questions over the appropriateness of this as an outcome measure. Although there is clear evidence to support a small proportion of catheter care procedures (indicated below) the majority of procedures are based on clinical experience and expert opinion. Long-term studies are difficult to carry out for a variety of reasons (not least the frailty of many long-term catheterised patients) and there are relatively fewer studies based on community dwelling patients. RCTs may not be the most appropriate or pragmatic design for these groups. Although there are now a number of Cochrane reviews relating to...
long-term catheter use it is clear that the quality of studies available frequently precludes drawing robust conclusions.

The published literature on SPC use is still relatively small, with much of it based on single centre cohort or case studies, or on short-term post-operative care following surgical procedures (not necessarily related to lower urinary tract symptoms). The majority of reports on SPC for long-term bladder drainage focus on the management of neurogenic bladder. Robust conclusions are often difficult to reach given the relatively short follow-up time frame of many studies and the lack of precise definitions of key outcome measures such as measurement of infection. Overall the risks associated with short- and long-term use of indwelling catheters are common to both urethral and SPC insertions, including CAUTI, tissue trauma, catheter encrustation leading to blockage, formation of bladder calculi and histological changes.

Quality of life measures, including evaluation of psychometrics, need to be developed further and tested in this population, which may have different needs than others with incontinence. Studies of incontinent people that include catheter users should present data in ways that give the reader information about this sub-population. Sensitivity and a proactive stance from care providers could prevent or minimize some of the stigmatizing effects of the catheter, including those related to privacy needs, dignity, and sexuality. Further product development may help catheter users attain a higher quality of life. Additional research on the effects of self-management/self-care may provide direction for teaching that could contribute to a higher quality of life for catheter users.

4. OVERALL RECOMMENDATIONS RELATING TO CATHETERS

a) Intermittent catheters

• Clean intermittent catheterisation (CIC) is a treatment of choice for those with ongoing bladder emptying problems and residual urine > 100ml who are able to manage the technique (Grade of Recommendation A).

• CIC technique can be taught to all ages of people with appropriate motivation and manual dexterity (or to a carer where this is acceptable to both parties). Appropriate education and ongoing support is needed (Grade of Recommendation C/D).

• Frequency of catheterisation needs to be based on individual need, to prevent over-filling of bladder (Grade of Recommendation C).

• An external lubricant or lubricant-coated catheter is recommended to minimise urethral trauma (Grade of Recommendation C).

b) Indwelling catheters

• Indwelling catheters should only be used after alternative management strategies have been considered and rejected as unsatisfactory (Grade of Recommendation A).

• Duration of catheterisation should be minimal (Grade of Recommendation A).

• A closed drainage system should be maintained to reduce risk of catheter-associated infection (Grade of Recommendation A).

• Asymptomatic bacteriuria should NOT be treated with antibiotics (unless urological instrumentation is planned) (Grade of Recommendation B).

• Routine urine culture in an asymptomatic patient is not recommended (Grade of Recommendation C).

• Silver-alloy catheters should be considered for short-term catheterised patients to reduce the risk of catheter-associated infection (Grade of Recommendation A) but further economic evaluations are required to determine cost-benefit to institutions.

• Catheter materials designed for long-term use (all-silicone, silicone or hydrogel-coating) should be used where a catheter is expected to be used long-term (i.e. >14days) (Grade of Recommendation B).

• Meatal cleansing with plain soap and water (not with antimicrobial agents) is recommended (Grade of Recommendation A).

• Addition of disinfectants to drainage bags, bladder irrigation and antibiotic prophylaxis are NOT recommended as routine infection-control measure (Grade of Recommendation A).

• If an indwelling catheter is being considered, SPC should be considered alongside UC, following appropriate risk assessment (Grade of Recommendation B).

• UC and SPC insertion should be carried out only by appropriately trained and skilled practitioners using aseptic technique (Grade of Recommendation C).

• UC and SPC catheters and drainage bags should be adequately supported to prevent meatal or cystostomy damage from traction (Grade of Recommendation C).
c) Catheter valves

• A catheter valve can provide an effective means of catheter drainage following appropriate patient assessment (Grade of Recommendation B).

• A combination of a valve during the day and free drainage at night through an open valve connected to a drainage bag could be an appropriate management strategy (Grade of Recommendation D).

5. PRIORITIES FOR RESEARCH

a) General

• Despite much published research (primarily on short-term catheter use in acute care settings), catheter studies have been hampered by methodological weaknesses. There is a need for agreement on key criteria to permit robust comparisons between studies: (i) criteria for symptomatic UTI, (ii) significant bacteriuria in a catheterised patient and its clinical/research usefulness (iii) standardised time frames for following patients in studies of catheter-associated infection eg 48h, 5 days, 7 days, 14 days 21 days etc (iv) documentation of the use of antibiotics prior to and during a study eg preoperatively in surgery or commencement of antibiotics for other conditions during the study, (v) patient follow-up to include post catheter removal.

• A standardised definition of UTI should be adopted as the primary outcome variable. At present the most recent CDC/NHSN surveillance definition of health care-associated UTI is an example [379]. Although criteria for both symptomatic UTI and asymptomatic bacteriuria are defined by the CDC/NHSN, it should be recognised that definitions are applicable to non-catheterised populations and specific to acute care settings and additional definitions apply to catheterized patients [342].

• Moreover, definitions which distinguish between asymptomatic and symptomatic infection in catheterized patients can be prone to coding errors. Inappropriately treated asymptomatic bacteriuria confounds the errors [540] and contributes to a lack in knowledge of effective ways to treat symptomatic CAUTI [541].

• Better adherence to CONSORT guidelines [542] eg double blind randomization with appropriate power calculations, intention to treat analysis with inclusion of study drop-outs

• Need for clinical studies which are adequately powered to detect differences in clinically and economically important endpoints in preference to (or in addition to) more easily measured surrogate endpoints such as bacteriuria.

• Comparative studies of different patient groups eg. males and females, different age groups, patients at home and those in institutional care, including patients’ comfort, satisfaction and quality of life measures.

• Further research on the development of biomaterials that resist microbial adherence and biofilm formation and /or prevent catheter-associated bacteriuria in both long-term and short-term catheter users.

• Further efforts aimed at reduction of short and LTC use, particularly acute care and nursing home populations. Targeted areas to include evaluation and management of skin problems, and alternative measures for people with diabetes mellitus, obesity and communication problems.

b) Intermittent catheters

There is lack of evidence demonstrating the effectiveness of any particular catheter type, technique or strategy. Variations in clinical practice and growth in the use of single-use catheters (particularly coated catheters) with associated increased costs mean that large, well-designed, parallel group RCTs are needed. RCTs are difficult to conduct in this area and must focus on the most important pragmatic questions, for both clinical and cost-effective reasons. Key issues are identified below.

• What evidence is there that coated (single-use) catheters are superior to uncoated (multi-use) catheters and in what ways (e.g. infection, comfort, convenience)? Further studies are needed on the risks / benefits of single use catheterisation (new catheter used at each insertion) versus single patient use (patient cleans, stores and re-uses the same catheter for several days) for patients whose long-term bladder management is by CIC.

• To assist assessment of cost-effectiveness, it is recommended that patient acceptability / satisfaction with procedure and a measure of health state utility are measured for different situations (e.g. at home and when away from home) as a secondary outcome variable.

c) Indwelling catheters

• Epidemiological studies of CAUTI in LTC use in community care settings.

• Better prospective data on long-term sequelae of indwelling catheter use, eg ongoing symptoms, strictures, calculi, bladder cancer.
XIII. PRODUCTS FOR PREVENTING OR CONTAINING FAECAL INCONTINENCE

The broader issues of conservative management of faecal incontinence are dealt with comprehensively in chapter 16 while this chapter deals with products for preventing or managing faecal incontinence. They fall into three main categories:

- Products that aim either to prevent or contain leaked stool.
- Products that seek to prevent or mask the offensive odour that occurs from leaked stool or flatus.
- Products for preventing or treating perianal skin damage associated with faecal incontinence (one of the primary complications of faecal incontinence and an important part of care).

Products dealing with skin health and odour are covered in Sections XIV and XV, respectively, while products for preventing or containing faecal incontinence are covered in this section (apart from absorbent pads, which are included in Section VI).

1. PRODUCTS TO PREVENT OR CONTAIN LEAKED STOOL

There is little knowledge about product management for people suffering with faecal incontinence. Peden-McAlpine et al. (2008) [543] show in their study the experiences of ten women with faecal incontinence. They show how a number of strategies, such as: bathroom rituals, eating habits or fibre supplements belong to the management strategies of the affected, so that they may actively participate in a normal public life. The use of aids is also a major strategy as Bliss et al. (2011) [544] also show. More than 1/3 of those questioned (189 participants) would no longer pursue their activities, when they had no aids at their disposal. Thereby, those who suffer seriously with faecal incontinence resort to absorbent aids, particularly to pantiliners from the range of feminine hygiene products. First and foremost of importance for the study participants was odour control, however, when asked about their satisfaction with various aspects of the product, they ranked odour control as the worst.

Products fall into three groups:

- Plugs to prevent leakage of faeces.
- Devices to channel faeces from the rectum into a storage container.
- Absorbent pads to contain leaked faeces (see Section 6).

An anal plug (Figure XIII-1) consists of a foam, cup-shaped plug that is collapsed and held by a film for insertion; the plug opens when the film comes in contact with the moist rectal mucosa [545] [546]. It is inserted like a suppository using a lubricant gel. It has a string for removal or it can be expelled by raising intra-abdominal pressure and pushing like during normal defaecation. The anal plug has been used mainly by community living people, both adults and children, who are independent in managing faecal incontinence and toileting. Another type

**d) Catheter valves**

- Clinical investigation of effect of catheter valves on incidence and frequency of catheter encrustation and blockage.
- Cost-effectiveness studies of disposable versus re-useable valves.
- Studies designed to demonstrate if catheter valves promote maintenance of bladder tone and capacity.
- Further examination of combination management strategies such as valve during the day and free drainage overnight.

**e) Quality of life**

- Identification of appropriate quality of life indicators/criteria and measures for catheterised patients.
- Development of a quality of life measurement instrument including both subjective measures and objective measures, including factors such as: frequency of catheter blockage, catheter-associated infection, hospitalization, unplanned catheter changes, adequacy of equipment, knowledge about self care, interaction with caregivers in catheter management.
- Case study analyses to maximise evidence gained through clinical experience and expert opinion, particularly where opportunities for formal research are likely to be unrealistic.
of experimental anal plug consists of a balloon at the end of a catheter connected to a notification device. The catheter is intended to be inserted into the rectum by the user and the inflated balloon acts as the anal plug; there are also vent holes on the distal tip of the catheter (Figure XIII-2). The disposable, double lumen, balloon-cuffed rubber catheter has an infra-red photo-interrupter sensor that is connected to a pager [547]. When faeces enter the rectum, a photosensor signal is sent to the pager which then notifies the person to inflate the balloon. Before a bowel movement, the balloon is deflated and the catheter is withdrawn. To prevent ischemic bowel damage, patients are advised to deflate the balloon for 10-15 min every 3-4 hours.

By contrast, devices for channelling faeces from the rectum to a storage container are used primarily by people who are acutely ill, critically ill, confined to bed, or in long-term care institutions and receive assistance in incontinence management and toileting by caregivers [548] [549] [550] [551] [552]. These devices do not prevent faecal incontinence and are used primarily for preventing or treating skin damage associated with faecal incontinence. They include rectal tubes, catheters, trumpets, and pouches.

Rectal tubes and catheters are inserted into the rectum and drain faeces through openings at their proximal end into a collection bag (Figure XIII-3). Sometimes a balloon slightly distal to the proximal tip is inflated with the aim of preventing leakage of faeces around the catheter and to retard inadvertent expulsion of the tube during defaecation [549]. This arrangement works best with liquid stool which is most likely to be able to flow without blocking the drainage lumen [553] [552]. Bowel management programs often include daily saline irrigations through the rectal catheter to maintain liquid consistency of stool and catheter patency. Differing amounts and frequency of irrigation have been reported (300 to 900 ml). Cutting the tip of the catheter off at an angle to facilitate drainage of stool of thicker consistency has been reported [554]. A rectal tube / catheter is contraindicated in patients who have intestinal mucosal disease, immunosuppression, gastrointestinal bleeding or bleeding tendencies, recent myocardial infarction or prostate surgery [555] [554]. Use of a rectal tube with or without inflating the balloon is controversial because of concerns of perforating the rectum, damaging the anal sphincter or rectal mucosa, stimulating intestinal secretion worsening diarrhoea and thus incontinence [553] [554] [556]. Critically ill patients, who often receive a rectal tube, may be at greater risk for intestinal ischemia and rectal damage because they experience shunting of blood from the gastrointestinal tract during shock or low perfusion states.

A rectal trumpet is a nasopharyngeal airway that is inserted into the rectum and connected to a collection bag at its distal end. The flange end of the trumpet is inserted into the rectum [557] (Figure XIII-4). A possible advantage of the rectal trumpet over a rectal tube is that it is shorter and has less contact with the rectal mucosa, so limiting the area of possible damage. Other limitations are similar to those for the rectal tube / catheter regarding risk of expulsion from forceful valsalva movements and dislodging during linen changes or from tugging on the collection bag [557]. Nasopharyngeal airways that can be used as a rectal trumpet are produced by several manufacturers.

An external anal pouch consists of a pliable wafer, which has an opening at its centre, an adhesive on the body side, and a collection bag on the other. The wafer adheres to the perianal skin (Figure XIII-5).
The bag has a resealable port at its distal end through which faeces can be drained without the need to remove the wafer from the skin. The port can also be connected to a larger, gravity drainage bag. Some pouches have a small folded flap that allows flatus to escape so that it doesn’t inflate and rupture the bag. The pouch avoids the risks of rectal or sphincter damage associated with the rectal tube or trumpet. If used without the additional drainage bag, it can collect leaked stool of any consistency without clogging. A limitation of the rectal pouch is difficulty in applying it on people who have a small space or severe oedema between the anus and vagina or scrotum. Other reported disadvantages include difficulties in maintaining the seal (especially when the perianal skin is already damaged); break of the seal when repositioning the patient; and skin tears by traumatic removal of the adhesive [557] [551].

An intra-anal stool bag is composed of a latex bag (20cm non-extended, to 26cm extended) that is inserted into the anus and an adhesive attachment (10 cm in diameter) applied perianally [558] (Figure XIII-6). There is a cut-out on the ventral urinary side of the adhesive wafer.

Aspects of patient assessment that are relevant to products to prevent or contain leaked stool include the following: a) physical characteristics (e.g. some anal plugs may be too large to fit smaller sized children), b) dexterity (e.g. some degree is needed to insert or remove an anal plug), c) mobility (e.g. rectal catheters are mainly used for patients who are in bed versus ambulatory), d) nature of incontinence (e.g. bowel catheters will require irrigation when stool consistency is not loose or liquid in order to remain patent; and e) personal priority and lifestyle (e.g., some persons will wear an anal plug on certain occasions such as when swimming, despite discomfort).

2. QUALITY OF DATA

Since the previous review there have been two observational studies in which the anal plug has been evaluated. One study was of adults [559] and...
3. RESULTS

a) Anal Plugs

Most evaluations of anal plugs have involved relatively small cohorts of ambulatory subjects. The largest sample had 48 subjects and 26 of 31 persons in the intervention group who wore the anal plug completed the study [563]. The aetiologies of faecal incontinence varied across studies and included spina bifida, imperforate anus, spinal injury, post-surgical incontinence, sphincteric injury, and obstetric trauma. Faecal incontinence was measured by self-report using a daily stool diary in six studies [563] [562] [547] [545] [546] [564]. A questionnaire /survey was used in one descriptive [565] and one repeated measures study [561]. The main reported outcome measures were: the number of episodes of faecal incontinence per number of anal plugs used due to self removal or need for defecation [545]; the number of patients experiencing no faecal incontinence [564] [562] [561] [546] [560] or improved faecal incontinence [546] while using the plug; score on a 10-point visual analogue scale for control of faecal leakage, [559]; the number of patients able to retain 150 ml of viscous fluid while using the plug [564]; and the change in a faecal incontinence severity score [563] [547]. The percentage of participants lost to follow-up ranged from 10% [545] to 80% [564].

The effectiveness of the plug in preventing faecal incontinence in adults ranged from 83% [564] to 38% [562] (Level of Evidence 3). Bond et al [563] conducted a randomized clinical trial of the effectiveness of an anal plug that included 31 adults and children with spina bifida in the treatment group and 17 adults and children in a control group; 84% of the treatment group and 100% of the control group completed 12 months of follow-up. There was no statistical difference in the faecal incontinence severity score between the group wearing an anal plug and the one that did not; however, the study was determined to be underpowered to detect differences. Norton and Kamm [546] compared two anal plugs for two weeks each in random order in a cross-over design. Of the 20 adults (16 female) participating, 10 (50%) were continent, and 9 (45%) withdrew after trying the first plug. Three anal plugs were compared by 10 adults for one week each in a cross-over design in an earlier study by Mortensen and Humphreys [545]. Continence was achieved in 83% of anal plug uses overall. Faecal incontinence occurred in 18%, 19% and 15% of uses when Plug 1, 2 or 3 were worn, respectively. Only one subject withdrew from the study. In a pre-post comparison of an anal catheter plug, seven of 18 adults (39%) with various aetiologies of faecal incontinence and a Cleveland Clinic FI severity score >7 completed a 14-day wear period [547]. The mean (standard deviation (sd)) faecal incontinence score during wear of the anal plug (5.2 (3.0)) was less than half that before its use (12.7 (3.6)). Thirty middle-aged patients (aged 63 (52-70) years (mean (range)) with intractable FI of various aetiologies tested the anal plug for three weeks; the score for control of faecal leakage on a visual analogue scale (1= very poor to 10= extremely good) was 9 (median) after 1 and 3 weeks of using the plug [559]. Christiansen & Roed-Petersen [564] reported that 86% of persons were able to retain 150 ml of viscous fluid while an anal plug was inserted.
In the study of children only, 38 children (ages six to 15 years) after anorectal malformation repair compared two anal plugs (one made of polyurethane and one of polyvinyl alcohol) for three weeks each in random order in a cross-over design. Approximately two-thirds (61%) completed the study. Twelve children (32%) were completely continent using either plug and five (13%) reported “total failure.” Two or fewer soiling accidents occurred in 74% using the polyurethane plug, and in 65% using the polyvinyl alcohol plug [561].

In a study of 20 children and adults with spina bifida, average age 12 years (range = 4-29 years), the weekly number of episodes of FI soiling decreased from 4 (0-28) to 0 (0-8) (median (range)) after using the anal plug [560]. A survey of adults and children showed that a higher percentage of children tolerated using an anal plug over a longer period of time [565]. Five of eight (63%) adult respondents who had faecal incontinence of various aetiologies stopped using an anal plug immediately while three used it periodically for 12 to 20 months. Two of seven child respondents stopped anal plug use immediately while five (71%) used it weekly for an average of 2.5 years.

The most common reported problems associated with wearing an anal plug included discomfort and failure to retain the plug. Despite efficacy, approximately two-thirds of the subjects in two studies [564] [546] said they would not continue to wear the plug due to discomfort. Discomfort occurred in 10% to 12% of the times that one of the three anal plugs were worn in another study [545]. In more recent studies, 23% and 33% of subjects reported discomfort [563] [560] and 23-25% withdrew from studies because of pain [562] or discomfort [560]. More men than women withdrew from one study because of discomfort [559]. Adults who experience discomfort do not seem to adapt over time [559]. After three weeks of wear, adults reported a score on a ten-point visual analogue scale for comfort while inserting the anal plug was 7 (5-9) and while removing it was 8 (7-10) (median (range)). There was no association between comfort of the plug and anorectal sensitivity during anorectal physiology tests in adults [546]. Children seem to experience less discomfort than adults while wearing the anal plug. [561] [559]. Approximately 20% of children reported that insertion of the polyvinyl alcohol plug was painful while 17% found removal of the polyurethane plug to be painful; one child experienced bleeding on removal of this second plug. Rectal bleeding also occurred in adults but infrequently [545].

Failure to retain the anal plug was reported by 13% of subjects in two studies [563] [562] and was noted by one child in the paediatric study as a reason for withdrawal [561]. The size of any plug tested was too large for six children in one study [561]. Twenty-seven of 30 adult subjects preferred a small size anal plug [559]. Other tolerance problems were fairly uncommon. In one study, adults rated all three anal plugs that were evaluated as relatively easy to insert. Two plugs were difficult to remove in only 5% and 6% of uses, respectively, while the third was difficult to remove in 23% of uses [545]. Other reported problems were feeling a need to defecate [546], inconvenience or difficulty in managing [546] [547], and local irritation [565].

### b) Rectal Trumpet

One case series study evaluated the use of a rectal trumpet in 22 acutely or critically ill patients with faecal incontinence and perineal skin damage [557]. For 90% of the subjects, the skin damage had been caused by wearing a rectal pouch immediately prior to the study. Subjects used the trumpet for periods varying between 36 hours and 16 days (mean 6.5 days; sd 4.4 days). The reasons for any discontinuation of use were reported. Outcome was determined using a daily questionnaire completed by patients’ nurses and the health of the perianal skin was noted by subjective assessment. No standardised definitions or criteria for restoration of skin integrity or healing of skin damage were reported. Two subjects were lost to follow up. Faeces were successfully diverted to and contained by the collection bag in all patients. Recovery from skin damage was reported in 7 (39%) patients and partial healing of skin in the remaining 11 (61%). Discomfort on insertion was noted for 41% of subjects (Level of Evidence 3).

### c) Rectal Catheter Systems

Closed rectal catheter and collection bag systems specifically designed for extended use and diversion of faeces are commercially available, primarily for acutely-ill or bed-ridden patients (Flexi-Seal™ and Flexi-Seal™ Signal™ Faecal Management System, Convatec A Bristol Myers Squibb Company; Princeton, NJ; Actiflo Indwelling Bowel Catheter (formerly Zassi® Bowel Management System); Hollister, Inc., Libertyville, IL; Dignicare® and Dignishield™ Stool Management Systems, Bard Medical). The catheters of these systems typically contain a retention cuff that collapses to assist with insertion (US FDA approved for up to 29 days) and a port for irrigation. In one system (Acti-flo) there is also a collapsible zone below the cuff that resides in the anus to allow normal anal sphincter function during use and a second port for sampling intestinal fluid. A third catheter has an inner balloon that can be inflated to serve as an anal plug to promote retention of an enema, for instance (Kim, US Patent 5 569 216, apparently not currently commercially available).

Six studies evaluated use of a rectal catheter system. Three studies used one type of catheter while the other three studies used three different types of systems. One study was of children [566]. The designs included a prospective single cohort in four studies [548] [567] [549] [566], a pre-post descriptive design [568], and a retrospective case-matched
pre-post design [569]. The largest sample size was 106 in the retrospective chart review whereas sample sizes in the prospective studies were relatively small, ranging from 20 to 42 subjects. In the studies of adults, subjects were burn patients in two studies [567] [569] and acutely or critically-ill patients in three studies [548] [568] [549]. In three studies, irrigation of the catheter with saline, a combination of lactulose and saline irrigation or use of an enema was used to keep the stool liquid and the rectal catheter patent [567] [569] [549].

In only two studies was the effectiveness of the rectal catheter system in reducing faecal incontinence reported (Level of Evidence 3). In the one paediatric study, 31 children (11 females) participated. Eight families refused to stop using the rectal catheter to complete an incontinence diary without use of a catheter. Two children had balloon extrusions and three were noncompliant resulting in their study withdrawal. The mean number of daily faecal incontinence episodes as reported on a daily diary decreased from 3 to 1.5 in males and from 1.6 to 1.1 in females (p<0.05 for both) [566]. Three children experienced no improvement of faecal incontinence. In the one adult study, 39 of 42 subjects (62% female) with diarrhoea in intensive care units in seven hospitals completed the study. There was up to 29 days of follow-up. Varying degrees and types of leakage around the rectal catheter were reported in 71% of 198 assessments; 35% of these leakages extended to pads on the bed or beyond [548]. Seven (17%) of subjects had difficulty retaining the rectal catheter. Section 6.11 discusses use of a small gauze dressing for absorbing small amounts of stool leakage and a moisture barrier as skin protective strategies that might also help prevent damage from stool leakage around a rectal catheter. Skin damage from the tape holding the catheter in place and rectal bleeding are other reported but uncommon complications [567] [548].

The effect of a rectal catheter on various outcomes associated with stool leakage has also been studied. Two studies reported costs savings in terms of reducing laundering of soiled bed linens. One study reported that the number of bed linen changes in burn patients with diarrhoea decreased eight-fold and dressing changes in hospitalized or burn patients decreased in half after a bowel system was introduced [567]. A multi-site study of 146 bedridden patients in the U.S. showed that one catheter (Hollister, Inc) reduced the rate of bed linen changes (1.2 changes per day) more than another (1.7 per day) (Convatec). Estimates of cost savings based on staff time and laundry costs was almost $14 USD per patient per day [570].

Other outcome measures of rectal catheter use included urinary tract infections, incidence of skin / soft tissue damage or infections, prevalence of pressure ulcers, and number of linen changes (Level of Evidence 3/4). In a retrospective review of medical records, approximately twice as many burn patients had skin / soft tissue or urinary tract infections before a bowel catheter system was introduced than after (p<0.01) [569]. A prospective study of acutely and critically-ill patients showed that 41% who had normal skin in the perineum or buttocks at baseline maintained normal skin during use of the bowel catheter, 44% with some degree of skin damage improved, and 8% had worsened skin condition [548]. The percentage of intensive care unit patients with a stage II or greater pressure ulcer was observed to be less at nine months after use of a bowel catheter was introduced. The total number of patients observed was not reported. The length of time during which the prevalence of pressure ulcers was determined prior to catheter use was also not reported [568].

The condition of the rectal mucosa was observed endoscopically in 40 patients total across three studies; the evaluations were not blinded or independent and did not use a rating scale [548] [567] [549]. All endoscopic observations were reported as being normal after rectal catheter use. Few complications associated with use of the rectal catheter system were reported in one study. Leakage around the rectal catheter seemed to be the most frequent problem. Catheter expulsion occurred in a small number of patients and skin damage from trying to secure the tube occurred only in one patient. Altered rectal sphincter function occurred using one of the catheters [549]. As the catheters are used more widely in clinical practice, there are more case reports of complications including rectal or lower gastrointestinal bleeding and need for blood replacement, mucosal pressure necrosis, fistula, and autonomic dysreflexia [571] [572] [573] MAUDE http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfmaude/search.cfm. (Level of Evidence 3).

d) Anal Pouch

One case series study evaluated the use of an external anal pouch (Technoline, Concordia, Moderna, Italy) in 120 nursing home or hospitalized patients (65 men, 55 women, ages 45-96 years) [574]. The nursing home residents (n = 92) were bedridden and had faecal and urinary incontinence or were treated for constipation for rectal enemas that drained into the pouch. Ten had a pressure ulcer. They used the pouch for four weeks or more. Acute care patients (n = 28, of which 10 were in the intensive care unit) had diarrhoea and were temporarily bedridden. Forty-five patients who had surgery of the perineal area received a pouch to collect post-surgical drainage for up to three days. In the nursing home residents free of pressure ulcers, no new ulcers developed. In those with a pressure ulcer, healing occurred in five residents, ulcer diameter was reduced by 50% in three residents, and there was less than 50% reduction in two residents. Of the nursing home and acute
care participants, 77% found the pouch comfortable and 75% thought it was better than a sanitary napkin. Seventy-seven percent of the nurses thought the anal pouch was easy to apply and 78% thought it was easy to remove. Reported complications included moderate pain on removal in 18 (15%) patients in the nursing home or acute care (Level of Evidence 3).

An internal anal stool bag (Terumo Corp., Tokyo, Japan) was applied to five bedridden patients (3 female, 2 male) aged 68-90 years [558]. Persons were administered a biscodyl suppository prior to insertion of the stool bag into the anus to control excretion of faeces. The bag was successful in collecting stool 50% of the time (Level of Evidence 3). The bag was removed after each stool was collected.

Bliss and Savik (2008) [88] carried out a study, to examine the use of a surgical dressing to absorb a small leak of feces. These anorectal dressings can be placed between the buttocks. Of 28 people who had faecal incontinence, 27 had used the dressing and 23 of them wanted to continue to use it. 79% reported no skin complications, and 80% of the participants rated their confidence in its effectiveness as very good to good. Use of the dressing lessened anxiety about faecal soiling in 81% and was thought to improve quality of life in 76%. The authors stated that new types of absorbent products will become available.

4. SUMMARY

- An anal plug can successfully prevent faecal incontinence but it is associated with high levels of discomfort, more so in adults than children (Level of Evidence 3).

- A rectal catheter system diverts faeces to a collection bag and promotes healing of damaged perineal skin but requires liquid stool consistency to remain patent. Some catheter systems enable irrigation of the rectum to maintain liquid stool consistency.

- Non-blinded and non-independent endoscopic observations suggest the rectal catheter does not cause rectal mucosal damage during the recommended length of use (≤ 29 d in the US). As rectal catheter usage increases in clinical practice, case reports of complications have become evident; among the common ones reported are perianal skin damage, rectal bleeding, and mucosal pressure necrosis. (Level of Evidence 3).

- A rectal trumpet can successfully channel faeces to a collection bag and there is some evidence that it can thereby enable damaged perianal skin to recover but it has been associated with discomfort and its safety has not been determined (Level of Evidence 3).

- An external anal pouch and an internal anal bag can be used to collect stool (Level of Evidence 3) but the adhesive wafers used to adhere them can cause skin damage upon removal. The internal anal bag has been primarily used when a bowel movement is induced using a suppository.

5. RECOMMENDATIONS

- Anal plugs may be tried but many patients are likely to use them on a limited basis or reject them due to discomfort (Grade of Recommendation C).

- The use of a rectal trumpet (i.e. a nasopharyngeal tube inserted into the rectum) in patients with loose / liquid stool consistency offers an alternative to the rectal pouch when pouch adherence is a problem and may preserve perianal skin integrity or facilitate healing (Grade of Recommendation C). The safety of the rectal trumpet has not been determined, but it suggests a lower risk due to its shorter length than a standard, longer rectal tube (Grade of Recommendation C).

- Use of a standard rectal tube with and without an inflatable balloon for faecal diversion is indicated primarily for non-ambulatory patients with liquid stools (Grade of Recommendation C).

- Use of an anal pouch attached to a drainage catheter to divert liquid stool is recommended, but there is a risk of skin damage. For this reason it is not recommended in cases where skin is already damaged or the need for faecal diversion is less acute (e.g. where stool is more formed) (Grade of Recommendation C).

6. PRIORITIES FOR RESEARCH

- Development of an anal plug that is more comfortable and tolerable.

- More rigorous evaluation of anal plugs using larger subject cohorts and more objective outcome measures over longer periods of use.

- More rigorous evaluation of rectal tubes / catheters and trumpets using larger subject cohorts and more objective outcome measures (e.g. for assessing health of the rectal mucosa) over longer periods of use.

- Development and evaluation of an external anal pouch that is easy to apply and remove, adheres to skin better and, perhaps, even promotes healing of damaged skin to which it would be applied. Further evaluation of an internal stool bag with similar adherent properties (as recommended for the external anal pouch) is needed.

XIV. SKIN HEALTH AND CONTINENCE PRODUCTS

1. BACKGROUND

The skin of an incontinent individual will be regularly exposed to contact with urine and / or fae-
ces and damage to the skin is the main physical health consequence of urinary and faecal incontinence. The majority of current knowledge about the effects of urine and faeces on skin has been obtained from studies with pads or pad materials on animals, healthy infants, and on body areas such as the forearm or back of adults. Where clinical trials have been conducted, they have usually been on infants and rarely on adults using pads. Skin irritation within the pad occlusion area is usually termed diaper dermatitis in infants. In adults the term perineal dermatitis (PD) has commonly been used, but more recently it has been proposed that incontinence-associated dermatitis (IAD) is a better term because affected skin areas are not confined to the perineum [575] [576]. A consensus panel in 2005 defined IAD as ‘erythema and oedema of the surface of the skin, sometimes accompanied by bullae with serous exudate, erosion, or secondary cutaneous infection [577] and this term and definition has been widely used since then [578] [575] [579]. More recently IAD has been classed as a sub-category of ‘moisture-associated skin damage’ (MASD) which includes intertriginous dermatitis and peristomal and periwound moisture-associated dermatitis [579] [580].

Literature reviews and consensus papers

There has been considerable interest in IAD over the last few years, particularly with regard to its definition and aetiology and there have been three review/consensus papers on the subject [578] [575] [579] and one focusing on the prevention and treatment of IAD [581].

a) The role of urine and faeces in skin irritation

Prolonged exposure to water alone has been shown to cause hydration dermatitis [582] [583] and prolonged occlusion of the skin (as within a continence product) has been demonstrated to reduce skin barrier function [584] and significantly raise microbial counts and pH [585] [586]. Repeated wetting and drying makes the skin more vulnerable to substances that are usually innocuous, e.g., bile salts [587] [588]. A product that simply maintains wet and occluded skin (even without the additional constituents of urine and faeces) is therefore likely to cause skin irritation and increase skin permeability to other irritants.

Using a hairless mouse model Buckingham and Berg [589] examined the role of faeces in the aetiology of diaper dermatitis. They identified proteases and lipases as the major irritants and noted that these faecal enzymes not only irritated the skin directly but also increased the susceptibility of the skin to other irritants such as bile salts. The irritant effect of faeces was virtually eliminated by heating, which destroys enzymes, and was restored by the replacement of specific enzymes [e.g. lipase and protease]. Skin damage appeared dependent on the concentration and length of exposure to enzymes in faeces [590].

A similar mouse model was used by the same researchers to examine the role of urine in the aetiology of diaper dermatitis [588]. They found that the irritant potential of urine by itself was minimal over short periods (48 hours) but after continuous exposure (10 days), skin damage became apparent. The researchers also measured skin permeability and found that continuous exposure to urine greatly increased skin permeability (more than 15 fold) compared to occluded skin or skin exposed only to water.

However, the combination of urine and faeces caused significantly higher levels of irritation than urine or faeces alone. The authors concluded that the presence of faecal urease results in the breakdown of urinary urea causing an increase in pH, which increases the activities of faecal proteases and lipases leading to skin irritation. The role of microorganisms - which comprise approximately 50% of the solid component of faeces - in skin damage is unresolved. Microorganisms on the skin of infants with and without diaper dermatitis were similar [591]. Zimmerer [592] sampled the microflora of the skin before pre-loading with pre-wetted patches containing urine and found that the microbial counts were significantly higher for wet patches relative to the dry patch controls. It was nearly impossible to establish infection with the opportunistic organism, Candida albicans, on normal skin without complete occlusion of the site [593]. Therefore, it is thought that bacterial or fungal infection is secondary to alterations in the skin barrier that allow penetration of the microorganisms [594].

Zimmerer et al. [592] examined the role of skin wetness in the development of diaper dermatitis by using the volar forearms of adult volunteers. They aimed to determine the effects of wet and dry diaper materials on skin health with respect to friction, abrasion damage, permeability and microbial growth. Pre-wetted patches of baby diapers were placed on the volar forearms of adults for two hours and then the skin was subjected to friction and abrasion. The coefficient of friction for the ‘wet’ skin was significantly higher than for ‘dry’ skin although increased fluid loading of wet patches did not further increase skin friction. Similarly, skin hydrated with a wet patch showed a significant increase in skin abrasion damage relative to a dry patch. Again, variations in the fluid loading of the patch did not produce significant changes in abrasion damage.

Although the volar forearm is most commonly used for skin experimentation, it has not been shown to be a valid model for the skin exposed to an incontinence pad, i.e. buttocks and groins. Schnetz and colleagues [595] demonstrated that trans-epidermal water loss (TEWL) measurements (used to measure both skin barrier function and excess water in the skin) from the volar forearm did not correlate with those taken from the face, although the left and
right side of the face showed good correlation. The researchers concluded that TEWL measurements for the study of facial cosmetics should be taken from the face rather than the forearm. Similarly, studies using the volar forearm may not be valid for the buttocks and groin. Skin in the perianal area was shown to be more sensitive to faecal irritation than that on the inner arm [596].

Recently Fader and colleagues (2010, 2011) [597] [598] reviewed the literature on measurement of TEWL for assessment of overhydrated skin and found that there was a lack of standardization in all components of the method including the analysis and interpretation of findings [597] and they describe the development and testing of a more valid and robust method and compare measurements made on younger and older women and on volar forearm and hip skin. The authors conclude that age did not significantly affect measurements but those made on the hip were consistently higher and more variable than those made on the forearm. It is recommended that the forearm is used for future work.

Berg [588] analysed the aetiological factors contributing to infant diaper dermatitis and developed a model (Figure XIV-1) to show its development and resolution. However, the applicability of this model to adults with incontinence has not been tested, and other factors such as low mobility and prolonged pressure - which are common in frail, older adults - are not accounted for in this model. In addition, this model assumes the presence of urinary and faecal incontinence, which is much less common in adult populations than urinary incontinence alone.

### b) Prevalence of incontinence-associated dermatitis / perineal dermatitis

Incontinence-associated dermatitis (IAD) has been defined most recently as “an inflammation of the skin occurring with or without erosions or secondary cutaneous infection”. Perineal dermatitis (PD) is an inflammation of the skin characterized by redness, tissue breakdown or denudement, vesiculation, oozing, crustng, soreness, itching, and in its more severe form, pain and fungal patches [599] [600] [575] within the pad area. In the largest study of assessment records of more than 59,000 residents in 510 nursing homes located in 31 US states, Bliss et al. [601] reported a prevalence of perineal dermatitis of nearly 6%. In studies with smaller sample sizes and other populations, perineal dermatitis (Table XIV-1) has been shown to affect about a quarter to a half of patients.

Recently there has been further clinical evidence supporting the role of faeces in the development of IAD. Bliss et al (2011) [544] studied the development of IAD in 45 critically ill adults in three critical care units. Most (76%) were male and all were free of IAD at the start of the study. IAD developed in 36% of patients and the median time to onset was 4 days (range 1-6). Severe IAD (denudement) occurred in 9% of the observed time. Frequent incontinence of loose or liquid stools and diminished cognitive awareness were significant independent risk factors for development of IAD sooner.

Shigeta and colleagues (2011) [610] studied the skin of 100 older Japanese patients in a nursing

---

**Figure XIV-1: Berg’s model of diaper dermatitis (1987).**
home who had faecal and/or urinary incontinence and wore absorbent products. Multivariable logistic regression analysis showed that the presence of diarrhea was an independent risk factor.

Bliss et al. [611] prospectively investigated the development of IAD using assessment data of 1,850 elders who were free of IAD at admission to a nursing home. The preliminary report showed that at three months after admission, faecal incontinence alone and double incontinence were significant predictors of IAD, but urinary incontinence alone was not a significant risk. The prevalence of IAD appears to be influenced not only by the type of patient (nursing home versus hospitalized) but also by the type of incontinence and whether or not a skin damage prevention program is followed.

**Measurement of IAD**

There is no widely available valid or reliable tool for the assessment of PD / IAD although four instruments have been published [614] [615] [601] [617]. One of these tools, the Perineal Assessment Tool, despite its name, is an instrument primarily for assessing the risk of IAD (versus assessing skin health) and it has been described and used by its developer as such [616]. The most recently published tool [617] has been subject to internal validation and determines degree of redness, amount of skin loss and presence of rash on 13 body locations; a revised version for dark-toned skin is also being tested. Most researchers have reported ratings of colour changes (degree of erythema) based on visual inspection, which may be confounded by the presence of reactive hyperaemia on areas subject to pressure (particularly the buttocks, hips and sacrum). In some studies (mainly those finding higher proportions of IAD) trained staff or researchers have been utilised to carry out skin inspections at pre-specified times and in others (mainly those finding lower proportions of IAD) the usual care staff have been asked to report skin problems or written records have been used; this may explain the wide range of prevalence reported.

Few studies report the severity of PD. In a prospective surveillance study of 981 nursing home residents with incontinence of urine and/or stool over six weeks, the most common anatomical locations of PD were the buttocks (73% of those with PD) and perianal area (70%) followed by the genitalia, scrotum and groin (36%) and thighs (24%) with the smallest percentage near the sacrum (9%). Approximately one-third of residents had PD in more than one location. Mild PD was by far the most common (69% of residents); severe PD affected only 8% of residents [616].

**c) Pressure ulcers and incontinence**

The role of urinary and faecal incontinence in the development of pressure ulcers is uncertain. Studies aiming to identify risk factors for the development of pressure ulcers have generally found that the presence of both urinary and faecal incontinence was a risk [617] [618] [619] [620], but some studies have only found faecal rather than urinary incontinence to be a risk factor [621] [622]. Pressure ulcer risk assessment scales all have a sub-scale of incontinence or moisture-level, and the main mechanism for the development of pressure ulcers has been thought to be the increased friction and increased vulnerability to abrasion of wet skin.

Some researchers have used pressure ulcer classification systems, such as those published by the National Pressure Ulcer Advisory Panel (NPUAP) or the European Pressure Ulcer Advisory Panel (EPUAP), to measure skin health. The validity and reliability of most of these tools have not been established. Doughty et al [623] and Bethell [624] described numerous other limitations of pressure ulcer staging systems and despite recent revisions of the NPUAP and EPUAP staging systems, many of the shortcomings still apply. The reliability of the EPUAP staging score (which is a modified version of the NPUAP score) has been tested recently in three studies using photographs of pressure ulcers. These photographs included ‘moisture lesions’ (defined as lesions resulting from prolonged exposure of the skin to excessive fluid because of urinary or faecal incontinence, profuse sweating or wound exudate). A high degree of reliability for classification of moisture lesions was found amongst 44 pressure ulcer experts (Kappa =0.80) [625]. However, inter-rater reliability was found to be much worse (Kappa = 0.37) when photographs were viewed by 473 non-expert nurses [626] and subsequently in

</table>
a European study of 1,452 non-expert nurses from five European countries (Kappa = 0.36). The authors concluded that better descriptors needed to be incorporated into the EPUAP system and more education was needed.

An education tool aimed at improving skills in pressure ulcer classification (the PUCLAS education tool) was developed by a workgroup of the EPUAP and was tested by Beeckman and colleagues [627] in a randomised controlled trial. 1217 nurses from Belgium, the Netherlands, UK and Portugal participated. At baseline 45% of skin photographs were classified correctly and results were significantly improved in the intervention group who received the PUCLAS education tool (63% classified correctly) compared to the control group (53% classified correctly). Furthermore the proportion of correct assessments for IAD was 71% in the intervention group and 36% in the control group. The authors conclude that the PUCLAS tool improved pressure ulcer classification.

However there is still debate regarding the validity of separately classifying IAD from pressure ulcers particularly when skin damage occurs over bony prominences. To investigate the validity of classifying moisture lesions, Houwing et al. [628] examined the histology of 14 biopsy samples of damaged patient skin. Skin damage was classified using the EPUAP system: 12 were moisture lesions, one was a grade 4 pressure ulcer (extensive tissue destruction / necrosis) and one was a combination of a moisture lesion and a grade 1 pressure lesion (non-blanchable erythema). Both pressure ulcers had a histological pattern suggesting ischemic pathology; the histology of the moisture lesions, however, was either of an ischemic or irritation pattern. Because of the overlap in histology patterns of some of the moisture lesions and the pressure ulcers, the authors concluded that there is no justification for classifying moisture lesions separately from pressure ulcer lesions.

This finding requires further study as there are several limitations of their study. First, the true aetiology of the skin damage and the veracity of the EPUAP classification were not determined; some moisture lesions seem to be partially over a bony prominence so that a mix of pressure and moisture damage cannot be ruled out, which might explain the mixed histology patterns. Secondly, the moisture lesions and the pressure ulcer were both described as having blanchable erythema.

Identification of moisture lesions as distinct from pressure ulcers is sought as a way to solve the tension between inadequate prevention / treatment of a pressure ulcer and inappropriate use of costly prevention relieving devices / measures. It is also of importance in determining care quality. Pressure ulcers are deemed as quality indicators in many countries and are considered to be preventable. Facilities may not be allowed to charge for the care and treatment of patients who develop pressure ulcers and may also be fined. The 'correct' classification of IAD and pressure ulcers therefore has financial and reputational implications.

Fader et al. [629], examined the effects of absorbent continence pads on mattress interface pressures using an articulated model or “phantom” as the subject and found that the presence of a pad significantly and substantially (around 20%) increased the peak pressures recorded between the buttocks and the pad / mattress. Peak pressures were frequently found at the locations of pad creases and it was considered that pad folding and compression may contribute to raised interface pressures. It is therefore possible that continence product use contributes to the formation of pressure ulcers by raising interface pressures.

Black et al. (2011) [579] have categorized IAD as distinct from pressure ulcers as shown in Table XIV.2

2. CLINICAL STUDIES OF THE IMPACT OF PRODUCTS AND PRODUCT MATERIALS ON SKIN HEALTH

In the 1980s, product manufacturers introduced diapers with super-absorbent polymers (SAP), which were designed to reduce skin wetness, buffer pH and reduce urine / faecal contact in order to help prevent diaper dermatitis. This led to clinical and laboratory studies to evaluate the efficacy of diapers with different materials, in particular, super-absorbent polymers (SAP) compared to those without, and compared to conventional washable diapers.

a) Quality of data

There are three types of studies testing the effects of different products or product materials on skin health: (i) clinical trials of normal infants wearing diapers; (ii) laboratory wet patch testing of adult forearms with diaper or continence pad patches; and (iii) clinical trials of adult absorbent pads containing different materials. The infant diaper studies were randomised controlled trials with large samples and blind measurement of outcomes. It should be noted that these studies were carried out by industry-employed staff. The infant and laboratory studies used a probe comprising two hygrosensors and thermistors (an evaporimeter) placed on the 'wet' skin to measure trans-epidermal water loss (TEWL), an indicator of skin hydration level. However, there is uncertainty about the optimum procedures for measuring TEWL, and different procedures and outcomes were used in the studies, making it difficult to compare results. Probably the most important threat to the validity of these studies is the selection of products or materials used in the study. None of the studies adequately described the products used - in particular, regarding their total absorbency. Thus it is possible that an alternative explanation for the fairly consistent findings that disposable pads with
SAP perform better on skin outcome measures may be that those with SAP simply had greater absorbency than those without.

b) Results

1. CLINICAL STUDIES OF INFANT DIAPERS

Campbell and colleagues [630] conducted four clinical studies involving 1,614 infants randomly assigned to either disposable diapers with SAP, disposable diapers without SAP or washable cloth diapers. Disposable diapers with SAP were associated with significantly reduced skin wetness as measured by TEWL, lower pH and lower ratings of diaper dermatitis when compared to the two other diaper products (Level of Evidence 2).

Lane et al., [631] randomised disposable diapers without SAP and disposable diapers with SAP to 149 newborn infants and assessed their skin condition seven times over a 14 week period. Skin rash ratings were significantly lower for infants wearing diapers with SAP at only one time period (14 weeks) (Level of Evidence 2).

Davis and colleagues [632] assessed 150 infants over 15 weeks in a cross-over study involving four different disposable diaper types, two with different levels of SAP and two with different levels of fluff pulp only. Both diapers containing SAP were associated with significantly less skin wetness and significantly lower pH. Clinical skin ratings showed significantly lower ratings for the SAP-containing pads compared to the lower weight fluff pulp pad, but not compared to the higher weight fluff pad (Level of Evidence 2).

2. LABORATORY STUDIES OF DIAPER PATCHES

Wilson and Dallas [633] used the adult normal volar forearm skin model to compare patches taken from 16 different infant diapers. They found that disposable diapers containing SAP left the skin significantly drier than washable diapers and disposable diapers without SAP (p<0.01). Disposable diapers without SAP did not differ significantly from reusable diapers and there were no significant differences between products within any of the three groupings (Level of Evidence 2).

However, in a subsequent study involving 20 disposable and washable adult incontinence pads incorporating a similar range of materials to the baby diaper study Dallas and Wilson [634] found significant differences between products within each of the three product groupings but not between groupings (Level of Evidence 2). Grove et al. [635] used a similar approach to compare three infant diapers and found a significant difference in skin wetness between two that contained similar quantities of SAP (p<0.001). The one in which the SAP was in a layer near the water-proof backing kept the skin dryer than that in which it was near the coverstock. The third diaper – which had a microporous (breathable) backing kept the skin significantly dryer than each of the other two (p<0.001) (Level of Evidence 2).

3. CLINICAL STUDIES OF ADULT ABSORBENT PRODUCTS

There has been one clinical study of adult incontinent patients comparing underpads with and without SAP, diapers with and without SAP and washable cloth underpads and which used skin condition as the primary outcome variable [22]. This study included 166 incontinent patients (urine, faeces or both) from three acute care facilities who were divided into the five groups. It is unclear whether randomisation to group occurred by patient or by facility. One facility used the washable cloth underpads only for their patients. Other patients tested either diapers or underpads and crossed-over from without SAP to with SAP products after six weeks. Skin measurements were made for colour, integrity and symptoms using rating scales. Both blind and non-blind measurements were made.

Findings were rather complex and difficult to interpret and no corrections for multiple comparisons.
appear to have been made. Overall there were no differences in skin measurements between the diaper and underpad groups but - for some measurement sub-groups - differences were found with mean colour scores being significantly higher (worse) in the without-SAP diaper group and the washable cloth underpad group. Blinded ‘worst’ skin colour scores were highest for without-SAP diapers and washable cloth underpads and lowest for with-SAP products. Overall the findings supported the favourable effects of SAP on skin health but, as with the infant diaper studies, total absorbency of the products was not reported (Level of Evidence 2).

Hu et al. [66] randomised an unnamed range of disposable insert pads with mesh pants to 34 nursing home residents who were matched (based on incontinence severity) with 34 residents who received the usual reusable cloth diaper product. Skin condition was rated at baseline and after the five week intervention period by a blinded nurse researcher. Skin condition was reported to be significantly better in the disposable pad group (Level of Evidence 2).

More recently Beguin and colleagues (2010) [636] tested a modified diaper design (incorporating a top layer of specialised cellulose – beneath the top sheet – to maintain skin pH, and air-permeable side panels to minimise skin occlusion) in a small study of 12 patients using a pre-post test design. Skin pH was significantly lower when patients used the modified diaper and 8 out of 12 patients had resolution of pre-existing skin lesions. A larger more robust trial would be needed to establish any important clinical benefit.

3. CLINICAL STUDIES OF SKIN-CARE PRODUCTS AND NURSING PRACTICES TO MAINTAIN OR IMPROVE SKIN HEALTH

The skin of incontinent people requires frequent cleansing to remove urine and / or faeces. Soap and water is in common use [637] but it is known that repeated exposure to anionic surfactants (common in soaps) results in skin irritation [638] [639]. In addition, the action of washing is also considered likely to contribute to mechanical damage of the stratum corneum.

Cleansing of skin soiled with urine and / or faeces should occur immediately if possible or promptly after episodes of incontinence [640] [641] [642] [643] [644] [579] [575]. In addition, an individualised schedule for cleansing the perineum according to patients’ needs or preferences [645] [646] [575] [579] or at routine intervals, such as daily or at bath time [647] [576] [640] [642] [648] has been recommended (Level of Evidence 3).

The practice of cleansing or wiping the perineum front to back is recommended as standard practice in the literature - particularly for women [649] [650] [651] [652] [653]; this recommendation is based on the physiological rationale of lowering presumed risk of contaminating the urethra with faecal bacteria and subsequent urinary tract infection [653]. One retrospective study of pregnant women found a significantly higher association of urinary tract infections in women who self-reported they wiped back to front (25.8%) than among those who wiped front to back (18.5%) [654] (Level of Evidence 2).

To minimize friction damage of the skin during the perineal cleansing process, gentle cleansing and patting dry the skin [655] [656] rather than rubbing or using a soft cloth is recommended by clinical experts [616] [657] [576] [643] [644] [658] [659] [659] (Level of evidence 4).

However there is some evidence that drying the skin by patting may be less effective than gentle towel drying or drying with a hair dryer [660]. Damp skin is more vulnerable to friction damage and special care may therefore be needed to ensure that the skin is dry. For already damaged skin, there are clinical anecdotes of using a small hand-held hair-dryer set on a low and cool setting rather than drying with a cloth. Further research into cleaning and drying techniques and products is encouraged.

Alternative cleansers are available which have been formulated with the intention of overcoming some of the limitations of soap and water. Although overhydration of skin is detrimental, an excessively dry stratum corneum develops cracks and fissures and can be as ineffective a barrier as an over hydrated one [583]. Soap has a high pH (9.5-11) [661] and under laboratory conditions skin that has been exposed to high pH solutions has been found to have increased stratum corneum swelling and other signs of skin damage. However, there is a lack of controlled clinical trials comparing standard (high pH) soap with pH neutral soap or cleansers.

Many modern cleansers are designed to be used without water [i.e. ‘no-rinse’] and are designed to provide a less aggressive skin environment than soap (e.g. lower pH) but this may compromise their effectiveness in cleaning the skin of urine and faeces. This question has been addressed by Ronner et al, (2010) [662] who compared soap and water and a no-rinse cleanser in terms of their ability to remove escherichia coli and staphylococcus aureus. This laboratory study employed volunteer volar forearms and found low level and comparable levels of residual bacteria on the skin.

The use of topical products aiming to prevent or treat skin irritation is common but there is a lack of standardisation in definitions and descriptions of products, which makes comparisons difficult. Products such as ‘moisturisers’ or ‘barriers’ may be applied to the skin after cleansing, and some cleansers also incorporate moisturisers. The aim of moisturisers (also known as emollients) is to hydrate the skin by reducing trans-epidermal water loss through occlusion (e.g. petrolatum), by drawing
water into the stratum corneum by the addition of a humectant (a hygroscopic substance, e.g. glycerol) or by adding water in the applied water-miscible product. These modes of action are often combined in the same product, but there are exceptions - such as petrolatum - which only work by occlusion [663]. Some products are designed specifically to prevent penetration of water into the stratum corneum (‘barrier’ products) such as liquid skin sealants containing polymers, and may allow trans-epidermal water loss whilst preventing external water penetration. Simple occlusive products such as petrolatum may also act as barrier products to water but also occlude trans-epidermal water loss.

The application of skin barriers is recommended on areas that would come in contact with leaked urine and/or faeces. In general these areas include the buttocks and perianal area, groin, and inner thighs. Community-living persons report leaking small amounts of faeces that remain between the buttocks. Clinically, nursing staff have observed seepage of faeces around a rectal catheter in hospitalized patients. In both groups, perianal skin protection is important, and skin barriers are recommended (Level of evidence 4).

Topical creams are commonly used to prevent and treat dermatitis but controlled experiments to assess efficacy on human and animal skin have produced equivocal results. Ghadiali et al. [663] showed that barrier recovery (measured by TEWL) on experimentally irritated skin was accelerated by the application of petrolatum and De Paepe K et al. [664] showed similar results using a different moisturising cream. Hannuksela and Kinnunen [665] showed that treatment with moisturisers prevented the development of irritation in an experiment involving frequent skin washing with liquid detergent. However, Gabard [666] was unable to demonstrate significant acceleration of barrier recovery to chronically irritated skin following application of different moisturisers using a chronic irritation model and also found that some creams enhanced irritation.

The efficacy of barrier products in preventing water penetration of the skin has been tested in laboratory settings. Vinson and Proch [667] applied wet patches with a water-soluble marker to skin coated with three different barrier products and measured dye extracted from the skin by absorbance spectrophotometry. One multiple barrier product performed significantly better than a petrolatum-based and an allantoin-based protectant. Waring and Hoggarth [668] used a Chromameter to measure skin colour change after staining skin with a water-soluble dye, covering it with a barrier product and washing the skin. Petrolatum products were found to be more effective barriers than dimethicone-based products. In a later study, Hoggarth et al. [669] investigated the barrier function and skin hydration properties of six skin protectants when applied to the volar forearms of 18 healthy volunteers. The researchers found that each had different performance properties with the water-in-oil products containing petrolatum performing better than the oil-in-water products containing dimethicone for protection against irritation or maceration. However the dimethicone products had higher hydration properties compared to the petrolatum products. Overall the water-in-oil petrolatum-based product was the only product to be efficacious for all performance variables. A limitation of some petrolatum-based moisture barriers compared to a non-alcohol barrier film for individuals wearing absorbent pads or briefs is that the petrolatum-based products have been shown to transfer from the skin onto the absorbent product and reduce fluid update by 54% to 90%. [605]. However this has not been tested in clinical trials and the effects of different topical products on the leakage performance of absorbent pads is unknown.

Other practices that may affect skin health include frequency of pad changing. Increasing pad changing may reduce skin wetness by application of a dry pad and may therefore benefit skin health. Increased pad changing is commonly recommended to prevent or treat dermatitis particularly in infants [670] Level of Evidence 4.

a) Quality of data

Several studies of skin cleansing and/or moisturising/barrier products to prevent perineal dermatitis have been limited by being uncontrolled [614] [671] [604] [672] and of small size and lacking adequate power calculations [673] [674] [602], or not including any clinical outcome measures [673]. Measurement of dermatitis may also have been compromised by reactive hyperaemia on skin areas subject to pressure. Only four randomised controlled trials of a skin cleansing regimes to prevent perineal dermatitis could be found, and two RCTs of products to treat dermatitis. Two trials focused on the costs of barrier products use. In addition there was one randomised crossover trial of pad changing frequency.

b) Results

1. Skin cleansing / moisturising products to prevent dermatitis

Byers et al. [673] compared four different cleansing/moisturising regimes including soap and water using a multiple cross-over design. Despite having a very small sample size (n = 12 elderly women) they found statistically significant differences in TEWL, pH and erythema between some of the regimes, and soap and water was found to be the least effective product for skin health. No clinical outcomes were measured and differences in outcomes were small (Level of Evidence 2).

Beeckman et al., 2011 [609] randomised 141 nursing home residents to receive standard cleansing with pH neutral soap and water with the use of a
3-in-1 perineal care washcloth impregnated with a 3% dimethicone skin protectant over a period of 120 days. Skin health was measured using the IAD skin condition assessment tool. Although no differences in the severity of IAD were found there were substantial differences in prevalence of IAD (experimental: 8.1% versus control: 27.1%, $p = 0.003$) (Level of Evidence 2).

**Cleansing products**

Cooper and Gray [657] randomised 93 long-term elderly subjects to skin cleansing with soap and water or with a foam cleanser over a 14 day period and blindly assessed perineal skin photographs at zero, seven and 14 days. The skin of 37% of subjects using soap and water remained ‘healthy’ compared to 66% of subjects using the foam cleanser. However, statistical analysis was not carried out (Level of Evidence 3).

Lewis-Byers et al. [658] randomised 32 nursing home residents with incontinence to a soap and water or no-rinse cleanser regime over a period of three weeks. No significant differences in skin condition were found but no power calculations were included (Level of Evidence 3).

Taken together, the evidence from these trials indicate that specialised cleansers may be better than soap and water for skin health, although there is still a need for further robust clinical trials. Reported staff opinion tends to favour specialised cleansers rather than soap and water and there may also be cost savings [614] [673] [674] [658] although the reliability and validity of the health economic analyses carried out to date has been questioned by Beeckman (2009) [581].

**Costs of barrier products to prevent dermatitis**

Zehrer et al. [605] compared the cost and efficacy of three incontinence skin barrier products in 250 nursing home residents from four facilities. A polymer-based barrier film was used either once daily or three times weekly, and one of two petrolatum ointments was used after each episode of incontinence. Residents were monitored for skin damage for six months. There were no significant differences in effectiveness among the various barrier film and ointment protocols of care. Time and motion measures were used to determine the costs of the products and associated nursing labour. Daily cost of barrier product ranged from $0.17 for the barrier film applied three times per week to $0.76 for a petrolatum ointment applied after each incontinent episode. When nursing staff labour to apply the barrier products was included in the cost analysis, costs increased from $0.26 per day for the less frequently applied barrier film to $1.40 per day for the more frequently applied petrolatum ointments (Level of Evidence 3).

Bliss et al. [616] randomly selected 16 nursing homes to compare the cost and effectiveness of four skin damage prevention regimens. In three of the four skin prevention regimens, a moisture barrier ointment or cream of different compositions (43% petrolatum; 98% petrolatum; and 12% zinc oxide + 1% dimethicone) was applied after each episode of incontinence, while in the fourth, a polymer-based alcohol-free barrier film was applied three times per week. All regimens used a pH-balanced, moisturizing cleanser of the same manufacturer as the barrier. Time and motion measures were documented for the amount of skin care products used, the number, type, and time of caregivers performing IAD prevention care, and the number and type of supplies used. Compared to the three regimens in which a barrier was applied after each episode of incontinence, the use of a regimen in which a barrier film was applied three times weekly had significantly lower costs for the barrier product, labour associated with barrier application, and total cost which included products, labour, and supplies. There were also savings in total product (cleanser and barrier) and total labour costs. The total cost was lowest for the regimen using the barrier film compared to the other regimens in which a barrier needed to be applied after each episode of incontinence. The total cost savings ranged from $0.40 to $0.85 per episode of incontinence (Level of Evidence 2).

Although both these studies demonstrated cost savings when using barrier-film products such savings are dependent on relatively infrequent application of the barrier-film product. This may be achieved by assigning product application to care staff on particular shifts but uncontrolled use of such products may be expensive.

2. **Skin products to treat dermatitis**

In a double blind controlled trial of 64 subjects, Anthony et al. [675] compared the efficacy of cream formulated to treat dermatitis (Sudocrem) with zinc cream BP. Thirty subjects showed inflammatory lesions of the buttocks and a significantly greater proportion of subjects allocated to Sudocrem showed reduction in skin redness at both seven days and 14 days. No differences were found in the prevention of inflammatory lesions between the two groups. Skin measurements were made over the ischial tuberosities but the effect of reactive hyperaemia was not accounted for. There was no control group receiving no skin treatment and therefore it was not possible to establish the efficacy of using cream as treatment per se (Level of Evidence 2).

Baatenburg de Jong & Admiraal [676] determined the cost of treating moderate to severe IAD in 39 nursing home patients in the Netherlands randomly assigned to treatment with a non-stinging barrier film or zinc oxide oil. The barrier film was applied every 48 - 72 hours for less severe skin damage and 24 - 48 hours for more severe damage. Zinc oxide oil was applied twice per day and after each episode of incontinence. Both barriers reduced IAD but the no-sting barrier film was significantly associated
with reduced severity of skin redness and skin loss, although skin assessments were not blinded. The cost per day of the nursing staff labour in the regimen using the barrier film was €68.58 (sd = €23.61) compared to €88.20 (sd = €22.88) in the regimen using the zinc oxide oil. The total cost (including barrier, labor and supplies) per day of the regimen using the barrier film (€76.13, sd = €25.48) was also less than for the regimen using the zinc oxide oil (€102.96, sd = €23.25) (Level of Evidence 2).

3. Pad changing frequency

Fader et al. [629] investigated the effect of different frequency of night-time pad changing on 81 incontinent nursing / residential home subjects from 20 homes. Following a two week baseline period, subjects were randomised by home to pad changing at 22.00 and 06.00 for four weeks followed by 22.00, 02.00 and 06.00 for four weeks, or vice versa. Blinded skin measurements of instrumental erythema (using an erythema meter), visual rating, trans-epidermal water loss and pH were made at baseline and during the last two weeks of each regime with instrumental erythema measurements used as the primary outcome variable. Trans-epidermal water loss measurements were significantly higher when pads were changed less frequently (22.00 and 06.00) indicating that skin was wetter. No other significant differences were found. However, five subjects developed stage II pressure ulcers in the less frequent pad changing regime compared to none in the frequent pad changing regime. Although more frequent pad changing did not demonstrate less dermatitis / erythema, the pressure ulcer findings - though non-significant - make it unwise to conclude that less frequent pad changing does not damage skin health (Level of Evidence 2).

4. SUMMARY

- Incontinence-associated dermatitis is a common problem amongst absorbent product users (Level of Evidence 2).
- Skin wetness overhydrates skin and potentiates the effects of other irritants (Level of Evidence 2).
- Faecal incontinence is more irritating than urinary incontinence, but the combined effects of urine and faeces are particularly damaging to skin (Level of Evidence 2).
- Absorbent pads containing super absorbent polymers are associated with reduced skin wetness (Level of Evidence 3).
- Wet skin is more vulnerable to friction and abrasion injury (Level of Evidence 2).
- Pressure ulcers are associated with urinary and faecal incontinence (Level of Evidence 2).
- Bodyworn absorbent products may raise interface pressures measured under the buttocks (Level of Evidence 3).
- There are indications that skin cleansers may be more cost-effective than soap and water (Level of Evidence 3) and may be better for skin health (Level of Evidence 2).
- Barrier skin products may impede water penetration into the stratum corneum (Level of Evidence 3).
- A regular and structured skin care regimen using topical preparations such as moisturisers or barrier creams is associated with a low incidence of perineal dermatitis (Level of evidence 4).
- More frequent pad changing has not been shown to prevent dermatitis, but less frequent pad changes may be associated with pressure ulcers (Level of Evidence 3).

5. RECOMMENDATIONS

- Absorbent pads with SAP should be selected in preference to those without (Grade of Recommendation B).
- Absorbent pads should be changed regularly to minimise skin wetness (Grade of Recommendation C).
- Patients with faecal or double incontinence should be changed as soon as possible after incontinence has occurred to prevent the development of dermatitis from protease and lipase activity (Grade of Recommendation B).
- Patients should be washed gently at times of pad change with either soap and water or cleansers. Cleanser may be less time-consuming than soap and water (Grade of Recommendation C).
- Skin barrier products should be applied to areas that potentially come in contact with leaked urine and/or faeces (Grade of Recommendation D).
- Barrier products may be applied to skin within the pad area to reduce water penetration of the skin (Grade of Recommendation C).
- Buttock and sacral areas should be protected using topical skin barrier products, containment products or diversion devices in patients vulnerable to IAD or pressure ulcer (Grade of Recommendation C).

6. PRIORITIES FOR RESEARCH

- Controlled randomized trials that investigate the effectiveness of skin care products or skin care regimes to prevent or treat perineal skin damage due to urinary and faecal incontinence are recommended. Trials which
aim to test the comparative effects of different cleansing regimes, different barrier products and use of barrier products compared to careful cleansing are needed in particular. Such studies should determine appropriate sample sizes using power analyses. Analyses need to be powered to distinguish effects on participants with faecal or double incontinence. Objective measures from instruments, standardized clinical assessments, and patient symptom ratings should be included.

- Laboratory-based studies on healthy volunteers are recommended to help select products and establish potential efficacy of products before undertaking RCTs.

- Further work is needed to examine the relationship between IAD and pressure ulcers, in particular the potential and/or methods to discriminate between them, including use of biomarkers and technology.

- Studies to identify markers or ways of discriminating between pressure ulcers and IAD are required. Trials to test the comparative effectiveness of different skin cleansing regimes are needed as are trials to determine whether skin barrier products deliver benefits over careful cleansing alone and, if they do, which work best.

### XV. ODOR CONTROL PRODUCTS

Fear of smelling is a major concern that preoccupies many people suffering from incontinence and it is an issue that has been raised in several qualitative studies that have explored the subjective opinion of the patient eg [677] [678] [5]. Accordingly, there is a demand for products which will mask odour or, preferably, prevent it.

#### 1. PRODUCTS FOR URINARY INCONTINENCE

Fresh, infection-free urine smells only slightly but bacterial action on urea over time yields pungent smelling ammonia.

A variety of anti-microbial solutions are available for washing such products as hand-held urinals or for treating urine spillage onto soft furnishings such as carpets. They aim to prevent smell by destroying the bacteria responsible for break down of urea. There are no robust published studies that have sought to evaluate such products. Another approach is to mask the smell of stale urine using a strong but (hopefully) pleasant smelling liquid. There are no robust published studies on such products either but anecdotal evidence suggests that, in time, the masking smell comes to be associated with the incontinence that it is intended to disguise. Several companies supply products (washable bedpads, carpets, chairs, clothing and bed linen) made with fabrics that have been treated with anti-microbial agents intended to reduce the smell of any urine on or in them. However, again, there have been no robust published studies to investigate efficacy.

One of the 12 disposable bodyworn pads for lightly incontinent women evaluated by Clarke-O’Neill et al. [18] was treated with a lavender scent but it was not found to perform significantly better than the other products in terms of preventing smell. However, the scent was appreciated by 18% of the 50 test subjects, who commented favourably on it.

#### 2. PRODUCTS FOR Faecal INCONTINENCE

Odour associated with faecal incontinence may occur from involuntarily leaked stool or flatus. In a study with subjects eating a self-selected diet, Moore et al. [679] identified the volatile chemicals primarily responsible for faecal odours as the methyl sulphides: methanethiol, dimethyl sulphide, and dimethyl trisulphide. Hydrogen sulphide was thought to make a smaller contribution. In a subsequent study with persons consuming a bolus of pinto beans and lactulose (a non-absorbable carbohydrate) Suarez et al. [680] attributed the odour of flatus to the sulphur compounds, hydrogen sulphide, methanethiol, and dimethyl sulphide. The intensity of the odour in flatus was related to the concentration of the sulphur-containing compounds: the ability of the human nose to recognise malodorous odour appears to be related to the amount of gas expelled [680]. Different states of health and gastrointestinal function, diet composition, relative concentrations of sulphide gases and, possibly, short chain fatty acids or ammonia are expected to contribute to the odour of faeces and flatus [679] and [680].

There are several commercially available devices that are designed to absorb the odour of flatus. One such product originally called the “Toot Trapper” and renamed the “Flatulence Filter” (UltraTech products, Inc., Houston, TX, USA) is a cushion or pad (which can be placed directly against the anus) that is lined with activated charcoal. Both the cushion and pad are encased in either a washable or a disposable cover. There are similar products by other manufacturers (e.g., Flat-D by Flat-D Innovations, Inc., Iowa, USA and GasMedic and GasBGon by Dairiair and manufactured by ECVC, Greenville, NC, USA). Pads comprising fabric covered activated charcoal that can be worn next to the anus or attached to a brief (GasMedic underair pad by Dairiair and Flat-D, Flat-D Innovations, Inc., Cedar Rapids, IA). There is also underwear (briefs) entirely made of covered activated carbon cloth (Underease protective underwear (UltraTech Products, Inc., Houston, TX). Ohge at al. [681] compared the effectiveness of
11 devices containing activated carbon in six normal adults (50% female) under controlled conditions in absorbing odoriferous rectal gases. Five types of seat cushions, four types of pads, and two types of briefs (one that held a pad next to the anus and one made of activated carbon fiber fabric) were tested. A mixture gas comprising 100 ml of nitrogen with traces of hydrogen sulphide (40 ppm), methylmercaptan (40 ppm) and hydrogen (5,000 ppm) was instilled into the rectum of the subjects via a rectal tube. Since hydrogen does not react with charcoal, the amount of unabsorbed sulphide was determined from the ratio of sulphide to hydrogen collected from the pantaloons relative to the ratio in the instilled gas. The subjects wore mylar pantaloons that were sealed at the thighs and waist with elastic bandages to reduce convection to the air.

The subjects’ clothing, apart from any device, absorbed approximately 22% of sulphide gas. The cushions absorbed an amount comparable to usual clothing, 20%. The various pads and the brief with an attached pad held near the anus absorbed 55-77% of the rectal gas. The underwear made of charcoal fabric was the most effective and removed nearly all (95-99%) of the sulphide gas. The charcoal fabric briefs are reusable and the charcoal is allegedly regenerable with heat. There are no reports of any odour absorbing devices being evaluated in persons with faecal incontinence. In vitro studies showed that each device had the capability of absorbing the rectal gases and that their performance efficiency depended on contact between the charcoal element and gas. Briefs entirely made of activated charcoal fabric appear to provide the greatest surface area for contact with malodorous rectal gas. The absorption of odorous gas by clothing suggests that washing outer clothing as well as underwear is important to reduce odour.

Some products aim to reduce the amount of malodorous flatus that is produced. Administration of the probiotic, Lactobacillus plantarum, (5 x 10⁷ cfu/ml) in a randomized trial of 60 patients with IBS significantly reduced flatulence (by half in 44% of patients). Only 18% of the placebo group reported reductions of flatulence [682]. Although administration of charcoal, yucca and zinc acetate reduced the percentage of episodes of malodorous gas [683], there are inconsistent findings about reductions in flatulence from ingesting activated charcoal in humans [165] [684]. Two clinical trials involving small sample sizes (19 and eight persons, respectively ) showed that the over-the-counter product, Beano, which contains α-galactosidase, reduced flatus frequency in normal persons following the ingestion of beans [685] [686]. A significant reduction in cumulative breath hydrogen excretion over an 8-hour period after α-galactosidase versus placebo suggests α-galactosidase reduces flatus production [686]. Although Ganiats et al., 1994 [685] reported a significant decrease in flatus using 240 galactosidic units (GalU), Di Stefano reported that effects of 1200 GalU but not 300 GalU were significantly different from placebo. One GalU is the amount of galactosidase that releases 1 μmol of galactose from its substrate in one minute [686]. Differences in the test diet or lack of adequate statistical power may explain these differences since neither study reported a power analysis. Although a reduction in the amount of intestinal gas produced may decrease the volume of odour, it may not decrease its potency or perceived odour.

A few products are available that aim to prevent, absorb, or control odour associated with involuntarily leaked stool or flatus associated with faecal incontinence. These include cushions and pads that absorb odour as well as probiotics and enzymes, which aim to reduce production of malodorous gas.

3. RECOMMENDATIONS

• Briefs made of activated charcoal fabric are recommended over pads or cushions containing activated charcoal for absorbing odoriferous rectal gas (Grade of Recommendation C).

• Since some pads absorb up to 75% of gas, there may be value in offering patients who have smaller amounts of gas the opportunity to compare pads and briefs for themselves. (Grade of Recommendation D).

• For those persons experiencing stool leakage due to flatus, over-the-counter α-galactosidase containing products, which reduce flatus frequency, can be tried in an attempt to reduce FI frequency (Grade of Recommendation B).

• Washing of outer as well as under clothing after flatus is recommended to reduce odour due to absorption of gas by clothing (Grade of recommendation of C).

4. PRIORITIES FOR RESEARCH

• Investigation of whether probiotics or changes in dietary intake can modulate or reduce the odour of flatulence or leaked faeces.

• Development of an absorbent product that can reduce the odour of leaked faeces while protecting the skin.

• Investigation of the efficacy of anti-microbial agents in textile products (soft furnishings and bedding) for reducing odour associated with urinary and faecal incontinence.

I. LITERATURE SEARCH

A systematic review of the literature using online databases Scopus, Medline/Pubmed, Embase, Biosis, Cinahl, Pyschinfo, Psychlit, ERIC, Cochrane Library, Web of Knowledge, and CNKI (China National Knowledge Infrastructure) was conducted. The focuses of the searches were from 2008 to March 1, 2012, although literature from the preceding 15 years was also searched to ensure thorough coverage. The following search terms were used in various combination: awareness, consumer, education, urinary incontinence, faecal incontinence, incontinence, continence, continence awareness, continence promotion, health education, public education, population-based prevention, health promotion, help-seeking, care seeking, continence nurse, continence advisor, public awareness, prevention, primary prevention, pelvic organ prolapse, interstitial cystitis, bladder pain syndrome, painful bladder syndrome, allied health care professionals, self-care practices, outcome measures. There was significant overlap between the searches made on different databases, as would be expected. Non-English language guideline references were noted, but excluded from the review unless they contained an English-language abstract providing sufficient information.

II. INTRODUCTION

Continence promotion, education and primary prevention involves informing and educating the public and health care professionals that urinary and fecal incontinence can often be prevented, can be treated successfully in most cases, and can always be managed. Other bladder disorders, with links to incontinence, such as bladder pain syndrome/interstitial cystitis and pelvic organ prolapse, can also be treated and managed successfully and are often included in continence awareness programs. The Fourth International Consultation on Incontinence (ICI) Continence Promotion, Education & Primary Prevention Committee stressed the importance of all health care professionals promoting primary prevention of incontinence [1]. It was acknowledged that this would require raising the level of community awareness, providing public education as well as addressing health care professionals’ education. While some advances have been made, these strategies remain a priority.

Taboos surrounding disorders of the bladder and bowel are gradually lifting in most cultures [2]. Two decades ago it was almost impossible to discuss urinary incontinence in the media. Today, in many countries, government funded initiatives and practice guidelines have been developed in the area of urinary and faecal incontinence [1,3,4]. Around the world, expert panels have suggested that urinary and fecal incontinence be combined through a multidisciplinary approach to further research priorities. Thus, there have been advances in promoting awareness of both of these conditions. Popular magazines, local and national papers, radio, and television, regularly cover topics of men and women relating to urinary incontinence in most developed countries. Many countries have run national or local public awareness campaigns, often spearheaded by a national continence organization. Many also have confidential “help lines,” which can be accessed anonymously. The internet provides a convenient source of health information for a growing number of consumers. Some experts believe that persons with incontinence might get valuable advice and comfort by using interactive services such as internet “chat rooms.” However, in many developing countries, accessible public information and campaigns relating to continence are limited or non-existent. Though information may be available in principle on the internet, access to the internet may itself be limited.

This chapter updates previous ICI chapters on four areas: continence awareness and promotion, service delivery, professional education, and primary prevention along with the recommendations in each area. The majority of information available relates primarily to urinary incontinence (UI) and faecal incontinence (FI) and less to bladder pain syndrome/interstitial cystitis (BPS/IC) and pelvic organ prolapse (POP). The first section reviews continence awareness by discussing health promotion and help-seeking (care-
seeking) behaviors (HSB) for these conditions. It is evident that progress has been made in the promotion of continence on a worldwide basis, but not much has changed in HSB for these disorders. There is a lack of evidence on translating awareness into behavioral change and on what triggers HSB. Information is provided on continence promotion programs and advocacy through worldwide organizations. Although there is a great deal of published information on building public and health care professional awareness of incontinence, there is minimal information on the effectiveness of changing public and professional attitudes and knowledge about it. The second section discusses service delivery and models of continence care. The third topic reviewed is the education of professionals in these areas (UI, FI, BPS/IC and POP) including the development and use of medical guidelines and care pathways. Finally, since these conditions are prevalent but often ignored by sufferers and professionals, the fourth and final topic addressed is population-based primary prevention research. There is a need for further research to substantiate the benefits of primary preventative strategies, including long term follow-up. The committee found more information about initiatives in all of these areas but very little evidence-based research to support the effectiveness of the initiatives or care.

III. CONTINENCE PROMOTION AND AWARENESS

1. BACKGROUND

Health promotion was defined by the Ottawa Charter for Health Promotion in 1986 as “the process of enabling people to increase control over and to improve their health.”[5] Hence, health promotion is an important factor in primary, secondary and tertiary prevention efforts directed at individuals, communities and populations with, or at risk of developing, incontinence.

Efforts to promote continence awareness may be enhanced by adopting evidence-based theories and methods from the field of health promotion. Health promotion frameworks can be used to plan and evaluate the effectiveness of strategies and programs used to promote continence. When planning health promotion interventions, consideration needs to be given to the demographic features of target groups including age, gender, culture, language and socio-economic background [6].

2. RAISING AWARENESS AND UNDERSTANDING

The main reason to educate consumers – individuals with, or at risk of, incontinence and their family members or informal caregivers – is to increase awareness of incontinence and the benefits of prevention and management, with goals of eliminating stigma, promoting help-seeking, and reducing suffering [7,8,9]. While in some countries there is strong governmental support, much of the health promotion effort related to continence issues is undertaken by the many professional bodies, non-governmental continence organizations, and advocacy groups listed in Appendix I. Health education activities can involve educational, health-care, and community service providers, and may include a range of components including materials that are accessible, comprehensible, trustworthy, and culturally sensitive, formal and informal health advice systems such as including a hotline, online support and health care professional learning systems [10].

Consumer education is a critical component of effective continence promotion. This includes both general information about UI [11] and methods to identify potentially modifiable risk factors for UI [12]. Patients with UI have a wide variety of ideas and attitudes about why they leak urine [13]. Knowledge about specific aspects of UI is often limited, indicating an area for improved consumer education.

Consumer knowledge about FI is also generally limited. A recent study found that many patients had a significant emotional component to their experience of FI and that knowledge about the terms used to describe the condition was often limited [14]. A United States (USA) Public Broadcast (PBS) Second Opinion medical television program was develop to educate consumers about FI and attempts to dispel the stigma of this condition (www.ibtv.org/video/detail.cfm/12719/ sopl_20101018_fecal_incontinence_ap). The Internet is frequently searched for health information, and coverage of relevant health topics is growing. This method of acquiring health information is widely accessible, anonymous and informal, with estimates indicating that around 20% of USA adults use the internet for this purpose [15]. Since one-quarter of adults do not go online, the percentage of health information seekers is 59% among the total U.S. adult population (http://pewinternet.org/Reports/2011/HealthTopics/Summary-of-Findings/Looking-for-health-information.aspx). Thus, accessing information about incontinence has become much easier in the age of digital technology, especially for internet users with a higher literacy level [10]. A 2011 Google search for “urinary incontinence” and “faecal incontinence” yielded about 4.8 million and 311,000 websites respectively; “interstitial cystitis” – 2.2 million sites, “bladder pain syndrome” – 105,000 sites and “pelvic organ prolapse” – 382,000 sites. These figures are all two to three times greater than a similar search in 2008. Many of the sites were related to non-government organizations such as the International Continence Society (ICS), the National Association For Continence (NAFC), the Simon Foundation, the Interstitial Cystitis Association (ICA), and the International Foundation for Functional Gastrointestinal Disorders (IFFGD).
In light of the reluctance of those affected by stigmatized illnesses such as incontinence to seek treatment or to ask health care professionals for information, the Internet may prove to be a useful tool for consumer education and public health outreach [16,17]. In a national survey of internet users in the USA, Berger et al[18] found a trend among people with a stigmatized illness such as UI to be more likely to report that internet use increased their communication with a health care provider and utilization of health care. The quality of these materials can vary widely and providers should help interested patients navigate resources that provide accurate information. A recent study showed that most websites that provide UI information are not certified by any accrediting body [19]. There were also differences observed between sites run by professional organizations, educational and government agencies, and companies either for profit or non-profit.

Among those who do not use the Internet, 60% are aware of publicly available Internet access points within their community [20]. However, people with low levels of education and low socioeconomic status are less likely to use the Internet [21]. Research has questioned the quality of incontinence information on the internet and suggested that validation is needed [22]. Healthcare professionals can assist patients in finding reliable information sources by providing details of reputable web sites [23].

The Internet has changed the way many people access health information, and has much to offer as a means of health education and raising awareness. But Internet access is far from universal, especially in developing nations and among older and poorer sections of society in developed nations. Thus, it is important that more traditional awareness-raising and education methods are still used, such as information posters, leaflets and booklets distributed through health outlets such as clinics and pharmacies, and articles in the popular media. In both developing nations and in countries with limited health systems and dispersed populations, more innovative techniques have been successfully used for health education, such as dissemination of information through community nursing infrastructures and lay health workers.

Social network sites may be the future source of information for consumers. Sajadi and Goldman[24] used the word “incontinence” to search for information on Facebook, Twitter, and YouTube, to evaluate its usefulness. Their conclusion was that social networks have insufficient useful incontinence content, especially from healthcare professionals and incontinence organisations. However, they recommended that medical professionals and societies target these avenues to reach and educate consumers.

3. HELP-SEEKING (CARE-SEEKING) BEHAVIOR

Estimating the prevalence of continence problems is difficult due to different definitions of incontinence, different populations and different data collection strategies,[25] and this lack of clarity regarding baseline prevalence of incontinence undermines efforts to determine the proportion of those affected that seek help. Despite the considerable impact of both UI and FI on quality of life (QoL), it is clear that many people never seek help for their incontinence, although the precise level of under-reporting is difficult to determine [26,27]. Perhaps of more concern is a recent comparison of HSBs in two surveys conducted sixteen years apart (1991 and 2007) which revealed that there had been virtually no increase in the proportion of women seeking help for lower urinary tract symptoms (LUTS) [28].

Qualitative research has described a process that takes place and influences the decision to seek treatment (or not), whereby consumers affected by incontinence, or other chronic, non-life-threatening conditions, weigh the perceived costs and benefits of treatment (in terms of discomfort and inconvenience as well as financially) against the effect of the condition on QoL [29].

Instead of seeking care, individuals with UI and FI alter their lifestyle and develop elaborate “self-care” practices (e.g., stopping exercising, use of protective products, dietary and fluid changes) to conceal and/or manage symptoms and improve QoL [30,31,32,33]. Data from focus groups of women showed self-reliance and the development of personalized strategies to alleviate symptoms [34]. Some patients have been known to make major changes in their lives (e.g., quitting their jobs). Surveys have also revealed extensive use of coping mechanisms for overactive bladder (OAB) symptoms of urgency and frequency (e.g., toilet mapping) [35].

Several studies have estimated levels of help-seeking for specific consumer groups. An integrative literature review of HSB for UI symptoms among non-institutionalized women of all ages indicated that less than 38% of women sought help for their UI symptoms [36]. Age, type, and severity of UI, and embarrassment have been found to be significantly related to seeking care [37,38,39].

Kinchen and colleagues [26] noted that women with UI waited more than a year before seeking help from a health care provider or professional [26]. This delay is in line with a European survey that reported that consumers wait from 2 to 11 or more years before seeking treatment [40]. Huang et al[41] reported that fewer than 50% of women in the USA with clinically significant UI reported seeking treatment. This was despite the fact that all women in this study had health insurance to cover such services and had continuous access to a primary care provider. Only 12% of women with UI attending obstetric and gynaecology clinics in Turkey had sought help for their incontinence [42]. Shaw and colleagues [43] surveyed adult women attending primary care practices in United Kingdom (UK) and of those who noted UI symptoms (n=3273), only 15.8% of women with
stress UI, 32.3% of those with urge UI, and 33.7% with mixed UI had sought help for urinary symptoms during the preceding 12 months. Rizk[44] found that of women affected by UI in the United Arab Emirates (UAE), only 30.9% had sought medical advice.

Surveys of individuals with FI also indicate a lack of HSB. In 2010, the IFFGD conducted an online survey to help explain what it is like to live with and manage FI from the point of view of those who experience the condition (http://www.aboutincontinence.org/pdfs/319-IFFGD%20Incontinence%20Survey%20(9-11).pdf). A total of 142 individuals completed the survey, responders were recruited primarily from the IFFGD websites. Ninety-seven (68%) of the survey responders indicated they had never been diagnosed by a physician, giving reasons such as “too embarrassed to bring it up” and “feel I can manage the condition on my own.” Of the 32% who had mentioned their FI problems to a physician, the physician implied there is not much to be done about it or it is a normal part of aging.

a) Barriers to seeking care

Understanding the barriers and reasons why people do or do not seek treatment for incontinence is hampered by the ethnic homogeneity of the existing data, which has been derived mostly from white populations, and there is a lack of comparisons with ethnic and minority populations. The strategies for promoting HSB need to be culturally appropriate to the populations of interest [45,46,47]. Rates of HSB for UI amongst minority groups may relate to a number of factors such as access to care, socioeconomic factors and access to or comprehension of health education campaigns or materials [48,49,50].

Help-seeking behaviour is dependent upon awareness and understanding [51] and lack of knowledge has been a significant barrier to people seeking help for continence issues. Furthermore, HSB for UI, FI, BPS and POP may be different depending on the person’s culture, ethnicity, gender and socioeconomic groups.

Questionnaires have been developed and validated which can be used to assess consumer knowledge about UI and POP [52]. In 2008, a study (n = 126) found that white women had greater knowledge of UI than non-white women while both groups of women had higher levels of knowledge of UI compared to POP [53]. Using this instrument, research has shown that there appear to be important differences in health literacy about these conditions in different racial and ethnic groups.

Another study found that Korean American women living in America tend to rely on information and social support from family and friends rather than seeking professional advice for UI [54]. The women in this study sought help less frequently, had less knowledge and more negative attitudes towards UI than other community members. It was suggested that these factors influenced help-seeking in this group of women [55].

In certain parts of the world, cultural factors can affect the experience of incontinence and HSB and the gender of the health care provider may be a barrier. Knowledge of continence issues in UAE women was researched by Rizk and Hassan [56]. It was found that UAE women perceive continence problems to be neurological or “senile” disorders rather than related to childbirth or menopause. Quantitative data was derived from a community-based descriptive cross-sectional study conducted in Sri Lanka from 2006 to 2007 with 1,718 married women, aged 15-49, of whom 9.8% reported problems of stress UI [57]. Although incontinence affected outdoor activities, sexual life, and sense of wellbeing, women did not consider it a health problem, rarely discussed it with others, and rarely sought treatment. Barriers to help-seeking included fear of vaginal examination, shame and embarrassment, and belief that stress UI was a natural consequence of aging and childbirth. Within all cultures, embarrassment or shyness may prevent some women from seeking care for UI [58,59,60,61]. These have been shown to impact help-seeking in Middle Eastern women, where both UI and FI are underreported. In the UAE, cultural attitudes and inadequate public knowledge, and male health care providers have been identified as barriers to seeking health care for women, despite the effect on QoL. Rizk[44] found that women affected by UI in the UAE, were troubled by their inability to pray (90%) and to have sexual intercourse (33.3%). Saleh[62] found similar results when surveying women in Qatar who reported that UI interfered with their ability to pray (64%) because of lack of cleanliness and need to void, and 47% reported that UI interfered with marital relationships. El-Azab and colleagues[63] found that encouragement from husbands, severe UI and the desire to be able to pray were associated with an increased likelihood of HSB [63].

Rizk and colleagues (2001) investigated the prevalence and HSB of UAE women with FI (n = 400, mean age 37.9) and also found that many did not seek medical advice because they were too embarrassed to consult their physician and preferred to discuss the difficulty with friends (64.7 %), assumed that FI would resolve spontaneously (47.1 %), felt it was normal (31.3 %), or they chose self-treatment as a result of low expectations of medical care (23.5 %). As with UI, women with FI were bothered by the inability to pray (92.2 %) and to have sexual intercourse (43.1 %).

These studies reinforce the need for different strategies to be targeted to cultural and minority groups with low levels of HSB for UI and FI. In addition, public education efforts related to UI should not just focus on older adults [64]. An earlier study of high-school and college age athletes in the USA found that more than 25% of the young women surveyed
experienced UI during strenuous physical activity, but 90% had never reported their symptoms to any-

one [65]. A recent study of nulliparous female ath-

letes also found that young women have low levels 
of HSB for UI [66]. This study found that UI issues 
occurred particularly during training and to a lesser 
extent, during competition in women of varying 
competitive levels ranging from high school to elite 
level athletes. The prevalence rates of UI in nullipa-

rous women in recent studies have varied from 28% 
to 52% and are influenced by the type of athletic ac-
tivity. A 2011 study found a lower prevalence rate of 
UI in women playing volleyball compared to higher 
rates occurring in women performing track and field, 
soccer and gymnastics [66].

Barriers to seeking help for continence issues that 
have been frequently identified in the literature in-
clude embarrassment, social stigma and the mistaken belief that incontinence is inevitable, untreatable, 
and/or a normal part of aging [67]. The authors of a 
Swedish study suspected that lack of knowledge, 
worries about different procedures and negative ex-
pectations may be important factors in reducing the 
desire to seek treatment among even those most severely affected [68]. Embarrassment and fear of 
humiliation have been identified as the major factor 
influencing reluctance to seek help among women 
with long-term UI [69]. Among women affected by UI in 
the UAE, reasons for not seeking help included 
embarrassment (38.2%), choice of self-treatment 
because of low expectations from medical care (38.2%) and assuming that UI is normal (23.3%) [44]. Among women with gynaecological cancers who experience concomitant LUTS, the failure to seek help for the latter symptoms has been attributed to a perception that the LUTS were not serious enough symptoms to warrant attention and lack of awareness of treatment options [70].

Advice given by physicians can affect a patient's ability to change health behaviours [71]. Opportunities to promote continence can present themselves during other health screening activities (e.g., yearly physical examination) [72]. While health care professionals may enable people to seek help, those who have a lack of interest in incontinence can negatively affect HSB in consumers [73,74].

Other initiatives to promote HSB can include providing written information [75]. Continence health promotion information provided in a brochure [76] and in a computer based program [77] have been found to improve HSB. However, language, level of education and cultural factors may also be bar-
riers to seeking help [78]. Consideration should be given to health literacy in target populations and this will affect the ability to read and understand health information in written formats. Poor health literacy results in lower rates of health seeking behavior [79].

The Boston Area Community Health (BACH)[80] population-based random epidemiological survey of urologic symptoms (n=5503) indicated that the stigma of UI also includes other LUTS. They reported that OAB symptoms of urgency and frequency were linked to social interruption, loss of socially-expected control of the body, not understanding the nature of the bladder problem, and the need to mix private behavior and public space. The stigma of OAB and UI was correlated to whether the problem was perceptible (i.e., odor, or observation of trips to the bathroom or soiled clothes) or concealed. Men reported feeling stigmatized for being seen making frequent trips to the bathroom and feared being viewed as impotent. Women feared being stigmatized based on having an unclean body and a compromised social identity. Like others, Hispanic individuals wanted to keep urinary symptoms a secret from others.

Surprisingly, the perception that incontinence is not important or serious enough to warrant treatment has even been found to affect HSBs in women with recurrent UI following surgery for UI and POP [81]. Women with POP have also reported that fear and embarrassment are barriers to seeking help. Symptoms such as nocturia have been linked with serious consequences such as falls and associated morbidity in older adults. Bladder and bowel incontinence is a deviation from social norms, which in most cultures there are defined complex and sensitive rules and behaviours for bladder and bowel emptying [82,83]. If incontinence occurs in adulthood, it can cause a decrease in self-esteem and feelings of not being “normal.”[84] These perceptions, which can affect help-seeking, are shared by the public as well as by many health care providers [85].

b) Gender-specific disparity

The impact of UI may also differ depending on gen-
der but little is known about gender differences in HSB. Teunissen and colleagues [86] interviewed in-
dependently living patients (56 men, 314 women) 60 
years and older with uncomplicated UI. Men reported higher impact scores than women, despite the fact that incontinence was less severe in men. The most important effect of incontinence reported in men was “being out of control,” while most women considered “feeling compelled to take several precautions” to be the most important consequence of UI. Researchers in Egypt interviewed 353 patients attending clinics at hospitals in Alexandria, Egypt [87]. They found differences in men and women as women suffered from at least one negative impact on their social lives com-
pared to men. The impact of symptoms on QoL ap-
peared to be the main trigger for seeking help for UI in both men and women. Women had fewer hospital admissions and hospital days and less use of diag-
nostic procedures and surgery.

There is very limited data on ways to improve men's awareness of bladder and bowel health [88]. Gen-
der specific health disparity may exist as men tend to be less proactive in HSB for UI. There is a need
for gender specific strategies to address this [89]. Men with LUTS have been found to seek help less frequently than women [90]. Consumer surveys conducted over a 5-year period by the USA continence advocacy group, the NAFC, indicated that only 26% of respondents (18% of men and 33% of women) reporting bladder control symptoms had discussed them with a doctor [91]. However, a study into the prevalence of UI in men in the USA found that while a low proportion of men with continence issues sought help, those who did, consulted their doctor within 12 months of the onset of symptoms, a shorter period than the length of time taken by women to seek help [92]. Men are more likely to seek help for LUTS if they have had advice from others or received information in the media, rather than seeking help as a result of their symptoms [93].

In certain parts of the world, the gender of the health care provider may be a barrier. Doshani et al [94] explored views and experiences of South Asian Indian women with UI and found that feelings of embarrassment were present, especially with male health care providers.

c) Symptom impact and bother

The level of perceived bother (physical, emotional and/or economic) associated with incontinence also affects HSBs. A number of studies have found that those affected by incontinence are not necessarily so bothered by it as to want to seek professional help. In Japan, it has been found that 55% of elderly continent people do not consider incontinence a bother [95]. Of women with UI attending obstetric and gynaecology clinics in Turkey, 53% were found not to be bothered by their incontinence [42]. In a population-based study in Sweden (a supplement to a comprehensive survey of public health and general living conditions), a postal questionnaire comprised of 12 questions on UI received a response rate of 64.5% from 15,360 randomly selected residents (aged 18–79 years) [68]. The prevalence of UI was 19% (when defined as “any leakage”) and most considered their problems to be minor. Only 18% of those with UI desired treatment. Of the 17% who had reported severe problems that interfered with daily life, 42% did not want treatment.

A recent study by Visser and colleagues [39] showed that older adult women, who did not consult a general practitioner (GP) about incontinence symptoms, were more often younger and had lower levels of distress due to their urogynaecological symptoms, but the main reason for not seeking help was they did not consider their symptoms to be severe enough [39]. An internet survey in the USA, the UK and Sweden, noted that in men and women who reported LUTS less than a third of respondents reported seeking treatment [96]. Rates of bother were greatest for those who reported multiple storage, voiding and post-micturition LUTS (men 83%, women 89%) and correlates of treatment seeking across genders included bother due to weak stream, incomplete emptying, perceived daytime frequency, nocturia and urgency.

With chronic problems like UI, FI, POP and BPS/IC, it is important to understand what triggers the consumer to consult a health care provider [83]. Yet factors that lead those affected to seek help for continence issues remain less well researched than those that prevent help seeking. Women with stress UI are more likely to seek help when there is severe leakage that is having a significant impact on their QoL [97]. The importance of the effect of UI on QoL is supported by Brazilian research [98]. An American study suggests that worsening severity of UI, along with increasing age and not being obese, were associated with an increased likelihood of help seeking [99]. Older people may be keen to seek help if they are concerned that a health issue, such as incontinence, impacts on their ability to remain independent and living in the community [100].

In conclusion, the most commonly reported reasons for not seeking help for incontinence are lack of knowledge and awareness, embarrassment, a perception that incontinence is not sufficiently important to warrant treatment or is “normal” either at certain stages of life or in association with childbirth or certain illnesses, and low expectations of the effectiveness of treatments offered. The more serious the impact of incontinence is on QoL, the greater the likelihood of seeking help, but this will be balanced against the perceived disadvantages of treatment in terms of cost, discomfort or inconvenience.

4. CONTINENCE PROMOTION PROGRAMS

Continence promotion programs vary across countries and cultures, but share the same aim of increasing awareness and understanding of incontinence.

Efforts to raise awareness of continence issues need to consider the following:

Target population - Continence promotion programs need to consider age, gender and culture of target populations. It is necessary to consult with target groups when planning programs in order to meet the needs of these groups and to enhance HSB [101].

Target issues - A continence promotion program needs to address risk factors and management options in different target groups. Community-based interactive continence promotion workshops conducted in a recent cohort study in Canada were shown to be well-received by participants and the interventions changed knowledge, attitudes, skills, and appeared to increase rates of HSBs [102]. A similar study showed that improved understanding about UI and POP was associated with improved QoL scores among women who attended a nurse-led educational workshop [103].

Promotional material – Newman [104] reported on a mail survey of 1,500 women, noting that most of the 422 respondents wanted more information regarding UI, and while they may not be equipped to fully...
understand the problem, they expect doctors, nurses, medical professionals, retail outlets, medical supply companies, and mail order houses to provide the information, including information through consumer advertising.

Communication and expectations – Health care professionals may launch campaigns or seminars to increase practice revenues. Commercial companies often fund public campaigns in order to sell their products, whereas continence organizations may be driven by missionary zeal or organizational growth. Regardless of motivation, care should be taken to avoid raising public expectations beyond what the services or products can deliver [105].

a) Creating public awareness

In the area of UI, building awareness among the general public has usually been attempted via the media. The USA National Institutes of Health, in partnership with the American Urogynecological Society, American Urological Association, American Foundation for Urologic Disease, NAFC, Society of Urologic Nurses and Associates and the Simon Foundation for Continence, launched a national awareness campaign in 1997. The Let’s Talk About Bladder Control for Women awareness campaign (http://kidd.niddk.nih.gov/kudiseases/pubs/bcw_ez/index.htm) offered easy-to-read booklets explaining the symptoms, types and causes of poor bladder control, as well as treatment options. The materials were designed to encourage and enhance communication between and among women and their health care providers. Free consumer and health care provider kits were available through a toll-free phone number. In 2007, the USA National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), National Institutes of Health (NIH) State of the Science Conference Statement on Prevention and Fecal and Urinary Incontinence in Adults paved the way for the 2011 national campaign, Let’s Talk about Bowel Control (www.bowelcontrol.nih.gov). In 2001, the NAFC in the USA produced and disseminated continence awareness public service announcements (PSAs) to 380 television media markets, including Hispanic outlets. In the UK, the Bladder and Bowel Foundation (BBF), supported by the pharmaceutical industry, has conducted a lengthy campaign to raise awareness of OAB and to encourage HSBs (www.bladderandbowelfoundation.org/?p=1550). The campaign has featured advertisement of a toll-free information line on television, in the print media and on public transport. The BBF also provides informational leaflets on a variety of continence-related topics and a website containing a great deal of information as well as a directory through which visitors can locate their nearest continence professionals and clinics. Another UK organization, Education and Resources for Improving Childhood Continence (ERIC), offers courses for school nurses on how to deal with school children with UI, as well as children with medical issues (http://www.telegraph.co.uk/education/primaryeducation/5956231/Pupils-start-school-still-in-nappies.html). In Australia, the government has provided a high level of support to continence promotion activities via the National Continence Program [106,107,108]. These are just a few examples of campaigns conducted by organizations to bring awareness to lower urinary tract conditions.

Media campaigns should use multiple channels to ensure the broadest coverage [109]. Channels can include print media, television and radio, while the Internet, phones, and other mobile devices are also effective outreach channels [110]. Specialised age and health publications offer potentially valuable channels for dissemination of continence advice. At a more local level, a useful channel for dissemination can be the use of posters and booklets placed in medical offices, hospitals, seniors’ centres, pharmacies and churches and direct presentations to the public, such as at senior citizen’s centres [111] or retirement communities [112]. In many cultures, an effective strategy for reaching the public is through an informed journalist. Journalists often use a “media hook,” an interesting story that will take priority over other news on the television, radio or newspaper. In addition, having a spokesperson affected by incontinence or finding a celebrity who is willing to speak for the cause can help [82]. These individuals can act as “influence leaders.”

The Japan Continence Action Society held a “Toll Free Telephone Clinic” and callers were asked how they heard about the line. The responses in 2006 were: 30% from television, 16% from the web, 11% from a newspaper, 9% from a book, 6% from a friend, 5% from a brochure, 3% from a magazine and 20% other and/or unknown. A UK campaign [113] found that newspapers were by far the most common source of information, followed by radio. However, with the growth of the Internet and social media, print campaigns may no longer be the most effective avenue for awareness.

Roe [114] suggested that local initiatives on the availability of services and how to access them, as well as health education information on UI, may be particularly effective in raising public awareness and should supplement national campaigns. Awareness raising materials include pamphlets, self-care instructions, visual aids, pictographs, posters, banners, decals and advertisements in newspapers, magazines, newsletters, CD and films. Muller [115] believed that the change related to increased public awareness and HSB for continence care is likely to fuel the demand for innovation in technology and products. The Simon Foundation for Continence developed an innovative community education initiative, The Bladder Health Mobile. The goal of this initiative was to provide education, increase public awareness, and promote early diagnosis and proper treatment of UI and other bladder control problems [116]. However, it was never launched due to a lack of funding.

Health literacy related to UI is an important issue,
and is a potential target for additional consumer education. Raising awareness of health problems and providing information on terms used to describe symptoms assists in promoting HSB [117]. The words "continence" or "incontinence," "interstitial cystitis," or "painful bladder syndrome," or bladder pain syndrome and "pelvic organ prolapse" are poorly understood [118] and simpler terms may achieve greater public recognition in many languages and cultures. The use of "overactive bladder" in advertising has increased reporting of the condition to primary care professionals in the USA. Palmer and Newman [74] reported on a USA health promotion project conducted in 2000 to determine the needs of senior citizens concerning bladder control issues. Focus groups of older adults attending health seminars in urban, community and church settings were conducted. The primary objective of the project was to determine the understanding of older adults in the areas of general health and their beliefs surrounding the problem of UI. The 82 participants were predominantly African-American women representing all socio-economic levels. Seniors expressed confusion when asked if "overactive bladder, bladder control issues and UI" were the same condition. An evaluation of Australia’s National Continence Management Strategy in 2006 noted that recognition of the barriers to help-seeking and identification of the most appropriate terminology and key messages would strengthen awareness raising strategies [106,119].

In the UK, campaigns and consumer literature often avoid clinical terms in favor of lay terms that focus on the need to go to the toilet often, worrying that one may not make it to the toilet on time or have “leaking” of urine or feces. In the area of bowel disorders such as FI, it is felt that people find it difficult to find the right words to discuss their symptoms [85]. The IFFGD in the USA has found that people will often report having diarrhea to their physician. If the physician or nurse does not question the patient any further regarding the ability to control gas, liquid or solid stool, the incontinence may not be discovered.

Lack of understanding about terminology and physiology may lead to difficulties with communication between patients and providers. A survey of 138 women attending continence clinics in the UK, Australia, and Italy found that over 20% of women were unsure of the meaning of basic continence terminology commonly used by health care providers [120]. Terms tested in this study included “daytime frequency, nocturia, urgency, urge UI, stress UI, and hesitancy.” Two recent studies highlight the confusion and lack of knowledge about LUTS. Smith and colleagues [121] study of focus groups with women who experienced OAB, showed that there were high levels of misunderstanding about symptoms and physiology, and miscommunication between patients and providers. The finding was more pronounced among the older women in this study. Senejian and colleagues [118] corroborated this finding and recommended that public health campaigns about UI and other pelvic floor disorders need to use terminology targeted to the basic understanding of consumers.

Some researchers have targeted health literacy of patients undergoing urodynamic testing [122]. Theoretically, this may help to improve understanding of the procedure and reduce patient anxiety. This particular study did not reveal significant differences in overall satisfaction between the group that received this additional information and those who did not. A similar study revealed that after reading this type of material, most women (78.1%) felt they understood the indications for urodynamic testing [123]. However, fewer felt they understood what the procedures would involve (68.2%) or that they had enough information about the tests (64.9%). Many patients still expressed anxiety or embarrassment about the procedure. Additional research will be needed to determine how best to deliver this type of information to improve patient experiences.

b) Program evaluation

Evaluating the effectiveness of health promotion programs is notoriously difficult. Evaluation methods should be established prior to developing the continence promotion program. Evaluation should include quantitative measurements and qualitative measures. Open-ended questions may be more sensitive than “direct satisfaction” questions [124]. Health promotion evaluation methods include process evaluation, impact evaluation and outcome evaluation.

Research-based evidence for the effectiveness of programs aimed at raising awareness of continence issues or at improving help-seeking behaviors is rare [125]. A number of studies have considered the effectiveness of leaflets or brochures in raising awareness of UI and of treatment options and while generally supportive of such information, the evidence is contradictory in some areas and far from conclusive. In a good quality study of 1,175 participants, Wagg et al [126] reported that a self-help standard treatment leaflet is as effective as structured help from a continence nurse in reducing bothersome urinary symptoms in women. A small Australian study considered an information leaflet to have influenced the HSBs of people with UI who had received it, but these were people who were identified in a primary care setting and had already reported a UI problem [127]. A similar study found that individuals given a continence education package, which included a Continence Educational Brochure, helped to improve the health-seeking behaviors of participants who were bothered by UI symptoms [128]. Within 3 months following the education, of the 111 participants who were bothered by UI symptoms, 49 participants (44.1%) indicated that they had discussed the issue of bladder or bowel problems with a health care professional, but this could have been either directly because of the information contained in the brochure or because of
information contained in the leaflet. But there is research that indicates that education alone may not improve a person’s understanding or experience with specific medical care. A study that investigated the effectiveness of detailed educational materials, about the urodynamic tests given to women undergoing these investigations, did not significantly improve their experience [129]. A Swedish population-based study found that the distribution of a brochure on UI to the general public was well received and can be an efficient method to spread knowledge and encourage self-management [130].

In France, the effect of direct health education was evaluated in a randomized study in sheltered accommodation for the elderly [131]. Twenty centers were randomized to either a single one-hour health information meeting or control group. During a 30-minute talk, a nurse encouraged people to visit a physician if they had urinary problems. A questionnaire three months later found that the experimental group was much more likely to have had treatment if they were incontinent (41% vs. 13% controls). Similarly, knowledge and symptoms were found to have significantly improved three months after a 2.5 hour nurse-led workshop for women with UI and POP [132].

A health promotion project called ‘Dry Expectations’ was developed and implemented in six ethnically diverse, predominantly minority, and inner city senior centres in the USA in 1996 [111]. The program was designed to address an older population. The project consisted of three phases: orientation and training of key staff members/peer educators at the centres (train-the-trainer model); educating seniors through four one-hour weekly sessions involving visual aids and completion of bladder records and quizzes; and follow up sessions with senior staff/peer educators to reinforce the previous training. The program was very well received by the participants and approximately 80% felt they had more control over their bladder by the end of the last session.

The interventions that are most effective in reaching the public and triggering the desired behaviour seem to vary between countries and cultures. Television and newspapers work best in Singapore, with a “cured” patient bearing testimony to former suffering and its alleviation having the most impact. In the USA, television advertising targeting OAB, funded primarily by pharmaceutical companies, has yielded a significant response. Nationwide television reaches more people than the circulation of any single newspaper or the distribution of a booklet through physician offices. In March 2008, Japanese National Television broadcast a program about UI during “golden time” (2000 to 2045 hours). The audience rating was 15.6%, the highest in a year (usual rating 12%), and more than 500 calls were received in one night, requesting repeat broadcast and more details about treatment. However, the Internet is rapidly becoming the most effective and quickest way to reach the largest number of people. But there are cultural differences in the how online health information is used, as well as the types of sites users prefer to surf [110].

5. RECOMMENDATIONS FOR CONTINENCE PROMOTION AND AWARENESS (GRADE D)

Based on the literature reviewed in this section, the following recommendations can be made:

• Continence awareness should be part of mainstream and on-going health education and advocacy programs with emphasis on eliminating stigma, raising awareness of effective treatments, promoting HSB and improving QoL.

• Continence awareness programs should include education, health-care, and community service providers.

• Research is needed to provide higher levels of evidence on the effectiveness of continence promotion programs to include:
  - Identification and understanding of barriers to HSBs
  - Translation of promotion research into improved clinical practice and identification of methods by which this occurs.
  - Effectiveness and impact of consumer education initiatives.

IV. CONTINENCE ADVOCACY

1. BACKGROUND

Advocacy is defined as the act or process of defending or maintaining a cause or proposal. Advocacy, as it pertains to incontinence, involves assisting individuals in finding necessary health care and treatment. Organisations consisting of professional and public members promote continence advocacy as a core mission.

There is little doubt that incontinence is a common problem that often goes unreported, with those affected anxious to conceal the problem and reluctant to discuss it. Misconceptions fuel this reluctance, such as the widespread belief that incontinence is normal in some circumstances, especially in women following childbirth or in both sexes after a certain age. Incontinence is associated with a very strong stigma that sets it apart from most other health problems and will inevitably influence behaviours. Whereas many formerly stigmatized health issues such as cancer and women’s health are more openly discussed today than previously, incontinence remains for the most part shrouded in silence [133,134]. Yet the effect of incontinence on self-image, emotional well-being and QoL cannot be underestimated. Lowered self-esteem, shame, embarrassment, despair and depression are often reported; incontinence can
affect the ability to form or maintain personal relationships, leading to isolation [135,136,137,138].

In such circumstances, there is a need among the general public for better awareness and understanding of bladder and bowel problems, and of the services and treatments that are available. There is also a need for both practical and emotional support to those affected and for advocacy on their behalf in pursuit of development in treatments and services. In response to these needs, continence advocacy organisations have emerged in many countries.

2. CONTINENCE ADVOCACY WORLDWIDE

A central goal of most continence advocacy organizations is the raising of public awareness and understanding of the types of incontinence, the risk factors for incontinence and treatments, services and management products available. These organizations provide a valuable voice for an often unheard consumer population in political and health-care governance, development and planning processes. In recent years, consumers and clinicians have been involved in identifying and prioritizing important areas of research relating to incontinence in order to inform research development and funding decisions [139,140]. In addition, through advocacy organisations, the consumers of health care have become more closely involved and influential in the activities of clinical professional organisations.

Another major role that has been adopted by many continence organizations is the direct provision of information support to those affected by incontinence and to caregivers. The types of information provided include background information about symptoms, risk factors and conditions, treatments and management strategies, and availability of, and access to, health and social services. Such information is provided through a variety of sources, including regularly produced magazines, internet-based information resources, telephone support lines (often staffed by qualified nursing or counseling staff), and printed media such as leaflets and booklets on a wide variety of topics. Other innovative strategies have included outreach work through travelling information road-shows and events [116]. Organisations also provide emotional supports to people with incontinence by putting them in touch with others similarly affected either through direct contact at meetings or through internet discussion forums.

For the Fifth International Consultation on Incontinence, forty-seven continent organisations in twenty-eight countries were identified, with an additional two international consumer-based organisations (Appendix 1). Continence organisations vary in scale and in nature, from small consumer or clinician groups that focus on quite specific bladder symptoms or conditions, to large and well-funded national organisations that address bladder problems generally. Often the founding and development of such organisations has resulted from the dedication of a small group of sufferers consumers, clinicians or both, who have worked tirelessly to promote awareness and understanding of incontinence among the public or colleagues and to provide better services and supports to those affected. They represent a wide diversity of models, including consumer-led, company-sponsored, consumer-only, professionals-only, and organisations which have deliberately set about trying to bring together all relevant stakeholders in a relatively democratic model. In every part of the world, these organisations play a dynamic role in building both public and professional awareness of this underserved and underreported condition.

a) Funding

The degree of funding available inevitably affects the level of work that organizations can undertake. Whereas in some countries, such as Australia, relatively strong governmental support has been provided for the work of continence support organisations, in other countries such as the USA and UK, financial support has come for the most part through charitable donations from individuals and foundations, or through the support of the pharmaceutical industry and continence products manufacturers. Most continence organisations are poorly capitalized, being either under- or unfunded (i.e., run by volunteers) and are held together initially by either a dedicated consumer advocate or an energized healthcare professional. In most cases, this professional is an urologist or nurse whose patient population includes persons with UI. In developing countries, where the need for improved awareness, support and services is often greatest, the availability of funding for continence advocacy work is particularly challenging. Lack of funding limits the work of continence organisations, and searching for funding can present a considerable burden in terms of time and skills for an organisation’s paid or voluntary staff. The very source of funding can present additional challenges: in most parts of the world, organisations are at least partially, if not totally, dependent upon funding from pharmaceutical and product manufacturers. In order to avoid a perceived or real conflict of interest, organisations are well advised to have clear and robust policies dictating the nature of their relationships with commercial entities, to declare their arrangements fully and, if possible, to ensure that they are not dependent for funding upon only one company.

b) Collaboration

Within countries, some previously separate consumer-led organisations have merged with clinician-led organisations in order to make best use of funding available and to prevent duplication of efforts [133]. In other countries there may be good reasons why this is not possible, while in some circumstances there is merit in the independence of groups focusing on specific areas within the continence field. However, both within countries and internationally, there is much to be gained from the networking and cooperation of organisations.
Duplication of effort in the production of materials and other activities can often be avoided, and although it may not be practical to develop global and uniform strategies for continence promotion and public awareness, much can be learned from the positive and negative experiences of other organisations in other countries. For instance, in 1998, the Asia Pacific Continence Advisory Board member countries including Thailand, Korea, China, Hong Kong, Taiwan, Malaysia, Indonesia, India, Philippines, Singapore and Pakistan joined to develop continence promotion programmes that collaborated with health care professionals and the general public. Their mission was to develop strategies to increase awareness and reduce the social burden of UI in the Asia Pacific Rim.

In addition, the cooperation and coordination of continence organisations on an international level can result in more effective engagement with influential international clinical and research organisations. Professionals (e.g., urologists, urogynaecologists, gynaecologists, geriatricians, primary care practitioners, physiotherapists, nurses) and professional organisations have been instrumental in promoting awareness of continence in all care settings. The International Continence Society (ICS) established the Continence Promotion Committee (CPC) to promote education, services and public awareness about incontinence throughout the world, and to facilitate communication, exchange of information and partnerships between continence organisations, health care professionals, governments, and industry. The CPC’s multinational and multidisciplinary representation, which includes representatives of continence organisations from around the world, aims to identify broad issues through an international forum that can facilitate translation at the local and national level. Each year at the ICS’s annual meeting, the CPC holds workshops around various themes that have a broad national focus, such as prevention, GP education and promotional strategies. Its relevance, as is the case with each of the national organisations, is to recognize the interface between continence management and continence awareness and promotion. The CPC is also promoting continence awareness through the hosting of public forums in conjunction with the ICS annual meeting and sponsorship of the yearly World Continence Week.

The level of evidence on the impact of national organisations increasing continence awareness is Level 3.

3. RECOMMENDATION FOR CONTINENCE ADVOCACY (LEVEL OF EVIDENCE-3, GRADE D)

Based on the literature reviewed in this section, the following recommendations can be made:

- Research is needed on the activities or effectiveness of organisations that target consumers or the general public.

V. SERVICE DELIVERY, MODELS AND ACCESSING CARE

1. BACKGROUND

There has never been a comprehensive examination of an optimal service or model for delivery of continence care. It is not known whether academic, specialist-led centres will achieve better and more cost-effective results than primary care clinics, domiciliary services or any other model. However, most experts believe that female UI is initially most effectively diagnosed and managed by primary care providers compared to specialist services. A large cross-sectional community mail survey of women with UI in France, Germany, Spain, and the UK found that many women actually prefer to be treated for UI by primary care providers, despite easy access to specialized services [141]. Appropriately trained continence nurses and physical therapists can provide high quality UI care for women; women are satisfied with care provided by continence nurses [142,143,144]. In 2000, the UK Department of Health issued guidance on continence services that outlined a good practice model to achieve more responsive, equitable, effective continence services [145].

In the USA, the primary sources of care for the majority of Medicare patients (primarily an elderly population) are family physicians and primary care physicians [146]. Less than 1 person in 1000 is admitted to an academic, medical centre hospital [147]. Thus, in the USA, elderly persons with UI and FI will probably be seen by primary care physicians for initial assessment. This is unlikely to address the needs of developing countries (such as the Asia Pacific area or in Africa) where dissemination of expertise to rural communities and isolated community health care workers is more logical. Continence services are being implemented in several countries using shared teaching and educational resources through co-operative arrangements of the respective Continence Foundations. Thus, the general practitioner (GP) or family physician plays an important role in the first line treatment of UI that may be treated successfully with conservative treatments in the majority of patients [148,149].

In fact, UI is often a complex and multi-faceted problem, particularly in frail or dependent individuals, and it may require input from a wide variety of disciplines to tackle it effectively. Drennan and colleagues [150] interviewed thirty-two caregivers about their strategies for managing a person with UI and dementia. They recommended that professionals, especially those in primary care, could be more proactive in questioning patients about incontinence and toilet habits to identify counter-productive and harmful strategies. Symptoms typically associated with incontinence may also be indicative of other conditions, as evidenced by the urgency and frequency symptoms of BPS [151,152]. The ICI Committee 19 addresses Bladder Pain Syndrome. While it may not be practical for all specialties to work in close prox-
Knowledge and attitudes about UI and care certainly influence consumer choices. Some studies suggest that as QoL worsens, care-seeking increases [156]. In some cultures, particularly those where living with extended family is more common, UI may be viewed as a family issue rather than a disorder affecting just one family member [157]. Family support is often seen as an important component when dealing with UI [158].

Buckley and Lapidus[159] conducted an online survey of 1,040 community-dwelling adults in the UK to examine attitudes and behaviours related to care-seeking for UI, FI, and nocturnal enuresis [159]. Overall, 75% said they would turn to their GP for help. However, a surprising 23% said they did not know where to turn for help. This confirms that there are still major needs for continence promotion and consumer education at the community level.

This can create a dilemma and raises many questions. Should health care professionals attempt to persuade or educate people who do not see UI as a problem that it is an abnormal condition? Should a patient who is “not bothered” by symptoms be treated because the partner or caregiver requests the physician’s assistance? This is concerning as Rodriguez, et al.[160] found that physicians underestimated the degree to which patients were bothered by their symptoms 25% to 37% of the time. Is lack of bother genuine or simply a defense against having to tackle an unpleasant problem? Does early intervention prevent later deterioration in symptoms? Does delay in treatment mean that success rates are lowered? There is scant evidence on any of these issues or on the most acceptable way of providing help.

Using narrative analysis of structured patient interviews, Bradway and Strumpf[161] found that women with UI who sought professional care were more likely to “tell a story,” describe UI as having a negative impact on their sense of self, were older, Caucasian, were in ‘good or excellent’ self-reported health, and had suffered from UI longer compared to those who did not seek care [161]. They also confirmed that many women found that UI impairs their sexual health and intimacy.

In contrast, some studies have shown that compared to general health care, many women prefer to take a more active role in their care for UI. In a survey of 265 Norwegian women with UI, O’Donnell and Hunskaar found that 60% of women wanted to be actively involved in their UI care decisions compared to only 38% for their general health care needs [162]. However, this may also be influenced by the context of care and the education level of the patient [163]. The findings are not universal, and may be more associated with a desire for adequate clinical information rather than a desire to make active treatment decisions [164].

It is the impression of all members of this committee that due to the high percentage of people not seeking help for UI (for all the above mentioned reasons), health care professionals must develop the concept of a “reaching-out” service and to actively provide service for incontinence care. This means promoting awareness, openly discussing and actively detecting UI, while providing simple and efficient therapy. While not all patients with voiding disorders (e.g., bothersome lower urinary tract symptoms including urgency, frequency, nocturia, poor stream and hesitancy) have incontinence, many of these patients will also benefit from a service that will provide assessment, education and relevant treatment prior to the potential onset of incontinence.

3. MODELS OF CARE

Continence care was defined by the Canadian Continence Foundation as “all measures directed
toward the prevention, improvement and or management of UI” (http://www.canadiancontinence.ca/pdf/en_dec2000vol_1.pdf). Models of care for the frail elderly with UI are covered by Committee 11: Incontinence in the Frail Elderly. A report on continence care services worldwide noted that services were scattered, inconsistent and considerable discrepancies exist in their funding. It was concluded that there is a need for accessible (and affordable) continence care and multidisciplinary teamwork [165]. Models of service delivery for FI, BPS/IC and POP have not been defined.

The provision of continence care and services in each country will depend on the organisation and infrastructure of its health services. It is difficult to make specific recommendations that will apply in such a variety of contexts. In addition, UI is so widespread and affects men and women of all ages who receive medical care from a variety of health care providers (e.g., PCP, family physician, geriatrician, gynaecologist, nurse practitioners). This means that there will seldom be one point of entry to continence care. There has been little systematic assessment of continence services aimed at identifying an optimal service. It is not known whether academic, specialist-led centres will achieve better and more cost-effective results than primary care clinics, domiciliary services or any other model. There are no studies directly comparing the effectiveness of specific delivery systems for continence care. A range of service delivery models is described below. The level of evidence on service delivery models is Level 4.

a) Single specialist

This is a service led by a consultant or specialist physician (urologist, gynaecologist or urogynaecologist), often focused around the “urodynamic unit” providing medical or surgical treatment. This is the most common model in developed countries; the best of them have a nurse continence advisor or continence nurse specialist as an integrated part of the service.

b) Nurse specialist or advisor

In some health systems, both UI and FI have traditionally been seen solely as a nursing problem, with little interest or input from other members of a multidisciplinary medical team. Except for a few isolated areas, the main intervention has been trying to help individuals and caregivers cope with symptoms, rather than attempting to treat the underlying cause of the UI. For example, in the UK, it is common for an elderly person presenting with UI to be referred directly to the district nurse “for assessment for pads and pants,” with no physical examination or further investigation considered.

There are many examples of nurse-directed models of incontinence care described in the literature. Farrell and colleagues [166] studied a modification of UI care that involved step-wise care delivery, including a continence advisor and nurses, which were found to be as effective as the traditional medical model. In countries such as Australia, New Zealand and the UK, a national network of Continence Nurse Advisors (CNAs) or Continence Nurses liaise, integrate services, and guide individuals through the referral route most appropriate to meet their needs. The efficacy of Continence Nurse Practitioners (CNPs) in the UK was reported by Matharu and associates [167] who studied four hundred and fifty (450) women over 40 years of age who underwent urodynamic studies in the UK after seeing a trained CNP. In patients diagnosed with bladder overactivity, the CNP had prescribed drug therapy to 79% of patients and pelvic floor muscle training (PFMT) to 64.8%. In those with urodynamic stress UI, 88% had appropriately been prescribed PFMT. Nursing assessment has the potential to assign patients the correct conservative treatment thereby shortening waiting times for urodynamics and specialist assessment.

There is more evidence that treatment of incontinent community-dwelling individuals by a “continence nurse” is beneficial in terms of clinical outcomes [168]. Jeffrey and colleagues[144] assessed the clinical effectiveness and patient satisfaction with nurse-led, telephone follow-up of women with lower urinary tract symptoms. Participants were offered telephone follow-up with a nurse instead of a conventional outpatient appointment. Suitability for this option was decided by the doctor who saw the woman at her last visit. In total, 116 women received “telephone consultations” and the mean overall satisfaction score was 77 (maximum score was 100). Only 16 patients (17%) did not prefer telephone follow-up to a clinic visit. The authors concluded that nurse-led telephone follow-up is associated with high satisfaction and has the advantages of consistent follow-up by the same clinician, convenience to the patient and cost-savings [144]. Shaw, Williams, and Assassa[169] conducted a postal survey of people in the UK receiving services for UI by CNPs. Participants expressed satisfaction with nurse-led services because of the interpersonal, technical, communication and information-giving skills of the nurses.

The nurse continence advisor (NCA) may be independent, but is usually associated with community/area health centres, where they may have variable professional support from GPs and family physicians. Continence nurses often work in both hospital and community settings, and the service is focused on primary care. This is particularly true for district nurses. Key roles include patient assessment and implementation of conservative management strategies where appropriate and facilitation of patient access to incontinence product subsidies or schemes.

The Department of Health in the UK has commissioned an evaluation of different models of nursing services, with and without specialist NCAs. It was found that where there is a continence nurse incontinent people are more likely to receive a tar-
targeted referral to specialists such as an urologist, are more likely to have had investigations such as urodynamic testing and are more likely to receive appropriate treatment and care for their UI. These patients were also more likely to report satisfaction with the service. In contrast, there are still concerns that general nurses continue to "contain the problem" instead of promoting continence, despite acknowledging its importance [170].

Unfortunately, there is often still an emphasis on containment and simple management of UI rather than on active therapy. Part of this may be due to cost, which has been shown to be lower for containment compared to active continence evaluation, promotion, and treatment [171]. Even in this case, provision of care may be substandard. An audit of the continence services in the UK revealed that rationing of pads and absorbent products was widespread, with most patients limited to four pads per day [172]. In addition, 59% of the continence services surveyed provided pads for children under the age of four, which is outside of the published national guidelines. This indicates a need for improved implementation of continence services with regard to use of pads and products.

In a series of studies performed in Leicestershire UK, the short and long-term outcomes of a new CNP-led service for urinary symptoms (three and six months after implementing the program) were examined and evaluated [173,174,175]. Williams, et al.[175] reported on a randomized, controlled study (RCT) of 3,746 community-dwelling individuals greater than 40 years of age (61% women) who had incontinence, frequency, urgency, and nocturia all impacting QoL. The experimental group was comprised of 2,958 patients. The standard care was the control group (n=788) who accessed GP services and existing continence services in the area. The experimental group received an 8-week primary intervention package by the CNP (21 generalist nurses who trained as CNPs). The CNPs delivered evidence-based behavioral interventions using predetermined care pathways in four visits over an 8-week period. Interventions included advice on diet, fluids, bladder training, pelvic floor muscle awareness and healthy eating. Individuals whose symptoms persisted after primary intervention were offered urodynamic testing. The CNP led service had a 10% higher cure rate than standard care with statistically and clinically significant reductions in urgency, frequency, nocturia and UI. In addition, QoL improvements were greater in users of the CNP-led service and higher levels of patient satisfaction were achieved. This is the first study to show the effectiveness of nursing services on urinary storage symptoms (rather than simply incontinence) and associated QoL. The authors noted that the public health value of a 10% reduction in symptoms is substantial when applied to such a common problem.

An additional number of studies support the efficacy of specialist NCA in the delivery of community continence care [148,176,177,178]. In the USA, urology nurses have been trained as "teachers" to successfully implement behaviour modification programs to groups [179]. Nurses may also play an important role in the evaluation and management of POP, a condition which is often associated with concomitant UI [180].

Regional continence nurses have also been successfully incorporated into primary care practices, however they need to be given both the authority and opportunity for interactions. A survey of 22 district continence nurses found that having regularly scheduled appointments with patients who were actively involved in their assessment and management led to the best nurse provider satisfaction and sense of professionalism [181].

In the USA, there has also been an increase in nurses who specialize in dealing with patients with pelvic floor disorders including UI, FI, POP and BPS/IC/PBS, although there are no academic or clinical proficiency requirements in order to be considered a CNP or "continence nurse specialist." Those nurses who do specialize in continence care have obtained their knowledge and skills through self-motivated activities [182]. Masters prepared or educated "advanced practice registered nurses" (APRNs) have become increasingly interested in, and knowledgeable about, the assessment, diagnosis, and treatment of people suffering with UI. These nurses are developing a nursing subspecialty in the care of individuals with UI and related pelvic floor dysfunction, providing comprehensive assessment and treatment (drug and conservative therapy), and acting as educators and researchers [183].

A 2000 study in the USA demonstrated significantly improved outcomes for three clinical problems, UI, depression, and pressure ulcers, when advanced practice gerontological nurses worked with nursing home (NH) staff to implement scientifically-based protocols [184]. In addition to working with NHs to provide resident evaluation as physician extenders, this research indicates that this service model using an APRN can be an effective link between current research-based knowledge about clinical problems and NH staff. This study also showed that consistent educational efforts with staff and NH residents demonstrated that interventions could improve or stabilize the level of UI in this population.

c) Multidisciplinary resource and referral centre

Multidisciplinary clinics, as service models, have been shown to provide comprehensive continence care. In multidisciplinary clinics, such as a "Pelvic Floor Clinic," the gynaecologist, urologist, colorectal surgeon, and continence nurse work together [185]. Some pelvic floor clinic staffing models also include physical therapists (PTs) and registered dieticians.
An Australian study took all community referrals of those who had been incontinent for at least two months and had at least one episode in the preceding two weeks to a continence clinic [186]. Patients were randomized to conservative treatment or control, with a crossover design. Patients were asked subjective questions about embarrassment, odor, depression, family relationships, isolation, and laundry, on a 4-point scale ranging from no effect to major effect upon life. The questionnaire was completed at the start, and at 2, 4, 8, and 12 months. Seventy-eight patients entered the study and 87% improved with treatment (versus 41% controls). Fifty-two percent were moderately or severely embarrassed at the start of the study period, but at 4 months, only 17% were. Depression decreased from 49% to 22% and isolation from 28% to 12%. Odor and the use of extra laundry also decreased. All benefits were maintained at 12 months. Controls did not improve on these items until crossed over to active treatment, despite feeling better. The authors conclude that conservative treatment in a multidisciplinary community clinic improves continence and well-being.

The Continence Foundation of Australia (CFA), funded by the Australian Government, employs CNAs to answer the National Continence Helpline and to provide advice to consumers and health professionals, including referral advice [187]. Evaluation of this service indicated availability and uptake of information, as well as increased traffic to the Bladder and Bowel website and the National Public Toilet Map. There had also been a general increase in the number of consumers seeking help for their incontinence.

An expansion of this service provision is exemplified by the National Centre for Continence in Israel, which aims to provide an integrated service [188]. The Center’s professional team not only treats incontinent patients, but also educates GPs and nurses who come from pre-selected peripheral/outing clinics. They also provide ongoing support and advice as well as a pathway for tertiary referral. A local team (GP and nurse) is also selected to be in charge of promotion, detection and treatment of incontinence at the clinic. They later become “in charge” of incontinence in their region. This model allows national distribution of continence services with support from the resource centre and provides interdisciplinary exchange, as well as maximum co-operation between Medical Centres and community health services. The national centre is funded by government and industry to provide a “Hotline” for the public, to promote education programmes in nursing and medical schools, hospitals and NHs, and to develop guidelines for diagnosis and management of incontinence by primary healthcare staff.

Multidisciplinary services should initially focus on a step-wise approach to evaluation and management. This need not be limited to tertiary level centers, but can be incorporated into care in local communities when providers with expertise are available [189].

The multidisciplinary model has also been used for delivery of community-based services. One model used a combination of clinic and home visits, multidisciplinary care delivery to targeted client groups, and use of multidisciplinary tools and provider education [190]. Overall, a generalist approach was found to be most effective in this study, although this may depend on the community context and other factors. The model shown in Figure 1 combines an academic center and community services. Although it was proven feasible, there were significant challenges due to funding and infrastructure [191]. This program in Canada is ongoing, and additional research will be needed to assess overall outcomes.

d) Primary care

Although primary care practitioners can certainly do a large portion of general continence care, the literature notes barriers to care provision and poor adherence to evidence-based recommendations [192,155]. This precludes efficient delivery of continence care and prevents appropriate first-line treatment. Cohen and colleagues [193] found that, among primary care providers, only 25% initiated a discussion of incontinence with their patients. In their cohort, older patients were less likely to be asked about incontinence compared with younger patients. Findings from a USA survey indicate that the majority of primary care practitioners were unlikely to ask about UI [194]. Forty percent recommended pad use for treatment, and only 17% were aware of clinical practice guidelines. The identical situation exists in other countries such as in Europe and Canada [195,196]. Although most primary care practitioners recognize that UI is common, only a minority have an organized plan for its evaluation and management, and report feeling very comfortable dealing with UI. Ten years ago, attempts by the U.S. Agency for Health Care Policy and Research, now known as the Agency for Healthcare Research and Quality (AHRQ), to use physician group interventions to raise awareness through UI guidelines failed to improve screening and management rates in the primary care setting [197]. There have been other innovative methods used to increase UI screening. Yazdany[198] prospectively randomized patient charts (n=88) to receive a chart-alert sticker (“Do you leak urine?”) that reminded resident physicians to ask about UI in their general gynaecology clinics. Overall, the rate that resident physicians inquired about incontinence increased with the alert-sticker from 4% to 34%. This method may be more easily implemented in electronic health records.

Many countries have sought to shift the provision of primary care from doctors to nurses in order to reduce the demand for doctors and improve healthcare efficiency. A Cochrane review found that quality of care is similar for nurses and doctors, since nurses tend to provide more health advice and achieve higher levels of patient satisfaction compared to doctors [142]. A RCT in the Netherlands compared usual care for UI in GP clinics to those that included...
a nurse specialist [199,200]. Short-term outcomes revealed better continence rates in those patients seen in clinics that involved care by the nurse practitioners. However, the results were not sustained at the one-year follow-up, and both groups had equivalent continence outcomes. A focus group analysis with the nurse practitioners revealed that they felt competent to provide the needed services and appreciated by the patients [201]. In addition, they felt they added value to the practice, particularly since many of the GPs were seen as lacking interest in UI. Overall, the results do suggest a benefit from this type of multidisciplinary care delivery. Future research will be needed to determine if long-term outcomes can be maintained and if the model may have other unmeasured benefits, such as better cost-effectiveness.

Therefore, primary care practitioners may not be the most appropriate professional to manage UI, and this committee’s recommendations include a care delivery model (see Figure 2) based on a chronic care approach that has been used successfully in other chronic conditions (e.g., diabetes, CHF, asthma) [202].

There are many factors that can persuade health care planners about the importance of adequate investment in community continence services. The prevalence and the number of incontinent people is likely to increase with an aging and increasingly dependent population and many frail, disabled or elderly people are incontinent for reasons extraneous to the urinary system (such as poor mobility, an inappropriate physical environment or lack of an individualised care regime). It is often best to provide an initial assessment for such individuals in their usual surroundings and to reserve hospital or clinic (specialist or academic) referral for those who do not respond to simple measures such as treatment of constipation, modifying a diuretic medication, or provision of accessible toilet facilities. A number of guidelines have suggested an algorithmic, step-wise approach to UI assessment and treatment, and many conservative treatments have a good success rate in primary care [203,204,205,206].

e) Other service models

In a structured literature review, Chin and colleagues found that primary care clinics for continence led by nurses and allied health professionals were common across the world [207]. Although there were a number of differences that were culture specific, there were also a number of key factors that predicted high quality care across all cultures. These included identification and recruitment of appropriate patients, improving access to care, enhancing engagement with primary care providers, using small teams with adequate training, developing structured referral lines,
and working to employ evidence-based practices including guidelines and treatment protocols. Group intervention models for delivering first-line treatment for UI is feasible [208,112,209] and may be an equally effective and potentially cost-saving approach to this form of therapy [210]. Even simple group education about UI in general, may improve self-care among postmenopausal women with the condition [11]. Another study has shown that nonmedical lay instructors can be taught how to instruct patients in proper pelvic floor muscle exercises [211]. This train-the-trainer model may be useful to help disseminate behavioural therapy on a more widespread basis.

Education of other professionals who interact with UI patients, but do not themselves provide direct health care, may also be quite useful. For example, improved education about UI and other lower urinary tract disorders among teachers may help improve not only their own continence health, but that of their students as well [212].

Many consumers seek information from the Internet, although the quality of materials can be highly variable. Some websites include an interactive component, including e-mail of other communication methods that allow users to interact with a health educator or other professional [213]. Computerized education methods have been developed to disseminate consumer education materials about UI [214]. Usability was considered good and these methods may help disseminate continence promotion materials.

1. Acute or sub acute care to community

Patients with UI who receive care in acute care hospitals have been shown to lack appropriate care because of the lack of knowledge amongst acute care nurses about assessment or management of UI [215]. Nursing education must change to improve this situation. The value of tackling this is shown in a retrospective review of 6,773 episodes of care in 54 medical facilities [216]. The discharge destination was altered by the presence or absence of UI – 57% versus 82% respectively being discharged home, and 29% versus 12% being discharged to a NH or other health care venue. In addition, the time in rehabilitation was 185.6 days for those with UI compared with 156.8 days without UI, and geriatric costs in evaluation and management were higher in the UI group. The level of functional independence and motor function also impacted outcome.

Continence promotion, education and treatment may occur in a variety of clinical settings, particularly in relation to other associated clinical conditions. For example, UI occurs commonly after acute stroke. Rehabilitation nurses who work with post-stroke patients could play an important role in continence care, however research shows this may not happen.
regularly. A recent multinational qualitative study examined a focus group of rehabilitation nurses in the UK, Sweden and China [217]. They found that only a superficial assessment of continence was routinely performed by most nurses in this setting. The authors noted a focus on containment and social continence although process models of practice were seen in all countries. Other studies have corroborated these findings and reveal the emphasis in the rehabilitation setting is containment rather than continence promotion or active therapy [218]. The results highlight a need for systematic assessment and development of patient-centered care plans.

Heart failure is another common clinical condition, particularly among older adults, that is frequently associated with UI. A recent study of 182 heart failure patients with at least monthly UI revealed that 83% had not asked for help with their incontinence symptoms and 64% were interested in learning more [219]. Many patients, particularly those with comorbid diabetes, were contemplating changing their behaviors and seeking care.

Clinical care around the time of pregnancy and delivery is another potential time for patient education and interventions aimed at preventing or treating UI [220]. Studies have shown that women are generally very receptive to this type of clinical education in the post-partum interval [221]. Additionally, women who were instructed in pelvic floor muscle exercise by a PT during the immediate post-partum period were more likely to continue the exercises at one year after delivery compared to controls [222]. However, in many cases, this opportunity is missed due to lack of training on the part of care providers. A study of nurse midwives in Australia found that the majority do not assess for UI in the peripartum period [223]. In addition, the survey respondents indicated a lack of guidelines for nurse midwives.

2. Elder services (Long term care or Nursing homes)

There is growth worldwide in the use of APRN “continence” specialists practicing in home care and LTC settings, providing expert consultation in UI and related disorders [183,182]. Many have developed innovative approaches to management of UI in NHs. Bucci [224] developed the CHAMMP (Continence, History, Assessment, Medications, Mobility, Plan) tool to educate NH staff in the USA on a comprehensive continence assessment and to assist in implementation of individualized plans of care. The CHAMMP program improved one facility’s Quality Measure Indicator Report. ICI Committee 11 discusses services for frail elders.

Many older adults rely on home care services for a variety of health care needs, including UI. The methods used to implement and deliver services can differ. A great deal depending on the care model used in a particular region. Implementation of guidelines is felt to be an important part of this process [225]. This allows care providers to try to put evidence into direct practice. A recent study examined 19 home care agencies in the Netherlands to determine if the quality of care systems influenced outcomes [168]. Most models included designation of the continence nurse and documenting UI-related actions on the patient care record. However, no differences in clinical outcomes were observed in this study of 155 home care teams. The authors concluded that additional research examining specific implemented practices would be required in the future.

Even within the long-term care setting, the focus is too often on containment and use of pads or absorbent products compared to active continence promotion or treatment. A recent Cochrane review supported this finding, and noted that none of the studies reviewed focused on attempts to maintain continence in facility residents [226].

One new innovative model has described the development of individualized continence profiles for use with NH residents [227]. This may help NH staff identify residents who may benefit from various forms of assessment and interventions. Another model has worked to involve NH residents more actively in their fluid intake and continence care. After a 12-week intervention, overall hydration status improved and time spent in wet diapers decreased significantly in a cohort of 153 NH residents who participated in the intervention [228]. Education of staff was felt to be important to the observed success in this study. Within the context of ‘person-centered care,’ there is a growing need to develop and encourage bladder rehabilitation and prevention with a proactive focus, particularly for older adults [229]. This may help to expand the focus beyond containment only in this population.

Another study found that the best performing long-term care facilities in terms of UI care generally utilized a multidisciplinary process improvement team [230]. In addition, more were likely to use a clinical practice guideline in evaluation and management compared to the poorer performing facilities.

Data have shown that a nurse’s level of knowledge and attitudes about UI may influence care within the NH environment [231]. Overall perceptions about physical functioning in older adults may also impact this issue in hospitalized patients [232]. Physical functioning is a complex entity and nurses in this focus group study identified system-level approaches that could be used to prevent additional functional decline in their patients. Education specifically targeted at family caregivers may also be important in the promotion of continence for community dwelling older adults. A recent report by Jackson and colleagues [233] used focus groups of family caregivers and health care professionals to identify the types of materials and methods of delivery preferred by participants [233]. Most wanted printed materials such as summary brochures or fact sheets with answers to frequently asked questions.
Electronic materials were not as readily desired in this study.

Distance learning techniques have been successfully used to teach and implement programs and strategies for management of UI in NH [234]. This training method might help to improve dissemination of information, particularly in rural and otherwise underserved communities in more remote locations.

3. Models in developing nations

Continence services are a relative luxury, to which countries with a low per capita income are unlikely to devote scarce resources, especially while other population health issues have precedence.

The potential demand for UI services in developing nations far outstrips the resources that are available. The provision of services will depend on dedicated healthcare professionals with support by government or industry, and by a local continence organisation to educate a new generation of service providers who will carry the services to remote communities. Increased use of advanced communication technologies can help to disseminate continence promotion materials among nurses and other health professionals worldwide [235].

In some instances, consideration will have to be given to cultural and social mores and taboos. For example, Ethiopia’s Health Minister has stressed the need to develop rural health services to reduce the incidence of fistula and to have first time mothers examined by Traditional Birth Attendants (TBAs). The ICI Committee 18, Vesico vaginal fistula in the developing world, addresses service for this specific condition. It is planned that TBAs will be trained to identify high-risk women and thereby divert expenditure from high cost physicians and urban health services to training community health workers and to health education. Attitudes on female circumcision, contraception and women’s health, matters that are often decided by their husbands, obviously have much wider implications than just continence care.

4. Recommendations for service delivery, models and accessing care

Making recommendations for interdisciplinary and multidisciplinary models for continence advocacy and service delivery remains a rather elusive goal. Although there have been more publications since the last ICI, there has been little evidence of substance generated. Implementation is quite difficult, funding is often limited, and there are few studies on outcomes. Based on the literature reviewed in this section, the following recommendations can be made:

- There is a need to move beyond the theory and work on research about the practice of continence care delivery and education. We recommend a care delivery model based on a chronic disease approach. (Grade D)
- There needs to be an increased emphasis on non-physician models of care (nursing, nurse practitioner, continence advisor, physiotherapy, physician assistants, etc.). (Grade C)
- Despite the proliferation of guidelines, there is increasing evidence that practicing clinicians are not following them. Implementation models should be developed on how to translate guidelines into practice. (Grade C)
- There still appears to be a shortage of physician specialists in continence care (urology, gynaecology, etc.) which needs addressed. (Grade D)

VI. PROFESSIONAL EDUCATION

1. Background

With the continued advances in health care, increasing public pressure to provide high quality evidence-based care, limited time for health professionals to update their knowledge and the recognised ineffectiveness of passive ‘lecture style’ education provision, the need for new models to change health care providers behaviour is essential. Nowhere is this more relevant than in the provision of care for those with UI and FI, where educational provision has been inconsistent at best.

Professional education is a key component in the provision and care of individuals with UI and FI. In their state-of-the-science statement on the prevention of faecal and UI, Landefeld et al [8] identified that education of health care providers alone is insufficient to improve detection and treatment of UI and FI. However, they recognise that in order to appropriately detect and evaluate incontinence professional education is required along with outreach and practice-based resources. To date, the education and training of those involved in the provision of continence care has been poor.

There is limited literature on the educational preparation and ongoing training of those health care professionals engaged in continence promotion, care, and referral and even less on the evaluation of education programmes in terms of educational or practice outcomes. It has long been recognised that professional education with reference to UI and FI remains only a small part of the basic training of physicians, nurses, or allied health professionals and on-going training is largely ‘ad-hoc’ with huge variation in the types, content and quality of such training. An early survey in the UK found minimal attention given to incontinence in both medical and nurse training, and a key recommendation for improving continence care was an increase in the quality and quantity of professional education [236]. This has clearly not occurred. While educational initiatives have been undertaken, they remain fragmented and inconsistent internationally. Most notable is the absence of evidence demonstrating an impact of professional or public education on the burden of suffering posed by OAB and UI. The
ICS has established an Education Committee to promote, organise and co-ordinate all educational advances undertaken under the auspices of the ICS. Details are available on the ICS website (www.icsoffice.org).

There is a paucity of published work on professional education on UI or FI. Similarly there are few studies addressing the effectiveness of education in improving the knowledge of learners, or on whether improved knowledge impacts patient outcomes. Information has been building since the publication of the ICI chapter in 2009, but the level of evidence on the effectiveness of professional education remains at Level 4. This section will examine the available evidence on the effectiveness of professional education on incontinence for different groups of health care professionals.

2. MEDICAL EDUCATION

a) Generalists (family physicians/general practitioners/primary care physicians)

Physicians (general, primary care, and family physicians) have been viewed as having a gate-keeping role in continence provision since they are often the most likely first point of contact when consumers seek formal help for their incontinence. Most physicians have received little education or formal training about incontinence, fail to screen for it, and view the likelihood of successful treatment as low, so most avoid the topic with patients. At the same time, there are no data confirming the benefits of screening as a method to reduce the burden of suffering from UI. A postal survey noted that only 18% of respondents said providers asked them to complete a questionnaire about bladder control during routine office visits, and a majority (69%) felt it would be very helpful in prompting discussion if their physician or health care professional provided a form for them to check off symptoms of incontinence [104].

Traditionally, UI and FI have formed only a very small part of the undergraduate medical curriculum. Education on UI has usually been fragmented across different organ systems, with training scattered between gynaecology, urology, and geriatric medicine. Bladder and pelvic floor anatomy is poorly covered in preclinical training and relevant physiology is rarely mentioned. A survey of urology residency directors, medical student educators in urology, and urology applicants identified UI as one of the eight most commonly cited topics to be included in a core urology curriculum [237]. Minimal training is provided on pediatric continence issues.

Recent studies have shown that there has been an overall decline in the amount of time devoted to urologic education in most medical school curricula [238]. Surveys have shown that general levels of knowledge about common conditions such as haematuria and OAB are low. In addition, respondents indicated a low likelihood of seeking urologic consulta-
Web-based training and the use of standardized patient case studies has become very popular in medical education and has been successfully incorporated into residency training programs. In one recent project, training about UI was included with a number of other geriatric syndromes [244]. In fact, those internal medical residents who received the information via web-based methods had better overall test results than those who completed paper-based training.

Some models of physician education have incorporated training on UI into modules on quality care. For example, the Assessing Care of Vulnerable Elders (ACOVE) project in the USA includes UI as one of the target conditions. A recent study looked at implementation of this information into community-based physician education within practice groups [245]. These authors found that dissemination of this information was well received by primary care physicians, and some intended to make changes in their practice related to this new knowledge. Similar studies have also found that primary care physicians specifically educated about UI assessment and interventions were more likely to recommend care for UI to their patients [246,247]. Large-scale dissemination of information using these types of training models might ultimately help improve access to care.

**b) Specialist physicians**

There is little new published evidence on medical specialist training in the form of effective training interventions. Specialist training in incontinence is not always adequate. Both UI and FI still may be perceived as exclusive to “super-specialists,” potentially alienating colleagues.

Even among subspecialists, training may not be ideal. A survey of 163 urodynamic services in the UK found that half the respondents felt their training in urodynamics was inadequate [248]. Marsh and colleagues [249] surveyed 100 gynaecologists and urologists in the UK and found widespread inconsistent and inappropriate diagnosis of PBS/IC [249].

Increased use of advanced surgical technology has led to greater need for procedure specific training. Examples include use of laparoscopic and robotic techniques for treatment of POP. Some of these procedures have a steep learning curve and require additional training for surgeons [250]. Structured training and curricula have been developed for a variety of surgical procedures used to treat UI and POP [251]. Inclusion of this training in residency will lead to increased numbers of physicians who are qualified to offer this type of care to patients suffering from UI. A variety of models have been developed to help teach some basic skills such as cystoscopy or methods for grading the degree of POP. One option includes the use of cadaver labs [252]. Others have used inanimate objects to replicate the female pelvis and teach basic anatomic concepts [253,254]. Script concordance models have been developed to assess clinical reasoning skills related to care for UI in older adults [255]. This may allow better measurement of clinical practice behaviours for this condition.

Ongoing education and utilisation of evidence-based training with incorporation of guidelines has been suggested as a way to maintain high quality standards of treatment, particularly for surgical care of UI [256].

In the USA, there has recently been a push to develop sub-certification for specialists who care for women with UI and associated pelvic floor disorders [257]. This has involved cooperation between the certifying boards in both urology and obstetrics and gynaecology. The field of ‘female pelvic medicine and reconstructive surgery’ has recently been approved by the relevant certifying boards. This means there will soon be a separate board examination in this field. Continued emphasis on quality education for specialist physicians is needed worldwide [258]. A study of gynaecologists in Germany found that most considered their specific post-graduate training in urologic issues and urogynaecology to have been inadequate. The vast majority of general gynaecologists in this study referred their patients with voiding or incontinence issues to subspecialists in urology or urogynaecology.

### 3. NURSING PROFESSIONALS

Nurses have a significant role to play in the area of incontinence since they are the largest single group of health care professionals around the world and are often the first to become aware that the patient is experiencing incontinence. Cheater and colleagues [25] found that in the UK, an average community nurse case load will comprise approximately one-third of patients with UI. There have been a number of recent studies that explore the use of new innovative methods of education provision for nurses. Rogalski [259] reports a persisting lack of educational emphasis on common symptoms like UI and recommends a curriculum model based on existing guidelines and best available evidence, which could address this shortfall and would increase the quality of continence service provision.

**a) Generalist nurses**

There are significant gaps in knowledge and clinical practice adoption related to both UI and FI, although nurses worldwide have played a major role in developing new information and testing interventions [260]. Although nurses can provide effective interventions in the area of UI, there is limited research on effective interventions for FI.

Innovative methods of improving knowledge among nurses have undergone recent evaluation. An important study undertaken by Cheater and colleagues [261] adds to the debate by examining the value of audit and feedback, and educational outreach, which in the past has often focused on doctors’ behaviours rather than nurses’. In this study, the researchers...
undertook a cluster-randomized trial to evaluate 194 nurses in 157 family practices with 1,078 patients with a diagnosis of UI. They found that when compared to educational materials alone, there were no improvements in care for either educational outreach or audit and feedback (all groups did improve, but differences between groups were not significant). McConnell et al.[73] described how advanced practice nurses learned evidence-based approaches to managing complex cases, including incontinence, in NH residents. Advanced practice nursing skills include evidence-based assessment and diagnosis for implementing management. The authors suggest that such practices can enhance both student and facility outcomes, although no systematic evaluation was undertaken.

Ostaszkiewski[262] describes a nursing leadership model to enhance continence care in older adults. Evaluation of the program suggests improved management and assessment of incontinence for individuals sustained after a two-year period. Leadership programs have proved effective in a number of areas in nursing provision. Within these more recent studies, the use of innovative methods of knowledge transfer and education are beginning to be adopted, and such methods used in other areas of professional education may be well suited to UI and FI.

Education related to UI may often be linked to training about other concomitant disorders or conditions. For example, training on prevention and treatment of pressure ulcers or dermatitis may include significant components related to UI [263,264,265]. Training about improved mobility in the geriatric population has also shown this educational link [266]. This can help to disseminate information about continence care and promotion to a wider audience of nurses who have direct patient contact.

Although APRNs may have good levels of knowledge and positive attitudes about treating UI in women, many have difficulty applying this directly to practice in the clinical setting [267]. These authors suggest that there needs to be increased exposure to these topics in clinical experiences during training for graduate nurses.

Programs have focused on nurse education for continence care in specific settings, such as the NH [268]. Competency-based UI education with use of case examples has been used successfully in the training of generalist nurses [269]. Experiential activities have also been used with good results [270].

b) Specialist nurses

Educational courses on incontinence are available for nurses in the UK, USA, Europe and Australia, and are beginning to appear in Asia, notably Hong Kong and Singapore. These courses vary from two to four weeks of face to face didactic courses to distance learning courses lasting 12 months that lead to a post-basic nursing certificate and, in some cases, post-graduate degrees.

In the UK, education programs are documented at the Association for Continence advice website (http://www.aca.uk.com/education_modules.php) and comprise information on 1 day courses, as well as diploma courses, degree modules and masters level study. Such databases of courses offer an excellent overview for students and providers. Likewise, the CFA (http://www.continence.org.au/pages/continence-courses.html) is an excellent resource for nurses to access information and be linked to educational organisations that provide a variety of programs which focus on or incorporate both UI and FI in the curriculum. Many can be continued through to post-graduate tertiary education. A number of these programs can be undertaken externally and therefore are popular with nurses in rural and remote areas, as well as students of nursing who practice in other countries. Clinical support is arranged to complement the theoretical components.

Internationally, there is inconsistency in the provision of specialist education to prepare nurses to practice as experts in the field of incontinence. Innovative web-based learning programs incorporating modern information and communication technology (e-learning) may offer one way of providing standardized programs of study to practitioners.

Beitz and Snarponis[272] describe their innovative on-line learning program which includes continence nursing. They feel that such teaching strategies are acceptable to nurses. As with physicians, it is unlikely that improving nursing knowledge alone will translate into improved clinical practice or into the ultimate goal of improved patient outcomes.

Jha, Moran, Blackwell, and Greenham[273] conducted a small study in the UK that showed improvements in both knowledge and attitudes of nurses who undertook a specially designed, full-time, 3 month program that included a continence module.

The level of knowledge about UI within the general nursing community appears to be less than ideal in both the USA[274,275,276] and Sweden [277]. Many non-specialist nurses (referred to as general nurses) desire, and have a need for, more education about what they can do to better manage incontinent patients. Moreover, the QoL of the incontinent NH resident is often more dependent upon the skill, education, and attitudes of the nursing aide than of the qualified nursing staff.
Improved education of school-based nurses regarding normal bowel and bladder habits of children may help to improve pediatric continence and promote healthy elimination patterns [278]. Although 61% of school nurses surveyed reported they had never received training on the topic, many (43%) had been asked to provide information to their teacher colleagues.

In the USA, although there are a growing number of nurses who are developing expertise caring for incontinent patients, there are no academic or clinical proficiency requirements to be considered a “continence nurse practitioner or specialist.” [279] In 1993, the Wound, Ostomy, and Continence Nurses Society developed the first certification program for continence care nurses in the USA. This nursing organization recently published a position statement on the role of continence nurses [280]. The Society of Urologic Nurses and Associates certifies different educational levels of nurses in the area of urology and in urodynamic testing. The norm is that most “continence” nurses in the USA obtain their knowledge and skill through self-motivated activities.

Recently, there has been some debate about the need to provide special education and credentialing to non-baccalaureate nurses regarding UI and associated conditions [281]. However, to date, most of the focus on UI education has been at the baccalaureate and advanced degree levels.

Other discussions have focused on whether specialty training in wound, ostomy and continence nursing should be at the doctoral level. In the USA, the new Doctor of Nursing Practice (DNP) degree may help to fill this training gap [282].

A study of 231 vulnerable elders with complex disease and enrolled in a ‘Special Needs Plan’ in the USA were shown to benefit from a nurse care management program with nurse practitioners in addition to physician care, as opposed to those who received care from a physician alone [247]. The model has continued to develop and requires further evaluation. A smaller study [168] in the Netherlands demonstrated that there were short-term benefits following referral to a continence nurse, however these benefits were not sustained long-term. Both studies demonstrate the need to further evaluate the effectiveness and sustained benefits of specialist continence nurses. A Cochrane Review [142] that explored the substitution of doctors with nurses showed similar patient health outcomes, at least in the short-term, over the range of care investigated.

Albers-Heitner and colleagues [283] evaluated the cost-effectiveness of involving UI nurse specialists in primary care compared to care-as-usual by GPs [283]. From 2005 until 2008, an economic evaluation was performed alongside a pragmatic multicenter RCT comparing patients with UI receiving care by nurse specialists with patients receiving care-as-usual by GPs in the Netherlands. One hundred eighty-six adult patients with stress, urgency, or mixed UI were randomly allocated to the intervention and 198 to care-as-usual; they were followed for 1 year. Main outcome measures were ‘QALYsocietal’ (Quality Adjusted Life Years based on societal preferences for health outcomes), the EuroQol-5D, ‘QALYpatient’ (based on patient preferences for health outcomes) (EuroQol VAS), and ‘Incontinence Severity weighted Life Year’ (ISLY) based on patient-reported severity and impact of UI (ICIQ-UI SF). Health care resource use, patient and family costs, and productivity costs were assessed. Compared to care-as-usual, nurse specialist involvement yielded slightly more favorable cost-effectiveness results. Based on these results, the authors recommended adopting the nurse specialist intervention in primary care.

c) Nursing assistants

There is also a need to address the training of nursing assistants (NAs) and aides, particularly in the long-term care setting. In the USA and many other countries, one concern is the high turnover rate among first-line caregivers in institutional and homecare settings, making it difficult to maintain desired training levels. Nursing assistants are often the people providing ‘hands-on’ incontinence care, and yet they often have the least training. Certainly, in terms of published evidence, there are few reports of efforts to train NAs. A cross-sectional study via postal survey to gather self-reported data from nurses and NAs in NHs was conducted in Taiwan [284]. Results indicated UI-related knowledge scale and practice behaviors differed significantly in both groups. The authors recommended that enhancing staff competence in incontinence care was needed in both levels of nursing to improve NH residents with UI. Educational efforts, particularly in the NH setting, must involve not only professional nurses, but NAs and other staff, as well. A study of nurses’ knowledge about UI in NHs that used a standardized examination about UI and associated care demonstrated that professional nurses answered about two-thirds of questions correctly, but that baseline knowledge among NAs and aides was much lower [285].

4. PHYSIOTHERAPY AND OTHER ALLIED HEALTH PROFESSIONALS

Physiotherapists or physical therapists (PTs) have long played a part in continence care and the management of UI. In some countries, patient self-referral to specialised PTs has become commonplace. Physiotherapist’s involvement in UI appears to be either on the basis of individual interest or through association with women’s hospitals or obstetric departments, rather than as part of a general physiotherapy practice [286]. As such, they tend to be highly motivated and enthusiastic.

Generalist PTs have been encouraged to be more aware of the risk factors for incontinence in males and females, to identify patients with risk factors for incontinence and to assist them
in seeking further advice or treatment. The “Red Flags” Project conducted in 2005 was a collaborative effort of the Australian Government’s National Continence Management Strategy and the Australian Physiotherapy Association’s Continence and Women’s Health Group to enhance HSB in people with incontinence visiting generalist PTs.

Throughout the world national physical therapy organizations have established continence physiotherapy sub-groups [287]. The International Organisation of Physical Therapists in Women’s Health represents over 20 member countries with PTs practicing continence and women’s health physiotherapy and offers professional development programs. A number of specialist continence PTs also treat men and children. Universities in many countries offer short courses or post-graduate continence education programs to PTs that may range from post-graduate degree courses to Masters and PhD programs [288].

The Scope of Practice for continence PTs may include PFMT, bladder training, management of sexual dysfunction, ano-rectal dysfunction and treatment of pelvic pain syndromes, FI and male continence issues.

Pharmacists have a variety of roles to play in continence care. In Australia, they have been avid consumers of continence education programs. In 2004, the Pharmacy Guild launched an educational and promotional program for their members with appropriate outcome evaluation measures. The public sees pharmacists as important and approachable sources of health information, especially information on medicines that may cause or exacerbate UI and FI. Many retail pharmacies display health promotion literature on a range of subjects, including UI. Pharmacists may also advise the consumer on appropriate continence products. Educational seminars for pharmacists are generally well received. There are a growing number of CME programs for pharmacists on the Internet, either through new products or through sites such as www.worldwidelearn.com.

Regulatory issues are often linked not only to quality of care, but also to reimbursement for clinical care and services. Reimbursement policies for services frequently determine which professionals are able to provide continence care. In the Netherlands, for example, the government pays for up to 14 visits to a PT for incontinence therapy. In the USA, patient’s visits to a PT are typically restricted by the need for referral and cost.

5. IMPACT OF CLINICAL GUIDELINES

In the past several years, there has been an explosion in the rate of development and publication of clinical guidelines for UI and associated conditions. Since the last ICI, at least 20 different guidelines or consensus recommendations have been published regarding UI and associated conditions. Many of these have been developed by professional organizations focused on urologic, gynaecologic, geriatric, or related fields. Some have been created and disseminated on behalf of national governing bodies. Several older guidelines have recently been updated using evidence-based methodology.

Most of the guidelines target physician practice, although some do include recommendations specific to PTs, nurses, or other health care professionals. Different guidelines focus on specific clinical areas, and some are gender specific. Some only examine issues related to either the assessment or the treatment of UI. Some of the treatment-centered guidelines are specific for either surgical therapy or conservative therapy. Others look at clinical conditions in specific patient populations including those with underlying neurological disorders, women with POP, or patients who have previously undergone surgical treatment for UI. There can be some confusion, particularly when guidelines present conflicting or even contradictory recommendations about specific issues of evaluation or management. Table 1 summarizes many of the recently published guidelines.

Guidelines have also been developed for different care settings. In the USA, the Centers for Medicare and Medicaid Services (CMS) issued F-Tag 315 in 2005. This guideline provides recommendations for bladder management in the long-term care setting. Nursing journals have published recommendations on ways to enhance implementation and compliance with the U.S. government regulatory guidelines [289].

Some guidelines have focused on education rather than on care delivery. The International Urogynaecological Association (IUGA) issued a set of guidelines specific for training in the area of female pelvic medicine and reconstructive pelvic surgery [290]. Other professional organizations have issued similar information under the headings of ‘consensus statements,’ ‘recommendations,’ and ‘curricula.’

Many of the published guidelines focus on younger, healthy, community dwelling adults. Guidelines for evaluation and treatment of UI and FI in children and the elderly population or those with significant comorbidity need to be developed. These will need to take into account issues such as cognitive impairment, which can influence continence status in older adults [291]. Fung [292] in a study in a large academic Veterans Affairs medical centre in the USA, used guidelines to develop condition-specific computerized templates to serve as guides for clinicians to ask questions and perform elements of a physical exam for two specific medical conditions:

</table>
UI and falls. This study demonstrated that a set of templates can be developed within an existing electronic health record system that can be used to prompt a clinician to obtain elements of a history and to perform physical examination.

In 2006, a national UK guideline was produced on UI in women [293]. Within the document, the area of surgeons’ competence is discussed; however, there is no mention of other care providers’ education and training (including GPs, nurses, physiotherapists, etc.). In order for services to be delivered effectively, primacy needs to be given to practitioners education and training in such documents.

a) Audits and assessments of guidelines

A number of recently published studies have examined the degree to which clinicians actually follow published guidelines. Many of these have focused on primary care providers.

A postal survey of Dutch general practitioners found that most adhered to guidelines when making the diagnosis of UI [199]. However, implementation of other measures and treatments were less robust. At least 25% reported difficulty adhering to the guideline due to lack of time, staff, diagnostic tools, competency in care delivery, and perceived low motivation on the part of patients. Others have questioned the utility of this specific guideline when viewed from the perspective of urologists [294]. They proposed future research to determine if recommendations for referral to specialists are adequate and if they will be implemented in a manner that will benefit patients. Another study with Dutch general practitioners identified therapeutic nihilism among the physicians and low motivation on the part of patients as major barriers to guideline implementation [86]. Other barriers included lack of time, difficulty explaining therapeutic options, limitations in patient mobility, and increased patient comorbidities.

A survey of primary care clinicians in the UK revealed that 56.8% agreed or strongly agreed that the NICE guideline on UI in women reflected their current practice [295]. However, more than half of clinicians indicated that they had not changed their practice to be fully compliant with the guideline. In another study, general practitioners in the UK identified knowledge limitations, time constraints, and access to resources on UI as important barriers to better implementation of the guidelines [296].

Adherence to guideline recommendations may also be less than optimal among specialist providers. Ismail [297] examined records of women undergoing sling surgery for treatment of stress UI at an academic medical center in the UK [297]. Only 45.3% of the patients had documentation in the medical record that they had previously tried conservative therapies. Documentation of underlying risk factors was highly variable. A similar study among urologists in Spain showed that compliance with guideline recommendations was less than ideal [298].

Rovner et al [299] examined published literature to determine the degree of adherence to the 1997 American Urological Association guidelines for the surgical treatment of stress UI in women [299]. They found that none of the 90 articles examined actually met all of the guideline criteria, although most complied with at least half of the recommendations. This directly influences the quality of literature available for evidence-based reviews and development of future guidelines.

Some components of guidelines may be particularly difficult to implement. For example, the NICE guideline recommendation that women undergoing PFMT should have a pelvic examination with assessment of muscle contractions may be challenging to perform in a busy clinical practice [300].

Studies have also examined the degree of awareness and adherence to guidelines among specific patient populations. Ismail reported on the results of a survey of 223 women in the UK who had recently delivered their first child [297]. According to the NICE guideline, these women should have been taught pelvic floor muscle exercises in the antenatal period. Although 95% reported awareness of the importance of the exercises, many did not have accurate information and only a small minority actually practiced them.

Guideline recommendations are not without controversy. In a retrospective database analysis of 6,276 women, Agur et al [301] noted that of women felt to have pure stress UI based on history alone, at least 25% were found to have other forms of voiding dysfunction based on urodynamics [301]. They concluded that the recommendation in the NICE guideline to avoid urodynamic testing in women with pure stress UI symptoms might be unwise and could miss other important findings, which could influence care.

Recent audits in the UK have shown that the mandate to develop and implement integrated continence care services has not been met [153,302,155].

There is even more limited data on whether adherence to guidelines actually leads to substantive changes in measurable continence outcomes [302]. In cases where organized services were available, overall quality outcomes were better compared to areas where these services were not offered [303].

A recent audit of the NICE guideline in the UK revealed that patient age may be associated with differential implementation of guideline recommenda-
tions for UI evaluation and treatment [304]. In this study, data from 7,846 women treated at either acute hospitals or primary care trusts in the UK, revealed that elderly women were significantly less likely to receive guideline compliant care compared to younger women. Actual levels of adherence by the care providers varied widely depending on the specific recommendation being evaluated. Levels of guideline adherence also appeared to differ between specialists providing care in acute hospital settings compared to general practitioners in the primary care trusts. In response to this finding, a recent editorial analysis asked rhetorically if lack of adherence to published guidelines for UI may actually represent a form of ageism on behalf of clinical providers and patients [305].

DuBeau et al.[306] assessed the knowledge and attitudes of NH staff (including directors of nursing and nursing home surveyors) following revised USA government guidelines on continence care (Tag F315 - http://www.cms.hhs.gov/transmittals/downloads/R8SOM.pdf) [306]. They used a questionnaire in a convenience sample of 558 staff attending workshops. The authors report striking deficiencies in knowledge amongst staff and identified managerial structures as barriers to guideline implementation. They suggest such barriers need to be overcome in order to improve the quality of continence care.

Realistically the likelihood of obtaining adequate independent funding for effective professional education on UI and FI is unlikely in the current economic climate.

6. RECOMMENDATIONS FOR PROFESSIONAL EDUCATION (GRADE D)

Based on the literature reviewed in this section, the following recommendations can be made:

- There remains a need for rigorously evaluated continence education programmes which adhere to defined minimum standards for continence specialists and generalists, utilizing web-based and distance learning techniques alongside audit and feedback, train-the trainer models and leadership models, as well as traditional methods.

- Models of education content delivery (professional and patient education) are changing with technology with increased emphasis on Internet, web modules, etc. There needs to be ongoing quality control that includes maintenance of accuracy, methods of delivery, etc.

- There is a need for research on the most effective means to educate professional groups on continence issues. Specifically, there is need for research on:
  - The effectiveness of innovative teaching methods in improving knowledge and practice.
  - Translation of research into improved clinical practice and identification of methods by which this occurs.

VII. PRIMARY PREVENTION

1. BACKGROUND

Urinary incontinence is a highly prevalent and chronic condition that can often be prevented by addressing modifiable risk factors through primary prevention [307]. Although the evidence base for FI, PBS/IC, and POP is more limited than that for UI, the conditions share many similarities with respect to risk and treatment, suggesting that similar benefits may derive from population-based strategies [1].

Primary prevention refers to efforts directed to an individual, community or population level, to promote protective health behaviours in order to reduce the risk of these conditions. Since the Fourth ICI, there continues to be an increasing body of evidence linking incontinence with other conditions. These links provide opportunities to benefit from cooperative efforts with other health promotion initiatives. Primary prevention of UI using behavioral modification programs, including lifestyle changes (e.g., weight loss, diet modification) has been investigated in at-risk populations, including older women, childbearing and obese women, and women with diabetes. Obesity and diabetes have now been recognized as independent risk factors for UI [307]. ICI Committee 12: Adult Conservative Management reviews the evidence base for prevention of UI and POP in those persons with associated known risk factors and includes the levels of evidence for the respective interventions. Reference has also been made to prevention in other chapters, including ICI Committee 11: Incontinence in the Frail Elderly. Consequently, the focus of this section will be on the principles of population-based prevention, its application in other health conditions, and suggestions for translation into preventative programs for incontinence.

2. POPULATION-BASED PREVENTION

Recent research has predicted that due to population increases and a rise in the number of older adults, there will be a worldwide increase in the prevalence of UI by 20% by 2018 [308]. This has led to repeated calls to boost efforts to provide better continence education, promotion and prevention strategies throughout the world [235].

Prevention strategies should include education about lifestyle factors and behaviours that increase the probability of incontinence, the normal functioning of the urogenital and gastrointestinal tracts, expected age-related and developmental changes, healthy bladder and bowel habits,
and how to find the appropriate treatment providers [309]. A meta-analysis of physical activity programs found that behavioural interventions (such as goal setting, exercise prescription and self-monitoring) were more effective in increasing levels of physical activity than cognitive interventions (described as health education and the provision of information) [310]. Interventions for UI and FI (e.g., lifestyle changes, bladder and bowel training, PFMT) may also be better suited to behavioural rather than cognitive interventions. In addition, programs developed to raise awareness of continence issues should consider targeting a range of groups, including people of different cultures, ages and genders [106]. Consideration should also be given to targeting specific groups, including those who are socio-economically disadvantaged, as they may be hard to reach through population-based programs [311].

In 2011, the CFA launched a population-based campaign titled “Pelvic Floor First” to address concerns regarding the negative impact of some forms of physical activity on pelvic floor health. The campaign sought to raise awareness of pelvic floor related bladder and bowel health issues and to educate people at risk of UI and FI. Fitness instructors taught ways to minimise strain on the pelvic floor muscle when exercising. The campaign consisted of a dedicated web page (http://www.pelvicfloorfirst.org.au), on-line and printed education materials, screening tools for men and women, referral information and accredited on-line training for fitness professionals. Health consumers could also obtain information materials from the web page as well as links for further support from continence health professionals and the Australian National Continence Helpline.

Community based continence education workshops have been found to increase knowledge of continence issues and continence related QoL in women. In a study of 51 women who attended a 2.5 hour workshop, there was an increase in continence knowledge that was sustained for three months after the workshop [103]. The authors conclude that learning self-management strategies are important to improve pelvic floor health and that education in a public forum may be beneficial for these patients.

In 2011, a panel of experts released a consensus statement, A Healthy Bladder [312]. This follows from consensus work conducted that has examined the evidence base for preventative strategies for incontinence,[313,314] reiterating the ongoing need for primary prevention efforts to be addressed not only by healthcare professionals, but also by policymakers and funding bodies.

Consideration should be given to the setting in which the health promotion program is to be delivered, such as schools, work places, community groups and health care institutions [315]. It is acknowledged that while some nations are successfully implementing primary prevention strategies, others have yet to effectively implement secondary prevention measures, such as assessment and management of continence conditions [316]. In Australia, the UK and the U.S.A, continence organisations have received additional support from national governmental departments and agencies resulting in greater resources being applied to preventative and continence promotion programs. Evaluation and research are essential components of population-based prevention programs[317] and it is necessary to include funding for these as part of the program.

The WHO has stressed the importance of intersectoral collaboration involving governments, local communities and the private sector in efforts to tackle the effects of obesity and lack of physical activity upon chronic health conditions (http://www.who.int/dietphysicalactivity/en/). This type of collaboration may assist in spreading the cost of preventative programs for incontinence. A proposed diabetes population based prevention program found that governments are often reluctant to commit to high expenditure programs when the results may not be apparent until a considerable time later [318]. If a preventative program was developed for a combination of chronic health conditions, such as diabetes and incontinence, there may be economies of scale that would make funding such a program more attractive to governments, particularly when there is evidence that bladder changes and UI can be reversed if diabetes is prevented.

There have been a number of population-based prevention programs throughout the world that have been developed to reduce the incidence of obesity and chronic health problems by promoting physical activity and daily consumption of fruits and vegetables. An evaluation of a program in Australia to increase fruit and vegetable consumption in children found that increased parental knowledge as a result of the program was the strongest predictor of fruit and vegetable intake [319]. Evaluation of data from these programs is likely to benefit researchers and practitioners planning continence prevention programs for adults as well as children. The evidence for population-based prevention strategies remains at Level 4, Grade C.

3. PREVENTION OF UI IN OLDER ADULTS

Older adults are a heterogeneous group, and therefore preventative strategies for older adults need to take into consideration the well aged as well as the frail aged. It is important to involve older people and upcoming generations in health promotion research and health promotion intervention programs targeted at older people [320]. Promoting self-efficacy, such that the individual has a belief that they have the capacity and skills to im-
prove their own health, has been used in research on prevention of older, well-educated women with UI [321]. Self-efficacy improves the ability to cope with symptoms and is linked to motivation, knowledge of the benefits of making changes, and adherence to behavior change [322,323]. Self-efficacy over UI may be enhanced if women are taught self-monitoring techniques, such as adjusting fluid and caffeine intake, resolving constipation, PFMT, and monitoring voiding intervals. Self-efficacy measures, such as the Geriatric Self-Efficacy Index for Urinary Incontinence can be used to determine adherence to behavioral programs developed for the prevention and management of UI [6].

Community continence education of older adults has been advocated in several studies. A descriptive cross-sectional study conducted in China found that community-dwelling older persons often expressed negativity toward UI [158]. They considered UI as shameful, their own fault, and not preventable. Despite these feelings, they indicated that UI was not a sufficiently serious problem to justify treatment. In addition, nearly half of the nurses surveyed reported ignoring the initial onset of UI. Findings from this study indicated a great need for UI education for community-dwelling older persons and community nurses [158]. A similar conclusion, that advocated the need for education, was drawn from a cross-sectional descriptive study of 182 community-dwelling Korean American women [324].

Workshops can be an effective tool for population-based prevention education in older women. Tannenbaum [102] carried out a quasi-experimental prospective cohort study to evaluate the effectiveness of an interactive continence workshop. Ninety-incontinent women, ages 55 to 87, were involved in this study. The interventions significantly increased knowledge and attitudes about the condition (94%). Sizeable proportions of participants either initiated self-treatment strategies, such as pelvic floor muscle exercises, scheduled toileting or dietary change (43%), or sought consultation with a health care provider (42%). The authors concluded that interactive continence workshops can promote self-management and consultation seeking among older women with incontinence. Incontinence-related knowledge, attitudes, self-perceived skills and intentions for seeking care improved after attending the workshops [102]. A behavioural modification program delivered to a group of women over 55 years of age reported the preventive effects of increasing pelvic floor muscle strength and increasing time between voids upon continence status, suggesting that preventive strategies are effective in older women [309,325].

Correlations have been found between poor general health and severe UI and/or FI in frail older people [326]. There are a number of strategies (e.g., mobility training, progressive strength training, balance and walking exercises), combined with behavioral interventions (e.g., pelvic floor muscle exercises) that may be successful in improving UI in this population. A systematic review of 3 RCTs and 4 quasi-experimental studies aimed to identify conservative interventions for reducing UI in non-institutionalized frail older adults [327]. With 683 participants involved (75% female), the studies concluded that multi-component behavioral interventions, including pelvic floor muscle exercises and bladder training, can improve UI frequency. However, there is need for more RCTs to demonstrate the efficacy of multidimensional treatments to guide clinical practice in the prevention and management of UI in frail older adults. (LOE 2)

4. PREVENTION OF Fecal INCONTINENCE

While it appears that people are seeking help more readily for UI, the problem of FI remains under-reported, [241] especially in older people, [328] and few physicians ask patients about it in those persons at-risk [329]. A variety of risk factors associated with FI is reported by Committee 16: FI: Conservative Treatment. Analysis of studies on FI is hampered by a lack of standardised terminology with regards to stool consistency, gas leakage and frequency of incontinent episodes [314,330,331]. In order to be all inclusive, search terms for FI were expanded to include additional terms, (stool consistency, gas leakage, frequency of incontinent episodes, flatus, coprorcrasia). However, there were fewer matched papers about this area. Only an RCT in China revealed that PFMT is effective on the prevention of coprorcrasia by sphincter preservation operation on mid-lower rectal cancer. One hundred and fifty-one participants who received the surgery were randomized to two groups. Intervention group (n=75) received PFMT for six months but the control group (n=76) did not. The results from 1, 3, and 6 month follow-ups showed that PFMT contributed a positive effect against the development of FI [332]. (LOE 2) While acknowledging that prevention of FI is important, it is recognized that more research is needed to determine the effectiveness of population-based interventions that focus on the risk factors of FI.

5. RECOMMENDATIONS FOR PRIMARY PREVENTION (GRADE C)

Based on the literature reviewed in this section, the following recommendations can be made.

- Primary prevention studies should not be limited to individual interventions, but also test the impact of population-based public health strategies.
- More high quality, randomised controlled trials are needed to strengthen the effectiveness of population-based primary prevention intervention.

## VIII. REFERENCES
patients are living longer and are at greater risk for developing a range of conditions, including urinary and faecal incontinence, as well as prolapse. In order to compete for precious healthcare resources, in this contracted global economy, continence clinicians must construct robust health economic analyses of any new treatments if we hope to see these new treatments implemented for the benefit of our patients. In this chapter we present a summary of the appropriate methods, then present a critical analysis of recent publications.

1. PERSPECTIVE

When a patient with urinary or faecal incontinence (and to some extent prolapse) walks into a doctor’s office in any country, they will have already incurred some personal costs in managing the condition at home, such as pads or laundry expenses. He or she will then have a basic consultation, tests will probably be ordered, a range of outpatient conservative (including pharmacological) treatments may be initiated, or a surgical procedure that may be recommended. These are treatment costs. At some stage, particularly in the elderly, the patient may suffer a urinary tract infection that may be associated with the incontinence/cystocele, or may slip and fall in their urine on the way to the toilet. These are the costs associated with treating the consequences of incontinence [1, 2].

The good news is that this new information is making its way into the economic analyses. The bad news is that economic analyses are becoming more complex and harder to evaluate. Because of their unique aetiologies, it is more accurate to talk about the subtype of incontinence, making the blanket term of “the economics of incontinence” less applicable. This chapter takes account of these considerations, and is arranged according to incontinence subtype.

In the last five to ten years, the “aging” of the post WWII baby boomers is changing the consumption of health care resources. The median lifespan of a woman in OECD countries is now 83 years, and rising, with similar enhanced lifespan in men. Thus
More importantly, this places an important duty upon researchers to describe explicitly where, when and how the costs were calculated. Researchers in one country need to be able to extract as much economic information as possible from the research carried out on a particular condition in other countries, to save "re-inventing the wheel" whenever possible.

Patients often observe very different "costs" for health care goods and services. In health care, we often think of cost as the amount to produce the good, whereas a charge represents the stated amount on a bill, which often includes profit for the manufacturer. Therefore, different accounting systems can yield very different cost estimates. For example, most of the hospital accounting systems in the U.S. focus on billing and payments. The charges listed on the bill usually overstate costs, on average by a factor of three, and are rarely paid in full by the payer. For example, in a study of the costs of surgery for female fecal incontinence in the US, hospital "charges" were defined as the amount on the hospital bill, but the hospital "costs" were defined as the amount that the hospital actually received in payment. Only after understanding this definition can one make sense of the fact that hospital “charges” for FI surgery rose from $48 million to $57 million over 3 years, but the hospital “costs” increased only slightly from $23 to $24.5 million over the same 3 years [4].

In the U.S., many researchers prefer to use payments as the estimate for cost. Researchers have developed imperfect methods for adjusting charges with a hospital-specific ratio of costs to charges to better estimate costs [5]. Charges, however, are not always available. Integrated health care systems, including Canada and the U.K., do not routinely generate bills. For these systems, researchers have developed methods for generating pseudo-bills and cost estimates [6-8].

Many cost determination methods are used. Most analyses include a combination of “gross costing” and “micro costing” [9]. These terms are similar to the phrases “top-down” and “bottom-up”. Accounting and billing systems use activity based micro-costing methods, whereby detailed estimates of time and products (inputs) are combined with unit costs to estimate total costs. Micro-costing (or “bottom-up”) is challenging to perform because a single inpatient stay or outpatient procedure might have hundreds or thousands of inputs. For example, Morris et al [10] performed over 3621 observations to determine expenditure on urinary faecal or mixed incontinence in a one month study of 29 patients in a sub-acute care facility. Even when there is just a single input, such as a tablet, the cost can vary by location or the time of purchase if prices fluctuate.

At the other end of the spectrum, gross cost methods (“top-down”) identify a limited number of important characteristics such as the Health Care Resource Group (HRGs) in the U.K., Diagnosis Related Groups (DRGs) in the U.S or Australia, and length of stay. However, DRG costing lack precision and can be problematic because this method does not track the actual treatment activities, but are based on an average treatment. For example, in Australia the DRG for Tension Free Vaginal Tape and Colposuspension is the same. In the section of this chapter on Sacral Nerve Stimulation (SNS) for faecal incontinence, the costs for temporary stimulation and permanent implantation vary considerably between Spain[11], Italy[12] and the UK[13] as shown in Table 1.

Table 1. Comparison of the costs of temporary and permanent SNS between Spain, Italy and the UK.

<table>

</tbody>
</table>

Accounting systems are limited in that they always report the health care payer’s costs or charges. If researchers want to estimate societal costs, which are often of most interest,[9, 14] one must include both provider-incurred costs and patient-incurred costs. This distinction is important for urinary incontinence, since most providers do not pay for routine care (e.g., pads and protection). These costs are usually incurred by individuals, and in the year 2000 the routine care costs in the U.S. were $1347 per person for urinary incontinence and $1554 for people with OAB [15].

Thus the conclusion drawn by a researcher may be heavily dependant upon their perspective. For example, a study from the USA analysed Medicare claims for the treatment of urinary incontinence among women aged 65 or older for 3 years (1992, 1995, 1998) including outpatient, inpatient and emergency department visits [16]. Such Medicare claims nearly doubled over the time frame, from $128 million to $234 million, largely due to increased numbers of women treated by office visits and ambulatory (day only) surgery for items such as collagen injections. When the per capita changes were analysed, and inflation was considered, costs had actually declined by 15%. However, the editorial comment following this article points out that Medicare claims have a payer’s perspective, do not quantitate pad usage, and cannot record pharmacotherapy for urge incontinence. Since we know that overactive bladder is more common as age increases, such pharmacotherapy is likely to be increasingly important in the over 65 age group, so that the conclusion of a 15% drop in per capita Medicare expenditure is not likely to be valid representation of costs in general. The editors pointed out that the article was mainly representative of patients with stress incontinence as a result. Such methodological issues are important.

In the example described above, the “perspective” that the researchers used was that of Medicare claims. In other words, Medicare was the “payer”, not
the patient. This highlights the fact that costs can be evaluated from several different perspectives. The four most commonly used perspectives are (1) overall society costs, which includes all aspects of care and treatment (which this committee recommends), (2) the payer, such as Medicare, (3) the provider, such as a hospital or managed care plan and (4) the patient.

In general, health economists prefer that a societal perspective (include all costs) is used [9, 14]. This facilitates comparison of the cost of illness across different countries. The problem is that different countries use different frameworks for reimbursing some or all of the costs of various conditions, so that international comparisons remain controversial.

2. COUNTRY SPECIFIC ECONOMIC ISSUES

From the perspective of a patient, large costs are often incurred when paying for routine care products, treatments, and long-term care. These patient costs vary by country. For example, in Sweden and Spain, the government (tax based) health insurance covers routine care products. In the UK, age-dependant patient subsidies are available for pads. In Germany and Spain, pad costs are reimbursed if prescribed by a doctor [17]. In Australia, low-income patients can apply for a subsidy to reimburse most of their routine care products, but more wealthy patients must pay all costs. In the USA, such products are rarely covered and can be very expensive [17].

The degree of government subsidy to the patient varies greatly by country. In the UK, most patients use the National Health Service (NHS) so that all office visits, tests, outpatient visits and surgical treatments are free to the patient. Pharmacotherapy does attract a small out of pocket payment for each drug. In Italy and Sweden pads are reimbursed, but not in Germany. Pads are not routinely subsidized, only at the discretion of the local Care Trust. In Australia, about 70% of patients only have government insurance, similar to the UK NHS, but 30% of patients also have private insurance so that inpatient treatments attract a rebate from their health fund. In the USA, adults over age 65 and those with a disability are covered by the Medicare program. This provides coverage for inpatient, outpatient and pharmacotherapy, although patients are generally responsible for sizable co-payments and nursing home care is capped. Those not covered by Medicare often have private insurance or Medicaid (a health insurance program for people with low incomes); nonetheless about 48 million Americans lack any insurance.

In the Netherlands, all legal residents are obliged to purchase a basic health policy (the purchase of a complementary policy covering extra health services remains voluntary). The choice of health insurer and type of health plan is free. The government establishes what is in the basic package and under what conditions people are entitled to care.

In regards to long term care benefits for those in residential care, considerable variation occurs. In the USA, Medicare and Medicaid benefits are time limited for re-imbursements to nursing homes and other assisted living facilities. Usually, after several months, benefits stop and payment must come from private insurance or the patient’s pocket. In Australia, low income patients who have no private superannuation (pension fund) can receive the “old age pension” which covers fully funded long term care, albeit in lower-calibre facilities than would be chosen by those who could afford better (similar to the Netherlands system). In Japan, generous long term benefits are provided to long term institutional residents, so that out of pocket payments are reduced.

3. COSTS AND TIME

Costs change over time and researchers need to account for temporal changes in their analysis. The easiest way is to present the costs in a specific year (e.g., 2012). Costs borne in past years should be inflated. In many countries, the governments track and publish inflation indices. In the US, inflation is represented in the Consumer Price Index (e.g., www.stats.bls.gov). In the UK, the Health Service Cost Index or the Retail Price Index, published by the NHS Executive, Leeds, UK, can be used to adjust the costs of health care services (www.statistics.gov.uk).

Caution is needed because general inflation relates to the cost of a consistent set of goods over time, e.g., the goods must be of the same quality over time, and thus the costs observed five years ago can be observed today. If so, then the inflation index is informative. However, medical goods change rapidly as do their quality. For example re-usable laparoscopic equipment has been replaced by disposable equipment that is usually more expensive, and the newer drugs for OAB are generally more expensive. This makes it difficult to determine whether any change in price is due to inflation or due to (real or perceived) improvements in quality. Thus, just inflating costs from many years ago can be misleading. Consequently, many researchers recommend against using price indexes that are developed specifically for medicine because these indexes do not take quality into account. Researchers must also be cognizant of the fact that the published success rates for various treatments change over time. For example, in Adang et al.[18] dynamic graciloplasty is portrayed as having a stable success rate over time in the treatment of faecal incontinence (see Figure 1). In fact, we now know that dynamic graciloplasty has a very poor success rate over 10 years, so that the estimated data shown below in figure 1 from 1998, is no longer accurate.

In addition, many continence treatments have costs that extend into the future. Drug treatments require that patients take drugs in the future. People have time preferences for money and future costs should be discounted to represent the present value. Controversy exists about the appropriate discount rate[19-21] but most international studies use a discount rate of 3% per annum. See Adang et al. [18] for example.
In summary, defining and measuring costs in health care can be imprecise. Often there is variation across regions and time. This variation needs to be taken into account in the economic analysis and the easiest way is to conduct sensitivity analysis to investigate how different cost estimates can influence the results. By this we mean re-running the analysis with different input parameters. As we describe in the next section, explicitly describing these contextual issues is crucial for interpreting results.

III. TYPES OF ECONOMIC ANALYSIS

1. OVERVIEW

A typology of economic analysis for health and medicine has emerged over the past few decades. This section reviews these studies.

a) Cost of illness (COI)

As already described, COI studies summate the costs related to a condition for a given population. The costs are annualized for a given year (i.e., 2012). A COI is a descriptive analysis. However, COI studies provide little information to decision makers about how to allocate scarce resources for treating conditions, because there is no attempt to measure the “value” of the relevant treatments.

b) Cost minimization analysis (CMA)

CMA compares the costs of alternative health care strategies, assuming that the benefits of the alternatives are equivalent. When the two treatments are truly equivalent in their risks, outcome, and an individual’s preference for them, then a cost minimization analysis is sufficient; the cheapest intervention is to be preferred.

c) Cost consequence analysis (CCA)

CCA is a variation on cost-minimization analysis, which involves assessing whether a new treatment results in a greater decrease in health care utilization than another treatment. Thus costs of the intervention are compared to health care utilization, such as the cost per hospitalization averted. There is a naturally appealing rationale for conducting this analysis. Unfortunately, when examined in detail, this rationale boils down to an analysis of whether the new treatment saves money in comparison to the alternative treatment. Accordingly, a cost-utility or cost-benefit analysis provides many advantages over a cost consequence analysis.

d) Cost-effectiveness analysis (CEA)

CEA refers to the broad class of calculations where the effectiveness measure is a general health outcome. CEAs with narrowly focused health outcomes (e.g., incontinence episodes) have well-known limitations. Most notably, the use of narrowly focused health outcomes will miss other important effects. For this reason, there has been widespread agreement on the use of quality adjusted life years (QALYs) as the preferred health outcome in cost-effectiveness analysis. In the US, CEA has become synonymous with cost-utility analysis.

e) Cost-utility analysis (CUA)

CUA refers to a CEA when QALYs are used as the outcome measure. Gold et al.[9] and Drummond et al.[14] have published texts that discuss standard techniques for conducting a CUA. In health and medicine, the CUA is considered to be the gold standard. Utilities capture all potential benefits of an intervention and allow comparisons with other health conditions, making cost-utility analysis a powerful research tool.

Compared to other medical fields, we have insufficient data on utilities in incontinence or on the effect of treatment or change in incontinence severity upon cost utility measures, to date.

Data in a CEA and CUA are represented by an incremental cost-effectiveness ratio (ICER). The ICER represents the average cost of the intervention group minus the average cost of the control group. This amount is then divided by the average utility of the intervention group minus the average utility of the control group (see Section IVb).

f) Cost benefit analysis (CBA)

Involves measuring the benefits in dollars. When everything is measured in dollars, optimal choice can be easily found by addition and subtraction. However, it is difficult to measure benefits in dollars, and many researchers and policymakers are averse to placing a dollar value on life. CBA is rarely used in health.

g) Summary

COI and cost-minimization analyses are simple, yet limited economic tools. Most new treatments offer ad-
ditional benefits at an additional cost. The CBA, CUA and CEA were designed to determine how much money it costs to obtain another unit of effectiveness. Although the CUA is the preferred method, there are many challenges with calculating a QALY. We will discuss these issues in more depth because different methods for calculating QALYs can have a very profound effect on the interpretation of the CEA/CUA.

2. DETAILS OF DECISION ANALYSIS

Decision analysis is a tool that can be used to summarize effectiveness data, costs data, or combine both cost and effectiveness data in a CUA. The value of decision analysis is highlighted by a multi-site clinical trial by Albo and colleagues[23] that compared Burch colposuspension to fascial sling for stress incontinence. They concluded that the fascial sling yielded a higher rate of successful treatment, measured as a composite outcome, but also resulted in greater morbidity. Even in well-designed multi-site clinical trials, the results may be ambiguous. Even in well-designed multi-site clinical trials, the results may be ambiguous. Decision analysis may be used to overcome this ambiguity. Decision analysis is a quantitative probabilistic tool for resolving problems when there is uncertainty with regards to treatment options.

There are two primary decision analytic methods (see below); each has its strengths and weaknesses. The starting point with any decision analysis is a clinical question, such as how to treat women with stress urinary incontinence or how to treat patients with faecal incontinence (see Fig 2 below from Dudding et al., 2008 [13]). The question should fully and fairly address the clinical questions. One might develop add on questions, such as how to treat women who had surgical failure or sacral nerve implants that become infected or in which leads migrate, but it is often best to address these more specific questions as part of the broader decision analysis.

A benefit of decision analysis is that researchers can combine data from multiple clinical trials and marry that data to observational information (e.g., long-term follow-up data). Decision analytic tools are flexible and can be used to identify the treatment that maximizes quality of life. One can also use the same model to address issues of cost-effectiveness. Hence, one of the first tasks in the decision analysis is to identify the primary outcome. Outcomes such as quality adjusted life years (QALYs), that can reflect treatment and disease, are recommended. By using QALYs, one can overcome conflicting data—for example, the finding that vaginal slings have higher success rates but also greater morbidity. As is discussed elsewhere in this chapter, QALYs value all aspects of quality of life and include mortality. Next, the researcher must

Figure 2. Decision tree for SNS treatment of faecal incontinence modified from Dudding et al (2008) with permission [13]
determine whether the model will include cost information or not. Some decision analytical models focus only on outcomes, while others add cost data to address resource allocation questions.

By combining data from multiple sources, decision analysis can be used to model lifetime costs and benefits. Researchers are often asked to identify the treatment(s) that maximizes lifetime benefits or lifetime cost-effectiveness. Randomized trials, while the gold standard for assessing causation, are time limited, often following participants for less than five years. Decision analysis can extend such data to consider future events, such as surgical failure rates, nursing home admission or life expectancy. Decision analysis can also be used to understand whether the analysis differs by perspective. Payers, providers and patients all have different perspectives, and decision analysis makes it relatively easy to consider each of these perspectives and whether they differ from a society perspective.

a) Steps in a decision analysis

Decision analysis can be boiled down into five steps. The first step involves identifying the structure of the problem and this requires the listing of all decision alternatives, all clinical outcomes, and a sequence of events. After completing step one, step two involves assigning probabilities to all chance events (e.g., death). Step three involves quantifying the benefits (e.g., QALYs) for all outcomes. The fourth step involves the mathematical calculation of expected utility for each strategy (or this can be taken from published data). Step four will often identify the preferred strategy. The final step involves conducting sensitivity analysis to check that the model is robust across a range of clinically meaningful possibilities.

Every decision model involves some assumptions. Frequently, assumptions are needed to incorporate clinical trial data in the model. For example, a common assumption is that the effect shown in a clinical trial is generalizable to the broader population—treating women with TVT will result in effects like those seen in Lier and colleague’s paper[24] (discussed later in the chapter). Some assumptions may seem trivial, but it is best to delineate each assumption along the way. Published decision analysis should include a table of assumptions along with other data inputs; frequently this is the first table in the decision analysis.

The clinical question and the structure of the problem (step 1) should provide guidance on the decision model. Frequently decision trees are used because they are simple and address the question at hand. Decision trees are so named because they look like a tree with a trunk, branches and leaves. For example see Figure 3, taken from a study of Botox therapy versus clam augmentation cystoplasty by Padmanabhan et al[25], to be discussed later in this chapter. While decision trees are easy to describe and conduct, it is hard to include changes over time in the analysis. Diseases often change over time and people may transition into and out of different health states over time. One strength of Markov models is their ability to include these time-related transitions. We will discuss decision trees first and then Markov models in more detail afterwards.

Figure 3. Decision tree for Botox treatment of severely refractory neuropathic DO patients, modified from Padmanabhan et al (2011) [25].

* indicates the treatment algorithm continues along the augment pathway
b) Decision Tree

In a decision tree, there is a distinction between a decision node and a chance node. A decision node is a point where a choice is made by the decision maker (typically a physician or patient). For example, for a woman with stress incontinence, the choice to operate (yes or no) would be represented with a decision node. A choice must have at least two options and more than two choices are permitted. However, each choice must be mutually exclusive. A patient cannot choose both operation and no operation. A chance node is a point where chance determines fate. For example, the decision maker chooses to operate or not operate, and hopefully the treatment is successful, but treatment success or failure is a chance node. Not only must chance nodes be mutually exclusive, but they must also be collectively exhaustive (one of the chances must happen and the sum of probabilities for all of the chances must add to 100%).

In addition to chance and decision nodes, there are terminal nodes. These nodes are the final outcome for the pathway taken. Sometimes understanding the nodes makes more sense when looking at the pictorial representation. Figure 4 shows a hypothetical decision tree for treating a patient with stress incontinence. In this hypothetical situation, we structure the model to have two options: surgery or drugs. It is overly simplistic in that we do not differentiate between drugs.

The main choice is surgery versus medical management. Surgery carries some risks—a small probability of operative death, for example, in the case of clam cystoplasty for refractory detrusor overactivity. The decision nodes are represented by squares while chance nodes are represented by circles. The terminal nodes are cure, no cure, operative death or non-adherence, which is the same as no cure. This is a hypothetical decision model, and most decision models are much more complex. Clearly this model could be expanded to include behavioral treatment and each decision node could be expanded to consider all relevant alternatives (autologous sling, Burch colposuspension, tension-free vaginal tape, trans-obturator tape).

For the next step in the decision model, one must include probabilities at each chance node. We must identify the probability that the disease is cured after operation. Researchers should review the published literature to find this probability and ideally some information about the distribution around this probability (e.g., probability= 58% with a 95% CI 51-68%).

After including probabilities, one must place values next to the terminal nodes. These values must be a single outcome and QALYs are preferred, although life years (unadjusted for quality) are used for some diseases. With outcomes and probabilities, one can then "run" the decision tree. Because there is one decision node with two options, we will be computing expected values for the two options. Running the model involves starting at each endnode and working left or backwards. The expected value for the surgical survival node is 3.8 QALYS. (Figure 5)

The expected value for the surgical operative death node is 0. When we combined a 10% chance of operative death (0 QALYS) and a 90% chance of survival (3.8 QALYS), we find the expected value of surgery is 3.42 (Figure 6). If we do the calculation for the lower branch, we get the expected value for drug therapy is 3.76 QALYS. Because 3.76 >3.42, we would recommend surgery over drugs IF the sensitivity analysis shows this result to be robust. The decision tree in the example focuses on QALYs for UI treatment and it ignores cost differences, but it could be easily modified to include cost information.

c) Markov Model

The decision tree, as shown above, assumes the chance of events is stable over time. Our knowledge about urinary incontinence suggests otherwise. A person, for example, could get surgery for stress incontinence, but over time we need to include the potential for surgical failure. Markov models are good
for incorporating changes in health states over time. At their core, Markov models are mathematical techniques, derived from matrix algebra, that describe the transitions a cohort of patients make among a number of mutually exclusive health states over time. The model works by cycling to make new calculations for each period of time.

The pictorial depiction of a Markov model is typically shown as a decision state. Figure 7 shows a very basic four-state Markov model. At each period in time, a person has to be in one and only one of the states. But with each change in time (cycle), the person can move to another state, shown with arrows, depending on the possible states and a probability. If the person dies, they are shown to enter the death state. The person cannot leave this state.

Some aspects of the Markov model construction are similar to a decision tree. Setting up the model is quite similar. One must identify the health states and the transition probabilities. What is quite different is that one must determine the cycle length—the rate at which you allow people to change states. The cycle length should be a clinically meaningful period of time and this choice is also frequently affected by the availability of data. There may be publications showing annual failure rates for surgery and so one could choose an annual cycle. For a Markov model, one needs to know the value for each state. Again, QALYs is the preferred metric. When the model runs, the program keeps track of the amount of time each person spends in each state. Transitions to other states are handled by transition probabilities (i.e. the likelihood of cure or failure). Decisions, such as the decision to change from one treatment to another, can affect transition probability. Models can use cohort simulations where a large hypothetical cohort of patients is run through the model. This does not provide information on the distribution of expected values. Monte Carlo simulations run each patient through the model a large number of times (e.g., 100). In doing so, this provides a distribution and variance information on patients.

With Markov models, sensitivity analyses remain a crucial step to test the robustness of the model. Recent advances in sensitivity analyses and in the graphical presentation of data general require the use of specific software. Although some people program Markov models into a spreadsheet, such as Excel, both Tree Age and Decision Maker software, are well known for their ability to streamline decision analysis and provide many advanced features that would be very difficult in Excel.

3. STATISTICAL ANALYSIS

In the last ICI chapter, we discussed alternative statistical techniques, but did not discuss bootstrapping, which has become quite common in cost utility analysis, especially in analyses alongside clinical trials. Bootstrapping is a method of resampling that enables researchers to estimate parameters based on the observed sampling distribution. It is particularly useful when estimating the confident intervals for the incremental cost-effectiveness ratio (ICER). The ICER involves dividing the mean difference in costs by the mean difference in utilities. Statistical software can easily determine whether two samples have different costs or different utilities (e.g., t-test). But software cannot easily calculate the confidence interval around the ratio of these two differences. Bootstrapping involves randomly drawing cases from the sample and replacing the case back in the sample. Resampling is done until the original sample size is met. The same process is then done again and again, typically 4000 times. Thus, by resampling, the analyst can calculate the ICER 4000 times, thereby providing a distribution around the ICER.

4. BUDGET IMPACT ANALYSIS

Providers and payers often have priorities that are not directly addressed by a cost-effectiveness analysis from a societal perspective. Budget impact analysis (BIA) was developed to inform a decision maker on how alternative technology will affect their budget. A BIA will often focus on the decision maker’s costs and over a short time frame (e.g., 1-3 years). Other parameters in the model, such as patient characteristics or input costs, can also be tailored specifically for the
decision maker. Making decision based solely on a BIA can lead to suboptimal societal results. Hence, scientists advocate that a BIA be done in conjunction with a CEA so that decision makers are informed about the broader social implications of their decision. The International Society for Pharmacoeconomics and Outcomes Research (www.ispor.org) has created guidelines for conducting a BIA and these can be found on their website.

IV. PRACTICAL ASPECTS OF ECONOMIC ANALYSIS IN THE CONTINENCE FIELD

1. HEALTH OUTCOME MEASURES SUITABLE FOR USE IN ECONOMIC ANALYSES

There are a number of health outcomes that are used in economic evaluations of incontinence. These include disease-specific outcomes, health status and health value (e.g., QALY). Each is discussed in turn.

a) Incontinence specific outcomes

Cost-Effectiveness in Health and Medicine[9] recommends using QALYs as the effectiveness measure in the CEA. However, the panel also notes that analysts can use a clinical outcome measure. For incontinence, clinical outcome measures include 24-hour pad test, a voiding diary, or urodynamics. These outcomes are attractive for clinicians because they often use these measures in clinical practice.

Clinical outcomes can be very valuable in identifying when a treatment is efficacious. However, using clinical outcomes in a CEA yields results that are limited in scope. A treatment might have improved a person’s quality of life, but had little effect on the clinical outcome measure. In this case, the results would be biased. In addition, a CEA with a clinical outcome measure might not be comparable to another CEA with a different clinical outcome measure. A clear advantage of cost utility analysis is that QALYs can be generalized beyond incontinence. For this reason, QALYs and CUAs are the gold standard.

b) Health Status and Quality of Life Measures

There are a number of frequently used and highly regarded general health status measures, such as the SF-36, the Sickness Impact Profile and the Nottingham Health Profile, which describe a person’s current health state. Instruments that assess how a person perceives or feels about their health state are called quality of life (QOL) measures.

Chapter 5 in this book reviews generic and disease – specific quality of life measures, which are useful for understanding the effects of a treatment. However, because they cannot be used to create QALYs they are of limited value in economic analysis. An example of an exception is the SF-36 for which Brazier et al. [26] have created a utility scoring system known as the SF-6D.

c) Health value

Although there are several ways of measuring the value of a health state, the most common are willingness to pay (WTP) [27] and the quality-adjusted life year (QALY). We focus on QALYs as they represent the current standard for measuring health value in cost utility analysis.

QALYs denote the relationship between the value of a given health state and the length of time a person lives in that health state. The value of a given health state is measured in ‘utilities’, where ‘utilities’ represent preferences for a given health state.

To understand utilities, consider the following: most people would prefer to be healthy over a given time rather than suffer constant urinary or fecal incontinence. Utility measurement refers to valuing these preferences on a perfect health-death scale with endpoints of 1.00 and 0.00, where 1.00 is perfect quality of life (best imaginable) and 0.00 is death equivalent quality of life. For example, the measured utility for urinary incontinence may be 0.60. If treatment improves this to 0.70, then the value of the treatment is 0.70 – 0.60 = 0.10. If this utility gain is maintained over time, say for 10 years, then the gain is 0.10 x 10 = 1.00 QALY. Because utilities are measured on an absolute scale (perfect health to death), they can be used across different health states and therefore can be used to compare the effect of interventions in different health fields, or different interventions within the same field. For example, the QALYs gained from treatment for incontinence could be compared with those gained from treatment for depression. Where treatment costs (including costs to the patient) are known, the treatment providing the lowest incremental cost-per-QALY gained is preferred as this ensures society gains the greatest benefit from the health care dollar.

Direct and indirect methods have been used to elicit utilities [28]. The most common direct elicitation methods for valuation include time trade off (TTO), standard gamble (SG), and the visual analog scale (VAS). For description of these methods, see our previous chapter in this ICI series [29].

1. INSTRUMENTS MEASURING UTILITIES SUITABLE FOR QALY CALCULATION

Multi-attribute utility (MAU) instruments can be used instead of the direct elicitation methods. Simply, a MAU-instrument decomposes HRQoL into health domains (e.g., mobility and emotions). Respondents provide estimates for each attribute, which are then ‘valued’ and summarized into a utility. The three most commonly used MAU instruments are Quality of Well Being Scale (QWB), Health Utilities Index (HUI) and EQ5D (as reviewed by Hawthorne & Richardson[30]).

Quality of Well-Being Scale (QWB)

The QWB has three dimensions (Mobility, Physical Activity, and Social Activity), with 3–5 levels each,
and 27 illness symptoms [31]. The QWB requires trained interview administration (15–35 minutes), although a shorter version is available; a self-report version is under development. The upper boundary is 1.00, lower boundary is 0.00.

Health Utilities Index (HUI)

The HUI uses 12 items that measure 8 domains (Vision, Hearing, Speech, Ambulation, Dexterity, Emotion, Cognition and Pain). The upper boundary is 1.00, lower boundary is −0.36.

EQ5D

The EQ5D was developed by the Euroqol team from 7 European countries [32, 33]. It has 5 items measuring Mobility, Self-care, Usual Activities, Pain/Discomfort and Anxiety/Depression. The upper boundary is 1.00, lower boundary is −0.59. This has become a very popular instrument in clinical trials because it has been widely used in many languages and it is very brief.

A recent study [34] tested the effect of stress urinary incontinence on quality of life, as measured with the EQ5D. Investigators in the Stress Urinary Incontinence Treatment (SUIT) study, a 12-month, prospective, observational, multicenter study multicountry in four European countries, described the association of SUI symptoms with the EQ5D among 3762 women seeking treatment for symptoms of SUI. Participants had a mean age of 58 years, mean body mass index of 27.7 kg/m², and had at least one comorbidity in addition to UI. The health state index scores were significantly and independently influenced by the presence of comorbidities affecting quality of life, total number of stress and urge incontinence episodes. In summary, the number of incontinence episodes and type of UI had a significant impact on the EQ-5D index score.

SF-6D

Whenever SF-36 raw scores are available, SF6D utilities can be computed [26]. The SF-6D measures physical functioning, bodily pain, mental health, physical role, emotional role, social functioning, and vitality. The endpoints for the SF-6D are 1.00, and 0.30 for the worst possible health.

The 15D

The 15D was created in Finland. It has 15 items, measuring Mobility, Vision, Hearing, Breathing, Sleeping, Eating, Speech, Elimination, Usual Activities, Mental Function, Discomfort & Symptoms, Depression, Distress, Vitality and Sexual Function [32]. The upper boundary is 1.00, lower boundary is +0.11.

The 15D is a generic, comprehensive, standardized, self-administered measure of HRQOL that can be used both as a profile and single index score measure [35]. The single index score (15D score) on a 0-1 scale and representing the overall HRQOL, is calculated based on population-based preference or utility weights. The 15D scores are shown to be highly reliable, sensitive and responsive to change, and valid for deriving quality-adjusted life years (QALYs) gained for resource allocation purposes. The 15D score is sensitive to urinary incontinence in a cross-sectional study [36, 37] and is sensitive to change in incontinence severity following intervention [24, 38]. A recent population-based survey of over 3700 Finnish adults found that increased severity of urgency and urgency urinary incontinence is associated with statistically significant decreases in the total 15D score and on all 15D dimensions (p<0.001 for all) [36].

The Assessment of Quality of Life (AQoL)

The Assessment of Quality of Life (AQoL) includes five dimensions: Illness (not used in utility computation), Independent Living, Social Relationships, Physical Senses and Psychological Well-being [39]. The upper boundary is 1.00, lower boundary is −0.04.

The Rosser Index has two dimensions measuring disability and distress, and measured 29 health states. Values (magnitude estimation) were from a convenience sample of 70 respondents [40]. A revised version in the early 1990s included discomfort as an additional dimension [40]. Administration requires a trained interviewer. The upper boundary is 1.00, and the lower boundary −1.49, which means that health states worse than death are permitted.

Note that many people with incontinence are not cognitively able to complete a MAU or go through a standard utility elicitation process. Some of the MAUs, such as the HUI3, have been validated for use with proxies. Although not always possible, if proxies are expected then proxies should be gathered for all cases, even those patients who complete the utility measure themselves, so that the method is applied in a standard, consistent fashion.

2. “DO IT YOURSELF” - HOW TO CONDUCT A COST UTILITY ANALYSIS: THE COMMITTEE’S RECOMMENDATIONS

The cost utility analysis (CUA) now represents the gold standard for medical decision making. Therefore, the remainder of this section highlights ten key issues that must be addressed in a CUA. These ten principles, summarized below, comprise an appropriate minimum standard for performing and reporting cost utility analyses. The principles were identified from guidelines established by the Panel on Cost-Effectiveness in Health and Medicine convened by the United States Public Health Service [9]. Each principle should be explicitly addressed in every study.

a) The Research Question must be clearly stated. All CUAs must compare at least two different treatments or interventions. One of these should include the current standard practices. For example when comparing surgeries for stress incontinence, one of the comparators should be a longstanding method, avoid comparing two new methods side by side.
b) The Time Frame over which costs and benefits are measured should be long enough to capture the economic impact of an intervention and future health outcomes. Pharmacology studies of 12 weeks duration give very little real economic information, and surgical complications/ failures seldom emerge in less than 1-2 years.

c) Perspective: The choice of perspective should be clear. Total society perspective (all payers) is the gold standard. Other perspectives, such as the payer or patient perspective, may be useful but must be stated clearly.

d) Probabilities are needed for each “chance” event, such as chance of cure or chance of an adverse event. The best sources of probabilities come from meta-analyses of randomized clinical trials, or if not available use data from individual clinical trials.

e) Costs: Units of expense and unit costs should be described in detail. Information on the source (e.g., charges, payments) and year of the cost data should be presented. If the costs were inflated and/or converted from another currency, then this must be described.

f) Outcome Measure: Measures of effectiveness depend on the type and objectives of analysis. Quality adjusted life years are the gold standard, as described previously in this chapter.

g) Analytic Model: Each intervention being assessed must be described and possible courses of events identified, including the expected course of disease, treatments, complications, and outcomes. This may be performed using a spreadsheet/ clinical trial path, or Decision Tree, or Markov Model.

h) Discounting: Since the value of both costs and benefits may decrease over time, discounting is used to calculate the present value of money and health states that will occur in the future. Future costs and utilities should be discounted to present value; 3% per year is a recommended starting point.

i) Incremental Analysis: The purpose of a CUA is to describe the relative value of one health care strategy compared to another. An incremental cost-effectiveness ratio (ICER) is the incremental cost divided by the incremental effectiveness of intervention a compared to intervention b, and is calculated as follows.

\[
\text{ICER} = \frac{\text{Average Cost}_{\text{intervention A}} - \text{Average Cost}_{\text{intervention B}}}{\text{Average Utility}_{\text{intervention A}} - \text{Average Utility}_{\text{intervention B}}}
\]

Averages should be used rather than other measures of central tendency, such as medians, because it is important to include the effect of outliers. The leverage of the outliers should be tested in a sensitivity analysis.

j) Sensitivity Analysis: A sensitivity analysis should allow the reader to understand whether the conclusion of the analysis would hold true if either the Costs or the Probabilities (of cure or complications) were to vary substantially. For example if one treatment costs €5,000 and has a cure rate of 90%, and the second treatment costs €2,000 with a cure rate of 80%, then the ICER will assess whether the resultant benefit in QALY/ Quality of Life makes the first treatment worthwhile.

Having reached this conclusion, the researcher should then vary the costs and the cure rates in the model, to see how much variation in real life would be allowed yet still maintain a valid conclusion.

Documenting these boundaries helps define the conditions under which a treatment is preferred. Researchers are developing innovative methods for conducting sensitivity analyses. Probabilistic models that use simulations are becoming more common, although they can be computationally complex. Some journals require probabilistic sensitivity analyses.

V. SUMMARY OF RECENT ECONOMIC ANALYSES

Two trends stand out while reviewing the recent literature. First, many studies are choosing relatively short time frames. This makes it difficult to project the long-term economic consequences. Second, a number of studies are claiming that one treatment is dominant with very small differences in parameter estimates. This raises questions about whether one treatment is non-inferior.

1. SURGERY FOR STRESS INCONTINENCE

Previous reports from this ICI committee[41] on the cost-effectiveness of surgical treatment for stress incontinence can be summarized as:

- minimally invasive surgery (TVT, injectable therapy) are likely to be cost-effective compared to more invasive surgeries like the Burch colposuspension
- studies are limited by poor longer-term data on the effectiveness of less invasive procedures, lack of primary and/or generalizable data on costs, clinical outcomes and utilities and not using a accepted and generalizable outcome (cost per QALY or cost per “cure”)
- there is a need for longer-term follow-up data from methodologically rigorous randomized trials to provide a better data to estimate the relative benefits and cost implications
Since the last ICI meeting in 2008, few cost-effectiveness analyses of surgical interventions for stress incontinence which systematically compare costs and outcomes within an RCT framework have been published.

In late 2008, the U.S Urinary Incontinence Treatment Network group estimated costs for incontinence management, health-related quality of life, and willingness to pay for incontinence improvement in women electing to have surgery for stress urinary incontinence [42]. This cross-sectional study included 655 incontinent women enrolled in the Stress Incontinence Surgical Treatment Efficacy Trial (SISTER), a randomized surgical trial. Baseline out-of-pocket costs for incontinence management were calculated by multiplying self-report of resources used (supplies, laundry, dry cleaning) by national resource costs (2006 USD). Post-treatment costs were given in a later report.

Health-related quality of life was estimated with the Health Utilities Index (HUI) Mark 3. Participants estimated willingness to pay for 100% improvement in incontinence. Potential predictors of these outcomes were examined by using multivariable linear regression. Mean age was 52 ± 10 years, and mean number of weekly incontinence episodes was 22 ± 21. Mean (SD) and median (interquartile range) estimated personal costs for incontinence management among all women were $14 ± 24 and $8 (interquartile range $3, $18) per week, and 617 (94%) women reported any cost. Costs increased significantly with incontinence frequency. Mixed leak cost more than pure stress incontinence.

The mean and median Health Utilities Index Mark 3 scores were 0.73 ± 0.25 and 0.84 (interquartile range 0.63, 0.92). Women were willing to pay a mean of $118 ± $132 per month for complete resolution of incontinence, and willingness to pay increased significantly with greater expected incontinence improvement, household income, and incontinent episode frequency. Urinary incontinence is associated with high costs, with women reporting expenses of nearly $750 per year out of pocket for incontinence management. Women were also willing to pay a lot - nearly $1,400 per year - for incontinence cure, reflecting the high degree of bother of the condition. Incontinence was also associated with a significant decrement in quality of life.

Subak et al (2010)[43] then studied 491 women who completed 24 months of the Stress Incontinence Surgical Treatment Efficacy Trial (SISTER) who underwent Burch colposuspension or sling surgery. Self-reported out-of-pocket incontinence management costs were measured at 24 months post-operatively. Women quantified the resources used for management of UI including number of supplies for UI and additional laundry and dry cleaning needed each week. Total costs for management of UI were estimated by multiplying these resources by national resource costs (2006 USD). The analysis combined both treatment groups to examine the effects of change in UI over 24 months on cost. Univariate and bivariate changes in cost were analyzed using Wilcoxon signed rank test. Potential baseline predictors of change in cost were examined using multivariate mixed models adjusting for age, ethnicity, baseline BMI, annual income, ≥3 UTIs, POP-Q stage, fecal incontinence, diabetes, prior non-surgical UI treatment, menopause, smoking, treatment group, and accounting for site clusters.

The mean (±SD) age of participants with complete resource use data at baseline and 24 months was 53 ± 10 years. The mean weekly UI frequency was 23 ± 21 episodes at baseline, which decreased by 86% at 24 months (P<0.001). Mean weekly cost was $14.88 ± $25 (median $8.42) at baseline which decreased to $4.10 ± $14 (median $0.09) at 24 months (P<00.001). The proportion of women reporting any cost decreased from 95% at baseline to 50% at 24 months (P<0.0001). There was a similar reduction in weekly cost for both treatment groups (-$10.83 for Burch vs. -$10.73 for sling; P=0.49). In multivariable analyses, cost decreased by $0.96 ± $0.23 per week for each decrease of 7 UI episodes per week (P<0.001) and was strongly associated with greater improvement in UDI and IIQ scores and decreased 24-hour pad weight (P<0.001 for all). In summary, incontinence management costs decreased by 73% ($580 per woman per year) and were strongly and independently associated with decreasing UI frequency 24 months following Burch or sling.

Lier and colleagues [24] performed a within trial cost-utility analysis in a randomized trial of trans-obturator tape (TOT) compared with tension-free vaginal tape (TVT) in the surgical treatment of stress urinary incontinence (SUI) among 194 women in Canada. Cure was assessed by objective pad tests. They assessed costs in 2007 Canadian dollars from the public-payer perspective, i.e. 807$ Can for surgical kits, plus day only surgical costs and 12 months of care costs. The 15D utility instrument was used to measure QALYs. At 1 year post-surgery, 81% of TOT patients were dry on 24 hour pad test, versus 77% of TVT patients; 15% of the TOT had groin pain (versus 6% of TVT) but whether this contributed to medical costs over 12 months was not clear. The TOT group had a non-significant average saving of $1133 (95% CI -2793; 442), or 17%, with no difference in average QALYs between groups (95% CI -0.02; 0.01). TOT was cost-saving in over 80% of sensitivity analyses, suggesting that TOT would be cost-effective compared with TVT in the treatment of SUI. However, longer-term assessment of clinical and economic outcomes are needed to confirm the finding and observe for effectiveness, surgical complications, and re-treatment.

Jacklin et al [44] published a decision tree/Markov model in 2010 which proposed to consider the cost...
utility of second line treatment for women with stress incontinence who had failed PFMT. The Markov model was controversial, because patients were expected to have either duloxetine or a TVT and then be followed up for 2 years, there was no opportunity for patients not responding to duloxetine to progress to a TVT. However patients failing the initial TVT were able to have a repeat TVT. The purpose of the article was to employ recently published long term follow up data for duloxetine (as initial studies only reported to 12 months, with 68% of women estimated to continue therapy, but recent studies showed much poorer continuation rates, i.e. 9% and 8% at 12 months and 2 years). No actual QALY data for the TVT patients were cited from the literature, and QALY date for duloxetine patients was cited from a small study [45].

Unsubstantiated assumptions were made about the QALY loss associated with adverse events from duloxetine therapy. An 8 week course of duloxetine cost £30 (which would be very low cost for this medication in most countries), a TVT cost £2,044. They concluded that TVT is a cost effective second line therapy, but duloxetine, although cheaper, is not cost effective because of high discontinuation rates and lower efficacy. One of the authors was part funded by NICE, a second author had previously been funded by the manufacturers of duloxetine.

Patel et al. [46] compared the operating/bedstay billing costs in 45 patients from South Carolina having surgery for stress incontinence with or without prolapse, who had either commercial mesh kits, or segments of prolene mesh that were sewn in by the surgeon, with or without biomaterials during 2007-2008. Operative billing sheets including operative time, hospital "cost", bedstay time, and the insurance billings were reviewed. Surgeon payment was not included. The definition of cost is unclear and may represent hospital charge rather than cost. In both pure stress incontinence or coexistent prolapse, the surgeon-made prolene mesh operations were less expensive than the surgical kits, not surprisingly. No efficacy data or QALY data were included.

In our last report, Wu et al. [47] had very recently performed a methodologically excellent cost-effectiveness analysis of Burch colposuspension compared with TVT for stress incontinence, using a Markov model to compare costs (2005 USD) and QALY’s (measured by the Health Utilities Index) over 10 years from a health care system perspective. In this well done study using state-of-the-art methods, Burch colposuspension was not cost-effective compared with TVT. However, if the tension-free vaginal tape failure rate was to increase over time, Burch may become cost-effective, reinforcing the need for long-term follow-up in surgical trials and cohorts.

In our last chapter, we reported a study regarding open vs. laparoscopic colposuspension by Dumville et al [48], which the Committee pointed out was a good example of the importance of evaluating costs over a long time frame to allow cost effectiveness to emerge. In the initial economic analysis of the two procedures at 6 months, healthcare costs were higher for the laparoscopic arm than for the open Burch arm (£1805 vs. £1433; differential mean cost £372; 95% CI 274, 471) due to increased theater costs. QALYs were slightly higher in the laparoscopic arm relative to the open arm (0.005; 95% CI -0.012, 0.023). The ICER was £74,400 at 6 months. At 24 months, higher mean QALY's persisted in the laparoscopic arm and modeling showed the ICER was reduced to £9300. While laparoscopic colposuspension was not cost effective compared with open colposuspension during the first 6 months following surgery, it may be cost effective over 24 months.

In the last report, we discussed the multicentre RCT of Manca et al (2003)[49] who assessed the cost effectiveness of TVT with open colposuspension for primary stress incontinence at 6 months, in 344 women from 24 centres in the UK and Ireland. The EQ-5D was used to measure QALYs. The TVT had lower mean costs and higher mean QALYs at 6 months, which persisted over 95% of sensitivity analyses. The 2 year and 5 year follow-up of this study has since been published but no further economic analysis appears to have been reported.

2. SURGERY FOR URGE INCONTINENCE

a) Studies regarding Botulinum Toxin A Injections (Botox A)

Three studies comparing Botox A with other treatments have been published since our last report. Wu et al (2009) from the USA performed a Markov model analysis of Botox A versus anticholinergic medication [50]. The model was conducted over a two year time frame, and assumed that 33% of patients would comply with anticholinergic therapy over this time. The Botox treatment cycles were more expensive (US$4,400) than the anticholinergic medication (US$2,560), but the Botox was more effective (QALY gain 1.63 versus 1.50), yielding an ICER of $14,377.

Wefer et al (2009) from Germany evaluated Botox A injections in 214 patients with neuropathic detrusor overactivity [51]. 300 IU of Botox were injected in each patient (which is common practice in neuropathic DO, but varies from some clinical practice in Idiopathic DO which 200IU are often given). The injections were given as inpatients. Pad costs per day were reduced from €2.11 per day to €1.05, and medications for urinary tract infection fell by half (from €162 per annum to €80 per annum). Unfortunately no QALY measurements were performed.

Robinson et al. (2010)[52] undertook a Markov model study comparing Botox with percutaneous tibial nerve stimulation (PTNS), over a 2 year time frame in refractory idiopathic detrusor overactivity. Repeat botox injections were assumed to occur every 8 months; 20% of patients were assumed to perform clean intermittent self-catheterization for 4 months.
QALY data was assumed from the literature. PTNS was cheaper than Botox (£1,700 versus £4,067) and had a lower ICER (£50,133 versus £111,953) but neither would satisfy UK NICE guidelines for cost-effectiveness (i.e. not less than £30,000 per QALY).

Padmanabham et al (2011) from USA performed a decision tree analysis of Botox injections versus Clam Cystoplasty[25] (which is an arguable model, since Sacral Nerve Stimulation has largely overtaken clam cystoplasty in the western world). Nevertheless, this was a group of severely refractory neuropathic DO patients, who were performing clean intermittent self catheterization (CISC) but still had upper tract dilatation and recurrent urinary tract infection (UTI). Their decision tree is shown in Figure 3 (earlier in this chapter). Botox 300 IU was injected every 6 months for 5 years, the cost of each injection was US$ 2,800, equaling 28,000 over 5 years. The Clam Cystoplasty cost US $33,000. In their model, it was assumed that 10% of patients would fail Botox, of whom 85% would go on to have a Clam Cystoplasty (this model is controversial in the modern day climate).

No QALY data were provided, but the authors concluded that if the durability of Botox benefits exceeded 5.1 months, then the cost effectiveness of Botox dominated, so long as the complication rate of the Clam Cystoplasty was less than 14%. The first proviso appears quite reasonable, but the complication rate of Clam cystoplasty is known to be higher than 14%, and the 1% mortality is not mentioned (which would have adversely affected any QALY data taken from a real life study).

b) Sacral nerve stimulation

Sacral Nerve Stimulation (SNS) is a minimally invasive FDA approved second line treatment for refractory overactive bladder (OAB) dry and wet. Currently five papers describe different aspects of cost analysis and cost-effectiveness of SNS, some with comparison to other treatment strategies for OAB [53-57].

Aboseif et al[53] in the U.S.A. retrospectively reviewed the costs related to SNS for a period extending from one year pre- to one year post-implantation. In a heterogeneous group of patients, also including patients with urinary retention and chronic pelvic pain, a one year SNS treatment reduced 92% of outpatient doctor visits and diagnostic and therapeutic procedure costs, along with a 30% reduction in drug costs [53]. This however did not include the costs of the neuromodulation implant itself, nor the surgical implantation costs. QALYs were not ascertained.

A cost analysis evaluation was also conducted in a large multicenter cohort study in France,[56] which included 190 OAB wet patients and neuropathic DO, as well as another 85 patients with OAB wet plus faecal incontinence (double incontinence). Treatment costs included insertion of preliminary tined leads under GA as an outpatient then permanent implant as an inpatient, with Botox injections given as an inpatient. Health-related travel costs were also included in the analysis, which extended from the pre-test evaluation, over the temporary stimulation procedure until two years after the implant procedure.

The median overall cost per OAB wet patient for the first two years was €16,403, which was on average €8,525 more per patient compared to patients on alternative treatments, which comprised conservative measures (medication and diapers/pads), botulinum toxin injection, enterocystoplasty or urinary diversion. Importantly, devices and hospital stays accounted for 40% and 52% of the total cost respectively. Although the authors provided a limited cost-effectiveness analysis over the two year period, the interpretation of the results are difficult because of the heterogeneity of the study population, surgical procedures and the lack of clear descriptions of the cost-effectiveness parameters. Their data, however, suggest that SNS for OAB wet is not cost-effective over the two years period. This is in agreement with the data from Siddiqui et al[57] (see below), and not surprising since the initial costs are very high due to the device costs. Interestingly, their data suggest that SNS may be cost-effective even in the short term for patients with double incontinence [56]. This deserves attention in future research.

Siddiqui et al [57] performed a cost-effectiveness analysis of SNS vs intravesical Botulinum Toxin A in patients with idiopathic “OAB wet” in the US. A two year period was chosen for evaluation because no long-term data were available for Botulinum Toxin A. The base case scenario included a staged implant procedure for SNS using the tined lead, and office injections of 200 units Botulinum Toxin A. For the SNS strategy, no data were provided on the procedure (local vs general anesthesia; outpatient vs inpatient clinic). The relevant base case estimates are provided in Table 2. Based upon their Markov decision model, the base case SNS treatment was more expensive ($15,743 vs $4,392) but also more effective (1.73 vs 1.63 QALY’s) than Botulinum Toxin A. During the two year period, SNS was not cost-effective with an ICER of $116,427 [57]. As stated above, the relevance of a cost-effectiveness analysis over a two years period with a costly implant device is questionable.

Two cost-effectiveness studies have considered the longer term, comparing SNS and Botulinum Toxin A in the Netherlands[55] and Spain [54]. The parameter estimates are provided in Table 2. In the Netherlands, Leong et al. (2011)[58] showed that SNS becomes cost-effective from the fourth year post-implant on, given an ICER threshold of 40,000€/QALY [55]. These data are based upon two procedures under general anesthesia (1) a staged SNS procedure involving a tined lead test phase in the operating theatre on an outpatient basis, followed by an inpatient stay for device implant; (2) inpatient stay for Botulinum Toxin A injection in the operating theatre.
These data are in agreement with the Spanish study by Arlandis et al., [54] which showed SNS to be cost-effective from 1 year post-implant on, given an ICER threshold of 30,000€/QALY. These results are based on (1) a staged SNS procedure involving a tined lead test phase; (2) 100 units Botulinum Toxin A. No further data were provided on the procedure (inpatient vs outpatient; local vs general anesthesia). In both studies, [54, 55] several estimates or assumptions had to be made due to the lack of long-term data beyond 1 year for Botulinum Toxin A injections and 5 year for SNS therapy, such as therapy transition rates after failure and drop out rates. To what extent these data are reliable and valid is currently unknown.

Furthermore, both studies quote a one year success rate for SNS of 90%, based upon Van Voskuilen et al., [59] that describes the effect of SNS in 39 patients with OAB over 15.5 months follow up. However, in that study 10 patients were lost to follow and were excluded from the analysis. Therefore the 90% success rate
may be an overestimation, and the worst scenario, considering the ten lost to follow up patients as failures would give a 61% success rate. How this would influence the cost-effectiveness evaluation is unknown. A similar consideration applies for the 5 years success rate of 70% based upon Van Kerrebroeck et al. which considers patients lost to follow up as last observation carried forwards.

Sensitivity analyses for several parameters estimated by expert opinion have been performed. In the Netherlands, SNS over a 5 years period remained cost-effective (ICER < € 40,000/QALY) when the estimated dropout rate of 4.3% for both treatments was changed to 2% or 6%, and when utility value for incontinence was changed from 0.73 to 0.80. SNS was no longer cost-effective over 5 years in the following cases:

a. when Botulinum Toxin injections were done under local anesthesia (which is common practice in several countries);

b. when the Peripheral Nerve Evaluation test for SNS screening is used (because of the lower success rate of 55% compared to 75% for Tined Lead screening);

c. when bilateral testing is done

d. when the new and smaller stimulator (Interstim II) is used [55].

Because there is no standard protocol of Botulinum Toxin A injection, a different protocol using 200 units every 14 months was evaluated in the Arlandis study, which proved cost-effective on the ICER < € 30,000/QALY threshold [54].

3. OUTPATIENT CONSERVATIVE THERAPIES

An important study regarding the baseline “cost of illness” for women with stress or urge leak was detailed in our last chapter (Subak et al.[61]).

A more recent study of the “Cost of Illness”[62] included 528 women with UI weekly or more enrolled in the Reproductive Risks for Incontinence Study at Kaiser population-based study. Similar to the prior studies, routine care costs were calculated with the use of national resource costs ($2005). Potential predictors of these outcomes were examined by multivariable linear regression. Among women with weekly UI, 69% reported incontinence-related costs. Median weekly cost was $1.83 (25%-75% interquartile range [IQR], $0.50, $5.23) and women spent a mean of $250 per year out-of-pocket for UI routine care. Costs increased with incontinence severity (P < .001) and body mass index (P < .001) were 2.2-fold higher for African American versus white women (P < .0001) and 42% higher for women with mixed versus stress incontinence (P < .05).

Since costs for incontinence management increase with leakage severity, data are needed to explore whether effective treatment will be associated with decreased incontinence costs.

Recently, Subak et al.[63] performed a planned secondary analysis among overweight and obese women, who were enrolled in a clinical trial of a weight loss intervention. The purpose was to estimate the effect of a decrease in incontinence frequency on incontinence management costs [63]. The study included 338 obese and overweight women with at least 10 weekly urinary incontinence episodes at baseline. They enrolled in a randomized clinical trial to determine the effect of an 18-month weight loss and maintenance intervention compared to a structured education program, upon the frequency of incontinence.

Quantities of resources used for incontinence management, including pads, protection, additional laundry and dry cleaning were reported by participants. They estimated direct costs for urinary incontinence management (“cost”) by multiplying resources used by national resource costs (in 2006 U.S. dollars). For the total cohort (combined randomization groups), mean (±SD) age was 53 ± 10 years and baseline weight was 97 ±17 kg. Mean weekly urinary incontinence frequency was 24±18 at baseline, which decreased by 37% at 6 months and 60% at 18 months follow-up (both P<0.001).

At baseline, adjusted mean cost was $7.76 ± $14 per week. Costs increased significantly with greater incontinence frequency. Mean cost decreased by average of 54% at 6 months and 81% at 18 months (both P < 0.001). In multivariable analyses, cost independently decreased by 23% for each decrease of 7 urinary incontinence episodes per week, 21% for each 5 kg of weight lost, and was strongly associated with greater improvement in UDI and IQ scores at 18 months (P < 0.001 for all). In this cohort of obese and overweight women enrolled in the clinical trial, management cost for urinary incontinence decreased by over 80% at 18 months ($327 per woman per year) and was strongly and independently associated with decreasing incontinence frequency. This suggests that effective incontinence treatment will be associated with decreasing costs of incontinence management.

Although not primary data, Imamura et al (2010) published a comprehensive review of the cost effectiveness of non-surgical treatments for women with stress incontinence [64]. In this report, a group of senior clinicians and other experts obtained funding from the Medical Research Council of the UK to evaluate 88 studies of conservative treatment involving 37 distinct treatment regimes, in a total of 9,721 participants. QALY data were taken from a study by Haywood et al[65] which employed the EQ-5D [64]. In brief, the authors found that a treatment strategy of Pelvic Floor Muscle Training (more than 4 visits) along with lifestyle advice, followed by a TVT where necessary, was the least costly strategy, at £1644 per person, and was the most effective, with a cost utility of 16.20 QALY per annum. This strategy had a 70% likelihood of being the most cost effective across a wide range of sensitivity analyses.
A smaller review of cost effectiveness evaluations for pelvic floor exercise interventions, which included data from 3 older studies (from 1996, 2003, 2006) has also recently appeared [66].

In the last Chapter, we reported an abstract from Ho et al. [67] in Australia who performed a “bottom up” study of the short and long-term treatment costs of conservative and surgical management of childbirth-related stress and mixed urinary incontinence (UI). This report has now been published in full [68]. Costs of treatment episodes during conservative and surgical management were calculated for a cohort of 150 women and related to cure. At 6-13 years follow up, personal and treatment expenditure was measured using a postal questionnaire. During active treatment, patients with stress UI treated conservatively incurred a median cost of AU$658 per capita (IQR 476–1191 AU$) compared to a median cost of $6,870 per capita for surgical treatment (IQR 6,320 – 7,508 AU$). Similar cost difference was seen for the two treatment options in mixed incontinence. Of regular clinic attendees, 39% of conservatively treated and 78% of surgically treated patients were cured.

At 6-13 years follow-up (82 women with a known address), 43 (52%) responded to the survey, of whom 46% remained cured. The median treatment cost for the total group of postnatal incontinence (irrespective of continence status) was AU$885.80 per patient cured (IQR 338–2,589 AU$). The costs per cure are shown in Table 3, in Australian dollars.

4. PHARMACOTHERAPY OF URINARY INCONTINENCE

a) Economics of pharmaceutical therapies

Although pharmaceutical companies must show that a new drug is safe and efficacious prior to approval and marketing, the requirement for economic studies (ie whether the new drug is cost-effective compared to standard treatment), varies from country to country. The U.S. Food and Drug Administration does not require any economic data in its review of a new drug. Instead it leaves economic questions to the purchasers (e.g., insurance companies, government purchasers or individuals), similar to the Netherlands. In the UK, however, the National Institute for Health and Clinical Excellence (NICE) requires economic review. They have denied approvals for new drugs that have an incremental cost effectiveness ratio greater than £30,000 per QALY. In Australia, manufacturers must prove cost-effectiveness in order to achieve listing on the Pharmaceutical Benefit Scheme (whereby patients pay a subsidized cost for the drug). However, only therapeutic efficacy and safety must be shown in order for it to be available in Australia as a non-subsidized “private” prescription.

In response to the regulatory requirements, drug developers routinely conduct economic evaluations. In the UK, such efforts are done as part of the NICE review. In the US, developers present economic data to purchasers for post approval marketing. Many purchasers (as in Australia) have formularies, or lists of medications that they are willing to pay for, and the economic evaluation is frequently part of the request to place the new drug on the formulary.

In the next sections, we review the recent literature on the economics of drugs for incontinence and overactive bladder.

1. PHARMACOTHERAPY FOR STRESS INCONTINENCE

Mihaylova et al. (2010) assessed the cost-effectiveness of duloxetine compared with conservative therapy in women with SUI [69]. Cost and outcome data from a 12-month, prospective, observational, multicenter, multicountry study were used (the Stress Urinary Incontinence Treatment (SUIT) study). Costs were assessed in 2007 £ from the healthcare plus patient perspective; outcomes were measured in quality adjusted life years using the EQ-5D. Duloxetine alone and with conservative treatment (not explicitly defined but varied by physician practice) were associated with incremental quality-adjusted life years (QALYs) of about 0.03 over a year compared with conservative treatment alone or with no treatment. Conservative treatment alone did not show an effect on QALYs. Duloxetine either dominated (lower

Table 3. Costs per cure, modified from Ho et al. (2012) [68]

cost and greater change in QALY) or had an incremental cost-effectiveness ratio (ICER) below £900 per QALY gained, compared with no treatment and with conservative treatment alone. Duloxetine plus conservative therapy had an ICER below £5500 (compared with no treatment or conservative treatment alone). Duloxetine compared with duloxetine plus conservative therapy showed similar outcomes but an additional cost for the combined intervention. While limited by the observational design, the study suggests that initiating duloxetine therapy in SUI is a cost-effective treatment alternative.

**(NOTE: Duloxetine failed the US approval for stress urinary incontinence due to concerns over liver toxicity and suicidal events. It is approved for SUI in Europe, where it is recommended as an add-on medication in stress urinary incontinence instead of surgery.**

In a similar vein, we reported in our last chapter that Brunenberg[70] conducted a Markov model to assess the cost-effectiveness of duloxetine alone and duloxetine after inadequate response to pelvic floor muscle training [PFMT] compared with PFMT or no treatment for women 50 years of age or older, which narrowly focused upon pharmacotherapy and PFMT for stress incontinence, with no consideration of surgery.

Das Gupta and colleagues[45] also developed a model to assess the cost-effectiveness of duloxetine for moderate to severe SUI, but they assumed that drug treatment was fully effective. Thus duloxetine studies published to date have methodological limitations.

### 2. Pharmacotherapy for Urge Incontinence

There are five commonly used medical treatments for overactive bladder: Oxybutynin (ditropan) as a tablet or as Oxytrol patches; tolterodine (Detrol), darifenacin (Enablex), trospium (Sanctura), solifenacin (Vesicare), and a sixth recent introduction, Fesoteridine (not yet widely used).

Many economic evaluations are funded by drug developers and compare the investigational drug to placebo or to an older compound that has known problems with side effects (e.g., immediate release oxybutynin). In the Fourth ICI report [41] we reported one study by Ko et al. [71] who conducted an independently funded economic evaluation of five antimuscarinic drugs (in eight formats) for overactive bladder (see **Figure 8**). They concluded that solifenacin had the lowest costs and highest effectiveness, compared to immediate-release (IR) oxybutynin, extended-release (ER) oxybutynin, transdermal oxybutynin, IR tolterodine, (ER) tolterodine, trospium, and darifenacin. However, their study did not meet minimum standards for cost-effectiveness analysis [9, 14]. It also focused on the payer’s perspective (rather than a societal perspective), had a short time frame.

![Figure 8. Decision-analysis model used to compare cost-effectiveness of antimuscarinic agents for the treatment of overactive bladder. Modified from Ko et al. (2006)[72].](image-url)
of 3 months, and used complete continence as the main effectiveness measure (rather than QALYs). Given these limitations, we recommended that these results must be interpreted cautiously and that additional studies using standard methods were needed.

3. Solifenacin Studies

Milsom et al[72] performed a cost effectiveness analysis of Solifenacin flexible dosing (5-10 mg) versus tolterodine 4 mg Sustained release in 4 Nordic Countries. The efficacy data was based upon the STAR RCT (Chapple et al, 2005[73]) and 2 other RCTs of solifenacin versus tolterodine and placebo. QALYs were not included in the original trials, but the EQ5D was estimated from original HRQOL data collected in 1997. The cost differences between solifenacin and tolterodine ranged from €6 to €127. The authors concluded that Flexible dose Solifenacin was more cost effective than Tolterodine 4 mg. This study was supported by Astellas.

Herschorn et al[74] undertook a Markov model based upon the VECTOR study, which compared Solifenacin 5 mg/ day versus Oxybutynin 15 mg/ day in Canada. The withdrawal rate due to side effects of oxybutynin (19%) was much greater than that for solifenacin (3%). No QALY data was included in the original VECTOR study. Their 8 week efficacy data was projected over 1 year, which is an arguable model. Solifenacin yielded a cost saving of Can $1,830 per annum, giving an ICER of Can $14,000. This study was also funded by Astellas.

Cardozo et al[76] performed a decision tree analysis of solifenacin, versus fesoteridine, oxybutynin ER, propiverine, tolteridine ER and IR in the UK. In this one year model, success was individually defined for frequency, urgency and urge incontinence. The model was problematic (Fig 9), in that it assumed if the patient had no success on a drug that was only available in one dose, then the patient was given no further treatment. The original study did not include QALY data, which were calculated from willingness to pay data published by Kobelt in 1998 [77]. The calculation of QALYs from willingness to pay is not a standard methodology and created confusion among the Economics Committee members. Because oxybutynin was so much cheaper than the other drugs (20% of total costs, versus 60-70% of total costs for the other therapies), oxybutynin was dominant for 2 of the 3 outcomes.

In 2005, Getsios and colleagues[78] published a review of the economic studies for overactive bladder, highlighting many of the limitations including a lack of comparisons of drugs to behavioral training.

4. Darifenacin Hydrobromide (Enablex)

Darifenacin was approved by the FDA in 2004, based on Phase II and III controlled clinical trials with over 8,800 patients. Short term efficacy (12 week) as well as longer term effects (24 and 52 week) were evaluated [79]. Abrams and colleagues [80] found that darifenacin was associated with significant improvements in quality of life as measured by the King’s Health Questionnaire at 12 weeks relative to placebo. Chancellor et al. [79] found that darifenacin and darifenacin combined with a behavioral modification plan both resulted in improvements in symptoms and quality of life, as measured by the Overactive Bladder Questionnaire (OAB-q), but there were no differences between the two groups. Unfortunately, neither the Abrams nor the Chancellor study measured utilities. Besides the Ko [71] article discussed above, there is little data on the cost-effectiveness of darifenacin.

5. Tolterodine (Detrol)

In late 2008, Burgio et al (The UTIN group) conducted a clinical trial of 10 weeks of open-label, extended-release tolterodine alone (n = 153) or combined with behavioral training (n = 154), followed by discontinuation of therapy and follow-up at 8 months [81]. Among 237 participants completing the trial, the rate of successful discontinuation of therapy at 8 months was the same in the combination therapy and drug therapy alone groups (41% in both groups; difference, 0 percentage points [95% CI, -12 to 12 percentage points]). A higher proportion of participants who received combination therapy than drug therapy alone achieved a 70% or greater reduction in incontinence at 10 weeks (69% vs. 58%; difference, 11 percentage points [CI, -0.3 to 22.1 percentage points]). Women in the combination therapy group reported better outcomes over time on the UDI and the OAB-Q (both P <0.001) for patient satisfaction and perceived improvement but not health-related quality of life. They concluded that the addition of behavioral training to drug therapy may reduce incontinence frequency during active treatment but did not improve the ability to discontinue drug therapy and maintain improvement in urinary incontinence. Economic evaluations are ongoing.
Two studies evaluating the cost-effectiveness of tolterodine versus percutaneous tibial nerve stimulation (PTNS) have recently been published. In 2009, Robinson et al. [82] undertook a cost minimization study of PTNS versus tolterodine ER 4mg, involving 1-2 year follow-up, from the perspective of the NHS. In the model, the two treatments were assumed to have equivalent efficacy (based on unpublished data), and adverse effects were considered to be cost neutral. The patients having tolterodine were followed for 2 years, the duration of follow-up for PTNS was not clearly stated. Tolterodine appeared to be the cheaper treatment but alteration of the variables in the model had a large effect.

In 2010, Chen et al. [83] performed a very similar evaluation of PTNS versus tolterodine, cost-utility values were obtained from the literature [84], yielding an ICER of $70, 754 per QALY, thus PTNS was not cost effective in the treatment of OAB over a 1-year period.

6. TROSPIUM CHLORIDE (SANTUCA)

Besides the Ko [71] article discussed above, there is little published data on the cost-effectiveness of trospium chloride.

5. COST IMPLICATIONS OF INCONTINENCE IN NURSING HOME SETTING

Two key aspects of cost of care for nursing homes are (1) cost of nursing home admissions attributable to urinary incontinence, and (2) the treatment cost of urinary incontinence. In the last 4 years, no new studies were found regarding this aspect of the economics of incontinence, therefore our previous findings are briefly summarized.

Additional nursing home admissions cost is often a major component in the total cost of urinary incontinence. In a 2001 study [16] the cost estimate was $2.4 billion in 1995 dollars. In a 2004 study [15], the cost estimate was $4.0 billion in 2000 dollars. In a 2006 study, [85] the attributable fraction (AF) statistics from published data was shown to be $6.0 billion in 2004 dollars. The Attributable Fraction (AF) statistics are obtained by using incontinence prevalence rates for those admitted to nursing homes, as compared to those who were not admitted to nursing homes. It shows that reimbursement for treatment of UI in the community might help or delay institutionalization and offset some costs of staying in nursing homes. The AF method has been used in the economic cost of mental illness, smoking, and cancer diseases. The new estimated magnitude shows that reimbursement for treatment of UI in the community might help or delay institutionalization and offset some costs of staying in nursing homes.

Holroyd-Leduc et al. [86] conducted a population-based prospective cohort study (from 1993-1995) in over 6,500 elderly (>age70) patients. After adjusting for confounders, UI was not an independent predictor for death, nursing home admission, or functional decline. Within nursing homes, labor costs are a major component of caring for incontinent patients. These costs are studied via time/motion observation, correlated with severity and type of incontinence. In 49 long-term care facilities in North Carolina, USA, it was found that the incremental labor costs (per shift) were $3.31 for patients with occasional UI and $5.61 for patients with frequent UI [87], in keeping with Morris et al. [10].

Bliss et al. [88] addressed the cost/effectiveness of incontinence-related treatment of skin condition in 16 US nursing homes. Four regiments of different moisture barriers were applied. Time and motion measurements included skin products and time spent. Using acrylate barrier film spray achieved cost savings of between $854 to $1,862 per resident, with better skin protection than the use of an ointment or cream.

6. LONGITUDINAL BURDEN OF DISEASE STUDIES

For the first time in the last ICI report, we found a number of studies that measure the cost of incontinence over the long-term time frame. As pointed out by Birnbaum et al. [89], the study of “the lifetime cost of illness” is a recent area of research. These authors combined case-control methods (to calculate annual medical costs of stress incontinence, etc) with knowledge of the incidence of the conditions, assuming “steady state conditions” of the costs, to project the lifetime costs of each disorder.

As regard the impact of incontinence upon employed women, Fultz et al. [90] sent a postal questionnaire to 2326 employed women, 37% had leaked urine in the past month. The impact of incontinence upon ability to concentrate, performance of physical activities, self-confidence, and ability to complete tasks without interruption increased with the severity of the leak and affected nearly 75% of all those with severe leak status. Similarly, Wu et al. [91] focused upon the work loss burden of women with OAB. The number of days absent was 15% higher among 3077 OAB employees compared to 6154 controls. OAB subjects had 4.4 more days off work than non-OAB subjects, yielding an annual excess cost of $1220 per OAB employee.

In the last chapter, Reeves et al. [92] employed a theoretical model based upon a large “EPIC” prevalence study of OAB [93] to derive the future cost burden for OAB in five European countries. They calculated an annual per capita expense of €269-706 per annum.

A more detailed analysis of OAB costs in Germany [94] that included psychiatric costs of OAB-related depression, and nursing care, indicated an annual per capita expense of €609-1170 per annum in that country.

Since the last report, this same group of authors obtained updated data for the treatment costs of “OAB wet” and “OAB dry” [95]. They also provided new data about the non-treatment costs of OAB, such as lost productivity, depression, sleep disturbance, falls
and fractures, skin infections and UTIs. The manuscript lists 23 website links that were used to access unit costs for each of the six developed countries (Canada, Germany, Italy, Spain, Sweden and UK). A summary of the costs in each country is shown in Table 4 [95], with summary data in Table 5 [95]. Overall, the annual treatment costs of OAB in six countries is shown to be €3.9 billion, with additional costs for nursing home stays (€4.7 billion per year) and loss productivity due to work absenteeism (€1.1 billion per year). The estimated total cost therefore for the ≈25 million patients with OAB in these countries is €9.7 billion.

Cisternas et al [96] undertook an analysis of the economic burden of overactive bladder syndrome in Medicare beneficiaries in the USA[96]. They obtained data for all Medicare claims for patients over age 65 during 2003-2004, compared with non-OAB subjects. Multiple regression analysis was used to estimate costs attributable to OAB after adjusting for demographic characteristics and comorbidities. They used a narrow definition of OAB (detrusor overactivity, urge incontinence, frequency with polyuria) and also a broader definition of OAB (that included incontinence without sensory awareness, nocturnal enuresis, continuous leakage, etc).

Costs were based on the amount of money reimbursed to providers by Medicare (which generally yields 80% of “allowed amounts”) that includes inpatient stays, skilled nursing facilities, outpatient visits and procedures such as cystoscopy. Figure 10 shows the prevalence of the two definitions of OAB compared to other chronic conditions. The prevalence of OAB in this over 65 group was 9-14% for the two definitions.

The mean annual expenditure attributable to OAB ranged from US$825 – 1184 per subject, which comprised 9-12% of all their medical expenditure.

*Excluding nursing home and productivity costs
†Not costed
The total cost of OAB expenditure was 1.8-3.9 Billion US $ per year. These authors also considered the consequences of incontinence. For example, the OAB cohort had a higher occurrence of events such as falls/fractures (46% OAB versus 34% non-OAB; RR = 1.4), urinary tract infections (42% OAB versus 17% non-OAB, RR = 2.4), and depression (21% OAB versus 12% non-OAB, RR = 1.8) all p < 0.001. The authors pointed out that this is the first study to evaluate the treatment costs of OAB in over-65 year individuals using "real-world" Medicare claims data.

In the last 4 years, the Committee found 3 publications reporting a new trend towards conducting Internet studies of the Burden of Disease associated with OAB. Because of difficulties in achieving telephone surveys, researchers have moved towards internet surveys, however the Committee feels that such method can be subject to considerable bias.

For example, Kannan et al [97] reported an internet survey in 2009 that was actually conducted in 2006, in which 62,833 American subjects who were members of an industry-based feedback panel were questioned as to whether they had LUTS or OAB. The survey compared 13,954 men and women with LUTS/OAB (comprising 24% of the survey population) with age matched subjects having similar comorbidities. They found that subjects with LUTS/OAB had approximately US $ 1,000 more health care costs per annum. They concluded that the projected costs of LUTS/OAB were US$ 51 Billion per annum more than age/comorbidity matched controls. However, in Discussion, the authors admitted that the study was quite biased towards subjects who were connected to the internet, yet not fully employed, i.e. having sufficient time to enroll in the Industry Feedback Panel.

A similar internet study was reported by Onukwugha et al [98], derived from the Epi LUTS study, which yielded a projected LUTS/OAB cost of 24.9 billion US$. Neither of these projected costs agrees with other cost estimates from non-internet based studies.

Finally Ganz et al [99] performed an overall estimate of the costs of OAB, which used a panel of expert urologists in Boston USA, via a Delphi technique to obtain consensus on the model. The authors accumulated all known costs for OAB, including patients in nursing homes. They projected costs based upon known projected prevalence figures, with respect to the ageing of “baby boomers” (Figure 11) showing a projected marked increase in OAB costs as this cohort "swells" the numbers of elderly in the community.
7. PROLAPSE TREATMENTS, COST IMPLICATIONS

Despite the high prevalence of pelvic organ prolapse and frequency of surgery for prolapse, there are minimal data on costs or cost-effectiveness of medical care for this condition.

In the previous chapter, we reported an important cost of illness study from 2001, regarding the annual treatment cost of surgery for pelvic organ prolapse in the U.S. [100]. Treatment costs of pelvic organ prolapse surgery were US$1,012 million (1997 US$; 95% CI 775-1,251 million). Hospitalization accounted for a majority of the total cost (71%) with the remainder being physician services (29%). Twenty-one percent of pelvic organ prolapse operations included urinary incontinence procedures (US$218 million). The annual treatment costs of operations for pelvic organ prolapse are substantial and similar to other surgical interventions for women (breast cancer, gynecologic cancer, urinary incontinence).

In 2009, Subramanian et al. [101] estimated the rate, type and costs of surgical interventions for pelvic organ prolapse (POP) in Germany, France, and England. They identified hospital admissions for pelvic floor surgery in 2005 from national hospital activity databases in each country: the German Hospital Episode, the French Medical Care Program Information System, and the National Health Service England Hospital Episode Statistics. Costs to the payer were estimated using the Diagnosis-Related Group reimbursement rates for each country. In 2005, the number (rate) of admissions for POP surgery was 36,854 (0.87 per 1000 women) in Germany, 36,679 (1.14 per 1000 women) in France, and 28,959 (1.13 per 1000 women) in England. Admissions for POP surgery constituted 10.4%, 16.7% and 16.9% of all admissions for female genital tract therapeutic interventions in Germany, France and England, respectively. At least 20% of hysterectomies were performed for the primary indication of POP. 57.4%, 45.0%, and 40.1% of all admissions for POP surgery included a hysterectomy. The costs to payers were €144,236,557, €83,067,825, and €81,030,907 in Germany, France, and England, respectively. These data effectively document the substantial burden and costs associated with POP surgery in the three countries studied using generalizable data and appropriate methods.

A multicentre international randomized controlled trial of pelvic floor physiotherapy for mild to moderate prolapse (the POPPY study) was published as an abstract in 2011[102]. A total of 447 women were randomized to either 5 physiotherapy visits over 16 weeks, or were given written instructions about lifestyle advice re constipation, obesity etc. Although the POPSS quality of life test [103] was employed, and showed significant benefit for physiotherapy treatment, the authors had not been able to find a QALY test that was responsive to change for prolapse treatment in the literature. The net cost of active physiotherapy treatment was £127 per patient, yielding an average decrease in POP-SS of 1.52 points. This would approximately equate to a 10% improvement in quality of life for one year, yielding a cost per QALY of £16,000.

In 2011, Hullish and colleagues from the UK [104] developed a Markov model to compare the relative cost effectiveness of treatments for post-hysterectomy pelvic organ prolapse (POP), including expectant management, use of a pessary, and surgery. They used probabilities from published studies and expert consensus and generalizable national costs from national charge data from the 2007 Healthcare Costs and Utilization Project Nationwide Inpatient Sample adjusted for all payor cost to charge ratio. They could not identify published HRQOL or utility scores for POP conditions, so estimated these based on a range of 1.0 for repaired POP without complications to 0.0 for major complication or re-operation. Over a 1 year timeframe, initial pessary use was the least expensive and had the lowest QALY. Vaginal reconstructive surgery had the highest QALY. Unfortunately, the results were not presented as incremental analyses so they are difficult to interpret. Sensitivity analysis demonstrated that these baseline results depended on several key estimates in the model: probabilities of POP complications, surgery following pessary use, and late complications following surgery, utility of pessary use, and the cost of robotic assisted surgery.

In 2011, Murray et al. [105] investigated the cost of traditional anterior colporrhaphy (AC), hand-cut mesh, and mesh kit anterior vaginal prolapse (AVP) repair using a decision analysis model. The model included mean operating room (OR) times, mesh extrusion rates, and recurrence rates obtained from a meta-analysis and Medicare reimbursement for surgeon fees and office visits, and hospital costs of supplies, OR time, and room and board. Non-kit mesh repair was $3,380, AC $3,461, and mesh kit $4,678. One-way sensitivity analyses demonstrated recurrence rate of AC would need to be 28% to be cost equivalent to non-kit mesh repair and the non-kit mesh cost must be < $480 (basecase $400) to remain less expensive than AC. Mesh kit repair did not reach cost equivalence, even with an OR time of 0 minutes. Two-way sensitivity analysis comparing mesh extrusion and AC recurrence demonstrated AC is less costly if recurrence is <20% or extrusion >25%.

As per our previous report, a Cochrane review of surgeries for the management of pelvic organ prolapse emphasized the importance of CEA and CUA [106]. They observed that abdominal sacrocolpopexy is associated with a lower rate of recurrent vault prolapse and dyspareunia than the vaginal sacrospinous colpopexy yet these benefits must be balanced against a longer operating time, longer time to return to activities of daily living and increased cost of the abdominal approach. Similarly, the use of mesh or graft
inlays at the time of prolapse repair may reduce the risk of recurrence and the addition of a continence procedure to a prolapse repair operation may reduce the incidence of postoperative urinary incontinence. Yet, these benefits needs to be balanced against possible differences in costs and adverse effects, which have not been assessed and, like surgical treatment for stress incontinence, are inherently appropriate for CEA since there may be differences between procedures in costs, clinical outcome and health-related quality of life.

Maher et al. [2004] performed a randomized trial of abdominal sacral colpopexy vs. vaginal sacrospinous colpopexy to treat vaginal vault prolapse among 95 women [107]. Secondary outcomes included the impact on cost (measured as Australian bed and operating theater costs) and general- and incontinence-specific quality of life. Two years after the operation, the subjective and objective success rates were similar between groups. The abdominal approach was associated with a longer operating time, a slower return to activities of daily living, and a greater cost than the sacrospinous colpopexy (P<.01). Both surgeries significantly improved the patient’s quality of life (P<.05). These data suggest that formal cost-utility analysis would be beneficial to further compare these two common procedures for pelvic organ prolapse. Additional data with generalizable costs and utility measures and long-term efficacy outcomes are needed.

In the chapter of this text regarding surgery for pelvic organ prolapse (Chapter 15), the authors give further references that provide surgical cost data for a variety of procedures, such as laparoscopic sacrocolpopexy, robotic sacrocolpopexy, versus abdominosacralcolpopexy, and laparoscopic sacrocolpopexy versus total vaginal mesh procedures. Readers are referred to that chapter for details, however no Utility measures were provided in these reports.

8. FECAL INCONTINENCE

a) Cost of illness

In the previous chapter, several cost of illness studies regarding faecal incontinence were reported. However these studies mainly employed previously collected databases[108, 109], or focused upon inpatients [10], subjects with constipation as the main complaint [108], women with faecal incontinence after obstetric injury [110]. Few conducted face-to-face direct enquiry of the personal costs of leakage of faeces[10]. Most did not employ a validated measure of severity [10, 108-110]. Deutekom et al[111] from the Netherlands did measure treatment and non-treatment costs along with the Vaizey continence score, no QALYs were measured and the relationship between cost and severity was not explored.

In 2011, Parkin et al[112] conducted personal interviews with a consecutive sample of 54 ambulatory home dwelling men (5) and women (49) patients who presented with faecal incontinence to a tertiary out-patient Unit, to collect cost data prior to the onset of treatment in relation to baseline severity as measured by St Marks score[113], maximum score 24 points.

Costs were determined by administering a 3 page questionnaire, modelled on the DBICI questionnaire for urinary incontinence[114]. Interviews were conducted face to face, taking approximately 15 minutes each. The information included basic personal hygiene costs (pads, laundry, wipes, cleansers), medication costs (loperamide, creams & stool bulking agents etc) and diagnostic costs (including medical attendance, anorectal physiology, colonoscopy). Following each interview, the personal hygiene items used by patients were costed from known tables compiled by visiting local pharmacies and suppliers. Costs were recorded in AUS.

The median age was 69.5 (IQR 61.5-74) and the major personal expense was for pads and personal hygiene items (median 70.89 per annum, IQR 0.63-310.68). Medicare costs included medical consultation and rebates for physiology testing and endoscopy (median $576.92 IQR). There was no relationship between these overall costs and incontinence severity. The Spearman rank correlation showed no significant relation between total personal costs and severity (r=0.21). When the costs just for pads and creams alone was evaluated, a relationship became apparent (r= 0.34, p=0.05, Figure 12).

b) Prevention

The cost effectiveness of two sphincter preserving treatments for anal fistula (anal fistula plug versus endoanal advancement flap) in the treatment of cryptoglandular fistulae to prevent faecal incontinence was studied by Adamina et al in 2010 [115]. The primary end-points were absence of drainage and fistula openings on physical examination at 6 months and absence of abscess formation at any time during follow-up.

This was a microcosting analysis of treatment costs, adjusted for inflation. Non-medical costs and lost productivity costs were not assessed, sensitivity analyses were performed. The study was flawed in that the success rates of healing in advancement flap group were lower than the majority of published studies on this technique. Cost-effectiveness was based on healing and complication rates, with no direct measurement of faecal incontinence. Use of the anal fistula plug saved $1,588 US per healed fistula.

Tan et al (2008) studied the cost effectiveness of primary sphincteroplasty versus delayed sphincteroplasty for anal sphincter injury, in the prevention of faecal incontinence [116]. They constructed a decision tree analysis over 10 years. QALYs were derived from SF36, but no direct QALY tests were measured. The primary sphincteroplasty was associated with a gain of 5.72 QALYs for a cost of £2,750,
the delayed sphincteroplasty yielded a QALY gain of 3.73 for a cost of £2,667, thus the primary sphincteroplasty was judged to be cost effective.

**c) Treatment costs**

Reflecting the increased use of sacral nerve stimulation (SNS) as a first-line surgical treatment for patients with faecal incontinence, recent cost-effectiveness analyses have primarily focused on this therapy. Brosa et al (2008) performed a cost effectiveness study of Sacral Neuromodulation for the treatment of faecal incontinence[11]. In their decision tree, they employed two decision pathways, firstly, for patients with an intact anal sphincter (IAS) and secondly for patients with a structurally deficient anal sphincter (SDAS) who had previously undergone a sphincteroplasty. Two of the authors worked for the Medtronics company (international makers of sacral neuromodulation equipment), and “4 authors received an unrestricted grant from Medtronics”.

Because recent NICE guidelines recommend Sacral Nerve Stimulation (SNS) as first line therapy in patients with an intact sphincter, and as second line therapy in those with a deficient sphincter[117], their aim was to evaluate the previous scenario (no option to perform SNS) with a new decision tree that included SNS. QALYs were obtained from Deutekom et al [118], [ie for patients with faecal incontinence QALY = 0.68, for patients with no faecal incontinence QALY = 0.87]. Costs were obtained from Spanish Health Costs Database[119]. Temporary SNS evaluation cost €1,484, whilst permanent SNS cost €10,700. Other treatments in the model were more expensive, such as Dynamic graciloplasty €12,000 and Artificial Anal Sphincter €12,000 (taken from Spanish DRG figures).

The timeline for the model was 5 years, with 3% discount rate per annum. Prevalence figures and Medtronics sales forecast were used to estimate numbers of patients likely to receive SNS over the next 5 years, to perform Budget Impact Analysis. Monte Carlo simulation analysis was performed for a cohort of 1,000 patients (i.e. Bootstrapping, see Methods of this chapter) to test sensitivity.

The results of their decision tree analysis showed that patients obtained an additional symptom free year of 0.31 and 0.34 per patient per 5 years in the two pathways respectively. In patients with an intact sphincter, SNS had a cost of €16,181 per QALY gained; for those with a deficient sphincter, SNS cost €22,195 per QALY gained. Budget Impact Analysis on the basis of 75-100 expected patients per annum would yield a budget impact of 0.1% in patients with faecal incontinence.

The authors commented that dynamic graciloplasty in 123 patients yielded complications in 74% of patients with a total of 189 complications [120]. Artificial anal sphincter was performed in 112 patients with 51 patients required a total of 73 further reoperations with 41 (36.6%) subjects requiring device removal [121]. No corresponding figures for reoperation rates were given for those undergoing SNS.
The relationship between the Markov model developed in the above paper by Brosa et al [11], and a patient cohort study published by a similar group of authors [122] also from Spain in the same year, is unclear. In the paper from Munoz-Duyos et al. [122], patient level cost data is given for 57 temporary evaluations under local anaesthetic in 47 patients, giving a success rate of 61% (which is lower than many other publications). Permanent SNS devices were implanted in 29 patients, who were followed for a median of 3 years.

The study was reported on an intention to treat basis over a five-year time horizon. Only treatment costs were evaluated. The actual Markov model was not provided. Costs were not discounted. No sensitivity analysis was performed. It is unclear how the QALY were determined, as no QALY tests were administered, and data arising from calculating QALYs from SF36 were quoted as being derived from the paper by Brosa et al [11]. Thus it appears that this report from Munoz-Duyos [2008] was in some aspects a duplicate of the earlier Brosa paper [11, 122].

Despite this paper being entitled a “cost effectiveness study” there was little individual cost data given, for example, the temporary evaluation cost was €397, and the SNS permanent device cost was €10,178. Mainly, group totals of costs were given, for example, operating room costs of €26,000 for all the temporary evaluations, and €17,000 for all SNS implantations in the study group. Thus the majority of costs were associated with implantation of the permanent SNS device (due to upfront device costs).

In patients with an anatomically intact anal sphincter, SNS versus maximum conservative treatment had an ICER of €16 181 per QALY gained, well within the €30 000 per QALY threshold accepted in Spain.

In 2010, Indinnimeo et al. [12] from Italy, published a cost effectiveness study of SNS based on the decision tree model of Brosa (who was a co-author of this paper also) [11]. The decision tree parameters appeared to be identical, based on the same NICE guidelines, but cost data from the Italian NHS reimbursement list were substituted. For example, the cost of temporary evaluation of SNS was €6,400, the cost of permanent implantation of SNS was €6,400, the cost of dynamic graciloplasty was €8,760 and the cost of artificial anal sphincter was €4,620 (as shown in Table 1, earlier in this chapter).

Clinical data were obtained from published studies and from “expert” panel consensus. Note should be made that one of the authors worked for Medtronic Italia and that some data on SNS were taken from a review in which the majority of patients were implanted using an open surgical rather than percutaneous technique. Treatment success was defined as “the cessation of the patient to seek further treatment due to a satisfactory reduction of incontinent episodes with the therapy”. Measurement of success was based on outcome at 6-month follow-up and it was assumed that loss in efficacy over time for each treatment was equal. The committee felt that this may have biased the results, as generally (for example) the efficacy of sphincter repair declines with time (80% <success at 1 year, 50% at 5 years, 20% at ten-years [123]). In contrast, loss of efficacy with SNS is more likely to occur in the first year (in the absence of device failure).

There were several difficulties regarding the design of the decision tree. Firstly, the study assumed that all patients with a structurally deficient anal sphincter should undergo sphincter repair. Structural deficiency was defined as damage up to 120 degrees in radial extent affecting partial or full length of the internal or external anal sphincter, or both.

No reference was given to sphincter function in assessing the role of sphincteroplasty.

The Committee felt that in real life, those with partial length defects or isolated internal anal sphincter defects would not be considered for sphincteroplasty; only patients with full length defects with adequate residual muscle bulk and function would generally be considered for sphincter repair.

Generally, the indications for sphincter repair or dynamic graciloplasty are end-stage faecal incontinence in the presence of a substantial muscular defect and/or neural defect of the anal sphincter. However, the Decision Tree analysis assumed that all patients (even those with intact anal sphincters) would undergo one of these operations, which seems to make the model flawed in the case of patients with an intact anal sphincter.

Secondly, the model also assumed that of those undergoing a neo-sphincter procedure, 95% would undergo dynamic graciloplasty and only 5% artificial anal sphincter. The Committee felt that artificial anal sphincter is more readily performed in current clinical practice, with the recent understanding of poor long-term outcome of dynamic graciloplasty. Only 65 DG were performed in 21 European Centres in 2011 (Personal correspondence Medtronic Inc.). Finally, the model indicates that colostomy achieved 100% continence. In practice patients may still be incontinent of mucous which can cause considerable morbidity and impact upon quality of life.

The cost utility analysis revealed an ICER (€ per QALY gained) of €28,285 in those with sphincter defects, and €38,662 in those with intact sphincters. These results were within €40,000 acceptability threshold of the Italian NHS. Their Budget Impact Analysis appeared to give a low estimate of the total number of patients being treated with SNS (that is 86 to 115 patients per year over five year period in a population of 48 million people).
Mitchell et al [2011] performed economic analysis of the use of local anaesthetic (LA) versus general anaesthetic (GA) for insertion of temporary test electrodes (single electrode helical wires were used rather than tined quadripolar leads) [124]. Because LA was used, determining the optimal site for electrode placement was based upon sensory perception of the stimulus effect, rather than motor response. However, one third of patients undergoing SNS are known to have poor sensory localization and are unable to define the exact location of the stimulus making electrode placement difficult [125].

This was a retrospective cohort study of 111 consecutive age and sex matched patients, 42% of patients had LA which cost £613, and 58% had GA which cost £743, yielding a saving of £130 for the LA cases.

All were planned as day case procedures, but 89% of LA patients went home that day versus 62% of GA cases. A greater proportion of patients had success in the GA group (77% versus 64%). The small sample size resulted in a modest effect and a large standard error with non-significant effects. Reduced cost with the LA procedure was not correlated with effectiveness, so it is difficult to make conclusions about the outcome of study.

In late 2009, Dudding et al [13] performed a cohort analysis of 70 consecutive patients treated with SNS at a single UK institution over a ten-year period [1996-2006] with subsequent followup for approximately 2 years, which was then projected over a 7 year time horizon. Unlike the previous publications, these authors collected data prospectively at the patient level for baseline cost information and evaluated actual success, failure and complications, which comprised the Decision Tree analysis (as previously shown in Fig. 2, Decision Analysis).

All of the patients had failed standard conservative therapy, and these costs were assessed at baseline, for comparison with subsequent intervention with SNS. A societal perspective was taken and sensitivity analysis was performed.

Treatment and non-treatment costs were assessed. The treatment costs were taken from UK national tariff and health resource group codes. Face to face data on routine care costs was not collected but careful calculations of typical costs of pad usage, loperamide consumption, outpatient visits etc were undertaken. The non-treatment costs were derived from publications regarding time off work [110, 126, 127] and loss of work productivity[111, 128], from non-British sources, yielding a figure of £912 per patient per annum (which may not have been applicable to the UK population studied).

QALY data were calculated from conversion of elements of the Short-form 36 questionnaire, which is a standard methodology [26], although it must be noted that the SF-36 was not designed for economic evaluations. Inconsistencies can occur with this conversion which makes it possible for a patient with a better health state to record a lower QALY value than a patient with a worse health state [129].

Because the study included a self-selected group of patients who had failed to benefit from conservative treatments, it may not be representative of all patients who undergo conservative management for faecal incontinence (many of whom do achieve success from conservative treatment).

All procedures were performed under general anaesthesia, but the costing for short stay procedures was such that this had little economic effect. The cost for temporary evaluation was £510, the cost of permanent SNS implant was £8,480. Figure 2 shows the clinical pathway with resultant success rates and complication rates of this patient cohort (earlier in this chapter). Complications occurred in nearly 20% of patients (several were mild but required some form of medical intervention); these were carefully costed in the manuscript at the patient level. The basic conservative regime cost £596 per QALY gained, and SNS cost £2159 per QALY gained. Sensitivity analysis was performed to assess robustness of the model and rates were discounted by 3.5%. Including all treatment and non-treatment costs the ICER for SNS was £25,070 per QALY gained. This equates to £1038 more per year to treat patients with SNS for a median reduction in 286 incontinent episodes (£3.63 per episode reduced). Lost productivity make up a large proportion of the total cost of faecal incontinence and this was reflected in this study. When lost productivity was included, the ICER was reduced to £12,959 per QALY gained for SNS versus conservative therapy.

In conclusion the ICER of £25,070 per QALY gained was within the £30,000 per QALY threshold recommended by the UK National Institute of Clinical Excellence as an effective use of UK NHS funding (Figure 2). In 2009, Dudding and Nugent[130] published an abstract which compared the costs of using a permanent quadripolar tined lead electrode for temporary testing as part of a staged implant versus the single electrode helical wire as part of a two-stage procedure. This was a decision tree analysis based upon published literature, which took into account success, failure and complication rates. On an intention to treat basis of 100 patients, a saving of £27.78 per patient can be made by adopting a staged implant strategy. They concluded that a permanent quadripolar electrode should be used for temporary SNS.
VI. SUMMARY AND FUTURE RESEARCH PRIORITIES

In the four years since the last ICI consensus conference, some high quality economic analyses of surgery for stress incontinence treatments have been published. The Committee notes that evidence regarding cost utility of outpatient therapies for stress incontinence remains limited, aside from the recent economic study of obesity treatment for this condition. However the economic analysis of therapy for overactive bladder syndrome requires greater effort, to encompass longer time frames and wider use of QALYs that can yield cost utility analysis (CUA). The Committee was disappointed to find that most of the recent economic studies of anticholinergic therapy did not include collection of raw QALY data.

In the last 4 years, the implementation of Sacral Nerve Stimulation for refractory detrusor overactivity has been the subject of several economic analyses, which are indeed important. However the Committee reiterates the need to collect primary data for QALY outcomes in future studies of this technique.

In the field of prolapse, it is not yet known whether any currently available QALYs are sensitive to treatment benefit, so that CUA may still not be feasible in this area. The recent POPPY study is to be commended for including patient-level cost data and quality of life information about conservative treatment.

As regards faecal incontinence, research into Cost of Illness remains rather preliminary, so that broader more long term studies are still needed. It is encouraging to see economic analyses of Sacral Nerve Stimulation in this field as well, however more data about Cost Utility in Faecal Incontinence is urgently needed.

As regards methodology, researchers need to consider carefully how they construct the model parameters for Decision Tree Analysis and Markov Models, so that “real life” assumptions are made. The gold standard remains Cost Utility Analysis in parallel with Randomized Controlled Trials, and we urge all clinicians to consider cost and QALYs as important outcome measures.

VII. APPENDIX – SEARCH STRATEGIES

We performed a comprehensive computerized medical literature search (PubMed) for the years 2007-2012 to identify all economic, health-related quality of life and cost-effectiveness analyses published on urinary incontinence, faecal incontinence or pelvic organ prolapse. Our initial search strategy was very broad and meant to be very sensitive but not specific. We performed a search for the following Medical Subject Headings (MeSH) and keywords: cost-effectiveness analysis, health care costs, quality-adjusted life years, costs and cost analysis, sickness impact profile, or utilities and urinary incontinence, overactive bladder, fecal incontinence, anal incontinence, uterine prolapse or pelvic organ prolapse. The initial searches were reviewed to identify articles appropriate for more detailed evaluation. Inclusion criteria were: urinary or fecal incontinence or prolapse as primary disease, data on costs available. Studies were excluded when they were a review or case-report.

I. INTRODUCTION

This chapter provides general recommendations for good research practice, including principles of clinical trial design and statistical methodology. In addition, we present specific recommendations applicable to trials for certain types of treatments and certain subgroups of patients.

1. LEVELS OF EVIDENCE

Most contributions to this consultation used the Oxford Centre for Evidence-based Medicine Levels of Evidence and Grades of Recommendation (http://www.cebm.net/levels_of_evidence.asp). However, as these are not an appropriate metric for recommendations in this chapter, the Research Committee used the following categories:

- High: Supported by strong evidence (multiple strong publications)
- Medium: Supported by moderate evidence (limited/moderate level publications)
- Low: Expert/Panel opinion

The report endorses consistent use of the methodology and approved terminology that will not only facilitate incontinence research by producing high quality studies but also facilitate communication about research. Recognized published guidelines produced by the International Continence Society (ICS) [1-15] and Society for Female Urology and Urodynamics (SUFU) [16-18] are useful examples of standardized terminology that advances communication in research.

Research is defined as “systematic investigation designed to develop or contribute to generalizable knowledge” [19] and participants accept risks to advance scientific knowledge and to benefit others [20]. The aim of clinical research in functional urology and urogynaecology is to evaluate treatments intended to prevent and/or significantly reduce symptoms of lower urinary tract dysfunction. The research methodology presented herein is intended to facilitate production of high-impact, high-quality research which will provide evidence needed to inform clinical practice, stimulate other investigators, generate new research ideas, and lead to a better understanding of physiology and pathophysiology of the human health and disease.

Although it is beyond the scope of this section to review the rules of conducting human subject research in depth and extensive coverage is available elsewhere [21-25], all investigators should understand the difference between “research” and “clinical practice”. At a minimum, criteria for an ethical research study should meet the following criteria:

- the study should well planned, scientifically sound with clearly defined aims;
- clinical research should be prospectively registered whenever possible;
- the study should be feasible with a realistic chance for completion;
- there should be a reasonable assumption that new knowledge will be provided at the end of the study; and
- there should be an expectation that the results will be published to advance scientific knowledge [21, 26].

Human subject research protocols must be approved by an Institutional Review Boards (IRB), although IRB approval should be regarded only as a minimal ethical standard for research. Ultimately it is responsibility of the investigator to ensure the research is ethically acceptable.

2. PRIMARY GUIDING ETHICAL PRINCIPLES

There are 3 primary guiding ethical principles for human research outlined by the 1979 Belmont Report on “Ethical Principles and Guidelines for the Protection of Human Subjects of Research” [27]. These principles are essential for ethical clinical research and are briefly reviewed in the following section.

a) Respect for Persons recognizes the voluntary nature of research participation and includes informed consent without undue influence.

b) Beneficence requires investigators to maximize
benefits and reduce risks to the subject. The primary concern of the investigator should be the safety of the research participant and careful consideration of the risk/benefit ratio; this includes an ongoing responsibility to monitor research and medical literature as the research proceeds. The investigator needs to critically consider within the expert medical community if there is clinical equipoise for the proposed interventions in their trial. Is one treatment no better than another? Are the research risks reasonable in relation to anticipated benefits? It is the responsibility of the investigator to ensure risks are minimized and potential benefits enhanced as well as that the knowledge gained outweighs the risks [26]. Of note, invalid research cannot be ethical no matter how favorable the risk–benefit ratio for study participants.

c) Justice requires that the benefits and risks be distributed fairly (i.e. not only using people without access to health care, prisoners, or those impaired). Justice is of particular concern in Phase I testing of pharmaceutical agents and in early investigation of surgical devices/implants. Payment offered for participation in such drug trials may be extremely attractive to poor and disenfranchised subjects. Early device studies may target countries with lax regulatory environment even if there is little intent to market the device there in the long term.

3. INFORMED CONSENT IS AN ETHICAL CORNERSTONE OF HUMAN SUBJECT RESEARCH.

Peer review of protocols by a multidisciplinary team may include members of the scientific community, clinicians, pharmacists, the public/patient groups, the legal profession and individuals who can provide an ethical perspective. Each member of this team reviews the protocol from their particular type of expertise and in doing so aids in safeguarding patient health and well-being.

4. SPECIFIC INFORMED CONSENT IS REQUIRED FOR RESEARCH PARTICIPATION.

The length and depth of detail in consent forms vary widely between institutions. In the extreme, they involve exhaustive pages of information, which explain every alternative treatment with its pros and cons in detail. A general list of requirements for a consent form includes: name of the investigators and contact numbers, a detailed description of the new treatment and its known side effects, rationale for why the new therapy may be preferred to standard therapy. A summary table of the results of previous studies using the drug can be helpful when available. A statement that the patient may decline to be in the study with no subsequent consequence to their ongoing medical care is generally provided and whether or not remuneration is expected. Additionally, there should be a statement about payment for medical care required during the course of the study if there is an adverse event associated with the intervention. An understanding that the patient will be randomly assigned to treatment should be included when relevant, written using terms that are meaningful to potential participants [28-29].

5. THE INVESTIGATOR HAS AN ETHICAL RESPONSIBILITY TO TAKE RESPONSIBILITY FOR ALL ASPECTS OF THE RESEARCH.

This will insure that the work is done rigorously and to maintain the integrity of the research [30]. International Committee of Medical Journal Editors (ICMJE) now requires that information about trial design be placed into an accepted clinical trials registry prior to participant enrollment [31]. For more information, see more extensive information available elsewhere [30, 32-35]. A list of registries acceptable to the ICMJE can be found on their website. One objective of trial registration is to reduce publication bias given that trials with positive findings are more likely to be published than those with negative findings. An important feature of one registry, clinicaltrials.gov, is a results database [36].

Consider this pragmatic, simple test to use when resolving an ethical research dilemma: “Imagine what you are preparing to do will be reported the next day on the front page of your local newspaper. If you are comfortable having colleagues, friends, and family know what you did, chances are you acted responsibly”.

6. ENSURING PARTICIPANT SAFETY IS PARAMOUNT.

An independent data safety monitor (DSM) or data safety monitoring board (DSMB) is important to evaluate the study on an ongoing basis to determine early evidence of significant harm or benefit [37-38]. Depending on the size, complexity, and risks of a trial, the DSMB is comprised of experts needed to monitor interim data to ensure the safety of the participants. The DSMB should be established prior to initiation of the trial. In addition to reviewing results of the study for safety monitoring they may evaluate interim analyses to ensure that a treatment is not producing unacceptable levels of side effects and/or efficacy [29, 37]. A priori stopping rules or boundaries are established to assess if the study should continue or be terminated due to futility (that is, no conclusion will be drawn due to low enrollment, few outcome events, or high drop out rates etc.), reaching an endpoint, or identifying increased risks. Guidelines for stopping the study should be agreed upon, prior to the start of the trial [30]. Interim analyses (in particular those based on efficacy) will have implications for the study power. Specialist statistical advice and support will be essential to address these issues [39, 40]. Investigators must not be aware of the results of interim analyses, however, since this may cause bias by influencing how vigorously any given patient is recruited into or followed up in the study, and most importantly, runs the risk of a type
II error (ie mistakenly concluding benefit when there is none). Nevertheless, emergency procedures for unblinding a patient’s allocation are required in case of a severe side effect or concomitant serious illness where knowledge of treatment assignment is essential for patient management and safety.

7. HIGH QUALITY DATA MANAGEMENT IS KEY TO PROVIDING VALID AND ETHICAL RESEARCH RESULTS [41].

In addition, ethical conduct of research includes timely and complete reporting. Clear guidelines for authorship have been established by medical journals [42]. Beginning with the research contract, authorship rules should be established according to accepted guidelines. In general, authorship credit should be based on 1) substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data; 2) drafting the article or revising it critically for important intellectual content; and 3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

9. FINANCIAL CONFLICTS OF INTEREST

Many investigators are involved in testing new drugs or devices developed by industry and have the potential to significantly supplement to personal income. It is acceptable for investigators to receive contracted financial support to perform this research and a principled partnership between industry and investigators is essential if we are to preserve medical progress [43]. Financial conflict of interest policies have been developed due to ethical concerns about potential biases that may influence trial design, conduct, over interpretation of positive results or not publishing negative results [30, 44]. It is important that investigators do not receive money directly (personal income) from industry sponsors but rather through a research contract through an appropriate entity with research oversight capabilities. Disclosure of these relationships helps maintain scientific integrity and preserve public trust in the scientific process. This is a rapidly evolving area and investigators are encouraged to clearly understand and disclose such relationships.

An investigator’s institution may have additional definitions and reporting requirements for financial conflict of interest disclosures. There are many potential relationships between physicians and industry; it is preferable that the nature of the relationship and its financial magnitude if any, be fully defined rather than categorized (i.e. “consultant”) so that the reader can appropriately assess the disclosure.

II. DEFINING THE RESEARCH QUESTIONS

The investigator(s) should take a deliberate approach to formulate the specific research question, based on a careful review of related clinical research and relevant studies that are well designed and clinically relevant. The research reviews provided by the Cochrane Incontinence Group (http://healthsci.otago.ac.nz/dsm/wch/obstetrics/cure) provide an excellent starting point for most major incontinence topics. Based on a thorough literature review, the investigator clearly describes the primary research question(s), summarizes the background information, and formulates the rationale, objectives and hypotheses for the study. The investigator(s) should formulate the simplest study design which will provide the highest quality of evidence to test the given hypothesis in a cost and time-efficient manner. Whenever possible, basic or translational research should occur as part of the clinical research study in order to advance discovering of underlying mechanisms or pathophysiology. This balance between breadth and depth greatly increases the yield of the research effort [45].

III. EXPERIMENTAL STUDIES

1. RANDOMIZED CONTROLLED TRIALS

Experimental studies have the potential to provide a higher level of evidence than observational studies. The randomized double-blind clinical trial (RCT) is considered the gold standard study design. Properly planned and executed, the RCT is the optimal approach to limiting allocation bias [46]. The study participants are assigned to a treatment group by a random (chance) mechanism that ensures adequate concealment so that neither the study participant nor the investigator can influence treatment group assignment in order to reduce allocation bias. Subject assignment must be concealed during enrollment (for example, by separating allocation from the process of recruiting subjects, and by using remote randomization such as by telephone or web-based procedures), and wherever possible treatment allocation must be concealed during the trial (for example, using blinding with or without placebo). In order to minimize bias, the randomization process must be concealed from those recruiting subjects to the trial [48-49]. This can be achieved most effectively by the use of central telephone randomization.
In drug studies, a pharmacy can maintain identical treatment drug and placebo already randomly allocated into individual subject portions. These are distributed consecutively as subjects are enrolled in the study. In some studies, blinding of subjects and health care providers may not be possible, for example in trials of some surgical procedures or health care delivery methods. In almost all cases, however, the personnel collecting outcome data should be unaware (blinded) to the subjects’ treatment allocation. RCTs require ethical equipoise and should be unaware (blinded) to the subjects' treatment received [50]. The intention-to-treat approach in pragmatic trials retains the full benefits of randomization and has the advantage that the comparison will more closely reflect the relative effectiveness of the treatments when applied in real clinical practice, where non-compliance is a common occurrence [51].

a) Simple randomization can use computer-generated random numbers, either prepared specifically for the trial or using existing tables of random numbers where the digits of 0-9 appear with equal likelihood in each entry. Treatments are assigned to odd or even numbers. As the total number of subjects in the trial increases, the balance of numbers and characteristics of subjects between the groups improves. In small trials, however, balance is not assured by simple randomization. Appreciable imbalances in subjects per group may be particularly important in a multicenter study where imbalances in assignment can occur within individual institutions.

b) Block randomization is one method used to prevent imbalances in subject numbers assigned to each group, particularly when the number of subjects in the trial is small. With block randomization, the total sample size is divided into blocks of a given size. Within each block, the group is assigned so that there are equal numbers allocated to each group. To prevent investigators from learning the block size and being able to guess order of assignment, the block size can be varied, usually at random from a small number of alternatives. In any case, blocking prevents serious imbalances in characteristics across groups when used in conjunction with stratification as described below.

c) Stratified randomization

Most disease states have factors known to influence the outcome of treatment, for example symptom severity or gender. A form of randomization that accounts for such factors is called stratified randomization [46-47]. Stratified randomization ensures equal distribution of subjects with a particular characteristic in each group when blocking is employed within strata. Stratification is usually restricted to a small number of factors, in particular those most likely to influence outcome. Despite its complexity, stratified randomization is usually helpful in a multicenter trial, so that both the numbers of subjects in each group and the important factors influencing the outcome can be balanced within each site. An alternative method exists to cater for more factors at once, known as minimization, where the characteristics of individuals already randomized alter in a systematic manner the chances of a given subject being allocated to the different trial groups, so as to maximize the resulting balance of these factors [46-47, 52]. Although the classical RCT involves the study of parallel groups, other options are possible and may overcome some of the limitations of the classical approach [53]:

d) Parallel Group Trials

This design generally includes one group of subjects assigned active treatment and a second (parallel) group a placebo or another treatment not believed to be an active treatment. The key feature of this design is that both groups (treatment and comparison group) are assembled and followed at the same time. In clinical trials of drugs the dose of the drug tested may be either a single dose or multiple doses to determine clinical benefit and/or minimize side-effects. More complex study designs can in some circumstances be worth considering — for example, factorial trials where two or more interventions can be investigated simultaneously [54-55], and cluster randomized trials whereby groups of participants (defined by some common feature, e.g. members of the same health maintenance organization, clinic, etc.) rather than individuals are randomly allocated to the trial arms [56]. This strategy might be employed when studying an intervention requiring policy changes in an institution, with a hospital, clinic, or health care system being the unit of randomization.

e) Crossover Trials

Subjects receive both the treatment being studied and the placebo/alternative treatment, with random order of treatment assignment. The benefit of crossover studies is that they eliminate the effect of variation between groups of participants seen in parallel trials, that is each subject serves as his/her own control. Crossover studies are particularly well suited for small studies, where the course of the disease under study is believed to be stable, and where the primary objective is to measure a short-term change in the outcome (e.g. urinary symptoms) in response to treatment. The duration of treatment required before the anticipated effect may be observed is critical in determining whether the crossover study design is appropriate — too long a period time before an effect becomes evident, and the disease state may vary before the study
participant has completed all arms of the trial; too short, and it may not be possible to detect the effect during the period of data collection. Carryover of treatment effects from one treatment period (or observation period if a placebo follows treatment) to another, make this a challenging study design to implement in many cases. To avoid a carryover effect, a washout period should be included, in which participants receive either placebo or no treatment. A run-in period in which signs and symptoms of the illnesses studied are monitored may be necessary before treatment begins to ensure that only those whose disease state is stable are entered into the study. Given all these features and limitations, this design is unlikely to be widely applicable in studies of interventions for incontinence.

There are two types of clinical trial designs that show the similarity of medical treatments: non-inferiority trials and equivalence trials.

f) Non-inferiority trials

The primary objective of a non-inferiority trial is to demonstrate that the new treatment is not acceptably worse than that of the standard treatment. This design may be appropriate when one treatment is less costly, may offer advantages related to improved quality of life, or has fewer side-effects, and the current belief is that both treatments have a similar effect on the disease or condition of interest. A key feature of this type of trial design is the ability to rule out a non-inferiority margin; that is, a minimum threshold for an unacceptable loss of efficacy [57-59]. As an example, if prior independent studies found similar effects of pelvic floor exercises and a drug in the treatment of stress incontinence, one might set up a study to demonstrate that no important difference in clinical effect was present between the two treatments by direct comparison. Currently there is considerable uncertainty about the design of non-inferiority trials as it relates to U.S. and European drug regulatory bodies [60-62] such that there have been recommendations to consider alternative designs [57]. Non-inferiority trials have been infrequently used in studies of urinary incontinence. A recent example is the Value of Urodynamic Evaluation (ValUE) trial, a non-inferiority randomized trial of preoperative urodynamic investigation in women undergoing stress urinary incontinence surgery [63].

g) Equivalence trials

The goal of an equivalence trial is to show that the experimental treatment is not more inferior and not more superior to a standard treatment by a given amount [64-66]. The clinically important difference between the standard treatment group and the new therapy is established prior to start of the study (Fleming TR 2000), and it is shown, by formal statistical testing, that the difference between the control and study treatments are not large in either direction (more beneficial or less beneficial).

A recent trial of midurethral sling surgery illustrates this type of study design [67].

h) Superiority trials

The most common study design for clinical trials of urinary incontinence and for many other diseases/conditions is the superiority trial where the goal is, in its most simple form, to show one treatment is better than another (or no treatment, placebo). The general approach is to establish a priori a clinically meaningful effect that you wish to detect. Once conducted, determining superiority requires that the findings permit the investigator to reject the null hypothesis that the two distributions of the treatment effect are equal, in favor of the new treatment being better than the control [58].

2. NON-RANDOMIZED CONTROLLED CLINICAL TRIAL(S)

This category includes trials in which treatment allocation is known to the investigator prior to obtaining informed research consent (for example, day of clinic appointment). This approach often results in baseline characteristics of the treatment groups being significantly different, decreasing the ability to interpretate trial results. Because of this major shortcoming, this type of study should be used rarely, if at all.

3. PRAGMATIC AND EXPLANATORY TRIALS

There is an important distinction between pragmatic and explanatory trials [68-69], and correspondingly, between intention-to-treat and per-protocol approaches to data analysis [50, 70]. This distinction has a number of facets. In pragmatic trials the interventions are designed to be as close as possible to treatment options in clinical practice (including multiple patient management choices) and entry criteria are usually relatively liberal in comparison with explanatory trials. In addition, pragmatic trials may involve a wide variety of outcome domains, including patient-completed questionnaires, and an economic evaluation of outcomes. As a result of intention-to-treat data analysis, pragmatic trials will tend to yield lower estimates of treatment differences than explanatory trials. It may be of interest to gauge the effect of treatment given full compliance; therefore, full data analysis ideally incorporates both intention-to-treat and per-protocol approaches [50]. The primary analysis, though, should follow the intention-to-treat principle.

Data from pragmatic trials are analyzed by intention-to-treat, according to the group to which subjects were randomized, regardless of the extent of compliance with the intended treatment. In explanatory trials, data are analyzed accounting for compliance. This per-protocol approach may exclude serious non-compliers, analyze data according to treatment actually received, or allow for degree of compliance in a statistical model.
At first sight, the explanatory approach appears more attractive. However, there are considerable limitations to the explanatory approach, particularly when the intention is to draw inferences from the trial to wider clinical practice (generalizability).

4. DRUG TRIALS ARE CATEGORIZED ACCORDING TO THE FOLLOWING DEFINITIONS [30, 50].

a) Phase I studies

The first studies of a drug in humans, often open label and uncontrolled, concentrating on safety and frequently but not exclusively carried out in healthy volunteers. Pharmacokinetic and tolerance information is obtained from Phase I trials.

b) Phase II studies

The first attempts to investigate treatment efficacy, often the first use of the drug in subjects and focusing on short-term outcomes. A common objective of Phase II studies is dose finding in terms of efficacy. Two sub-types may usefully be distinguished: Phase IIA studies where single treatments are considered in relation to a minimum response prior to further investigation; Phase IIB where direct comparisons are made between interventions, albeit on a small scale and not necessarily involving randomization [71].

c) Phase III studies

Large-scale, authoritative randomized studies performed once the most likely effective and tolerated treatment regimens have been established. The objective is often to establish that the intervention is suitable for registration/approval with the appropriate regulatory authority. Trials are conducted after submission of a new drug application (NDA), but before the product’s approval for market launch. Phase IIB trials (between submission for approval and receipt of marketing authorization) may supplement or complete earlier trials, or seek different kinds of information (for example, quality of life or marketing). Phase III trials are also used to investigate the effectiveness and cost-effectiveness of various interventions – that is, non-drug including organizational issues – and not necessarily with reference to regulatory authorities. All Phase III trials should be subject to a formal sample size calculation – for instance to obtain sufficiently precise estimates of the comparisons between treatments or to have a reasonable chance (power) of detecting a difference if one exists (see section II C 7 below).

d) Phase IV studies

These investigations are usually carried out after registration/approval, to investigate the drug’s safety and efficacy in different populations. Such post-marketing surveillance studies are typically larger and simpler than regulatory studies; they may lack a control group and are often conducted using surveys.

5. BIAS, BLINDING AND EFFECTS ON VALIDITY

Bias can be introduced at many stages of a study including patient selection, randomization, assessment of outcomes, and statistical analysis and interpretation. Bias occurs because of previously conceived ideas held by those involved, which consciously or unconsciously affect their actions and observations. In addition to observer bias, an amount of observer error is inherent in outcome measures that require clinical interpretation.

a) Blinding

In order to minimize bias, research design should strive for the highest practical level of blinding. Blinding is the process by which key elements of knowledge are withheld that can otherwise lead to bias. Blinding should not be confused with concealment of allocation, referring to withholding knowledge of assignment in advance, which is a prerequisite for the validity of any trial [48, 72]. While blinding is important, its effect is lower than that of concealment of allocation [73]. In most drug studies placebo pills allow blinding of all relevant participants.

b) Unblinded trials

They are conducted in an open manner where both subjects and study investigators are aware of which treatment has been assigned. While certain types of therapy may require investigation in this manner (e.g., some surgical trials), there remains considerable opportunity for bias. Both subjects and investigators may have preconceived ideas regarding the benefits of a particular treatment that can influence the reporting of symptoms and/or their outcome.

c) Single blind trial

Commonly, in a single blind trial, ‘single blinding’ may refer to blinding the outcome assessor (but not the subject); this is common in trials in which blinding the subject is not possible (such as pelvic muscle exercise trials). It is important to specify who is blinded to which aspects of study execution, rather than using only the vague term “blinded”. Hence, in these studies the only possible blinded person is the assessor. It may be advantageous for the clinical staff to be aware of the assignment to allow them to monitor the health and safety of individuals, since the potential effects of the treatment (side effects) will often be known in advance. Single blinding ameliorates biased reporting of symptoms and/or side effects by subjects. However, clinical staff can influence data collection and change other aspects of subjects’ care when they know which study treatment subjects are receiving.
IV. ELIGIBILITY CRITERIA

Eligibility criteria impact every aspect of a study’s progress, from recruitment to analysis to acceptance of the study’s results by the community. Yet, in the planning phase of a study, this vital aspect is often given short shrift. Eligibility criteria will differ, depending on the main goal of a study. For a Phase I trial, designed to understand safety of an intervention, eligibility criteria should be very narrow, and should focus on minimizing risk and maximizing ability to demonstrate proof of concept. A Phase II trial, designed to test the efficacy of a treatment in a fairly ideal population, will have broader eligibility criteria, but will exclude individuals in whom it is highly unlikely a treatment will be helpful, or highly likely that a treatment might be harmful. If a treatment shows promise at this point, eligibility criteria for a Phase III trial are as broad as possible, to test the effectiveness of the treatment in as real world of a setting as possible, thus maximizing generalizability. Conclusions can only be as broad as the eligibility criteria allow. Thus, a drug found to be effective in a study that included only healthy middle-aged people can be recommended for that group, but not for older people, children, people with medical conditions, or other groups excluded by the eligibility criteria.

While some exclusion criteria are necessary to reduce risk to potential participants, it is important to include individuals in whom the treatment would likely be used once widespread. For example, in testing a new drug for urgency incontinence, that is excreted by the kidneys, it is important to exclude people with high serum creatinine levels, but equally important to include older individuals with multiple co-morbidities, as these are also likely to benefit from a drug for urgency incontinence once released.

Particularly in longer-term studies of pelvic floor disorders, some exclusion criteria are needed to maximize potential for follow-up. Such studies often exclude people likely to move or die during the study period, people with conditions that impair adherence (such as drug or alcohol dependence, severe mental illness or homelessness) or factors that make follow-up more difficult (such as lack of a telephone). For ethical reasons, it is important to either exclude people with significant cognitive impairment (such that informed consent is impossible) or to plan a consent process with a legally authorized representative in mind. However, all exclusions impact the generalizability of the conclusions and so such trade-offs must be carefully thought through.

Additionally, inclusion criteria related to the condition of study must be considered in concert with the consideration of the primary outcome measure. If an inclusion criteria defines “disease”, it is essential that the outcome measure does not include this same measure or cut-point as “success”. For example, if a surgical trial comparing two treatments for pelvic organ prolapse defines prolapse as >/= stage II (and excludes from enrollment only women with <</= Stage I prolapse) and the primary outcome measure defines successful treatment as prolapse at or above the hymen, then women enrolled with maximal prolapse at points 0 or -1 may be considered successfully treated when in fact, their condition has subjectively not changed. It is also important to note that a given condition, such as stress urinary incontinence, will be present or absent depending on which outcome measure is used to define it. Avoid using one outcome measure to exclude women from a study and then a different outcome measure defining the same condition as the primary outcome measure.

V. SAMPLING STRATEGIES

Every study must address its sampling strategy, that is, the selection of participants. In principle, sampling should involve random selection. In practice, however, this ideal is rarely met outside of large-scale epidemiological studies. For example, RCTs are drawn from a subset of the population, often limited to those with access to academic medical centers plus the willingness and ability to participate. Where this is the case, it is crucial to provide descriptive information about the study sample, so that its representativeness can be judged. Guidelines for reporting of RCTs include requirements to state the study population, give details of inclusion and exclusion criteria, and present clearly the numbers of eligible subjects who were not randomized and the reasons [32, 48-49].

A study may require a sample that is representative of the community overall or one representative of patient groups suffering the condition/disease. In principle, this is achieved by taking a simple random sample from a known population. In practice, a list of all eligible individuals is obtained and then a sample is drawn by a method in which each member of the population has an equal probability of selection (“epsem”). Even in ideal circumstances, however, some sophistication on this basic method is usually desirable or necessary. For example, in stratified sampling, subjects are arranged into subgroups and the sampling is performed within each subgroup separately. This ensures that the sample is representative of the population in terms of these subgroup character-
In multi-stage random sampling, the population is first divided into primary sampling units (such as hospital, health center, or surgeon), and a sample of primary units is selected. The secondary sampling units, usually individual subjects, are selected within the primary sampling units. A special case of multi-stage random sampling is cluster sampling where all individuals within each primary unit are included. Standard procedures for sampling should be followed [56, 74].

It is important to note that, while the technicalities of random selection of subjects for a study are closely related to the random allocation of subjects in an RCT (and indeed there are similar issues in trials relating to stratification and clustering)[56], there is an important distinction in the objectives of the two procedures. First, the (ideally random) selection from the population of eligible subjects concerns the external validity or generalizability of the study findings (RCT or otherwise). Independent of this, the random allocation of subjects in an RCT is concerned with the internal validity or comparability of the trial groups. It is usually obvious whether the study can be performed at a single institution, or whether a multicenter study will be required. Single institution studies have the benefit of being less complicated from a logistical perspective. While multicenter trials are more complex to manage and are usually more expensive, they provide larger numbers of participants in a shorter period of time, and increase the generalizability of research findings.

VI. DATA COLLECTION

Although the number of questions in a single study should be limited, it is still relevant to record as many as observations as is possible without jeopardizing recruitment or retention with onerous demands. Strong consideration should be given to collection of the following data groups [16], [75].

a) Baseline data:
b) Observations:
   1. Patient’s observation/Subjective measures
   2. Clinician’s observation/Objective measures
c) Tests
   1. Quantification of symptoms—bladder diary, and
   2. Pad tests for incontinence outcomes
   3. Urodynamics
d) Follow-up
e) Quality of life measures
f) Socioeconomics

It is useful to consider collection of the following variables:

- Age
- Race/ethnicity
- Gender
- Body mass index (height and weight)
- For women – obstetric history, including parity and menopausal status
- Smoking status
- Co-morbidities such as cardiovascular, respiratory and neurologic conditions and diabetes
- Medication use
- Past surgical history
- Level of education
- Mental and physical status
- Prior treatment for pelvic floor disorders, including behavioural, pharmacological and/or surgical interventions
- Sexual function

VII. OUTCOME MEASURES

Specific discussions of the most appropriate outcome measures for particular studies of incontinence and pelvic organ prolapse are discussed elsewhere in this consultation. The purpose here is to define the general concepts of primary and secondary outcomes, which are relevant to both sample size determination and data analysis. The distinction between these two sets of outcomes depends on the context of the trial, and should be decided at the planning stage of the study. Primary and secondary outcomes should not be confused with the distinction between primary and secondary analyses of trial data.

1. PRIMARY OUTCOMES

Primary outcomes are those viewed by the researchers to be of central interest. Sample size calculations are based on anticipated changes in the primary outcomes. The final study population may or may not be sufficient to allow robust comparisons of secondary outcomes. Trial results that are based on the primary outcomes can lead to responsible alterations in standards of patient care.

The number of primary outcomes in a particular trial will depend on the nature of the interventions and the number of independent domains. The number of primary outcomes is usually limited to three. Sample size calculation is based on the primary outcomes. The number and nature of outcome domains in a particular study will vary depending on the study’s perspective. Careful selection of outcome measures
that are valid and clinically relevant is intrinsic to the success of research; usually no single measure can fully express the outcome of an intervention.

2. SECONDARY OUTCOME

Secondary outcomes can be relatively large in number. They are not the focus of the main study objectives and are rarely used directly in sample size estimation. Secondary outcomes are exploratory, i.e., as hypothesis-generating exercises for which independent confirmation is essential or used to monitor: e.g. safety, side-effects, costs or patient acceptance.

3. TYPES OF OUTCOME MEASURES

Traditionally, a patient’s success after a particular treatment was reported by the physician, using subjective information that differed from physician to physician. Given the mismatch between physicians’ and patients’ perceptions of treatment effectiveness, this type of physician reported outcome measure has been largely replaced with patient-reported outcomes (PROs). The Food and Drug Administration defines a PRO as any report of the status of a patient’s condition that comes from the patient, without interpretation of the response by the clinician or anyone else.

There is emerging consensus that PROs are most appropriate when describing success or failure of therapies. However, physician-reported outcomes can yield valuable information about mechanistic effects of therapies and are also vital in developing predictive data for future use. As an example, a patient’s report of a bulge is a reasonable outcome measure for a study of surgical treatment for POP. However, if, over time, women with stage II POP after treatment who were initially asymptomatic became symptomatic, it would be pertinent to include prolapse stage, as an anatomic outcome measure, in the definition of success.

Other types of physician reported outcome measures (often called “objective outcomes”), used frequently in pelvic floor disorder research, include results obtained from urodynamic testing (e.g., presence or absence of detrusor overactivity incontinence), radiologic imaging (e.g., various angles measured during pelvic ultrasonography), physical examination (e.g., the POP-Q system for assessing pelvic organ prolapse), laboratory values, biomarkers, etc., as well as tests collected by the patient but interpreted by the physician (such as pad tests and bladder diaries).

The primary types of PROs include [76].

• Disease/condition specific: measure patients’ perceptions of a specific condition.
• Population specific: specific to a certain population (for example, women or men or elderly) with or without a given condition.
• Dimension specific: assess one aspect of health status. The primary dimensions studied include:
  * Physical function (e.g., activities of daily living)
  * Symptoms (e.g., urinary incontinence)
  * Psychological well-being (e.g., depression)
  * Social well-being (e.g., sexual function)
  * Cognitive function (e.g., mental status evaluation)
  * Role activities (e.g., household or work activities)
  * Personal constructs (e.g., body image)
• Generic measures: measure broad aspects of health which can be used to compare across populations (The SF-36 is a commonly used measure). These are often less responsive to clinically significant changes in health than condition-specific instruments
• Utility measures: (e.g., EuroQol) incorporate preferences or values attached to individual health states. This type of instrument produces evidence for the overall value of health states to society and can be used in cost-utility analysis.
• Summary items: participants summarize an overall picture of their status in one item (for example, the transitional item queried in the SF 36: “Compared to one year ago, how would you rate your health in general now: excellent, very good, good, fair, poor?”
• International Classification of Functioning, Disability and Health (ICF), WHO 2001
• Unified and standard language and framework for description of health and health-related states
• Body, Individual, Society
  * Body functions and structures
  * Activities and participation
• Body functions: physiological and psychological functions of body systems
• Body structures: anatomical parts
• Impairments: problems in body function or structure such as significant deviation or loss
• **Activity:** execution of a task or action by an individual

• **Participation:** involvement in a life situation

While not yet in wide use, web-based resources for administering computerized adaptive tests are being developed. One example is the Patient Reported Outcomes Measurement Information System (PROMIS) system (www.nihpromis.org). Using this type of testing, researchers can lower participant burden substantially. For example, in a measure of physical function, someone who endorses inability to dress themselves would not be asked the next series of questions in a typical validated physical function questionnaire about walking or exercising; someone who endorses ability to run marathons would not be asked questions about less strenuous activities. Nascent work has begun on the use of the PROMIS system in pelvic floor disorders [77].

Investigators should strive to use validated outcomes measures whenever possible. A fully validated outcome measure is demonstrated to 1) be reproducible when administered to the same person twice, 2) yield results that align with other gold standard measures (content validity), 3) change with successful treatment (be responsive to change), and 4) measure what it is intended to measure (face validity). (A full discussion of psychometric properties needed to validate a questionnaire can be found elsewhere in this consultation.) Much progress has been made in this area over the last decade, and therefore, when planning a study, the default position should always be choosing a validated outcome tool as a primary outcome measure. However, it is important to note that just because a questionnaire is “valid” does not mean it can be used in any population in any language. Researchers must take care to use instruments in the populations for which they were intended.

**Adverse event recording and analysis** is an important aspect of outcome measures, especially when the benefits may be offset by harms. Adverse event assessment should be systematically included in every interventional study. The Clavien-Dindo system for structured reporting and analysis of surgical complications has been used in several studies comparing pelvic floor interventions [78]. In this system, complications are classified into one of four categories based on the type of therapy needed to correct the complication.

**The timing of outcome assessment** should reflect the study question. Studies reporting efficacy of incontinence treatment should follow subjects for a minimum of one year. Although early follow-up can provide important insights about adverse events, a great deal more emphasis needs to be placed on long term effectiveness. The follow-up time for a trial should be at a fixed time (for logistical reasons, this is in practice often a short time window) relative to randomization rather than when treatment was actually received, since again this is the only way of ensuring a valid comparison. The planned timing of follow-up at a fixed time relative to randomization should, however, allow for any likely delays in receiving treatment, e.g., due to surgical waiting lists.

## VIII. Statistical Concerns

### 1. Sample Size Considerations

There is no single answer for sample size determination; often the calculation proceeds around a ‘circle of specifications’ (involving, say, power, targeted difference in effect size and population available for study). Furthermore, the ideal of the target being the minimum for clinical significance cannot always be met; rather, the aim in practice is to produce a convincing argument (among the researchers themselves, and also to funding bodies and regulatory agencies) that the sample size has an adequate chance of detecting differences that are (a) feasible, and (b) worthwhile detecting in clinical terms. A common failing is selecting a target difference that is too large, often derived from differences that have been observed or published previously rather than based on considered clinical judgment. Preliminary investigations into the levels of treatment effects that patients themselves consider worthwhile should be carried out much more commonly than is the case at present.

Sample size should be calculated in the planning stage of all studies. There are many formal equations to assist in this process, details of which will not be given here [70-71, 79-80]. Rather, the emphasis for this discussion is on the concepts involved and the information required for the calculations to proceed.

### 2. Sample Size Calculation

One approach to sample size calculation is based on the required precision of an estimate, which is relevant to both descriptive and analytical investigations. The basic issue is one of precision (measured by the standard error, SE) or margin of error (which depends on the SE but is more specifically defined as half the width of the 95% confidence interval [CI] around the estimate). The higher the level of precision specified in advance (i.e., the smaller the SE and the narrower the CI), the larger the sample size will need to be. However, the margin of error depends on the nature of the primary outcome variable, i.e., whether it is a continuous variable (such as maximum urinary flow rate) or a binary variable (such as the presence or absence of self-reported urgency incontinence). For a continuous variable, the variability (standard deviation) of the measure must be estimated for relevant subjects; this may
be derived from some combination of clinical experience, the literature, or a pilot study. The larger the variability, the larger the sample size required. For a binary variable, its prevalence must be estimated in the population to be studied, since the SE for such variables depends on their prevalence.

**A second approach**, based on power, is the most commonly used and requires that the study have adequate probability (power) of detecting a given (target) magnitude of effect. It requires similar prior information, including estimates of the variability for continuous measures and the magnitude of proportions for binary variables. In addition, it requires specification of three other quantities: the significance level, the power, and the target difference. Significance is a statistical term that tells how certain one can be that a difference or relationship exists. It does not necessarily imply that the result is clinically relevant, just that the result is likely to be accurate. The significance level, termed alpha, is conventionally, though not necessarily, set at 5%. Power is defined as the probability that the study will detect (as statistically significant at the alpha level specified) a given target difference between the groups, if such a difference exists. Power is commonly specified in the range of 80% to 90%, which implies a risk of not detecting the target difference of between 20% and 10%, respectively. For a trial involving anything other than minor risks and expenditure, a power closer to 90% than 80% would seem preferable [32], which leads to a larger sample size (as does a stricter alpha level of, say, 1%). This is most pertinent when a lack of statistical significance is obtained in a small trial, particularly when the sample size was not planned using a power calculation [47]. This is the basis for the adage that “the absence of evidence is not evidence of absence”[25]. A planned unequal allocation to the trial groups also requires an inflation of the sample size [47], as does interim analyses. By multiplying the number of significance tests performed, studies with interim analyses generally require stricter significance levels at each analytical point [50, 70].

**3. THE TARGET DIFFERENCE**

This is the last, and arguably the most important, quantity that must be specified for the power-based approach to sample size calculation. The target difference is defined as the minimum difference between treatment groups considered to be clinically significant. Clinical significance is an entirely different concept from statistical significance. Investigators must estimate the clinical significance as the magnitude of difference (in means or proportions) that would lead to a change in clinical management for the target group of patients. For example, a study might propose that a 20% difference in incontinence episode frequency is a clinically meaningful response. Ideally, such an assumption would be based on surveys of patient behavior but in practice the decision is often based on clinical judgement. In any case, the smaller the clinically significant target difference, the larger the required sample size. Statistical significance means that the observed difference, whatever its magnitude, cannot reasonably be considered as being due to chance. Statistical significance (denoted by the p-value) represents the strength of evidence against the null hypothesis [81]. The degree of clinical significance can be inferred only with the additional information of a confidence interval for the comparison between groups. A very large trial may achieve a high level of statistical significance with a very small effect size and therefore be of little clinical significance. A trial designed in such a way poses ethical challenges because many extra subjects are exposed to risk without meaningful benefit.

With each approach, appropriate adjustment for attrition (loss to follow-up) should be performed. This is commonly achieved by simply increasing the planned sample size in proportion to the anticipated attrition (i.e. to predict the reduced effective sample size that will be available for the analysis).

**IX. ANALYSIS**

The analytic plan should be consistent with study aims and the a priori analytic plan should be included at the time of the protocol entry into a clinical trials registration system. Currently, high tier journals will often request the statistical analysis plan and protocol at the time of the review of the report. This section will not contain any technical details of statistical methods, which are available in standard texts [47, 82-83], but rather will summarize concepts of data analysis.

It is established practice that the primary analyses (for both primary and secondary outcomes) of an RCT should be on an intention-to-treat basis [48, 72]. **Secondary analyses** incorporating non-compliance and/or which treatment was actually received may be justified in addition to the primary analyses. In practically all situations, hypothesis tests should be two-sided (i.e., allowing for the possibility that the difference could have been in either direction, that is benefit or harm), rather than one-sided. One-sided tests are only appropriate if a difference in one direction is not just unlikely, but would not be of interest, such a demonstrating only superiority of a new drug.

Regardless of the type and complexity of statistical techniques used in analysis, the general underlying principles behind hypothesis testing and estimation apply. In particular, the statistical significance of a hypothesis test should be interpreted critically. The actual p-value should be considered, rather than just whether or not it is below an arbitrary threshold such as 5% [48]; indeed, the p-value is better considered a measure of the strength of evidence against the null hypothesis, on a continuum or 'shades-of-grey
[83-84]. The direction and magnitude of the trial comparison should be presented with an appropriate confidence interval to indicate the possible clinical significance and precision of the comparison [48, 85].

Appreciable loss to follow-up in a trial (which is not the same as adherence with intended treatment, lack of efficacy, or the observation of adverse events) may present serious problems both in terms of generalizability of the findings to the wider population and, in the case of differential loss to follow-up across treatment groups, to the validity of the comparisons. Indeed, strictly speaking any missing outcome data means that not all of those allocated to the various randomization groups can be included in the analysis [86], and this might lead to the conclusion that the term ‘intention-to-treat’ should only be used if follow-up is complete. Under current guidelines, intention-to-treat relates more to the broad strategy adopted by the researchers for data analysis [39, 87]. Results should always be accompanied by a full and clear statement of how deviations from intended treatment and missing outcome measures have been handled in the analysis. The discussion should include how missing outcome data may have affected the conclusions [86]. Sensitivity analyses can be used to test the exclusion of, or assumptions about, missing values; practical examples of such analyses are becoming more common [88]. Another design strategy, modified intent to treat (MITT), is common in drug trials. It requires the participant to take at least a single dose of the study medication in order to be included in the analysis.

It is essential that a statistical analysis plan be developed for the trial prior to implementation. The CONSORT statement provides an outline of the various stages of data analysis for RCTs [32, 72]. Here we present the underlying concepts of data analysis at a particular follow-up time relative to randomization, and considers initially the simplest case of a clinical trial with two treatment groups. Multiple treatment groups will be covered briefly, but repeated measurements of outcomes and interim analyses involve considerably more complex methods of planning and analysis, for which expert help is essential [71, 89].

• Stage of data analysis

The first stage of data analysis is to address the representativeness of randomized subjects compared to the target population of eligible patients. The number of eligible patients who were and were not randomized should be provided, along with reasons for excluding potential study participants. This aspect of the findings of the trial will only prove useful if all eligible patients are considered: in practice there is a tendency for researchers to avoid approaching certain potentially eligible patients (selective pre-screening), for any of a wide variety of reasons, and this behavior may introduce bias in which subjects from the target population are included in the study. The presentation of this information is facilitated by use of the CONSORT flow diagram [48, 72]. Use of the CONSORT guidelines is associated with improved quality of reporting of trials generally [32]. Descriptive statistics should also be given of important characteristics of health care professionals approached for involvement in recruiting subjects to the trial, both for those taking part and those declining.

The second stage of data analysis is to compare the two groups at randomization (baseline) including demographic, prognostic, and outcome variables. A common error at this point is to rely on statistical testing for these comparisons [47, 50, 70]. If the randomization procedure has been performed correctly, then any statistically significant differences in baseline characteristics are likely due to chance. Statistical testing of this kind is not a test of the comparability of trial groups; rather, it is a test of the allocation procedure [47, 50, 70]. It may be seriously misleading, particularly if lack of a statistically significant difference for a given characteristic is taken to imply comparability. Baseline comparability is best assessed by simply obtaining descriptive statistics for the groups and making a judgment as to whether any observed differences are likely to be influential or not. If differences are likely to be influential, they should be considered in the analyses. Notable exceptions to this are baseline measures of the outcome variables, which should be considered in the analysis regardless of the situation at baseline, since removing variance in the outcome measure that is purely attributable to differences between individuals at baseline has potentially marked benefits in terms of precision and power [50]. Investigators should consider stratifying the randomization on any strongly prognostic variable (for reasons of efficiency rather than bias). Since there are practical limitations as to how many variables a trial can stratify for, a technique known as minimization may also be considered [46, 74]. Any variables stratified or minimized at randomization should be allowed for in the analysis [50]. In incontinence research, variables such as prior failure of therapy in drug and surgical studies or the degree of anatomic support in surgical or injectable trials or degree/amount of incontinence might be considered important enough to stratify, or to include in the analysis if unequally distributed.

The next stage of data analysis is to perform the primary (comparative) analyses for the outcome variables. First, though, it is essential to derive and report actual numeric data – even if simply in the form of descriptive statistics – rather than just reporting for instance a percentage change, even if the latter are relevant and provided as well. Graphs can be misleading, especially when subsections of the scales are magnified, and should be used to supplement or clarify the numerical data,
not to replace it. Primary outcomes should initially be analyzed by intention-to-treat comparisons of the groups as randomized, both using hypothesis tests for statistical significance and CIs for comparisons between the groups to assess clinical and statistical significance, usually adjusting for baseline measurements of the outcome variable. With a small number of primary outcomes, multiple testing is not a concern. However, when a large number of statistical tests are performed for secondary outcomes, corrections to the observed p-values should at least be considered.

The most commonly used procedure for multiple testing of many outcomes is the Bonferroni correction [47, 50, 82]. The Bonferroni correction is fairly conservative in reducing the risk of a statistically significant effect occurring purely by chance, at the cost of reduced power for individual outcomes. This is particularly pertinent when, as is usually the case, the outcomes are positively associated with one another. While there are alternative procedures that improve this deficiency, none of them are entirely satisfactory [50]. It is emphasized that whatever strategy is adopted to deal with multiple testing, the major errors are to rely solely on p-values rather than present confidence intervals “CI's as well, to over-simplify the presentation of p-values to just non-significant "NS" or "p<0.05" rather than to quote the actual p-values, and above all to report selectively the results of significance tests.

Another example of a “multiplicity” is where there are more than two treatment groups, e.g., when different doses of a drug are being investigated or when more than one ‘active’ procedure is being compared with placebo [50]. Similar issues to multiple testing of different outcomes are involved here, but there are a greater variety of commonly used procedures available to deal with the central concern of finding a difference purely by chance. Standard methods for dealing with this multiple comparisons problem include the procedures attributed to Tukey, Newman-Keuls and Dunnett [90].

Secondary analyses of trial data include per-protocol analyses with adjustments using regression methods for pertinent process measures such as degree of adherence with the allocated treatments. Secondary analyses also include planned subgroup analyses, such as the investigation of different intervention effects across age, ethnic, or disease severity groups. Subgroups should be analyzed by using appropriate interaction terms in regression models [48, 70]. Using interaction terms rather than performing repeated, separate, subgroup-specific analyses considerably reduces the risk of false positive findings [91-92]. Subgroup analyses should be carried out sparingly, specified in advance (preferably with a clinical rationale), and above all should not be reported selectively [48, 92-93]. This last point relates not just to subgroup analyses but to all stages of reporting randomized trials. Pre-specification of the primary outcomes in the study protocol and analysis plan, along with clear statements about all the outcomes considered is essential to avoid selective reporting. The large volumes of data accumulated in major multicenter RCTs almost guarantee that something “significant” can be identified by “data-mining”. If not identified by the investigators as an a priori item of interest such findings should be viewed with great skepticism.

**X. REPORTING RESEARCH RESULTS**

Over that past decade, progress has been made in reporting research results. However, faster progress would occur if investigators would follow the reporting recommendations. As part of the “Enhancing the QAility and Transparency Of health Research” (EQUATOR) Network project, a website was developed at www.equator-network.org. On the website, the Consolidated Standards of Reporting Trials (CONSORT) statement provides guidelines for reporting the design, detailed methods, and results of RCTs. For studies of diagnostic tests the Standards for Reporting of Diagnostic Accuracy (STARD) [94] statement fills the same role and information is also included on the EQUATOR website. Guidelines for reporting meta-analyses are described by the Quality of Reporting of Meta-analyses (QUORUM-37) and Epidemiologic research reporting guidelines are contained in STROBE, Strengthen the Reporting of Observational Studies in Epidemiology [38, 72].

The CONSORT statement is specifically designed to provide standards for reporting RCTs [48, 72]. It includes a checklist of items that should be included by authors preparing manuscripts. Adherence to these guidelines and the use of flow diagrams in particular is associated with improved quality in reporting of RCTs [95]. Errors in presentation of statistical information are extensively covered in many textbooks [47, 82]. This section will emphasize the most important points on reporting of RCTs, to ensure an objective and comprehensive presentation of the trial itself, and also to facilitate any subsequent synthesis of research evidence including formal meta-analyses of RCTs. Meta-analyses are themselves the subject of separate reporting guidelines: the QUORUM statement [96]. However, such guidelines are not a panacea [97]; deficiencies in reporting are still common [72]. [98]

The CONSORT statement for reporting parallel group randomized trials have recently been updated. Statements have also been issued for pragmatic trials [99-102] and noninferiority and equivalence trials. The CONSORT statement includes a checklist of items and a comprehensive set of characteristics of a clinical trial to assist investigators to write reports of their findings, journal editors and
• The design, conduct, analysis and presentation of meta-analyses should follow QUORUM guidelines. HIGH
• Reporting studies of diagnostic tests, including urodynamics, should follow the STARD statement guidelines. HIGH

XI. SPECIAL CONCERNS FOR SPECIFIC STUDIES

1. BEHAVIORAL AND PHYSIOTHERAPY TRIALS

a) Terminology

The lack of consistent terminology severely hampers our ability to build a body of literature about conservative interventions. The terms “behavioral therapy”, “lifestyle intervention”, “conservative treatment”, “non-surgical treatment”, “physiotherapy”, “biofeedback”, and pelvic floor muscle exercise” are often used interchangeably and incorrectly to describe both the same, and different interventions. While such therapies are discussed elsewhere in this consultation, we here advance this committee’s opinion about appropriate terminology:

b) Behavioral interventions

According to Oxford Advanced American Dictionary, the term behavioral is “the way someone behaves, especially towards other people”, and behavioral science is the study of human behavior. We recommend that behavioral science be limited to studies that evaluate how people do or do not behave as desired.

c) Lifestyle interventions

Lifestyle interventions for UI are discussed elsewhere in this consultation and have traditionally included change in diet, intake of caffeine and carbonated soft drinks, fluid restriction, weight loss, smoking cessation and advice of increasing general physical activity level. Behavioral science can be used to understand how and why people change life-style to, for example, adhere to exercise and weight loss programs, but it should not be used as term to replace specific therapies such as physiotherapy or pelvic floor muscle training.

d) Physiotherapy

Physiotherapy refers to assessment, prevention and treatment given by an authorized physiotherapist (ICS physiotherapy committee www.icsoffice.org). It involves “using knowledge and skills unique to physiotherapists” and, “is the service only provided by, or under the direction and supervision of a physiotherapist” (WCPT 1999). This implies that the term physiotherapy should only be used in trials where the professional providing the intervention is a physiotherapist. We recommend describing the actual intervention instead of using the term physiotherapy: eg pelvic floor muscle training.

Recommendations on Study Conduct and Statistical Methods

• The role of quality RCTs as providing the strongest level of evidence in incontinence research should be fully acknowledged by researchers, journal reviewers, and editors. HIGH
• Careful attention to the planning and design of all research, especially RCTs, is of the utmost importance. HIGH
• Appropriate expertise in biostatistics and clinical trial design should be employed at the design phase of a RCT and thereafter on an ongoing basis. HIGH
• The design, conduct, analysis and presentation of RCTs must be fully in accordance with the CONSORT Statement. HIGH
• The design, conduct, analysis and presentation of observational studies should follow STROBE guidelines. HIGH

reviewers in the review of manuscript submitted for publication and permit consumers of the literature to critically appraise articles. Clear statements about the objectives of the trial, intended study population, and planned comparisons. Subgroup or covariate analyses should be clearly specified and justified. The method of randomization should be stated, as should the unit of randomization; in most cases, this will be the individual participant but occasionally an aggregate group of subjects will be allocated jointly in a cluster randomized design [56]. Cluster randomized designs are also now the subject of separate reporting guidelines [103], and involve particular complications in terms of data analysis [104]. For all trials, specifications for the sample size calculation (primary outcomes, target differences, etc.) should be stated and justified. In addition, the precision actually obtained in a study must be presented. This requires confidence intervals as well as the observed p-values, at least for primary outcomes but preferably for all outcomes. The principal confidence intervals should be for comparisons between the groups, rather than for differences in the outcomes within the trial groups [47, 50]. Results should include a trial flow diagram, with numbers and reasons for the exclusion of eligible subjects, the number randomized, and subsequent losses to follow-up [32]. Protocol deviations should be described and explained [70]. Harms of the trial should be described for each treatment group. Finally, the discussion should include a brief summary of the trial’s findings, possible explanations for the results, interpretation of the findings in light of the literature, limitations of the trial including internal and external validity, and the clinical and research implications of the study [48].
with or without biofeedback, electrical stimulation, pelvic floor muscle training with vaginal cones or resistance device etc. This accurately describes the intervention and is neutral towards profession. Publications should report the actual profession of the interventionist (e.g., physiotherapist, general practitioner, urogynecologist, urologist, midwife, nurse, fitness instructor), rather than using the vague term, “therapist”.

e) Biofeedback

Biofeedback encompasses “a group of experimental procedures where an external sensor is used to give an indication on bodily processes, usually in the purpose of changing the measured quality” [105]. Biofeedback equipment was developed within the area of psychology, mainly for measurement of sweating, heart rate and blood pressure under different forms of stress. Today, a variety of biofeedback apparatuses are commonly used in clinical practice to assist with PFMT, and the biofeedback can be either visual, auditory or both. In many textbooks the term “biofeedback” has been used to classify a method as different from PFMT. However, biofeedback is not a treatment on its own. It is an adjunct to training. For example, it may measure the response from a single PFM contraction or provide visual feedback during attempts to relax the muscles. Hence, a more precise terminology is PFM training or relaxation with or without biofeedback.

In addition to traditional biofeedback apparatuses, other instruments can offer valuable feedback. Vaginal and anal surface EMG, urethral, vaginal or anal squeeze pressure measurements, ultrasound and MRI can all be used to make the patients more aware of muscle function, and to enhance and motivate patients’ effort during training [106].

f) Conservative interventions/treatments

Conservative interventions include all of the above, and this term includes everything except medication and surgery. As several studies have found that more than 30% of women with pelvic floor dysfunction are not able to perform a correct PFM contraction at the first consultation [107-110] it is mandatory to report how ability to perform a correct contraction was assessed before commencing an exercise trial. Also in electrical stimulation research one should report in which way response to the stimulation was assessed.

Although there is level A, grade 1 evidence for some of the conservative interventions such as PFMT for SUI, a variety of new conservative methods to treat the condition are frequently suggested in clinical practice and in the literature. These new methods are often presented as being effective, but are usually a hypothesis based on theories, data from small experimental laboratory studies/ small clinical series, or associations found in large epidemiological studies. If the clinicians like the approach, it soon enters clinical practice and textbooks without any further critical testing [113]. A model for how new therapies ideally should enter clinical practice has been proposed [114]. In this model the new idea should go through at least the 4 first stages before they enter practice:

Clinical observation and laboratory studies
- Clinical exploration
- Pilot studies
- Randomized controlled trials
- Refinement, eg dose-response issues
- Active dissemination of the method if it has proven to be effective

It is important that the patients participating in the 3 first stages before the RCT are given full information that they are participating in an experimental treatment, and that the clinician does not know if this new approach is effective. The patients also need to be informed if there are other proven effective treatments available.

g) Reporting of trial characteristics

In addition to reporting the specific type of intervention (eg PFMT with biofeedback compared to PFMT alone or electrical stimulation) and the profession administering the intervention, the intervention needs to be described in such detail that other investigators can reproduce the intervention. This includes:

- Ability to perform a correct PFM contraction.
- Frequency: number of home training sessions and supervised training sessions (eg every day, 3 times/week)
- Number of repetitions and sets (eg. 12 sets x 3 times/ day)
- Duration: length of each training session (eg. 20 minutes), and duration of the total training period (eg, 3 months, 6 months)
- Intensity: In exercise science, this is usually reported as % of one repetition maximum for strength training. In pelvic floor muscle training it is often described as attempts to reach maximum contractions or utilizing submaximal contractions. Another description of intensity is the holding time in seconds, eg: 6-8 sec
- Adherence: the degree to which participants follow the prescribed protocol, usually reported as a percentage of the total possible.

Educational material provided, such as DVDs, brochures and booklets should be described.

Assessment: All devices used for assessments (eg manometers, dynamometers, ultrasound and EMG) must be described in detail, and their re-
responsiveness (ability to detect small changes), reliability and validity should be reported [111].

h) Adherence vs effectiveness

It is important to note that adherence is not the same as the effectiveness of a program, as it is possible to have high adherence, but still little effect of training. Hence, when reporting the effect of conservative interventions it is ideal to measure also the exposure variable that the treatment is expected to change (eg muscle strength, ability to relax etc). This variable should not be confused with the primary or secondary outcomes of the intervention (eg leakage measured with pad testing, number of leakage episodes or QoL).

In many areas of conservative interventions there are high quality RCTs, systematic reviews and meta-analysis showing statistically significant and clinically relevant differences between the intervention and the untreated control group or other interventions. Of conservative therapies, PFMT for SUI/MUI has the strongest evidence to support its use; further, the more intensive the program (more supervision, higher dosage of training) the better the effect. Therefore, when comparing new methods and innovations with established PFMT, it is important to compare the new intervention with the current best evidence, meaning the effective arm of the reported RCTs. Unfortunately it is common to compare new methods with an ineffective training protocol, thereby overestimating the effect of the new method and claiming that it is equal to or better than “the old method”. When comparing different methods the dosage also needs to be the same in both treatment arms, eg when comparing PFMT with and without biofeedback, the number of supervised sessions, length of the sessions, frequency of home treatment and duration of the intervention must be the same.

i) Adverse events and cost

There are few adverse effects or complications reported after conservative interventions, but they do exist, eg in electrostimulation [112], and adverse effects or lack of adverse effect, and inconvenience to the patients should be reported. Although seldom harmful, conservative treatments are time consuming and can be costly for participants and paying parties because of the need for close follow up during the interventions. Cost effectiveness studies are crucial to fully understand where conservative therapies fit in the treatment armamentarium.

j) Outcome measures

The need for use of responsive, reliable and valid outcome measures in research is covered elsewhere in this chapter. The RCTs published in conservative treatment have applied a huge variety of outcome measures, making systematic reviews and meta-analysis difficult or impossible to conduct. Therefore, in future research it is important to use established and recommended outcome measures. In addition to description and use of responsive, reliable and valid primary and secondary outcome measures, future studies should include description and assessment of adherence to the intervention protocol, measurement of the independent variable (the intervention; eg strength training, relaxation training) and measurement of the possible underlining mechanisms of how the treatment works. It is usually not possible to blind the participants or those providing the intervention, but the assessors of outcome should always be blinded to group allocation.

k) Specific and non-specific effects

There have been some concerns that the effect of conservative treatments can be attributed to non-specific effects such as the extra attention of the therapist. The role of the therapist is to educate, motivate and empower the patient to be able to perform the actual program, secure high adherence, and minimize drop-outs. In patient reported outcomes and reports on quality of life it may be difficult to separate the effect of the attention and the actual effect. However, the effect of the attention is less likely to affect outcomes such as muscle strength, urodynamic assessments, pad testing and morphological changes measured by ultrasound and MRI. To minimize bias, all assessments should be conducted by investigators blinded to treatment allocation; the logistics of this should be addressed during the planning phase of the study. In a high quality RCT, Dumoulin et al address the problem of attention in physiotherapy research [115]. Women with persistent UI, three months after childbirth were randomized to either two different training regimens or a control group receiving relaxation massage for the back and limbs for the same amount of time as the supervised training groups. 70% were cured on pad testing in both treatment groups while there was no effect on urine loss in the relaxation massage group. Participants in the massage control group had improvement in disease specific quality of life.

l) Power calculations and number of participants

Some of the RCTs on conservative treatments are flawed by small sample sizes, this being especially evident in electrostimulation studies and may account for negative effects caused by type II errors. It is important that future studies use results of previous published studies to make appropriate power calculations that incorporate estimates of drop-outs and loss to follow-up to decide the optimal number of participants needed. Recruiting large numbers of participants may come at the expense of the rigor of the intervention [116]. Weak interventions (eg non-optimal training dosages or
suboptimal electrostimulation parameters) are unlikely to be effective and do not yield the true effect of an intervention. In meta-analyses, adding RCTs with large sample sizes but weak and ineffective interventions, can dilute the effect of smaller RCTs with higher methodological and interventional quality [116].

m) Long term studies

To date there are no quality criteria for how to report long term follow-up studies or how to conduct meta-analyses of long term studies. Challenges in long term follow-up studies include cross over to the more effective treatment after cessation of the original RCT, co-interventions during the follow-up period, recurrent events (e.g. new pregnancy), competing events (other diseases leading to incontinence) and loss to follow up. For conservative interventions it is expected that any training effect will diminish over time if no maintenance training is conducted or the pre- or co-contraction of the pelvic floor muscles has not reached an automatic level during the original trial. In order to control for as many of the above mentioned factors as possible, it is recommended that the long term follow up study should be planned together with the original RCT. Loss to follow-up and adherence to the protocol during the follow-up period must be reported [106, 111-117].

Recommendations for conservative treatment trials:

- Use correct terminology to describe the intervention. HIGH
- Report details of ability to perform correct contraction, dose-response issues and adherence. HIGH
- Use recommended outcome measures with high responsiveness, reliability and validity. HIGH
- Compare new methods with the best available intervention. HIGH
- Use power calculation in planning the study. Avoid large sample sizes and weak (ineffective dosages) interventions. HIGH
- For long-term follow-up studies report crossover, co-interventions, recurrent and competing events, adherence in the follow-up period and loss to follow-up

2. EXPERIMENTAL DEVICES AND MATERIALS

Surgical research presents unique challenges to efforts at optimizing patient care. It is important to create a pathway for real advances while simultaneously protecting patient safety. When new procedures are substantially different from prior operations there should be a broad based preliminary exploration leading to a comparative trial if warranted. At the same time, many minor modifications of surgical procedures are inappropriate for randomized trials and if required, surgical progress would be slowed [118].

a) Randomisation

It has been argued that the first patient in whom a procedure is performed should be randomized [119-120]. Alternatively, it has been suggested that case series for new procedures are allowed until the procedure finds its intended use and to avoid doing studies while those performing the procedures are on the “learning curve”. Typically, new surgical procedures for incontinence have been reported as case series [121-122]. Not only do surgical case series provide the lowest level of evidence for treatment effects, case series may be “harmful”. An accumulation of “positive” case series may present a premature certainty about benefits of a procedure and make it even more difficult to perform randomized trials [123-124]. Influential members of the surgical community may endorse a new procedure and if the procedure is considered better it may be difficult to get surgeons and patients to randomize or a trial may appear to be unethical with a “proven” procedure [119, 123, 125].

b) Adoption by clinicians

Therefore, devices often are widely adopted by clinicians based on anecdotal data, marketing, or small case series. This raises a unique problem for trials in this area: 1) Surgeon buy-in can be difficult to obtain as some surgeons (“early adopters”) may perceive that the newest therapy is best and thus be unwilling to randomize patients to receive the traditional therapy, 2) Other surgeons (“late adopters”) may perceive that the newest therapy is best and thus be unwilling to randomize patients, 3) Patients may be unwilling to be randomized to traditional therapy because they are influenced by marketing forces propelling the newest devices to the forefront, and 4) Device companies frequently modify their materials or technique recommendations; therefore, by the end of the 3-5 years it typically takes to complete the earliest outcome assessment for a surgical randomized trial, the device tested is no longer the same as the device used in the trial. Thus, the results may be discounted as being no longer applicable.

c) Recruitment procedures

An important area of concern in surgical and device studies is patient recruitment procedures. Both in this regard and for all components of a study, we strongly support reporting according to the CONSORT guideline for randomized trials and the STROBE guidelines for observational studies. Subjects should be enrolled in a manner that minimizes selection bias. The protocol should detail the procedure by which consecutive patients meeting
the inclusion criteria are selected. All situations in which a patient meets the inclusion/exclusion criteria but is not offered enrollment by the investigator should be documented. The number of patients who decline enrollment should be stated, along with the reasons. It is vital that clinician researchers do not “cherry pick” from their patients, that is, that they do not limit recruitment to those patients considered to have the greatest chance of cure or lowest chance of risk. The study population should be as generalizable as possible. There should be a complete accounting of all participants in the study including the reasons for subject withdrawal.

Participants must be well informed about what is known and not known about devices or procedures being tested. They should not be led to assume that because a device is on the market, it is “safe and effective”, as gaining knowledge about this is the purpose of the trial.

3. SURGICAL STUDIES

Cross-sectional studies of surgical procedures by type can provide estimates of prevalence, variation by age, race, and region as well as morbidity and mortality [126-127]. This type of information raises important health policy questions regarding physician practices, patient preferences for incontinence treatment, and differential access to and the utilization of care.

Case series are the most common study design found in the surgical literature, especially for new “innovative” surgical procedures. This is true despite the fact that case series cannot account for selection bias on the part of both the patient and surgeon, non-reporting bias of failures or loss to follow-up, lack of long-term follow-up, and provide the lowest level of evidence for treatment effects. Observational studies can provide important information about effectiveness and complications of surgical procedures, and also are very helpful in designing and selecting potential randomized clinical trials.

The randomized controlled trial is the accepted “gold standard” for research of treatment effects. In all surgical specialties, there has been growing concern regarding the limited number of randomized controlled trials for surgical procedures, poor methodological standards in those that have been performed, and a perception that surgeons are reluctant to rigorously test new surgical interventions [119, 123, 128-129]. A number of reasons for the paucity of surgical trials have been suggested including the lack of a regulatory board similar to the Food & Drug Administration responsible for the development of new medications [130].

The body of literature of surgical randomized trials in pelvic floor disorders is small, though increasing. However, many RCTs have serious limitations including a sample size too small to detect differences between groups, lack of blinding of the participants and/or individuals assessing the outcomes, short follow-up, inclusion of limited number of surgeons only, poor description of the technique, and lack of standardized outcome measures. Multi-center treatment networks are useful to overcome some of these limitations.

Differential drop out after randomization (or for cohort studies, after the intervention) can introduce bias. In a large and methodologically sound randomized controlled trial comparing the tension-free vaginal tape (TVT) and colposuspension, a large number of women withdrew from the colposuspension arm after randomization [131-132]. The loss of participants after randomization introduced bias in favor of the TVT because the drop outs had less severe incontinence resulting in the colposuspension group having more severe incontinence. It has been suggested that participants were only willing to continue if they were randomized to the “new and better” TVT procedure [132-133]. Accounting for subjects “lost to follow-up” must also be detailed as per the CONSORT and STROBE recommendations. In the UK TVT RCT, drop out after surgery was similar for both procedures. In contrast, in two large study comparing two incontinence procedures performed by the Urinary Incontinence Treatment Network, randomization was done in the operating room after the patient was anesthetized and therefore no participant was lost to randomization [134],[67].

For studies of specific surgical procedures, the technique should be described in such detail that it could easily be reproduced in another study. Standardization of the procedure may vary depending on the research question [135]. Surgical trials using a small number of highly skilled surgeons are analogous to medical trials where only compliant patients are randomized, reflecting efficacy of the procedure in an ideal setting. It may be more generalizable to a mixture of skill level among surgeons in the community, and so reflect effectiveness of the procedure in usual practice [124].

Masking of participants as to their assigned intervention and those assessing the outcome is particularly important for surgical trials for incontinence because there may be enthusiasm by the patient or surgeon for a new procedure, many outcomes are based on the patient’s own assessments such as symptom and quality of life scores, and the intervention is primarily for improvement of symptoms [118].

For new surgical procedures, important issues of adequate informed consent and conflicts associated with incentives for developing, starting and using new procedures have been raised. Informed consent for a new procedure must include:
• acknowledgement that the procedure is new and has not been shown to be more effective than a traditional approach
• discussion of potential complications, especially any integrally related to the procedure or device
• disclosure that information on complications are limited, and
• disclosure that the long-term benefits are unclear [122].

Incentives for adopting new procedures prior to sufficient evidence can arise from self-interest by attracting patients to one’s practice, industry marketing, and patient desire for “cutting edge” techniques. Industry sponsorship or a surgeon’s financial interest must be disclosed.

Organizations and treatment networks have been established to address many issues related to surgical interventions. Examples include the UK National Institute of Clinical Excellence (NICE www.nice.org.uk), the Australian Safety and Efficacy Register of New Interventional Procedures-Surgical (ASERNIP-S www.surgeons.org/asernip-s), and the US treatment networks: Urinary Incontinence Treatment Network (UITN nih.gov/patient/uitn/uitn.htm) for the NIDDK and the Pelvic Floor Disorders Network (PFDN). The NICE and ASERNIP-S provide systematic reviews of new operations, assessment of effectiveness, and recommendations that the technique has sufficient data for widespread use, or that the techniques appear unsafe, or that further audit/research are required before its widespread usage. The UItN and PFDN were established to provide the infrastructure for multicenter large randomized controlled trials for incontinence and prolapse.

Recommendations for Surgical and Device Trials:

• The safety and serious side effects of new operations must be completely defined with adequate follow-up so that risks can be weighed against efficacy. At a minimum, this requires more use of large scale, independent, prospective, multicenter cohort studies when RCTs are not practical. HIGH
• Safety and serious side effects of incontinence devices must be completely defined with adequate follow-up, especially for use of implantable devices and biologic materials, so that risks can be weighed against efficacy. HIGH
• Valid informed research consent is required in all trials of surgical interventions, which is separate from the consent to surgery. HIGH
• We recommend ongoing research into the usefulness of pre- and post-operative predictive testing (such as urodynamics, ultrasound, MRI, etc) in surgical trials. HIGH
• Reports of successful treatment should be limited to subjects with a minimum (not mean) of one year follow-up and should include a patient perspective measure. Specific assumptions about subjects lost to follow-up should be stated. HIGH
• Randomization for surgical trials should occur at the time of surgery to minimize drop-outs and switch of procedure HIGH
• Long-term follow-up of RCT cohorts in an observational cohort is recommended. HIGH

4. PHARMACOTHERAPY TRIALS

Although many RCTs have been published in recent years on pharmacotherapy for urinary incontinence a great deal more remains to be learned. The trials have almost all been limited to 8-12 weeks of treatment giving very little information about long term safety and efficacy of drug therapy. Inclusion criteria are often stringent, such that the study population of healthy middle-aged people bears little resemblance to the patients for whom providers wish to prescribe medication. There is less than adequate information about special patient groups—men, children, neurogenic patients, and especially the frail elderly. Because incontinence creates such an impact on the older population, good studies to define the utility and safety of drug therapy are greatly needed in this group.

An issue of special relevance in trials of pharmaceutical agents (although germane to other treatment modalities) is the controversy regarding placebos in clinical trials. Regardless of whether a drug is effective or not, simply giving a drug to a patient may produce a beneficial response. To assess if a drug has an effect over and above the placebo response, it is usually tested against an inactive substance (placebo). In incontinence studies, the placebo effect may be quite large, anywhere from 30-50% in recent published studies. To account for this, investigators and regulators have generally demanded a placebo arm in most clinical trials of medication. While this may be acceptable to participants for short trials, it is neither ethical nor feasible to withhold treatment for longer periods of time. Further, clinicians and patients generally want to know how a new drug compares with established treatment.

Masking, while desired in all types of trials, is especially important in pharmacological trials. Further, it is feasible to do in such trials (as opposed to surgical or conservative interventions, in which masking may not always be possible) and thus should be prioritized. However, the identical appearance of two pills does not guarantee that participants will be unaware of group assignment. Side effects

1883
common with anti-cholinergic therapy, such as dry mouth, may unmask participants. Studies should assess the degree to which masking was successfully maintained.

**Recommendations for Pharmacotherapy Trials**

- As effective drug therapy is available for most forms of incontinence, active drug comparator arms are recommended for most trials. **HIGH**
- Very little is known about the safety, efficacy and tolerability of drug therapy beyond 12 week trials. A concerted effort is needed to create this type of information base. Long-term follow-up of RCT cohorts in an observational cohort is recommended **HIGH**

**XII. COST ANALYSIS**

Economic and health policy outcomes are gaining increasing importance, as policy makers deliberate the values of different therapies. The financial burden on the health care system, the patient and patient’s family of various treatment options makes cost an important outcome to measure. We recommend that cost analyses be planned with clinical studies whenever possible. Costs may be influenced by economic and political factors that are subject to change at any time; however, when basic units of work, time, and resources are carefully defined, models of costs remain useful even if market forces change in an unforeseen manner.

In health and medicine, economic analyses are descriptive and/or comparative. Descriptive data include the socioeconomic cost caused by the disease and its current treatment, whereas comparative data provide an economic evaluation of different treatment strategies and interventions where costs are compared to health outcomes.

There are several relevant types of cost analysis, some of which require a high level of expertise to conduct:

- **Cost of illness analysis** (COI) typically quantifies the burden of medical expenses (direct costs) and the resulting value of lost productivity (indirect costs) attributable to a specific condition such as an illness or injury [136], [132].

- **Cost effectiveness analysis** (CEA) measures the costs and consequences of two or more diagnostic or treatment pathways related to a single common effect or health outcome. It then summarizes the results in ratios that demonstrate the cost of achieving a unit of health effect for different types of patients and for variations of the intervention [137], [133].

- **Cost utility analysis** (CUA) is a form of cost effectiveness analysis in which particular attention is paid to the quality of health outcome related to treatment. In CUA, health effects are expressed in terms of quality-adjusted life years (QALYs) [138], [107]. A QALY is a measure of health outcome that assigns to a given period of time a weighting that corresponds to the health-related quality of life during that period, and then aggregates these weights across time periods. The QALY is important because it considers both quantity and quality of life.

- **Cost benefit analysis** estimates the net social benefit of an intervention by comparing the benefit of the intervention with the cost, with all benefits and costs measured in dollars [24], [134]. Health outcomes are converted into monetary values using “willingness to pay” (the value an individual would pay for reduction in illness severity) or “risk of death” or “human capital” methods (an individual’s value to society based on productivity or future wages) [139-140], [135-136].

**Recommendations on Cost Analysis in Incontinence:**

- Cost analysis should be incorporated into clinical studies whenever possible [137]. **HIGH**

**XIII. RECOMMENDATIONS FOR SPECIFIC PATIENT GROUPS**

1. **MEN WITH LUTS**

When considering men with LUTS, one must consider some unique factors which may influence urinary tract symptoms independently of any intervention, and so confound any data. These are the presence of the prostate gland which can cause bladder outlet obstruction (BOO), and the rarity of sphincter incompetence except in men who have undergone surgery for benign or malignant prostatic disease. For short term outcomes after intervention studies, these factors are unlikely to be relevant, but longer term follow up, and large observational or epidemiological studies may need to take these factors and changes over time into account when analyzing data. The prostate gland may complicate research outcomes as a result of outflow obstruction (either at baseline, or development of a new problem during follow up studies). Also, for patients with prostate cancer (either at the time of enrolment, or during follow up of longer studies), it is likely that both the disease, and the treatment given (surgery or radiotherapy) may alter urinary tract function and symptoms independently of any intervention in the study and thus confound the outcomes. Overall, about 2/3 of men with LUTS have urethral obstruction and over 50 % have detrusor overactivity, al-
though a much smaller number have urinary incontinence due to detrusor overactivity [141].

If prostate size is considered to be a variable that could affect outcomes, measurement of prostate volume should be made before and after treatment. The method used to measure volume and its reliability and validity should be provided if available or their absence indicated. Any associations between outcomes and change in prostate size should be tested for using appropriate methods and reported. Consideration should be given to stratifying participants by prostate volume when there is suspicion that response to therapy may be size dependent.

Insofar as about 2/3 of men with LUTS have bladder outlet obstruction (BOO), any research protocol in men should consider inclusion of a method to screen for it. At the least, maximum free urinary flow rates and measurement of post-void residual urine should be recorded before and after treatment and the effect of therapy on these parameters should be documented simultaneously with assessment of the primary outcome variables. Synchronous pressure-flow studies are generally desirable and should be included whenever feasible. Several pressure-flow nomograms have been proposed to diagnose obstruction in men. The ICS nomogram is recommended and it is important to specify which if any nomogram is being used [142].

**Recommendations for Research in Men:**

- Measurement of prostate size should be performed before and after treatment (at the same time as continence outcome measures where possible) whenever prostate size is considered to be a potentially important variable, or to change during the intervention and follow up. **HIGH**
- Maximum free flow rate and measurement of post-void residual urine should be recorded pre-treatment and the effect of therapy on these parameters should be documented simultaneously with assessment of the primary outcome variables. **HIGH**
- Participants should be stratified by prostate size at randomization when size is considered to be a potentially important determinant of treatment outcome. **LOW**

2. WOMEN WITH LUTS

**a) Hormonal effects**

Our knowledge of hormonal influences on the lower urinary tract remains limited. Recent RCTs and prospective cohort studies have demonstrated that hormone replacement therapy (HRT) does not improve or may worsen incontinence [143-145]. It therefore seems appropriate that information about menstrual and hormonal status should be an integral part of the baseline history. New studies designed to examine the influence of hormones on incontinence (if considered ethical by an appropriate review board) should include details of hormonal status (premenopausal, postmenopausal without HRT, post-menopausal with HRT), the route and type of HRT (oestrogen only, combined sequential, combined continuous), and whether or not oophorectomy has been performed.

**b) Obstetric History**

The influence of vaginal childbirth on the structure and function of the female pelvis is the focus of much recent and ongoing research but the complex interactions remain incompletely understood. While it is clear that childbirth, and particularly vaginal childbirth increases the risk of incontinence and pelvic organ prolapse, the potential effect of further childbirth on previous or current treatments of incontinence (especially surgery) has yet to be determined.

Potentially confounding variables include: number and route of deliveries (vaginal/Cesarean), use of forceps or vacuum, infant birthweight and head circumference, duration of second stage of labor, use of episiotomy and any vaginal or perineal trauma, and epidural anaesthesia. The importance of these variables will depend upon the specific study design; for randomised studies the allocation process should balance these between groups, but consideration should be given to stratifying or minimizing the randomization against one or more of these important factors, depending on the exact intervention. For epidemiological or observational research each of these factors should be collected and included in univariate and multivariate analyses.

**c) Pelvic Organ Prolapse**

The effect of pelvic organ prolapse on lower urinary tract function remains poorly understood. Pelvic organ prolapse may potentially affect lower urinary tract function by obstruction of the urethral outflow, and thereby mask sphincter weakness (so called “occult” stress incontinence). Emerging evidence suggests that prolapse may contribute to the symptoms of OAB and correction of the prolapse may modulate these symptoms. Thus, it is important to include assessment of pelvic organ prolapse in incontinence research on women. A validated assessment method for prolapse should be used to identify the stage of prolapase; the Pelvic Organ Prolapse Quantification System (POP-Q) [9] is recommended. Research protocols should be developed, either excluding women with prolapse severity beyond a specified stage, or the analysis plan should include stratification for stage of prolapse in randomization, and adjustment for prolapse stage in any analysis. For larger studies where regression analyses are planned, stage of prolapse should be considered a mandatory factor for inclusion. Prolapse should be graded at the same time as the outcome assessment for incontinence and LUTS is performed.
Recommendations for research in women:

- Specific information about menopausal status, hysterectomy, parity/obstetric history, and hormonal status should be included in baseline clinical trial data and controlled for in specified analyses in the research protocol. HIGH
- High quality, symptom and bother scores (e.g., ICIQ-FLUTS, KHQ, PISQ, ICIQ-FLUTSsex) validated in women should be employed when assessing outcomes. HIGH
- Standardized assessment of pelvic organ prolapse (by POPQ) should be performed before treatment and at the time of other outcome assessments in all research where prolapse and continence outcomes are being assessed. HIGH
- Criteria for cure/improvement/failure from incontinence treatment should be defined in the protocol based on patient perception as well as objective and semi-objective instruments such as validated questionnaires, diaries and pad tests. HIGH
- Assessment of the impact of treatment on sexual function should be performed with other outcome assessment when appropriate. MEDIUM

3. FRAIL OLDER AND DISABLED PEOPLE

There are a number of unique and pertinent research issues for this population.

In the frail elderly, important variables include:

- **Demographic information**: Advancing age, white race, and women [145-148] are associated with an increase risk of incontinence and each of these variables should be adjusted for in most analyses.
- **Medical Conditions**: Medical conditions related and unrelated to the lower urinary tract have been shown to increase the risk of incontinence in older women and are especially important to assess in the frail older population [147, 149-151]. Prior hysterectomy has also been suggested as a potential risk factor for incontinence in older women [152-153].
- **Medication Inventory**: Certain medications may exacerbate incontinence and therefore a complete medication inventory is essential [151, 153-155].
- **Physical function**: Mobility is often impaired in the frail elderly and impacts urinary control [156], therefore mobility should be assessed using validated instruments such as the Bartel Orcats or ADL scales [156-157]. Data on walking aids or wheelchairs, gait speed, and manual dexterity may also be collected.

- **Cognitive function**: Cognitive function impairment and/or dementia increase the risk of incontinence [158]. The Mini-Mental Status Scale Examination [130] assesses global cognitive function, and the Confusion Assessment Method (CAM) [159] is a standardized assessment for delirium. A battery of neuropsychological tests to measure subtle impairments in cognitive function include the Buschke Selective Reminding Test (verbal learning and memory) [160], the Digit Symbol (incidental memory, visual scanning and motor speed) [161], and the Trails A (attention and visual) [162].

Outcome measures should be selected for applicability to the frail elderly. Commonly used self-reported measures of frequency of urinary symptoms, severity, or level of bother may not be possible in the cognitively impaired frail elderly patient. Similarly, voiding diaries that have been shown to be valid and reliable in assessing urinary frequency, nocturia, and incontinence episodes by type [138, 162-164] may not be feasible or reliable. Motivated and trained staff, caregivers, or family members may be able to adequately collect diary data; however, this has not been validated.

In nursing home or inpatient settings, wet checks by staff at set intervals have been used in a number of studies. There are limitations to the measurement including visually determining what is “wet” because of new absorbent materials and staff reports not always being reliable or valid, due to underreporting [165-166]. To overcome the limitation of defining wetness and underreporting, 24-hour pad weighing tests [167-168] may be used. Pad weighing tests and wet checks are feasible and can provide important outcome data if staff is well trained and checks are often [14]. New outcome measures specific to the frail older population such as increased socialization or decreased caregiver burden need to be developed.

4. CHILDREN

The conduct of clinical research in children is generally more difficult than in adults. Four overriding issues separate pediatric research from the general recommendations. First, physiology varies widely within the group referred to as “children”; differs from adults, and changes with time. Because children are growing, any treatment, especially pharmacological and surgical therapy, may affect them profoundly in the long term. This is particularly true of the immature brain, nervous system and other incompletely developed systems. Second, compliance with therapy is more complicated as children may depend on caregivers to administer treatment in many studies. Third, reporting of symptoms and outcomes may be difficult. Symptoms reported by a caregiver may not be interpreted in the same way as the child. Finally, the issue of informed consent is complex with children.
Urinary incontinence in children falls into four main categories: neurogenic (myelomeningocele and other less common neurogenic etiologies), monosymptomatic nocturnal enuresis, detrusor overactivity, and dysfunctional voiding without neurologic disease. This issue of age groups is most crucial in children with myelomeningocele. These children are often on medication beginning at a very young age and continuing for many years; the long-term safety of medications in children must be established in all age groups. Therapy for other causes of incontinence in children tends to start at a later age, by which time size is the main difference between children. We recommend that clinical studies have long-term (five years or more), open label extension arms to monitor safety, particularly focusing on normal growth and development and the effects on treatment of liver and central nervous system function.

Assessment of compliance with therapy is always difficult, and even more so with children. Compliance with voiding diaries, a significant issue in the adult population, may be even more problematic with children. The social and family interactions between the child and parent or carer can influence the accuracy of data collection and treatment compliance, both positively and negatively.

Outcome measures are not as well developed in children as in adults. Validated, age-specific symptom and disease-specific quality of life instruments must be developed for the pediatric population. Early efforts in this area have been reported for dysfunctional voiding [169] and daytime incontinence [170]; much more work remains to be done. Invasive urodynamics can be used when deemed appropriate (specifically in the neurogenic population); however, the test-retest reproducibility of urodynamic investigations in children is still under investigation.

Recommendations for Research in Children:

- Long-term follow-up is of critical importance in the pediatric population in order to ascertain the effect of a treatment on normal growth and development. **HIGH**
- Research is needed to develop standardized outcome measures including validated, age-specific symptom and disease-specific quality of life outcome measures. **MEDIUM**

## 5. NEUROGENIC POPULATIONS

### a) Classification

Classification of NLUTD has three primary aims—to aid in discriminating or identifying an unknown underlying neurological disease process, to characterize the nature of the dysfunction so as to develop a treatment plan, and to assess the risk of secondary effects (e.g. on the upper tract) which may influence the necessity and aggressiveness of treatment. The latter two are clearly relevant to research in neurogenic incontinence and must be reflected in study design and patient description.

It is difficult to find a classification system of NLUTD as a base for research that is satisfactory for each of the three aims. The published systems have been reviewed in detail [171]. Both the disease process and the site of the neurologic lesion(s) are relevant in the study of NLUTD, yet even this information is inadequate to predict the functional characteristics for an individual patient. There is no one method that meets the broad needs of classification in this group. Typical or classic cases are often well described but it is especially difficult to describe mixed and incomplete lesions. Thus, classification systems necessarily oversimplify or become extremely cumbersome. Finally, it must be acknowledged that the complexity of neurologic diseases and variations in individual behavior almost always call for a customized approach to therapy, further complicating research in the neurogenic patient.

All of these factors complicate study design as it becomes difficult to create workable inclusion and exclusion criteria that apply to other than a narrow segment of the neurogenic population. Ideally a broad population of potentially relevant participants would be enrolled in research studies with full characterization of both the neurologic condition and the nature of the lower urinary tract dysfunction so as to allow for subgroup analysis.

### b) History and evaluation:

Study planning is best undertaken with the cooperation of urologist, neurologist, and other clinicians who have a specific interest and special training in the neurogenic patient. Baseline data collected by history in subjects with neurogenic lower urinary tract disorders should include:

- bladder volumes by diary or examination (maximum voided or catheterized volume, post voiding residual urine, total capacity);
- mechanism of bladder evacuation: normal (volitional), spontaneous involuntarily (“reflex”), Credé, sterile intermittent catheter (SIC), clean intermittent catheter (CIC), intermittent catheter by second person, or suprapubic or urethral catheter;
- use of external appliances (e.g., diaper or pad use, condom catheter, urethral catheter, suprapubic tube);
- the typical time span of continence (continence interval) following last bladder evacuation and maximal continent bladder volume.
- bowel function, sexual function, and specific neurologic deficits
- the evolution of the condition of (changes in)
the upper tract should be included in the outcomes evaluation of treatment for NLUTD. Where possible these factors should be controlled for in analyses, and stratified for in randomization for interventional studies, or patients with certain factors should be excluded. The details will depend on the research question to be asked.

c) Urodynamics:

Baseline urodynamics are recommended for research studies of neurogenic incontinence, because the symptomatic response is usually of lesser relevance, compared to objective response in NLUTD, especially where NDO or reduced compliance is involved in the dysfunction. Neurogenic disorders commonly cause complex and generalized lower tract dysfunction, often with combined bladder and urethral sphincter abnormalities.

Recommendations for Research in Populations Affected by Neurogenic Lower Urinary Tract Dysfunction:

- Detailed urodynamic studies are recommended for classification of neurogenic lower urinary tract disorders in research studies because the nature of the lower tract dysfunction cannot be accurately predicted from clinical data. Videourodynamic studies are preferred but are not mandatory. LOW
- An area of high priority for research is the development of a classification system to define neurogenic lower urinary tract disorders. Relevant features could include the underlying diagnosis, the symptoms, more precise documentation of the neuromuscular lesion by clinical neurophysiologic testing, and the nature of the urodynamic abnormality. LOW

6. Recommendations for Research in Populations Affected by Faecal Incontinence:

- High quality, validated, symptom and bother scores (e.g., ICIQ-BS, Wexner score, FQIL, Manchester Questionnaire, FISI) should be employed when assessing outcomes HIGH
- Due to the high concordance of faecal and urinary incontinence, and the potential for urinary incontinence therapy to affect bowel function, data on faecal incontinence should be collected at the outset and during trials of urinary incontinence whenever practical. HIGH

7. Recommendations for Research in Populations Affected by Bladder Pain Syndrome (Including Interstitial Cystitis)

- Broader entry criteria should be used to reflect the full spectrum of the BPS/IC patient population. MEDIUM
- The primary endpoint of BPS/IC trials should be patient driven and the Global Response Assessment is recommended. A wide spectrum of secondary endpoints will be useful in defining the effect of treatments. MEDIUM

8. Recommendations for Research in Populations Affected by Pelvic Organ Prolapse

- A validated standardized assessment of prolapse (e.g POP-Q) should be used for baseline and outcome assessments. HIGH
- Complete reporting of outcomes including a validated assessment of anatomy, functional status, and complications is essential. HIGH
- Complications/adverse events (especially for mesh) must be explicitly and completely
- Long term outcomes (> 2 years) of intervention studies are needed HIGH

XIV. Conclusions

The 2012 Consultation examined and classified available data in order to determine the level of evidence that supports our care of incontinent patients. This committee’s contribution was to provide guidance to facilitate high quality research for the next Consultation. All quality research, be it prospective or retrospective, clinical or preclinical, begins with a clear research question and benefits from detailed planning—establishing a clear and relevant hypothesis, developing a trial of appropriate magnitude to accept or reject the hypothesis, and defining methods of adequate sensitivity and specificity to produce credible data.

INTRODUCTION

The 5th International Consultation on Incontinence met from February 23rd – 25th 2012 in Paris and was organised by the International Consultation on Urological Diseases and the EAU, in order to develop consensus statements for the diagnosis, evaluation and treatment of urinary incontinence, faecal incontinence, pelvic organ prolapse and bladder pain syndrome.

The consensus statements are evidence based following a thorough review of the available literature and the global subjective opinion of recognised experts serving on focused committees. The individual committee reports were developed and peer reviewed by open presentation and comment. The Scientific Committee, consisting of the Chairmen of all the committees then refined the final consensus statements. These consensus statements published in 2013 will be periodically re-evaluated in the light of clinical experience, technological progress and research.

6. RECOMMENDATIONS FOR EPIDEMIOLOGY
7. RECOMMENDATIONS FOR CLINICAL RESEARCH

Annex 1: Bladder Charts and Diaries
Annex 2: International Consultation on Incontinence Modular Questionnaire (ICIQ) - ICIQ UI SF (short-form)
The consultation agreed to use the current International Continence Society definitions (ICS) for lower urinary tract dysfunction (LUTD) including incontinence, except where stated. These definitions appeared in the journal Neurourology and Urodynamics (2002; 21:167-178 and 2006; 25:293) or can be viewed on the ICS website: www.icsoffice.org

LUTS are divided into storage symptoms and voiding symptoms.

Urinary incontinence is a storage symptom and defined as the complaint of any involuntary loss of urine. This definition is suitable for epidemiological studies, but when the prevalence of bothersome incontinence is sought, the previous ICS definition of an "Involuntary loss of urine that is a social or hygienic problem ", can be useful.

Urinary incontinence may be further defined according to the patient’s symptoms

- Urgency Urinary Incontinence is the complaint of involuntary leakage accompanied by or immediately preceded by urgency.
- Stress Urinary Incontinence is the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing.
- Mixed Urinary Incontinence is the complaint of involuntary leakage associated with urgency and also with effort, exertion, sneezing and coughing.
- Nocturnal Enuresis is any involuntary loss of urine occurring during sleep.
- Post-micturition dribble and continuous urinary leakage denotes other symptomatic forms of incontinence.

Overactive bladder is characterised by the storage symptoms of urgency with or without urgency incontinence, usually with frequency and nocturia.

Overactive Detrusor Function, is characterised by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked.

The overactive detrusor is divided into:

- Idiopathic Detrusor Overactivity, defined as overactivity when there is no clear cause
- Neurogenic Detrusor Overactivity is defined as overactivity due to a relevant neurological condition.

Urodynamic stress incontinence is noted during filling cystometry, and is defined as the involuntary leakage of urine during increased abdominal pressure, in the absence of a detrusor contraction.

3. Bladder Pain Syndrome *

- Bladder pain syndrome is defined as an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes.

4. Pelvic Organ Prolapse

- Uro-genital prolapse is defined as the symptomatic descent of one or more of: the anterior vaginal wall, the posterior vaginal wall, and the apex of the vagina (cervix/uterus) or vault (cuff) after hysterectiony. Uro-genital prolapse is measured using the POP-Q system.
- Rectal prolapse is defined as circumferential full thickness rectal protrusion beyond the anal margin.

5. Anal Incontinence *

- Anal incontinence, defined as “any involuntary loss of faecal material and/or flatus” and may be divided into:
  - Faecal incontinence, any involuntary loss of faecal material
  - Flatus incontinence, any involuntary loss of gas (flatus)

* To date, these definitions are not included in the current ICS terminology
The following phrases are used to classify diagnostic tests and studies:

- **A highly recommended** test is a test that should be done on every patient.
- **A recommended test** is a test of proven value in the evaluation of most patients and its use is strongly encouraged during initial evaluation.
- **An optional test is a test** of proven value in the evaluation of selected patients; its use is left to the clinical judgement of the physician.
- **A not recommended test** is a test of no proven value.

These conditions are highly prevalent but often not reported by patients. Therefore, the Consultation strongly recommends case finding, particularly in high risk groups.

The main recommendations for this consultation have been abstracted from the extensive work of the 23 committees of the 5th International Consultation on Incontinence (ICI, 2012).

Each committee has written a report that reviews and evaluates the published scientific work in each field of interest in order to give Evidence Based recommendations. Each report ends with detailed recommendations and suggestions for a programme of research.

The initial evaluation should be undertaken, by a clinician, in every patient presenting with symptoms/signs suggestive of these conditions.

# 1. History and General Assessment

Management of a disease such as incontinence requires caregivers to assess the sufferer in a holistic manner. Many factors may influence a particular individual’s symptoms, some may cause incontinence, and may influence the choice and the success of treatment. The following components of the medical history are particularly emphasized:

## a) Review of Systems:

- Presence, severity, duration and bother of any urinary, bowel or prolapse symptoms. Identifying symptoms in the related organ systems is critical to effective treatment planning. It is useful to use validated questionnaires to assess symptoms.
- Effect of any symptoms on sexual function: validated questionnaires including impact on quality of life are a useful part of a full assessment.
- Presence and severity of symptoms suggesting neurological disease.

## b) Past Medical History:

- **Previous conservative, medical and surgical treatment**, in particular, as they affect the genitourinary tract and lower bowel. The effectiveness and side effects of treatments should be noted.
- **Coexisting diseases** may have a profound effect on incontinence and prolapse sufferers, for example asthma patients with stress incontinence will suffer greatly during attacks. Diseases may also precipitate incontinence, particularly in frail older persons.
- **Patient medication**: it is always important to review every patient’s medication and to make an assessment as to whether current treatment may be contributing to the patient’s condition.
- **Obstetric and menstrual history**.
- **Physical impairment**: individuals who have compromised mobility, dexterity, or visual acuity may need to be managed differently.

## c) Social History:

- **Environmental issues**: these may include the social, cultural and physical environment.
• **Lifestyle**: including exercise, smoking and the amount and type of food/fluid intake.

**d) Other Treatment Planning Issues:**

• **Desire for treatment** and the extent of treatment that is acceptable

• **Patient goals** and expectations of treatment

• **Patient support** systems (including caregivers).

• **Cognitive function**: all individuals need to be assessed for their ability to fully describe their symptoms, symptom bother and quality of life impact, and their preferences and goals for care. They must be able to understand proposed management plans and to discuss, where appropriate, alternative treatment options. In some groups of patients formal testing is essential e.g. cognitive function testing for individuals for whom the clinician has concerns regarding memory deficits and/or inattention/confusion, and depression screening for individuals for whom the clinician has concerns about abnormal affect. Proxy respondents, such as family and caregivers, may be used to discuss history, goals of care, and treatment for individuals with dementia, but only if the individual is incapable of accurate reporting or weighing treatment decisions.

2. **Physical Examination**

The **more complicated** the history and the more extensive and/or invasive the proposed therapy, the **more complete** the examination needs to be. Depending on the patient’s symptoms and their severity, there are a number of components in the examination of patients with incontinence and/or pelvic organ prolapse.

Physical examination should be performed regardless of whether the patient is a child, a woman, a man, someone with neurological disease or a frail elderly person.

**a) General status:**

• Mental status

• Obesity (BMI)

• Physical dexterity and mobility

**b) Abdominal/flank examination:** for masses, bladder distention, relevant surgical scars

**c) Pelvic examination:**

• Examination of the perineum and external genitalia including tissue quality and sensation.

• Vaginal (half-speculum) examination for pelvic organ prolapse (POP)

• Bimanual pelvic and anorectal examination for pelvic mass, pelvic floor muscle function, etc

• Stress test for urinary incontinence.

**d) Neurological testing (see chapter on assessment)**

3. **Urinalysis**

In patients with urinary symptoms a _urinary tract infection_ is a readily detected, and easily treatable cause of LUTS, and urine testing is highly recommended. Testing may range from dipstick testing, to urine microscopy and culture when indicated.

**Conclusion**

For simple treatments, particularly non-invasive and inexpensive therapies, management may start without the need for the further investigations listed below.

---

**II. RECOMMENDED FURTHER ASSESSMENT PRIOR TO, OR DURING, SPECIALIST ASSESSMENT**

The tests below are recommended when the **appropriate indication(s) is present**. Some recommended tests become highly recommended in specific situations.

This section should also be read in conjunction with the relevant committee reports.

1. **Further Symptom and Health-Related QoL Assessment**

In patients with _urinary symptoms_ the use of a _simple frequency volume chart_ or _bladder diary_ (examples in Annex 1) is highly recommended to document the frequency of micturition, the volumes of urine voided, incontinence episodes and the use of incontinence pads.
The use of the highest quality questionnaires (Grade A, where available) is recommended for the assessment of the patient’s perspective of symptoms of incontinence and their impact on quality of life.

The ICIQ is highly recommended (Grade A) for the basic evaluation of the patient’s perspective of urinary incontinence, with other Grade A questionnaires recommended for more detailed assessment. Further development is required in the areas of pelvic organ prolapse, bladder pain syndrome, and for specific patient groups, as only Grade B questionnaires are currently available (see Annex 1).

2. Renal Function Assessment

Standard biochemical tests for renal function are recommended in patients with urinary incontinence and a possibility of renal impairment.

3. Uroflowmetry

Uroflowmetry with the measurement of post void residual urine is recommended as a screening test for symptoms suggestive of urinary voiding dysfunction or physical signs of POP or bladder distension.

4. Estimation of Post Void Residual Urine (PVR)

In patients with suspected voiding dysfunction, PVR should be part of the initial assessment if the result is likely to influence management, for example, in neurological patients.

5. Imaging

Although routine imaging is not recommended, imaging of the lower urinary tract and pelvis is highly recommended in those with urinary symptoms whose initial evaluation indicates a possible co-existing lower tract or pelvic pathology. Initial imaging may be by ultrasound, or plain X ray.

Imaging of the upper urinary tract is highly recommended in specific situations. These include:

- Haematuria,
- Neurogenic urinary incontinence e.g. myelodysplasia, spinal cord trauma,
- Incontinence associated with significant post-void residual,
- Co-existing loin/kidney pain,
- Severe pelvic organ prolapse, not being treated
- Suspected extra-urethral urinary incontinence,
- Children with incontinence and UTIs, where indicated
- Urodynamic studies which show evidence of poor bladder compliance.

In anorectal conditions, anal US or MRI prior to anal sphincter surgery is highly recommended, when obvious anatomic defects are not evident. Defaecating proctography or dynamic MRI is recommended in suspected rectal prolapse which cannot be adequately confirmed by physical examination.

6. Endoscopy

Although routine cysto-urethroscopy is not recommended, LUT endoscopy is highly recommended:

- When initial testing suggests other pathologies, e.g. haematuria
- When pain or discomfort feature in the patient’s LUTS, these may suggest an intravesical lesion
- When appropriate in the evaluation of vesicovaginal fistula and extra-urethral urinary incontinence (in childbirth fistulae, endoscopy is often unnecessary).

In anorectal conditions, proctoscopy or flexible sigmoidoscopy should routinely be performed in the evaluation of patients with faecal incontinence. Colonoscopy, air contrast barium enema or CT colography is highly recommended in the presence of unexplained change in bowel habit, rectal bleeding or other alarm symptoms or signs (see Basic Assessment chapter).

7. Urodynamic Testing

a) Urodynamic evaluation is recommended

- When the results may change management, such as prior to most invasive treatments for UI and POP,
- After treatment failure, if more information is needed in order to plan further therapy,
- As part of both initial and long-term surveillance programmes in some types of neurogenic lower urinary tract dysfunction,
- In “complicated incontinence” (for details please see relevant subcommittee reports).
b) The aims of Urodynamic Evaluation are

- To reproduce the patient’s symptoms and correlate these with urodynamic findings
- To assess bladder sensation
- To detect detrusor overactivity
- To assess urethral competence during filling
- To determine detrusor function during voiding
- To assess outlet function during voiding
- To assess residual urine

8. Small bowel follow-through, CT entography or capsule endoscopy.

These tests are recommended in the presence of unexplained diarrhoea or when Crohn’s disease is suspected.

III. OPTIONAL DIAGNOSTIC TESTS

1. Additional Urodynamic Testing

Video-urodynamics may be useful in the management of UI in children, in patients who fail surgery and in some neurogenic patients, to obtain additional anatomical information. Both US and X-ray imaging can be used.

If a more detailed estimate of urethral function is required, then the following optional tests may give useful information:
  - Urethral pressure profilometry
  - Abdominal leak point pressures
  - Video-urodynamics
  - Electromyography

If initial urodynamics have failed to demonstrate the cause for the patient’s incontinence then the following tests are optional:
  - repeated routine urodynamics
  - ambulatory urodynamics

2. Pad Testing

Pad testing is an optional test for the routine evaluation of urinary incontinence and, if carried out, a 24 hr test is suggested.

3. Neurophysiological Testing and Imaging

The information gained by clinical examination and urodynamic testing may be enhanced by neuro-physiological testing of striated muscle and nervous pathways.

Appropriately trained personnel should perform these tests. The following neuro-physiological tests can be considered in patients with peripheral lesions prior to treatment for lower urinary tract or anorectal dysfunction.
  - Concentric needle EMG
  - Sacral reflex responses to electrical stimulation of penile or clitoral nerves.

Pudendal nerve latency testing is not recommended.

Further imaging of the central nervous system, including spine, by myelography, CT and MRI may prove useful if simple imaging, for example by spinal X-rays in patients with suspected neurological disease, proves normal.

4. Further Imaging

Cysto-urethrography, US, CT and MRI may have an indication:
  - Suspected pelvic floor dysfunction
  - Failed surgery, such as recurrent posterior vaginal wall prolapse or failed sling surgery
  - Suspected fixed urethra

5. Cysto-urethroscopy

This is an optional test in patients with complicated or recurrent UI (e.g. after failed SUI surgery)

6. Anorectal physiology testing

Anorectal manometry is useful to assess resting and squeeze anal pressures.
3. Management Consensus statements

The consensus statements are derived from the detailed work in the committee reports on the management of incontinence in children, men, women, the frail elderly and neurological patients, as well as those with obstetric fistula, pelvic organ prolapse, bladder pain syndrome, and faecal incontinence. The management of incontinence is presented in algorithm form with accompanying notes.

The Consultation recognises that no algorithm can be applied to every patient and each patient’s management must be individualised. There are algorithms for

I. Urinary Incontinence in Children
II. Urinary Incontinence in Men
III. Urinary Incontinence in Women
IV. Fistulae
V. Pelvic Organ Prolapse
VI. Urinary Incontinence in Neurological Patients
VII. Bladder Pain Syndrome
VIII. Faecal Incontinence in Non-Neurological Patients
IX. Faecal Incontinence in Neurological Patients
X. Urinary and Faecal Incontinence in Frail Older Men and Women

These algorithms are divided into two for groups I to III, VII and X. The two parts, initial management and specialised management require a little further explanation.

Although the management algorithms are designed to be used for patients whose predominant problem is incontinence, there are many other patients in whom the algorithms may be useful such as those patients with urgency and frequency, so-called “OAB dry”

The algorithms for initial management

are intended for use by all clinicians including health care assistants, nurses, physiotherapists, generalist doctors and family doctors as well as by specialists such as urologists, geriatricians and gynaecologists. The consultation has attempted to phrase the recommendations in the basic algorithms in such a way that they may be readily used by clinicians in all countries of the world, both in the developing and the developed world.

The specialised algorithms

are intended for use by specialists. The specialised algorithms, as well as the initial management algorithms are based on evidence where possible, and on the expert opinion of the 400 healthcare professionals who took part in the Consultation. In this consultation, committees ascribed levels of evidence to the published work on the subject and devised grades of recommendation to inform patient management.

It should be noted that these algorithms, dated December 2012, represent the Consultation consensus at that time. Our knowledge, developing from both a research base and because of evolving expert opinion, will inevitably change with time. The Consultation does not wish those using the algorithms to believe they are “carved in tablets of stone”: there will be changes both in the relatively short term and the long term.

Essential components of basic assessment

Each algorithm contains a core of recommendations in addition to a number of essential components of basic assessment listed in sections I to III.

- General assessment
- Symptom assessment
- Assessment of quality of life impact
- Assessment of the desire for treatment
- Physical examination
- Urinalysis

Joint decision making

The patient’s desires and goals for treatment: Treatment is a matter for discussion and joint decision making between the patient and his or
her health care advisors. This process of consultation includes the specific need to assess whether or not the sufferer of incontinence wishes to receive treatment and, if so, what treatments he or she would favour. Implicit in this statement is the assumption that the health care provider will give an appropriate explanation of the patient’s problem and the alternative lines of management, and the indications and the risks of treatment. The assumption that patients almost always wish to have treatment is flawed, and the need to consult the patient is paramount.

In each algorithm, treatments are listed in order of simplicity, the least invasive being listed first. This order does not imply a scale of efficacy or cost, two factors which need to be considered in choosing the sequence of therapy. The order is likewise not meant to imply a suggested sequence of therapy, which should be determined jointly by the treating health care provider and the patient, considering all the relevant factors listed above.

In the initial management algorithms, treatment is empirically based, whilst the specialised management algorithms usually rely on precise diagnosis from urodynamics and other testing.

The assumption is made that patients will be reassessed at an appropriate time to evaluate their progress.

◆ Use of Continence Products

The possible role of continence products should be considered at each stage of patient assessment and treatment, and if treatment is not (fully) successful, subsequent management.

- **Firstly**, intermittent catheterisation or indwelling catheter drainage often have a role to play in addressing urinary retention.
- **Secondly**, assisted toileting using such devices as commodes, bedpans, and handheld urinals may help to achieve dependent continence* where access, mobility and/or urgency problems undermine a patient’s ability to maintain independent continence*, be it urinary and / or faecal.
- **Finally**, containment products (to achieve contained incontinence*) for urine and / or faeces find an essential role in enhancing the quality of life of those who:
  - Elect not to pursue treatment options
  - Are awaiting treatment
  - Are waiting for treatment to take effect
  - Are unable to be (fully) cured

Further guidance and care algorithms on which products might be suitable for a given patient are given in Committee 20.

I. URINARY INCONTINENCE IN CHILDREN

A. INITIAL MANAGEMENT

Children present specific management problems for a variety of reasons: assessment requires help from their parents and caregivers; consent to treatment may be problematic; and cooperation in both assessment and treatment may be difficult.

1. Initial assessment should involve a detailed investigation of voiding and bowel habits using bladder/bowel diaries and structured and validated questionnaires.

The child’s social environment and general and behavioural development should also be formally assessed and recorded. Physical examination should be done to detect a palpable bladder, faecal loading and exclude anatomic and neurogenical causes. Urine analysis and culture is sufficient to exclude the presence of infection. If possible, the child should be observed voiding.

Referrals for specialist treatment are recommended for children who have complicated incontinence associated with:

- Recurrent and febrile urinary infection
- Voiding symptoms or evidence of poor bladder emptying
- Urinary tract anomalies
- Previous pelvic surgery
- Neuropathy or neuropathic origin
- Bowel dysfunction not responsive to treatment
- Comorbid behavioural (e.g. ADHD and ODD) and emotional disorders.

Initial treatment is recommended for the remaining patients who have:

- Nocturnal enuresis without other symptoms (mono-symptomatic enuresis).
- Daytime symptoms of frequency, urgency, voiding postponement, straining, interrupted voiding, urgency incontinence with or without night-time wetting.

2. Treatment

Initial treatment for mono-symptomatic nocturnal enuresis should include:

- Parental and child counselling and motivation
- Review of bladder diary with attention to night-time polyuria
- A choice between either bed wetting alarm (Grade A) and antidiuretic hormone analogues of desmopressin (Grade A). It may be a parental and child choice if advantages and disadvantages are well explained.

Daytime incontinence should be managed holistically including:

- Counselling, timed voiding, behaviour modification and bowel management when necessary (Grade B);
- Antimuscarinics may be used if there are symptoms that suggest bladder overactivity (Grade A)
Initial Management of Urinary Incontinence in Children

**HISTORY/ SYMPTOM ASSESSMENT**

- Nocturnal enuresis (monosymptomatic)
- Daytime ± Nighttime wetting ± Urgency / frequency

**CLINICAL ASSESSMENT**

- General assessment (see relevant chapter)
  - Physical examination: abdominal, perineal, ext. genitalia, back/spine, neurological
  - Assess bowel function -> if constipated, treat and reassess
  - Urinalysis ± Urine culture -> if infected, treat and reassess
  - Assess post-void residual urine by abdominal examination (optional: by ultrasound)

**PRESUMED DIAGNOSIS**

- MONOSYMPTOMATIC NOCTURNAL ENURESIS
- URGENCY INCONTINENCE
- RECURRENT INFECTION
- DYSFUNCTIONAL VOIDING

**TREATMENT**

- **MONOSYMPTOMATIC NOCTURNAL ENURESIS**
  - Explanation/education
  - Enuresis Diary
  - Alarm
  - Desmopressin

- **URGENCY INCONTINENCE**
  - Explanation/education
  - Fluid/voiding regime
  - Bladder training
  - Antimuscarinics
  - Alarm (bed wetting)

- **RECURRENT INFECTION**

- **DYSFUNCTIONAL VOIDING**

**SPECIALISED MANAGEMENT**

- “Complicated” Incontinence associated with:
  - Urinary tract anomaly
  - Neuropathy
  - Pelvic surgery
  - Voiding (emptying) symptoms
  - Recurrent urinary infection
  - Bowel dysfunction not responsive to treatment
  - Comorbid behavioral and emotional disorders

*At any stage of the patient’s care pathway, management may need to include continence products*
I. URINARY INCONTINENCE IN CHILDREN

B. SPECIALISED MANAGEMENT

Two groups of children with “complicated” incontinence should have specialist management from the outset (Fig. 2).

- Children whose incontinence is due to, or associated with, urinary tract anomalies and neuropathy.
- Children without urinary tract anomalies, but with recurrent febrile infection and, proven or suspected, lower urinary tract dysfunction.
- Children who fail the basic treatment, but who have neither neurogenic nor anatomical problems, should also receive specialist management.

Assessment and treatment should follow evidence-based practice parameters and guidelines.

1. Assessment

- As part of further assessment, the measurement of urine flow (in children old enough), together with the pelvic ultrasound estimate of residual urine and appearance of the bladder wall and rectum are highly recommended. An evaluation of the upper urinary tracts with ultrasound is also highly recommended. Those who do not improve with treatment and have neither neurogenic nor anatomical problems should be reassessed using micturition charts, symptom scores, urinalysis, uroflowmetry and residual urine determination.

If there are recurrent and febrile infections, upper tract imaging and possibly a VCUG should be considered. However, endoscopy is rarely indicated.

- Urodynamics should be considered:
  - If the type and severity of lower tract dysfunction cannot be explained by clinical findings.
  - If invasive treatment is under consideration, for example, stress incontinence surgery if there is sphincteric incompetence, or bladder augmentation if there is detrusor overactivity.
  - If upper tract dilatation exists and is thought to be due to bladder dysfunction. Invasive urodynamic studies are generally not recommended if the child has normal upper tract imaging and is to be treated by noninvasive means.

- Spinal Imaging (US/X-ray/MRI) may be needed if a bony abnormality or neurological condition is suspected.

2. Treatment

The treatment of incontinence associated with urinary tract anomalies is complex and cannot easily be dealt with in an algorithm. In many children more than one pathophysiology demands treatment. If there are complex congenital abnormalities present, the treatment is mostly surgical and it should be individualised according to the type and severity of the problem (please see Children’s Committee Report).

Care should be given by specialist children’s nurses and therapists.

- Initial treatment should be non-surgical.
  - For stress urinary incontinence (SUI): pelvic floor muscle training (Grade C).
  - For suspected bladder overactivity (OAB): fluid/voiding regimes and antimuscarinics (Grade A).
  - For voiding dysfunction: timed voiding, voiding re-education, pelvic floor muscle relaxation (+/- biofeedback), intermittent catheterisation (when PVR >30% of bladder capacity) (Grade B/C).
  - For bowel dysfunction: high fibre diet and laxatives as appropriate.

The child’s progress should be assessed and, if quality of life is still significantly impaired, or if the upper urinary tracts are at risk, surgical treatment is likely to be necessary.

- If surgical treatment is required, then urodynamic studies are recommended to confirm the diagnosis.
  - For SUI, sling surgery, bulking agent injection and AUS may be considered.
  - For DO/poor compliance, botulinum toxin (for DO, and off-label) and bladder augmentation may be performed.
  - If the child cannot do IC then a Mitrofanoff channel may be needed.
Specialised Management of Urinary Incontinence in Children

**EXPERT HISTORY & PHYSICAL EXAMINATION**

**CLINICAL ASSESSMENT**

**DIAGNOSIS**

**TREATMENT**

Incontinence without suspicion of urinary tract anomaly
- Urinalysis: if UTI, treat and reassess as appropriate
- Treat bowel dysfunction and reassess
- Renal / bladder ultrasound
- Assess post void residual
- Flow rates ± electromyography
- Behavioural Evaluation

if abnormal -->
- Consider:
  - Micturating cystogram
  - Renal scintigram
  - Urodynamics
  - Cystourethroscopy
  - Spinal imaging

- Timed voiding
- Pelvic floor relaxation ± biofeedback.
- Pharmacotherapy - Antimuscarinics
  - α-blockers
- Intermittent cath.
- Bowel management
- Antibiotic if infection

- Correct anomaly (see: surgical treatment in children)

Incontinence with suspicion of urinary tract anomaly

- Pelvic floor muscle training
- AUS
- Sling
- Bulking agent injection
- Fluid/voiding regime
- Antimuscarinics
- Bowel management
- Botulinum toxin
- Bladder augmentation

*At any stage of the patient’s care pathway, management may need to include continence products*
II. URINARY INCONTINENCE IN MEN

A. INITIAL MANAGEMENT

1. Initial Assessment should identify:

- **Complicated** incontinence group
  Those with pain or with haematuria, recurrent infections, suspected or proven poor bladder emptying (for example due to bladder outlet obstruction), or incontinence following pelvic irradiation or radical surgery, are recommended for *specialised management*.

*Poor bladder emptying* may be suspected from symptoms, physical examination or if imaging has been performed by X-ray or ultrasound after voiding.

- **Four other main groups** of men should be identified by initial assessment as being suitable for *initial management*.
  - Those with *post-micturition dribble* alone,
  - Those with *overactive bladder* (OAB) symptoms: urgency with or without urgency incontinence, together with frequency and nocturia
  - Those with *stress incontinence* (most often post-prostatectomy),
  - Those with *mixed* urgency and stress incontinence (most often post-prostatectomy)

2. Management

- For men with *post-micturition dribble*, this requires no assessment and can usually be treated by teaching the man how to do a strong pelvic floor muscle contraction after voiding, or manual compression of the bulbous urethra directly after micturition. (Grade B)

- For men with *stress, urgency or mixed* urgency / stress incontinence, initial treatment should include appropriate lifestyle advice, pelvic floor muscle training, scheduled voiding regimes, behavioural therapies and medication. In particular:
  - Lifestyle interventions (Grade D)
  - Supervised pelvic floor muscle training for men with post radical prostatectomy SUI (Grade B)
  - Scheduled voiding regimes for OAB (Grade C)
  - Antimuscarinic drugs for OAB symptoms with or without urgency incontinence (Grade B) if the patient has no evidence of significant post-void residual urine
  - $\alpha$-adrenergic antagonists (a-blockers), can be added if it is thought that there may also be bladder outlet obstruction. (Grade C)

- **Should initial treatment be unsuccessful** after a reasonable period of time (for example, 8-12 weeks), *specialist advice* is highly recommended.

Clinicians are likely to wish to treat the *most bothersome symptom* first in men with symptoms of *mixed* incontinence.
Initial Management of Urinary Incontinence in Men

**HISTORY**
- Post-micturition dribble
- Incontinence on exertion (usually post-prostatectomy)
- Incontinence with mixed symptoms
- Urgency / frequency, with or without urgency incontinence

**GENERAL ASSESSMENT**
- General assessment (see relevant chapter)
- Urinary symptom assessment and symptom score (including frequency-volume chart and questionnaire)
- Assess quality of life and desire for treatment
- Physical examination: abdominal, rectal, sacral, neurological
- Urinalysis ± urine culture → if infected, treat and reassess
- Assessment of pelvic floor muscle function
- Assess post-void residual urine

**CLINICAL ASSESSMENT**

**PREMISED DIAGNOSIS**

**STRESS INCONTINENCE**
- Presumed due to sphincteric incompetence

**MIXED INCONTINENCE**
- Treat most bothersome symptom first

**URGENCY INCONTINENCE**
- Presumed due to detrusor overactivity

**DISCUSS TREATMENT OPTIONS WITH THE PATIENT**
- Lifestyle interventions
- Pelvic floor muscle training ± biofeedback
- Scheduled voiding (bladder training)
- Incontinence products
- Antimuscarinics (OAB ± urgency incontinence) and α-adrenergic antagonists (if suspected bladder outlet obstruction)

**SPECIALISED MANAGEMENT**

*At any stage of the patient’s care pathway, management may need to include continence products*
II. URINARY INCONTINENCE IN MEN

B. SPECIALISED MANAGEMENT

The specialist may first reinstitute initial management if it is felt that previous therapy had been inadequate.

1. Assessment

- Patients with “complicated” incontinence referred directly to specialised management, are likely to require additional testing, such as cytology, cystourethroscopy and urinary tract imaging.

If these tests prove normal then those individuals can be treated for incontinence by the initial or specialised management options as appropriate.

If symptoms suggestive of detrusor overactivity, or of sphincter incompetence persist, then urodynamic studies are advisable in order to arrive at a precise diagnosis, prior to invasive treatment.

2. Treatment

When basic management has failed and if the patient’s incontinence markedly disrupts his quality of life then invasive therapies should be considered.

- For sphincter incompetence the recommended option is the artificial urinary sphincter (Grade B). Other options, such as a male sling, may be considered (Grade C).

- For idiopathic detrusor overactivity, (with intractable overactive bladder symptoms) the recommended therapies are: Botulinum toxin A (Grade B), neuromodulation (Grade C), and bladder augmentation (Grade C).*

*Note: At the time of writing, botulinum toxin for idiopathic DO is being used “off-label”.

- When incontinence has been shown to be associated with poor bladder emptying and detrusor underactivity, it is recommended that effective means are used to ensure bladder emptying, for example, intermittent catheterisation (Grade B/C).

- If incontinence is associated with bladder outlet obstruction, then consideration should be given to surgical treatment to relieve obstruction (Grade B). α-blockers and/or 5α-reductase inhibitors would be an optional treatment (Grade C). There is increased evidence for the safety of antimuscarinics for overactive bladder symptoms in men, chiefly in combination with an α-blocker (Grade B).
Specialised Management of Urinary Incontinence in Men

1. **HISTORY/SYMPTOM ASSESSMENT**
   - **Post-prostatectomy incontinence**
   - **Incontinence with urgency / frequency**
   - **“Complicated” Incontinence:**
     - Recurrent incontinence
     - Incontinence associated with:
       - Prostate or pelvic irradiation
       - Radical pelvic surgery
   - Consider urodynamics and imaging of the urinary tract
   - Urethrocystoscopy (if indicated)

2. **CLINICAL ASSESSMENT**
   - **STRESS INCONTINENCE**
     - due to sphincteric incompetence
   - **MIXED INCONTINENCE**
     - Treat major component first
   - **URGENCY INCONTINENCE**
     - due to detrusor overactivity (during filling)
     - with coexisting bladder outlet obstruction
     - with coexisting underactive detrusor (during voiding)

3. **DIAGNOSIS**
   - Consider:
     - Urethrocystoscopy
     - Further imaging
     - Urodynamics
   - Lower urinary tract anomaly/pathology
   - Post-prostatectomy incontinence
   - Incontinence with urgency/frequency

4. **TREATMENT**
   - If initial therapy fails:
     - Artificial urinary sphincter
     - Male sling (see chapter 13)
   - If initial therapy fails:
     - α-blockers, 5ARI
     - Correct anatomic bladder outlet obstruction
     - Antimuscarinics
   - If initial therapy fails:
     - Botulinum toxin A
     - Neuromodulation
   - Correct anomaly
   - Treat pathology

* At any stage of the patient’s care pathway, management may need to include continence products
III. URINARY INCONTINENCE IN WOMEN

A. INITIAL MANAGEMENT

1. Initial assessment should identify:

- **“Complicated” incontinence group.**
  Those with pain or haematuria, recurrent infections, suspected or proven voiding problems, significant pelvic organ prolapse or who have persistent incontinence or recurrent incontinence after pelvic irradiation, radical pelvic surgery, previous incontinence surgery, or who have a suspected fistula, should be referred to a specialist.

- **Three other main groups** of patients should be identified by initial assessment.
  - Women with **stress incontinence** on physical activity
  - Women with **urgency, frequency** with or without urgency incontinence
  - Those women with **mixed** urgency and stress incontinence

Abdominal, pelvic and perineal examinations should be a routine part of physical examination. Women should be asked to perform a “stress test” (cough and strain to detect leakage likely to be due to sphincter incompetence). Any pelvic organ prolapse or urogenital atrophy should be assessed. Vaginal or rectal examination allows the assessment of voluntary pelvic floor muscle function, an important step prior to the teaching of pelvic floor muscle training.

2. Treatment

- For women with **stress, urgency or mixed** urinary incontinence, initial treatment should include appropriate lifestyle advice, pelvic floor muscle training, PFMT), scheduled voiding regimes, behavioural therapies and medication. In particular:
  - **Advice** on caffeine reduction (Grade B) and weight reduction (Grade A)
  - **Supervised pelvic floor muscle training** (Grade A), **supervised vaginal cones training** for women with stress incontinence (Grade B)
  - **Supervised bladder training** (Grade A) for OAB.
  - **If oestrogen deficiency** and/or **UTI** is found, the patient should be treated at initial assessment and then reassessed after a suitable interval using vaginal oestrogens. (Grade B).
  - **Antimuscarinics** for OAB symptoms with or without urgency incontinence (Grade A); duloxetine* may be considered for stress urinary incontinence (Grade B)

PFMT should be based on sound muscle training principles such as specificity, overload progression, correct contraction confirmed prior to training, and use of the Knack for 12 weeks before reassessment and possible specialist referral.

Clinicians are likely to wish to treat the **most bothersome symptom first** in women with symptoms of mixed incontinence. (Grade C).

- Some women with significant **pelvic organ prolapse** can be treated by vaginal devices that treat both incontinence and prolapse (incontinence rings and dishes).

*Duloxetine is not approved for use in United States. It is approved for use in Europe for severe stress incontinence (see committee report on pharmacological management for information regarding efficacy, adverse events, and 'black box' warning by the Food and Drug Administration of the United States).
Initial Management of Urinary Incontinence in Women

HISTORY

- General assessment (see relevant chapter)
- Urinary symptom assessment (including frequency-volume chart and questionnaire)
- Assess quality of life and desire for treatment
- Physical examination: abdominal, pelvic and perineal
- Cough test to demonstrate stress incontinence if appropriate
- Urinalysis ± urine culture -> if infected, treat and reassess

If appropriate
- Assess oestrogen status and treat as appropriate
- Assess pelvic floor muscle function
- Assess post-void residual urine

CLINICAL ASSESSMENT

PRESUMED DIAGNOSIS

STRESS INCONTINENCE
presumed due to sphincteric incompetence

MIXED INCONTINENCE
Treat most bothersome symptom first

OAB -with or without URGENCY INCONTINENCE presumed due to detrusor overactivity

- Life style interventions.
- Pelvic floor muscle training for SUI, MUI, or OAB
- Bladder retraining for OAB
- Antimuscarinics (OAB ± urgency incontinence) or Duloxetine** (SUI)

TREATMENT *

- Other adjuncts, such as electrical stimulation
- Vaginal devices

SPECIALISED MANAGEMENT

Complicated incontinence
- Recurrent incontinence
- Incontinence associated with:
  - Pain
  - Haematuria
  - Recurrent infection
  - Significant voiding symptoms
  - Pelvic irradiation
  - Radical pelvic surgery
  - Suspected fistula

* At any stage of the patient’s care pathway, management may need to include continence products

** Subject to local regulatory approval (see black box warning).
III. URINARY INCONTINENCE IN WOMEN

B. SPECIALISED MANAGEMENT

1. Assessment

Women who have “complicated” incontinence (see initial algorithm) may need to have additional tests such as cytology, cystourethroscopy or urinary tract imaging. If these tests are normal then they should be treated for incontinence by the initial or specialised management options as appropriate.

Those women who have failed initial management and whose quality of life is impaired are likely to request further treatment. If initial management has been given an adequate trial then interventional therapy may be desirable. Prior to intervention urodynamic testing is highly recommended, when the results may change management. It is used to diagnose the type of incontinence and therefore inform the management plan. Within the urodynamic investigation urethral function testing by urethral pressure profile or leak point pressure is optional.

Systematic assessment for pelvic organ prolapse is highly recommended and it is suggested that the POP-Q method should be used in research studies. Women with co-existing pelvic organ prolapse should have their prolapse treated as appropriate.

2. Treatment

- If urodynamic stress incontinence is confirmed then the treatment options that are recommended for patients with some degree of bladder-neck and urethral mobility include the full range of non-surgical treatments, as well as retropubic suspension procedures, (Grade A) and bladder neck/sub-urethral sling operations:(Grade A). The correction of symptomatic pelvic organ prolapse may be desirable at the same time.

For patients with limited bladder neck mobility, bladder neck sling procedures, (Grade A) injectable bulking agents (Grade B) and the artificial urinary sphincter (Grade B) can be considered.

- Refractory urgency incontinence (overactive bladder) secondary to idiopathic detrusor overactivity may be treated by botulinum toxin A (Grade C)*, neuromodulation (Grade A) or bladder augmentation (Grade C).

- Those patients with voiding dysfunction leading to significant post-void residual urine (for example, >30% of total bladder capacity) may have bladder outlet obstruction or detrusor underactivity. Prolapse is a common cause of voiding dysfunction.

* At the time of writing, botulinum toxin is being used “off-label” and with caution.
Specialised Management of Urinary Incontinence in Women

**HISTORY/SYMPtom ASSESSMENT**
- Incontinence on physical activity
- Incontinence with mixed symptoms
- Incontinence with urgency / frequency

**CLINICAL ASSESSMENT**
- Assess for pelvic organ mobility / prolapse
- Consider imaging of the UT/ pelvic floor
- Urodynamics (see notes)

**DIAGNOSIS**
- URODYNAMIC STRESS INCONTINENCE (USI)
- MIXED INCONTINENCE USI/DOI
- DETRUSOR OVERACTIVITY INCONTINENCE (DOI)
- INCONTINENCE associated with poor bladder emptying

**TREATMENT**
If initial therapy fails:
- Stress incontinence surgery
  - bulking agents
  - tapes and slings
  - colposuspension
- Botulinum toxin
- Neuromodulation
- Bladder augmentation

If initial therapy fails:
- Correct anatomic bladder outlet obstruction (e.g. genito-urinary prolapse)
- Intermittent catheterization

If initial therapy fails:
- Stress incontinence surgery
  - bulking agents
  - tapes and slings
  - colposuspension
- Botulinum toxin
- Neuromodulation
- Bladder augmentation

“Complicated” incontinence:
- Recurrent incontinence
- Incontinence associated with:
  - Pain
  - Haematuria
  - Recurrent infection
  - Voiding symptoms
  - Pelvic irradiation
  - Radical pelvic surgery
  - Suspected fistula

Consider:
- Urethrocystoscopy
- Further imaging
- Urodynamics

HISTORY/ SYMPTOM ASSESSMENT
- Clinical assessment

TREATMENT *
- At any stage of the patient’s care pathway, management may need to include continence products
In the developing world fistulae are often a consequence of poor peri-natal care. The epidemiology, aetiology, diagnosis, treatment and prevention have been described in detail during the recent International Consultation on Obstetric Fistula.

In contrast to the field of obstetrical fistulae where the numbers of patients are high, the prevalence of non-obstetrical fistulae seems to be much lower. The published series have small patient numbers, are usually retrospective and have a low level of evidence. The published obstetrical series show impressive numbers and demonstrate the level of skill that many of the fistula surgeons have obtained while working in difficult and isolated situations.

Both committees are convinced that obstetric fistula surgeons in the developing world and reconstructive pelvic surgeons in the developed countries can learn a lot from each other.

**GENERAL INTRODUCTION**

**PART I: OBSTETRIC FISTULA**

**INTRODUCTION**

Epidemiological studies on obstetric fistulae are inadequate.

The incidence of fistulae is expressed per 1,000 deliveries and would appear to be between 0.1% rising to 1.5 per 1,000 pregnancies in rural areas.

The major risk factors appear to be age at first marriage, short stature, pregnancy with a male child rather than a female child, failure to attend antenatal care, low socio-economic status, low social class, lack of employment and illiteracy.

The consequences of obstetric fistulae include divorce (16-92%), social isolation, worsening poverty, malnutrition, sexual dysfunction and mental illness (including anxiety/depression), insomnia, general ill health and thoughts of worthlessness and suicide.

**ASSESSMENT**

Early detection of fistulae could improve by examining all women after their delivery or Caesarian section who suffered prolonged labour and who are at risk of developing an obstetric fistula.

Associated pathologies should be actively searched for and should be taken into account in the treatment plan: all components of the ‘obstructed labour injury complex’ should be examined.

Classification of fistulae is recommended. Although many classification systems exist, the committee recommends the use of the Waaldijk classification, since it is supported by the largest amount of data. It involves precise measurements of the distances between the external urinary meatus and the distal edge of the fistulae, together with the widest diameter of the fistulae. Fistulae are classified into types 1, 2 and 3. Type 3 fistulae are those fistulae other than vesico-vaginal fistulae (VVF) and include recto-vaginal fistulae (VVF) and uretero-vaginal fistulae. (Grade C)

The formal classification of the fistulae should be done under anaesthesia when the patient is on the operation table, just before surgery.
Management of VVF depends on whether the fistulae is diagnosed within two or three months of its occurrence or whether the woman presents late with an established fistula. (Algorithm 1)

Early fistulae (less than 75 days after obstructed labour). There is evidence that early catheter care will result in the cure of a significant minority of VVF. (Grade C)

Established fistulae (>75 days after obstructed labour) and those that fail catheter treatment should be treated surgically by a fistula surgeon. (Grade C)

TREATMENT

If catheter drainage fails, then fistula repair will be necessary. There are certain principles behind fistula repair:

- Necrotic tissue must be removed prior to fistula repair.
- Fistula repair must only be undertaken by a properly trained surgeon.
- Adequate post-operative care is essential.
- Proper follow-up should be arranged.

A vaginal approach under spinal anaesthesia is preferred.

A tension-free single layer closure of the bladder wall and closure of the vaginal wall in a separate layer are advocated. A Martius flap in primary obstetric fistula repair is not recommended.

In principle most fistulae can be dealt with by vaginal approach, but an abdominal approach can be useful in some cases (e.g. concomitant reconstructive procedures). Advanced training and surgical skills are prerequisites for treating this type of fistula.

When reporting on outcome after fistula repair, authors should make a clear distinction between fistula closure rates and post-operative stress incontinence rates and the time at which the follow-up was organized.

Prevention of post-operative stress incontinence must be added to the surgical procedure if the urethral closing mechanism is involved. This can be done by a good repair of the pubocervical fascia and refixation or by adding a sling procedure.

MANAGEMENT OF THE COMPLICATIONS OF VVF

The complications of vesico-vaginal fistulae are many but include:

- Persistence or recurrence of urinary incontinence
- Persistence of lower urinary tract symptoms or occurrence of new lower urinary tract symptoms, including overactive bladder
- Urinary tract infections
- Upper urinary tract symptoms, including loin pain
- Dyspareunia and sexual dysfunction
- Infertility
- Neurological symptoms
- Psychological problems and mental illness
MANAGEMENT OF OBSTETRIC VESICOVAGINAL FISTULAE *

Early fistula (<75 days)

Surgeon with fistula knowledge available

yes

Catheter

Examine weekly

Healed

Not Healed

no

Catheter for 4 weeks

Healed

Fistula repair by fistula surgeon

Established fistula (>75 days)

* At any stage of the patient’s care pathway, management may need to include continence products
PART II: NON-OBSTETRIC FISTULAE

INTRODUCTION

Iatrogenic urogenital fistulae are known complications of pelvic surgery and oncological treatments such as radiotherapy, chemotherapy or a combination of both. In the oncological context, fistulae may also occur as a result of primary or recurrent malignancy. The development of fistula following radiotherapy for primary treatment should trigger a search for evidence of tumour recurrence (Grade D).

- Urogenital fistulae are more frequent in women who have undergone hysterectomy.
- The risk of injury to the bowel or urinary tract and of subsequent fistula formation is higher in women with malignant disease undergoing radical surgery than in women with benign disease undergoing simple surgical procedures.
- Several modifications to conventional radical hysterectomy have been described, although they have not consistently been shown to mitigate the risk of urinary fistula postoperatively.
- Data on exenterative surgery are inconsistent, although the risk of fistula formation may be higher following exenteration for recurrent disease as compared to that following radical hysterectomy for the primary treatment of malignancy.
- The rate of visceral injury and fistula formation is inconsistently reported following laparoscopically assisted radical hysterectomy, but may be somewhat higher than following open surgery.
- Local ablative treatments applied in gynaecological oncology, whilst apparently relatively low risk as single treatments, may carry considerable risk for fistula formation when repeated.
- The rate of fistula formation following radiotherapy for gynaecological cancer appears to be of the same order as that following surgical treatment.
- The risk of fistula formation following radiotherapy for locally recurrent malignancy is higher than following its use in primary disease.

- The use of neoadjuvant or adjuvant therapies is likely to be associated with a greater risk of fistula development than the primary treatment alone.
- The most common non-obstetric causes of fistulae involving the gastrointestinal tract are diverticular disease, Crohn's disease, malignancy and radiotherapy.

ASSESSMENT OF FISTULAE

- Leakage of stool, urine, or possibly both is the hallmark sign of a fistulae. The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intraoperative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistulae.
- CT and cystoscopy appear more consistent in the confirmation and location of possible intestino-vesical fistulae, than other investigations (Grade C).
- Level 3 evidence indicates that the routine use of cystoscopy with dye testing at gynaecological surgery has high sensitivity, specificity and negative predictive value in the detection of ureteric injury, although false positive tests do occur. The clinical and cost-effectiveness of routine cystoscopy remains to be established. (Grade C)
- Ureteric injury or fistulae may be suspected in patients following pelvic surgery if a fluid leak or pelvi-calyceal dilatation occurs postoperatively. (Grade D)
- Uretero-arterial fistula may be suspected in patients presenting with haematuria with a history of relevant pelvic surgery and indwelling ureteric stent. (Grade D)
- Elevated levels of creatinine in drainage fluid following pelvic surgery are suggestive of a urinary tract injury. (Grade D)

MANAGEMENT OF VESICOVAGINAL FISTULAE

The literature relating to surgical fistulae is extensive, but of limited quality.

- Spontaneous closure of surgical fistulae does occur, although it is not possible to establish the rate with any certainty; if a vesicovaginal fistulae is diagnosed within six weeks of surgery, indwelling catheterisation can be considered for a period of up to 9 weeks (i.e. up to 12 weeks after the causative event). (Grade C)
• Attention should be given as appropriate to skin care, nutrition, rehabilitation, counselling and support prior to and following fistulae repair. (Grade D)

• Perioperative antibiotic prophylaxis should follow local policies. (Grade D)

• There is no benefit from mechanical or laxative bowel preparation prior to colonic surgery; it is reasonable that this recommendation be extrapolated to apply to fistulae surgery. (Grade B)

• There is no proven benefit to delayed repair of vesicovaginal fistulae; the timing of repair should be tailored to the individual patient and surgeon requirements, but can be undertaken as soon as any oedema, inflammation, tissue necrosis, infection are resolved. (Grade B)

• There are no high quality data to indicate greater cure rates for any one technique as compared to others; level 3 evidence indicates similar success rates for vaginal and abdominal, and for transvesical and transperitoneal approaches. (Grade C)

• Surgeons involved in fistulae surgery should have appropriate training, skills, and experience to select an appropriate procedure for each patient. (Grade D)

• The majority of vesico-vaginal and all urethro-vaginal fistulae can be repaired vaginally, regardless of aetiology. (Grade C)

• Where concurrent ureteric re-implantation or augmentation cystoplasty are required, the abdominal approach is necessary. (Grade D)

• A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their use in any specific setting. (Grade C)

• Conventional and robotically-assisted laparoscopic approaches have both been shown to be feasible in selected cases; the indications for, or optimal patient for these techniques is not yet clear. (Grade C)

• A period of continuous bladder drainage is crucial to successful fistulae repair; there are no high level data to support any particular type, route, or duration of catheterisation; current practice suggests: 10-14 days for simple and/or post-surgical fistulae; 14-21 days for complex and/or post-radiation fistulae. (Grade D)

**RADIATION FISTULAE**

• Whilst diversion is used more widely in radiation-associated fistulae of all types as compared to non-radiated fistulae, there is low level evidence that repair procedures can achieve successful fistulae closure and continence in appropriately selected cases. (Grade C)

• Where urinary and/or faecal diversions are required, attempts should be made to avoid using irradiated tissues wherever possible, and to minimise the potential for anastomotic complications. (Grade C)

• There is low level evidence to support the use of interposition grafts when repair of radiation-associated fistulae is undertaken. (Grade C)

• In patients with intractable urinary incontinence from radiation-associated fistulae, where life expectancy is very short, ureteric occlusion might be considered; there is insufficient evidence to recommend any particular technique. (Grade D)
MANAGEMENT OF IATROGENIC VESICOVAGINAL FISTULAE

**HISTORY**

**CLINICAL ASSESSMENT**

**PRESUMED DIAGNOSIS**

**MANAGEMENT** *

Leakage of urine from vagina/perineum

Clinical examination
Urethro-cystoscopy
Imaging (Xray/CT/MRI, US)
Evaluate upper urinary tract

**VVF**

Primary simple
Consider catheter 4-12w
Vaginal repair
Consider timing
Martius flap optional

Primary complex
Vaginal or other approach
Consider timing
Use interposition flaps

Recurrence
If small, consider catheter 4-12w
Vaginal repair or other approach
2-3 months
Martius flap or Interposition flaps

Post-irradiation
Vaginal repair or other approach
6-12 months
Martius flap

Assess fistula closure & assess continence status

* At any stage of the patient’s care pathway, management may need to include continence products
MANAGEMENT OF FISTULAE INVOLVING BOWEL

• There is limited evidence to support a non-surgical or conservative surgical approach in colo-vesical fistulae where there are minimal symptoms or evidence of limited bowel involvement. (Grade C)

• There is only limited low level evidence to support a non-surgical approach in colo-vesical fistulae associated with diverticular disease; nevertheless, in the frail elderly, or in patients who have limited symptoms of urinary infection or urinary diarrhoea it is reasonable to consider a trial of conservative management. (Grade D)

• A one-stage approach to surgery for intestino-vesical fistulae is appropriate in many cases, but should be limited to those patients whose nutritional state is good, and where there is no evidence of additional intra-abdominal pathology (e.g. severe inflammation, radiation injury, advanced malignancy, intestinal obstruction) or major co-morbidity. (Grade B)

• A laparoscopic approach to one-stage management has been shown to be feasible, although there is no high level evidence to allow comparison of outcomes with open surgery. (Grade D)

MANAGEMENT OF URETERIC FISTULAE

• Surgeons undertaking complex pelvic surgery should be competent at identifying, preserving and repairing the ureter. (Grade D)

• Ureteric stents are not required as prophylaxis against injury during routine gynaecological surgery, while their role in more extensive surgery remains to be established. (Grade B)

• Most upper urinary tract fistulae should be initially managed by conservative or endoluminal techniques where such expertise and facilities exist. (Grade C)

• Persistent ureterovaginal fistulae should be repaired by an abdominal approach using open, laparoscopic or robotic techniques according to availability and competence. (Grade D)

• For patients with ureteric fistulae associated with advanced pelvic cancer and poor performance status, palliation by nephrostomy tube diversion and endoluminal distal ureteric occlusion is an option. (Grade C)

MANAGEMENT OF URETHRO-VAGINAL FISTULAE

Recommendations

• Urethrovaginal fistulae are preferably treated by a vaginal approach. (Grade C)

• A variety of autologous tissue interposition techniques have been described, but their value remains uncertain. (Grade C)

• Urethrovaginal fistulae repair may be complicated by stress incontinence, urethral stricture and urethral shortening necessitating long-term follow-up. (Grade C)
MANAGEMENT OF IATROGENIC URETERIC FISTULAE

**HISTORY**

Extra-urethral vaginal urinary leakage and/or signs of ureteric obstruction

**CLINICAL ASSESSMENT**

Clinical examination
Urethro-cystoscopy
Imaging (Xray/CT/MRI, US)
Evaluate upper urinary tract obstruction

**PRESUMED DIAGNOSIS**

Ureterovaginal fistula

**MANAGEMENT * **

Endoluminal technique (stenting, nephrostomy) for at least 6 weeks

Unable to stent (initially)...

Re-evaluate for fistula closure, ureteric obstruction

Persisting fistula or ureteric obstruction

Healed

Ureteric reimplantation (open, laparoscopic or robotic)

*At any stage of the patient’s care pathway, management may need to include continence products*
Pelvic organ prolapse includes urogenital and rectal prolapse. Treatment for pelvic organ prolapse should be reserved for symptomatic women, except in rare, selected, cases.

1. ASSESSMENT

Symptom enquiry may reveal a variety of symptoms. Symptom severity may not correlate with the severity of the anatomical changes.

Physical examination should:
- define the severity of maximum anatomical support defect,
- assess pelvic floor muscle function and
- determine if epithelial/mucosal ulceration is present.

Post void residual should be measured; nearly all elevated post void residuals resolve with treatment of urogenital prolapse. Imaging of the upper tract is indicated when treatment of vaginal prolapse beyond the hymen is observation only (i.e. no pessary or surgery).

2. MANAGEMENT

- Observation is appropriate when medically safe and preferred by the patient (Grade C).
- Pelvic floor muscle training may:
  - reduce the symptoms of urogenital prolapse (Grade A), although topographic change is not expected
  - prevent or slow deterioration of anterior urogenital prolapse (Grade B)
- Pessaries, when successfully fitted, may improve protrusion symptoms (Grade B). Regular follow up is mandatory. Support pessaries that concurrently treat stress incontinence should be considered when appropriate.
- Local oestrogens may benefit hypoestrogenic women for the prevention and/or treatment of vaginal epithelial ulceration (Grade C).
- Reconstructive surgery should aim to optimise anatomy and function (see full text for grades of recommendation for specific surgical techniques). Pre and postoperative pelvic floor muscle training may promote quality of life and fewer symptoms after surgery for urogenital prolapse (Grade C).
- Obliterative surgery is reserved for selected women who agree to permanent vaginal closure (Grade B).
**Management of Pelvic Organ Prolapse**
(including urogenital prolapse and rectal prolapse)

**HISTORY**
- Bothersome pelvic organ prolapse
- Complex or recurrent prolapse

**CLINICAL ASSESSMENT**
- Symptoms Screening: assess bothersomeness, frequency and severity of urinary, ano-rectal, genital and sexual symptoms
  - Urinary: PVR, cough stress test, urinalysis.
  - Physical Examination: Sufficient to determine the site and severity of prolapse and detect other significant findings
    - Selective use of urodynamics when results would alter planned treatment
    - Selective use of upper tract imaging when observation is planned
  - Ano-Rectal: Endoscopy, lower GI tract imaging

**DIAGNOSIS**
- UROGENITAL PROLAPSE WITH OR WITHOUT OTHER PELVIC SYMPTOMS
  - Observation
  - Lifestyle interventions
  - Pelvic floor muscle training
  - Pessary
  - Reconstructive surgery
  - Obliterative surgery

- RECTAL PROLAPSE WITH OR WITHOUT OTHER PELVIC SYMPTOMS
  - Observation
  - Lifestyle interventions
  - Transperineal surgery
  - Transabdominal surgery

**MANAGEMENT**
- Specialist management

*At any stage of the patient’s care pathway, management may need to include continence products*
VI. URINARY INCONTINENCE IN NEUROLOGICAL PATIENTS

A. INITIAL MANAGEMENT

I. STRONG GENERAL RECOMMENDATIONS

- Patients with known neurological disease often need evaluation to exclude bladder dysfunction, not only if symptoms occur, but as a standard assessment as neurogenic bladder has a high prevalence in this disease (for prevalence figures see chapter).

- A possible neurological cause of "idiopathic" incontinence should always be considered. Diagnostic steps to evaluate this include basic assessments, such as history and physical examination, urodynamics and specialised tests.

- Incontinence in neurological patients does not necessarily relate to the neurologic pathology. Other diseases such as prostate pathology, pelvic organ prolapse, might have an influence. These have to be ruled out.

- Extensive diagnostic evaluation is often useful and necessary to tailor an individual treatment based on complete neurofunctional data. This may not be needed in every patient e.g. patients with suprapontine lesions or in patients where treatment will consist merely of bladder drainage due to bad medical condition or limited life expectancy.

- There is often a need to manage bladder and bowel together.

II. INITIAL ASSESSMENT

- The management of neurological urinary incontinence depends on an understanding of the likely mechanisms producing incontinence. This can in turn depend on the site and extent of the nervous system abnormality.

- Therefore neurogenic incontinence patients can be divided into those having:

  - peripheral lesions (as after major pelvic surgery) including those with lesions of the cauda equina (e.g. lumbar disc prolapse);
  - sacral spinal cord lesions involving the sacral micturition centre
  - suprasacral spinal cord lesions (suprasacral infrapontine spinal cord lesions);
  - central lesions of the brain or brain stem (stroke, Parkinson’s disease).

- History and physical examination are important in helping distinguish these groups.

III. INITIAL TREATMENT

- Patients with peripheral nerve lesions (e.g. denervation after pelvic surgery) and patients with spinal cord lesions (e.g. traumatic spinal cord lesions) should get specialised management (A).

- Initial treatment for patients with incontinence due to suprapontine pathology, like stroke; need to be assessed for degree of mobility and ability to cooperate. Initial recommended treatments are behavioural therapy (C) and anti-muscarinic drugs for presumed detrusor overactivity (A). Continence products (B) or catheters (C) may be necessary for non-cooperative or less mobile patients.
Initial Management of Neurogenic Urinary Incontinence

**HISTORY, level of lesion**
- Peripheral nerve lesion (e.g. radical pelvic surgery).
- Sacral cord/cauda equina lesion (e.g. lumbar disc prolapse).
- Suprasacral infrapontine and pontine lesions e.g. trauma, multiple system atrophy.
- Suprapontine cerebral lesion (e.g. Parkinson’s disease, stroke, multiple sclerosis).

**CLINICAL ASSESSMENT**
- Further history.
- General assessment including of home circumstances.
- Urinary diary and symptom score.
- Assessment of functional ability, quality of life and desire for treatment.
- Physical examination: assessment of sensation in lumbosacral dermatomes, anal tone and voluntary contraction of anal sphincter, bulbocavernosus and anal reflexes, gait, mobility, contractures, hand function.
- Urine analysis + culture (if infected: treat as necessary).
- Urinary tract imaging, serum creatinine: if abnormal to specialised management.
- Post void residual (PVR) assessment by abdominal examination or optional by ultrasound.

This assessment will give basic information, but does not yield precise neurourolological diagnosis.

**PRESUMED DIAGNOSIS**
- Stress urinary incontinence due to sphincter incompetence with negligible PVR.
- Urinary incontinence due to detrusor overactivity.
- Urinary incontinence associated with poor bladder emptying (significant PVR).
- With negligible PVR.

**MANAGEMENT**
- Behavioural modification.
- External appliances.
- Intermittent catheterisation **with or without** Antimuscarinics.

Depending on cooperation and mobility:
- Behavioural modification,
- Antimuscarinics,
- Contience products,
- Indwelling catheter.

**Specialised management preferable for more "tailored" treatment**

* At any stage of the patient’s care pathway, management may need to include continence products
** Some patients omit IC through personal choice or inability to self catheterise.
Most patients with neurogenic urinary incontinence require specialised assessment: *urodynamic studies should be used* with videourodynamics if available when surgical interventions are planned or when the “bladder may be unsafe”.

*Upper tract imaging* is needed in some patients and more detailed renal function studies will be desirable if the upper tract is considered in danger: high bladder pressure, upper urinary tract dilatation, recurrent or chronic upper tract infection, (major) stones, (major) reflux.

In patients with *peripheral lesions* clinical *neurophysiological testing* may be helpful for better definition of the lesion.

Also for specialised management conservative treatment is the mainstay (*A*). Management of neurogenic urinary incontinence has several therapeutic options. The algorithm details the recommended options for different types of neurological dysfunction of the lower urinary tract. The dysfunction does not necessarily correspond to one type/level of neurological lesion but *must depend* mostly on *urodynamic findings*. One should always ascertain that the management is *urodynamically safe* (low pressure, complete emptying).

It is recommended to look at *urinary* and *bowel* function *together* if both systems are affected, as symptoms and treatment of one system can influence the other and vice versa (*A*).

As therapeutic approaches can differ in various neurological diseases, the most prevalent diseases are discussed separately in the chapter.
Specialised Management of Neurogenic Urinary Incontinence

**LEVEL AND EXTENT OF LESION, HISTORY AND CLINICAL ASSESSMENT**
- Peripheral nerve lesion (e.g. radical pelvic surgery)
- Conus cauda equina lesion (e.g. lumbar disc prolapse)
- Suprasacral infrapontine and pontine lesion (e.g. trauma, multiple sclerosis)
- Suprapontine cerebral lesion (e.g. Parkinson’s disease, stroke, multiple sclerosis)

**SPECIALISED ASSESSMENT**
- Urodynamic testing (usually videourodynamics)
- Urinary tract imaging

**DIAGNOSIS**
- Stress UI due to sphincteric incompetence
- Incontinence associated with poor bladder emptying due to detrusor underactivity / sphincter overactivity
- UI due to detrusor overactivity

**CONSERVATIVE TREATMENT**
- Artificial sphincter
- Bladder neck sling
- Antologous sling
- Bulking agents
- Bladder neck closure
- (Synthetic midurethral tapes)**

**SURGICAL TREATMENT**
- Urodynamic testing (usually videourodynamics)
- Urinary tract imaging
- Indwelling cath. + aM
- Continence products + aM
- Botulinum toxin to detrusor

**Stoma/diversion may be an option in selected cases**

- If urethral hypermobility is the cause of SUI; the long-term risks of tapes in the neurogenic population are undefined
- Intravesical botulinum injections undertaken according to national licensing. Sphincteric botulinum injections are not currently licensed.
I. DEFINITION

Bladder Pain Syndrome in the absence of a universally agreed definition, the European Society for the Study of Interstitial Cystitis (ESSIC) definition is given along with the definition of the American Urological Association

- **ESSIC**: Chronic pelvic pain, pressure or discomfort of greater than 6 months duration perceived to be related to the urinary bladder accompanied by at least one other urinary symptom like persistent urge to void or urinary frequency. Confusable diseases as the cause of the symptoms must be excluded.

- **American Urological Association Guideline Definition**: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks duration, in the absence of infection or other identifiable causes.

II. BLADDER PAIN SYNDROME (BPS)

1. NOMENCLATURE

The scientific committee of the International Consultation voted to use the term “bladder pain syndrome” for the disorder that has been commonly referred to as interstitial cystitis (IC). The term painful bladder syndrome was dropped from the lexicon. The term IC implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. Painful Bladder Syndrome, as defined by the International Continence Society, is too restrictive for the clinical syndrome.

Properly defined, the term Bladder Pain Syndrome appears to fit in well with the taxonomy of the International Association for the Study of Pain (IASP) (see below), and focuses on the actual symptom complex rather than what appears to be long-held misconception of the underlying pathology.

Bladder Pain Syndrome

Bladder pain syndrome is the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. There is no proven infection or other obvious local pathology. Bladder pain syndrome is often associated with negative cognitive, behavioural, sexual, or emotional consequences as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.

2. HISTORY / INITIAL ASSESSMENT

Males or females whose symptoms meet the requirements of the definition of bladder pain syndrome should be evaluated. The presence of commonly associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms of bladder pain syndrome also suggests the diagnosis. Abnormal gynecological findings in women and well-characterized confusable diseases that may explain the symptoms must be ruled out.

The initial assessment consists of a frequency/volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology, cystoscopy, and urodynamic evaluation are recommended if clinically indicated and/or the diagnosis is in doubt. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and microscopic or gross haematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms, are they diagnosed with BPS.

Grade of recommendation: C
3. INITIAL TREATMENT

- patient education,
- dietary manipulation,
- non-prescription analgesics,
- stress reduction,
- pelvic floor muscle relaxation techniques comprise the initial treatment of BPS. In the patient with findings suggesting pelvic floor dysfunction, pelvic floor muscle physical therapy with myofascial trigger point release and intravaginal Thiele massage is often an effective therapeutic intervention.

The treatment of pain needs to be addressed directly, and in some instances referral to an anaesthesia/pain centre can be an appropriate early step in conjunction with ongoing treatment of the syndrome.

Treatment should be focused on the most bothersome or distressing symptoms(s).

- When conservative therapy fails or symptoms are severe and conservative management is unlikely to succeed,
- oral medication, or
- intravesical treatment can be prescribed.

It is recommended to initiate a single form of therapy and observe results, adding other modalities or substituting other modalities as indicated by degree of response or lack of response to treatment. Grade of recommendation: C

4. SECONDARY ASSESSMENT

- If initial oral or intravesical therapy fails, or before beginning such therapy based on clinician judgment, it is reasonable to consider further evaluation which can include urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anaesthesia.

Findings of detrusor overactivity suggest a trial of antimuscarinic therapy.

The presence of a Hunner's lesion suggests therapy with transurethral resection, fulguration of the lesion, or direct steroid injection into the lesion. Distention itself can have therapeutic benefit in 30-50% of patients, though benefits rarely persist for longer than a few months. Grade of recommendation: C

5. REFRACTORY BPS

- Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. Many of these are best administered within the context of a clinical trial if possible. These may include neuromodulation, intradetrusor botulinum toxin, oral cyclosporine A, or clinical trials of newly described pharmacologic management techniques. At this point, most patients will benefit from the expertise of an anaesthesia pain clinic.

- The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urinary stream.

- Urinary diversion with or without cystectomy has been used as a last resort with good results in selected patients.

- Augmentation or substitution cystoplasty seems less effective and more prone to recurrence of chronic pain in small reported series. Grade of recommendation: C
Bladder Pain Syndrome

- Pain management is a primary consideration at every step of algorithm
- Patient enrollment in appropriate research trial is reasonable option at any point
- Evidence supporting neuromodulation, cyclosporin A, and botulinum toxin for BPS indication is limited. These interventions are appropriate only for practitioners with experience treating BPS and willing to provide long-term care post-intervention.
Patients with faecal incontinence present with a variety of symptom complexes. As many people are reluctant to admit to having faecal incontinence, it is important to proactively enquire about it, especially in known high risk groups (such as older community-living individuals, post partum women who might have had an obstetric injury, and patients with loose stools).

- **History** will include bowel symptoms including loose stools, severity and types of incontinence, systemic disorders, neurological disorders, and anorectal surgeries (e.g., haemorrhoidectomy), obstetrical history for women, medications, diet, chronic straining, cognitive status, and effects of symptoms on quality of life.

- **Types of incontinence:** *urgency faecal incontinence*, often a symptom of external anal sphincter dysfunction; *flatus incontinence* (leakage of rectal gas) may indicate rectal sensory impairment and/or internal anal sphincter dysfunction; and *soiling after defaecation*, typically related to a defect in the internal sphincter or poor closure of external sphincter due to rectal prolapse or stage III/IV haemorrhoids.

- **Physical examination** will include anal inspection, abdominal palpitation, a brief neurological examination, digital rectal examination and usually proctosigmoidoscopy or colonoscopy.

- **Further diagnostic testing** needs to be considered if the patient has symptoms such as an unexplained change in bowel habit, weight loss, anaemia, rectal bleeding, severe or nocturnal diarrhoea, or an abdominal or pelvic mass and bowel pathology when organic conditions such as cancer, inflammatory bowel disease (IBD), a recto-vaginal fistula, full thickness rectal prolapse, or cloacal deformity are suspected. *Condition specific management* is indicated for these patients.

Reversible factors (such as inadequate access to toilets and side effects of medications resulting in loose stools) should be assessed and addressed at the outset.

**II. INITIAL INTERVENTIONS**

- Initial management can often be performed in primary care. After environmental factors and local or systemic pathology have been excluded, *initial interventions include*:
  - Discussion of **options** and **goals** of management with the patient
  - Provision of patient or caregiver **information** and **education** (Grade A)
  - Adjustment of **diet** and fluid advice, **fibre** intake (Grade A)
  - Establishing a **regular bowel habit** (Grade C) or **urgency training** if relevant (Grade C)
  - **Anti-diarrhoeal** medication can help if stools are loose (Grade B)
  - **Rectal Irrigation** to achieve complete rectal evacuation of faeces (Grade B)
  - Use of **continence products** including various types and sizes of absorbent pads, briefs, etc., to contain leaked faeces and prevent skin damage
III. SECONDARY INTERVENTIONS

- If initial interventions fail to improve symptoms after 8-12 weeks, consideration should be given to referral to an incontinence specialist (e.g., gastroenterologist, continence nurse, advisor physiotherapist, or colorectal surgeon) for other interventions or further assessment.

- **Pelvic floor muscle training (PFMT)** – contraction of pelvic floor muscles multiple times per day to improve strength of contraction and increase awareness of anorectal muscle function. (Grade C)

- **Biofeedback therapy** – behavioural treatment designed to enhance the strength of sphincter contraction and improve rectal sensation using specialised equipment. Biofeedback therapy can be combined with PFMT to improve strength. (Grade B)

IV. SECONDARY ASSESSMENT

- A variety of anorectal investigations, including manometry, anal ultrasound, and possibly MRI, defaecography, and neuro-physiological testing can help to define structural or functional abnormalities of anorectal function and guide management if initial and/or secondary interventions are ineffective

V. TERTIARY REFERRAL, SURGICAL OR MULTI-DISCIPLINARY CONSULTATION

- **Faecal** incontinence that fails to respond to initial and secondary management requires specialised consultation by a gastroenterologist, colorectal surgeon, urogynecologist, and/or a multi-disciplinary team.

RESEARCH RECOMMENDATIONS

- Data should be collected on faecal incontinence whenever practical as part of research on urinary incontinence.

- Development of techniques for diagnosing FI and its severity using new and available technologies

- Well designed and adequately powered studies are needed to evaluate all treatment modalities currently available including
  - Effectiveness of lifestyle modifications including weight loss, exercise, modifying diet and eating pattern and supplementing dietary fibre as primary and adjuvant management strategies
  - Comparative effectiveness trial comparing instrumented biofeedback training to neuromodulation for the treatment of FI
  - Effectiveness of tibial nerve stimulation

- Studies are needed to develop interventions for supporting coping and self-management of faecal incontinence, odour, and urgency and increasing care seeking
Initial Management of Faecal Incontinence

Initial Clinical Assessment
- Initial Interventions
- Address Reversible Factors

Condition Specific Assessment and Management
- Active case finding or patient presents with faecal incontinence
- Initial Interventions
- Action case
- Recto-vaginal fistula, cloacal deformity
- For cancer, IBD, impaction, full thickness rectal prolapse
- Manometry and/or ultrasound
- Neuro physiological testing, etc.
- MRI
- Possible additional tests

Initial Interventions
- Toilet access, medication side effects, loose stools etc.
- Diet and eating pattern modifications, dietary fibre supplements
- Education of patient and/or caregiver
- Medications (Iberamide)
- Bowel habit training
- Medications

Secondary Interventions
- Pelvic floor training
- Biofeedback
- Pelvic floor ultrasound
- Biofeedback
- Pelvic floor surgery
- Physiotherapy

Secondary Interventions
- Continence specialist consult
- Continence products such as an anal plug
- PFMT etc.
- Tertiary referral, multi-disciplinary consult

Initial Interventions
- Medication and diet review
- Proctosigmoidoscopy
- Assessment of impact on quality of life
- Physical examination

Initial Interventions
- Reversible factors
- Toilet access, medication side effects, loose stools etc.
- Diet and eating pattern modifications, dietary fibre supplements
- Education of patient and/or caregiver

I. INITIAL ASSESSMENT AND MANAGEMENT

The reader is referred to the relevant sections on “Dynamic Testing” and “Conservative Treatment for Faecal Incontinence.” In general, patients referred for surgical management of faecal incontinence must either have failed conservative therapy or not be candidates for conservative therapy due to severe anatomic or neurological dysfunction.

Prior to surgical management of faecal incontinence, the integrity of the anal sphincter complex should be assessed. This assessment is best performed with endoanal ultrasound, though pelvic MRI may also be useful. Ancillary tests include anal manometry, electromyography, and defaecography.

Patients with rectal prolapse, rectovaginal fistulae, and cloacae often have associated faecal incontinence. Initial therapy should be directed at correction of the anatomic abnormality (in the case of rectovaginal fistula or cloaca, this surgical repair may include overlapping sphincteroplasty.) If the patient has persisting faecal incontinence, she should undergo repeat assessment, including especially endoanal ultrasound.

II. SPECIALISED MANAGEMENT

The surgical approach to the incontinent patient is influenced by the presence and magnitude of an anatomic sphincter defect. If no defect is present, or if the sphincter defect is minimal, options include SNS and injection therapy.

For patients with moderate sphincter defects, sphincteroplasty, SNS or injection therapy can each be considered. For patients with large sphincter defects (>120 degrees), sphincteroplasty is likely the best option, though a PNE trial for SNS can be considered.

Patients with sphincter defects of greater than 180° or major perineal tissue loss require individualised treatment. In some cases, initial reconstruction can be performed. Should incontinence persist, alternatives include stimulated muscle transposition, artificial anal sphincter implantation, or sacral nerve stimulation.

III. SALVAGE MANAGEMENT

For patients who remain incontinent following sphincteroplasty, repeat endoanal ultrasound should be undertaken to reassess the status of the repair. If no defect is present, or if the sphincter defect is minimal (<30 degrees), options include SNS and injection therapy. If there is a large persisting sphincter defect, repeat sphincteroplasty can be considered.

Patients who have failed sacral nerve stimulation can be considered for injection therapy or sphincteroplasty if a sphincter defect is present. Other alternatives include stimulated graciloplasty and implantation of an artificial anal sphincter.

Patients who fail surgical therapy for faecal incontinence, or who do not wish to undergo extensive pelvic reconstruction, should consider placement of an end sigmoid colostomy. While this procedure does not restore continence, it does restore substantial bowel control and appears to improve social function and quality of life. Novel therapies can also be considered under protocol: PTNS, the magnetic anal sphincter and sling procedures.

IV. SPECIAL SITUATIONS

Individuals with severe spinal cord dysfunction (due, e.g., to injury or congenital abnormality) should be considered for an Antegrade Continence Enema (ACE) procedure or colostomy.
Surgical Management of Faecal Incontinence *

Candidate for surgery for FI → EVALUATION EAUS ± other tests → Persistent Surgery for anatomical abnormality

SEVERE SPINAL CORD IMPAIRMENT → ACE Colostomy

RECTAL PROLAPSE, CLOACA, RECTOVAGINAL FISTULA

No Sphincter defect → Sphincteroplasty

Sphincter defect → Biomaterial injection

First line

Second line

ABS DG ACE Colostomy Novel therapies
PTNS MAS MAS
Puborectal sling

* At any stage of the patient's care pathway, management may need to include continence products
Patients with known neurological disease may present with symptoms related to neurologic bowel dysfunction – difficulty in defaecation, constipation and faecal incontinence which disturb their activities of daily living and quality of life. Many have permanent impairments and functional limitations and disabilities, which are due to neurological deficits and complications.

**I. INITIAL ASSESSMENT**

- **History taking:** this includes
  - Neurological diagnosis and functional level
  - Previous and present lower gastrointestinal (LGIT) function and disorders
  - Severity of neurogenic bowel dysfunction
  - Current bowel care and management including diet, fluid intake, medications affecting bowel functions
  - Co-morbidity / complication e.g., urinary incontinence, autonomic dysreflexia, pressure ulcers, sexual dysfunction
  - Patient’s satisfaction, needs, restrictions and quality of life
  - Environmental factors and barriers and facilitators to independent bowel management.

- **Physical examination:**
  - Cognitive functions; motor, sensory and sacral reflexes – voluntary anal sphincter contraction, deep perianal sensation, anal tone, anal and bulbocavernosus reflexes
  - Spasticity of the lower limbs
  - Abdominal palpation for faecal loading and rectal examination

**Functional assessment:**
- hand and arm use, fine hand use, mobility – maintaining body position, transfer and walking ability.

**Environmental factors assessment:**
- toilet accessibility; devices for bowel care and mobility; caregivers’ support and attitude;

**II. BASIC INVESTIGATIONS:**
- Stool exam, plain abdomen XRay

**III. INITIAL TREATMENTS**

- **Patient education and goals-setting** - complete defaecation on a regular basis and faecal continence based on right time, right place, right trigger and right consistency
- **Adequate fibre diet and fluid intake:** appropriate trigger according to preservation of sacral (anorectal) reflex – digital rectal stimulation; suppository and enema; if no anorectal reflex, manual evacuation; abdominal massage can also be helpful
- **Prescribe medications** – stool softener, laxative, prokinetic agents, anti-diarrhoea drugs as necessary
- Assistive techniques may be necessary for
  - defaecation – irrigation
  - for incontinence – anal plug

The diagram does not apply to management in acute neurological patients that need regular bowel emptying.
Initial Management of Neurogenic Faecal Incontinence

**HISTORY, level of lesion**
- Sacral cord/cauda equina lesion (e.g. lumbar disc prolapse). Peripheral nerve lesion (e.g. radical pelvic surgery)
- Suprasacral infrapontine and pontine lesion (e.g. trauma, multiple sclerosis)
- Suprapontine lesions (e.g. Parkinson)

**CLINICAL ASSESSMENT**
- History taking including diagnosis, pre-morbid bowel function and sensation and their disorders, current bowel and bladder programme, co-morbid diseases/disorders, QOL and needs
- Physical & neurological examination including cognitive function, voluntary anal contraction, sensation, sacral reflexes, digital rectal examination, abdominal palpation for faecal impaction
- Functional assessment including hand and arm use, fine hand use, balance, transfer and walking
- Environmental factors assessment including toilet accessibility, assistive device, caregivers' support and attitude
- Basic investigation: stool exam, plain film abdomen in selected patients (diarrhoea, impaction not felt on rectal examination)

This assessment will give basic information but does not permit a precise diagnosis of neurogenic bowel dysfunction

**PRESUMED DIAGNOSIS**
- Incontinence due to sphincter incompetence
- Incontinence due to lack of cognitive function, sensory awareness disorders, unable to control by voluntary anal contraction
- "False incontinence" due to faecal impaction

**TREATMENT**
- Manual evacuation
  - Assistive device – anal plug, mini-enema, transanal/transrectal irrigation
- Digital rectal stimulation
  - Chemical stimulant: suppository, mini-enema, stool softener, laxative; given by patient/caregiver
- Faecal disimpaction
  - incl. enemas and transanal/transrectal irrigation

Patient education, adequate fibre diet and fluid intake; regular bowel care, preferably ± 3 times a week

Specialised management preferable for more "tailored" treatment

* At any stage of the patient's care pathway, management may need to include continence products
I. ASSESSMENT

- Some patients with neurogenic faecal incontinence will need specialised assessment, especially if initial management is unsuccessful to look for comorbidity and certainly before performing invasive treatment.

- Do not assume that all symptoms are due to neuropathy, e.g. women with neurological pathology might have had childbirth injury to the sphincter.

- Special investigations: manometry, endoanal ultrasound, (dynamic) MRI, (needle) EMG. These specific bowel functional tests and electro-diagnostic tests must be considered optional as their value in neurological pathology is not sufficiently demonstrated so far.

II. TREATMENTS

- Transanal irrigation (C)
- Electrical stimulation sphincter, (C)
- Percutaneous neuromodulation: further research is required.
- Surgical management of neurogenic faecal incontinence has different options which need a very strict patient selection.
  - Antegrade Continence Enema ACE (C)
  - Graciloplasty (C)
  - Artificial sphincter (C)
  - Sacral Anterior Root Stimulation SARS (C)
  - Botulinum Toxin (C)
  - Neuromodulation (C)

It is recommended to look at urinary and bowel function together if both systems are affected, as symptoms and treatment of one system can influence the other and vice versa (A).

As therapeutic approach can differ in different neurological diseases, the most prevalent diseases are discussed separately in the chapter.

Also for specialised management, conservative treatment for neurological faecal incontinence is the mainstay.
Specialised Management of Neurogenic Faecal Incontinence *

**Primary assessment, history, level and extent of lesion, clinical assessment**

- Sacral cord/cauda equina lesion (e.g. lumbar disc prolapse). Peripheral nerve lesion (e.g. radical pelvic surgery)
- Suprasacral infrapontine and pontine lesion (e.g. trauma, multiple sclerosis)
- Suprapontine lesions (e.g. Parkinson)

**Specialised Assessment**

- Functional bowel testing / functional imaging
- Consider neurophysiological testing and anorectal manometry.

**Diagnosis**

- Faecal Incontinence through loss of bowel sensation, sphincter deficiency or severe rectal prolapse

**Conservative Treatment**

- Transanal irrigation
- Electrical stimulation of sphincter
- Percutaneous neuromodulation: further studies

**Surgical Treatment**

- ACE
- Graciloplasty
- Artificial anal sphincter
- SARS
- Botulinum Toxin for anal sphincter spasticity
- Neuromodulation

**Stoma/diversion may be an option in selected cases**

* At any stage of the patient’s care pathway, management may need to include continence products
There is no reason to suspect why interventions which have proven efficacy in the community dwelling elderly should not also be effective in frail older people. Clinicians should, however, take due regard of the practicality, potential benefits and dangers of employing any single intervention in this population. Frail older people do require a different approach addressing the potential role of co-morbid disease, current medications (prescribed, over the counter and/or naturopathic), and functional and cognitive impairment in urinary and faecal incontinence. The extent of the investigation and management should take into account the degree of bother to the older person and/or caregiver, the goals for care, the degree that the older person is able to undertake any intervention and the overall prognosis and life expectancy. Effective management to meet the goals of care should be possible for most frail older people.

I. HISTORY AND SYMPTOM ASSESSMENT

- Active case finding for urinary and faecal incontinence should be done in all frail older people (Grade A). History should include comorbid conditions and medications that could cause or worsen incontinence. Physical examination should include a rectal examination for faecal loading or impaction (Grade C), functional assessment (mobility, transfers, manual dexterity, dressing and undressing ability, ability to toilet) (Grade A), a screening test for depression (Grade B), and cognitive assessment (to assist in planning and management, (Grade C)). The mnemonic DIPPERS (see urinary and faecal incontinence algorithms) covers some of these comorbid conditions. Note that urogenital atrophy does not, in itself, cause urinary incontinence and should not be treated for this purpose (Grade B). The patient and / or caregiver should be asked about the degree of bother of urinary incontinence and/or faecal incontinence(Grade B); goals for urinary and faecal incontinence care (dryness, decrease in specific symptoms, quality of life, reduction of comorbidity, lesser care burden) (Grade B); and likely cooperation with management (Grade C).

- Evaluation for bowel “alarm” symptoms (rectal bleeding, positive blood screening from stool studies, obstructive symptoms, recent onset of constipation, weight loss, and a change in stool calibre) will need more extensive evaluation (Grade A)

- Urinalysis is recommended for all patients, primarily to screen for haematuria (Grade C). Treatment of otherwise asymptomatic bacteriuria/pyuria is not beneficial (Grade C), and it may cause harm by increasing the risk of antibiotic resistance and severe adverse effects. e.g., Clostridium difficile colitis (Grade C).

- Stool studies may not be needed in all patients with faecal incontinence. Patients with diarrhoea, especially those with more acute onset diarrhoea, may need to be tested for infectious causes of their diarrhoea. Other stool studies could involve testing for malabsorption syndromes.

- The utility of the Clinical Stress test in this population is uncertain (Grade D).

- Wet checks can assess urinary incontinence frequency in long-term care residents (Grade C):

A post voiding residual volume (PVR) test is impractical in many care settings and there is no consensus for the definition of what constitutes a “high” PVR in any population. A PVR measurement is not recommended in the routine initial assessment of frail older people with urinary incontinence.

- However, there is compelling clinical experiemental evidence for PVR testing in selected frail older people with: diabetes mellitus (especially long standing); prior urinary retention or high PVR; recurrent UTIs; medications that impair bladder emptying (e.g., opiates); severe constipation; persistent or worsening urgency urinary incontinence despite antimuscarinic treatment; or prior urodynamics showing detrusor underactivity and/or bladder outlet obstruction (Grade C). Treatment of contributing comorbidity may reduce PVR. Trial with catheter may be considered for PVR > 200-500 ml if the PVR is felt to contribute to UI or urinary frequency (Grade C).

- Nocturia Assessment of frail elders with bothersome nocturia should identify potential underlying causes including nocturnal polyuria (by bladder diary/frequency-volume chart or wet checks; oedema on examination) (Grade C),primary sleep problems (e.g., sleep apnoea); and low voided volumes (e.g., from high PVR).

- Stool impaction/loading. If suspected on digital rectal examination, an abdominal x-ray may be necessary to further evaluate the degree and location of impaction/loading in frail older adults.
II. CLINICAL DIAGNOSIS

The most common types of Urinary Incontinence in frail older people are urgency, stress, and mixed urinary incontinence. Frail older people with urgency urinary incontinence also may have detrusor underactivity and high PVR (without outlet obstruction). There is no evidence that antimuscarinics are less effective or cause retention in this situation (Grade D).

The most common types of faecal incontinence in frail older people are related to urgency and passive leakage. Passive leakage can refer to leakage, seepage and staining following bowel movements that are not associated with faecal urgency and may also occur with faecal impaction. Because constipation and impaction often contribute to faecal incontinence in older adults, these are considered separately in the algorithm.

III. INITIAL MANAGEMENT

- Initial treatment should be individualised and influenced by goals of care, treatment preferences and estimated remaining life expectancy, as well as the most likely clinical diagnosis (Grade C). In some frail older persons the only possible outcome may be containment; management with continence products, especially for people with minimal mobility (require assistance of >2 people to transfer), advanced dementia (unable to state their name), and/or nocturnal urinary and faecal incontinence.

- Conservative and behavioural therapy for UI includes lifestyle changes (Grade C), bladder training for more fit alert persons (Grade B), and prompted voiding for frailer, more impaired older people (Grade A).

- For the select cognitively intact older person with UI or FI, pelvic floor muscle therapy can be considered, but there are few studies (Grade C). Antimuscarinics may be added to conservative therapy of urgency UI (Grade A-C, depending on agent).

- For the select cognitively intact older with FI, biofeedback may be considered, but few studies exist among frail older adults.

- Alpha-blockers may be cautiously considered in frail men with suspected prostatic outlet obstruction (Grade C). All drugs should be started at the lowest dose and titrated with regular review until either care goals are met or adverse effects are intolerable.

- DDAVP (vasopressin) has a high risk of severe hyponatraemia in frail older persons and should not be used outside specialist centres (Grade A).

- Improving stool consistency can be done with dietary fibre and supplementary fibre in older adults (Grade C). In older adults with diarrhoea, loperamide may be considered at low doses to improve stool consistency. However, close monitoring for constipation and impaction is needed.

IV. ONGOING MANAGEMENT AND REASSESSMENT

Optimal urinary and faecal incontinence management is usually possible with the above approaches. If initial management fails to achieve the desired goals the next steps are reassessment and treatment of contributing comorbidity and/or functional impairment.

V. SPECIALISED MANAGEMENT

If frail older people have either other significant factors (e.g., pain, haematuria, bowel “alarm” symptoms), UI or FI symptoms that cannot be classified as urgency, stress, or mixed or overflow or other complicated comorbidity which the primary clinician cannot address (e.g. dementia, functional impairment), then specialist referral should be considered. Referral may also be appropriate when there is been insufficient response to initial management. The type of specialist will depend on local resources and the reason for referral: surgical specialists (urologists, gynaecologists, colorectal surgeons), gastroenterologists, geriatricians or physical therapist (functional and cognitive impairment); or continence nurse specialists (homebound patients). Referral decisions should consider goals of care, patient/caregiver desire for invasive therapy and estimated remaining life expectancy.

Age per se is not a contraindication to UI or FI surgery (Grade C), but before surgery is considered, all patients should have:

- evaluation and treatment for any comorbidity, medications, and cognitive or functional impairments contributing to UI that could compromise surgical outcome (e.g., dementia that precludes patient ability to use artificial sphincter) (Grade C)

- adequate trial of conservative therapy, including pharmacological therapies where relevant (Grade C)

- discussion (including the caregiver) to ensure that the anticipated surgical outcome is consistent with goals of care in the context of the patient’s remaining life expectancy (Grade C)

- urodynamic testing or anorectal manometry, because clinical diagnosis may be inaccurate (Grade B)

- preoperative assessment and perioperative care to establish risk for and to minimize common geriatric post-operative complications such as delirium and infection (Grade A), dehydration and falls (Grade C).
Management of Urinary Incontinence in Frail Older Men & Women

**Active Case Finding in all Frail Elderly people**
- Assess, treat and reassess potentially treatable conditions, including relevant comorbidities and ADLs (see text)
- Assess QoL, desire for Rx, goals for Rx, patient & caregiver preferences
- Targeted physical examination (cognition, mobility, neurological and digital rectal examination)
- Urinalysis
- Consider bladder diary or wet checks, especially if nocturia is present. PVR in specific patients (see text)

**URGENCY UI***
- Lifestyle interventions
- Behavioural therapies
- Consider trial of antimuscarinic drugs

**SIGNIFICANT PVR***
- Treat constipation
- Review medications
- Consider trial of alpha-blocker (men)
- Catheter drainage if PVR 200-500 ml, then reassess (see text)

**STRESS UI***
- Lifestyle interventions
- Behavioural therapies (See text)

If insufficient improvement, reassess for and treat contributing comorbidity ± functional impairment

If continued insufficient improvement, or severe associated symptoms are present, consider specialist referral as appropriate per patient preferences and comorbidity (see text)

**UI associated with:**
- Pain
- Haematuria
- Recurrent symptomatic UTI
- Pelvic mass
- Pelvic irradiation
- Pelvic / LUT surgery
- Prolapse beyond introitus (women)
- Suspected fistula

* These diagnoses may overlap in various combinations, e.g., Mixed UI, DHIC (see text)

* At any stage of the patient’s care pathway, management may need to include continence products

**HISTORY/SYMPTOM ASSESSMENT**
- Delirium
- Infection
- Pharmaceuticals
- Psychological
- Excess urine output
- Reduced mobility
- Stool impaction (and their factors)
- Avoid overtreatment of asymptomatic bacteriuria

**CLINICAL ASSESSMENT**

**CLINICAL DIAGNOSIS**
- Pelvic mass
- Pelvic irradiation
- Pelvic / LUT surgery
- Prolapse beyond introitus (women)
- Suspected fistula

**INITIAL MANAGEMENT***
- (if Mixed UI, initially treat most bothersome symptoms)

**ONGOING REASSESSMENT and MANAGEMENT**
Management of Faecal Incontinence in Frail Older Men & Women

**Active Case Finding in all Frail Elderly people**

- Assess, treat and reassess potentially treatable conditions, including relevant comorbidities and ADLs (see text)
- Assess QoL, desire for Rx, goals for Rx, pt & caregiver preferences
- Targeted physical examination (cognition, mobility, neurological and digital rectal examination)
- Urinalysis
- Consider bowel diary and clean checks, especially if nocturia is present. PVR is specific patients (see text)

**Rx reversible causes:**
- Delirium
- Infection
- Pharmaceuticals
- Psychological
- Excess stool output (diarrhoea)
- Reduced mobility
- Stool impaction (and their factors)

**CLINICAL DIAGNOSIS**

**Urgency FI**
- Lifestyle interventions
- Behavioural therapies
- Biofeedback
- Improve stool consistency

**Constipation/ Faecal Impaction**
- Treat constipation (osmotic laxatives) if impacted, Glycerine or Bisacodyl suppositories. Phospate enemas if severe.
- Review medications that may contribute to constipation
- Consider biofeedback if dyssynergic defaecation is suspected

**Passive FI**
- Lifestyle interventions
- Behavioural therapies
- Biofeedback
- Improve stool consistency

**IF insufficient improvement, reassess for and treatment of contributing comorbidity ± functional impairment**

**If continued insufficient improvement, or severe associated symptoms are present, consider specialist referral as appropriate per patient preferences and comorbidity (see text)**

- Pain
- Rectal bleeding
- Change in stool calibre
- Weight loss
- Chronic diarrhoea
- Faecal impaction
- Inflammatory bowel disease
- Pelvic irradiation
- Malabsorption syndromes
- Prolapse beyond introitus (women)
- Suspected fistula

**HISTORY/SYMPTOM ASSESSMENT**

**CLINICAL ASSESSMENT**

**INITIAL MANAGEMENT**

**ONGOING REASSESSMENT and MANAGEMENT**

**1945**

**These diagnoses may overlap in various combinations, e.g., Urgency-related, passive/seepage, and impaction (see text)**

* At any stage of the patient’s care pathway, management may need to include continence products
4. Recommendations for Further Research in Epidemiology

1. Longitudinal study designs are needed to: (i) estimate the incidence and remission rates of urinary incontinence (UI) anal incontinence (AI) and pelvic organ prolapse (POP) and to (ii) describe the natural course of these conditions and (iii) to investigate risk factors and possible protective factors. In addition similar studies regarding other lower urinary tract symptoms (LUTS) should be initiated.

2. Although there is today more information regarding prevalence, incidence, and other epidemiological data in developing countries further information is still needed. It is recommended that fundamental research regarding prevalence, incidence and other epidemiological data in developing countries should be encouraged, and tailored to the cultural, economic and social environment of the population under study.

3. Some potential risk and protective factors deserve more attention. For example, the role of pregnancy and childbirth in the development of UI, AI and POP must be studied in a fashion that links population-based methods to clinical assessment of pregnancy, delivery and birth trauma and follows women over many years. Such a design is necessary because the effect of pregnancy and childbirth may become clear only years later when the woman is older and because the woman will not then be able to report the exact nature of the tear, episiotomy, etc.

4. There should be more emphasis on the associations between UI, AI and POP and specific diseases like stroke, diabetes, and psychiatric diseases.

5. The variation of disease occurrence in groups of different racial origin yet similar environmental exposures, lend support to the presumed genetic influence on the causation of UI, AI and POP. This again provides circumstantial evidence for a genetic contribution to pelvic floor muscle disorders since most of these studies have been unable to control for heritability in relation to the complex interaction of environmental factors.

The aetiology of UI, AI and POP is widely recognised to be multifactorial, yet the complex interaction between genetic predisposition and environmental influences is poorly understood. Genetic components require further investigation. Twin studies provide a possible means of studying the relative importance of genetic predisposition and environmental factors. By comparing monozygotic female twins with identical genotype, and dizygotic female twins who on average share 50 percent of their segregating genes, the relative proportions of phenotypic variance resulting from genetic and environmental factors can be estimated. A genetic influence is suggested if monzygotic twins are more concordant for the disease than dizygotic twins whereas evidence for environmental effects comes from monozygotic twins who are discordant for the disease.

5. Recommendations for Further Basic Science Research

1. Integrate data from reductionist experiments to inform the formulation of better systems-based approaches in the investigation of the pathology of the lower urinary tract (LUT), the genital tract (GT) and the gastro-intestinal tract (GIT).

2. Encourage greater emphasis on basic research to characterise tissues receiving relatively little attention: ie the lower gastrointestinal tract; the bladder neck and urethra.

3. Generate improved experimental approaches to investigate the pathophysiology of the LUT and GIT by:
   • developing fully-characterised animal models
   • using human tissue from well-characterised patient groups.
   • developing emerging areas such as: tissue engineering; protein structure modelling
   • increasing collaborations between biological, physical and mathematical sciences.

4. Use genome-wide bioinformatic surveys to generate testable hypotheses regarding the physiological and pathophysiological functions of the LUT and GIT.

5. Develop centres of excellence in LUT and GIT research
   • integrate expertise from university departments, academic medical units and industry
   • encourage translational approaches to research.
   • develop inter-institutional research-training programmes to allow new researchers the opportunity to better interact and exchange ideas.
Continence promotion, service delivery, education, and primary prevention involves informing and educating the public and health care professionals that urinary and faecal incontinence are not inevitable, but are treatable or at least manageable. In addition, other bladder disorders such as bladder pain syndrome and pelvic organ prolapse can be treated successfully. Progress continues to be made in the promotion of continence awareness through advocacy programmes and public access to information on a worldwide basis. Professional education of these conditions has increased. However, screening and help-seeking behaviour have not noticeably improved. Published studies focus on developing better models of existing service provision and education, rather than testing new strategies to increase screening. There have been advances in primary prevention of urinary incontinence.

- Continence awareness should be part of mainstream and on-going health education and advocacy programmes with emphasis on eliminating stigma, raising awareness of effective treatments, promoting help-seeking behaviour and improving QoL.
- Continence awareness programmes should include education, health-care, and community service providers.
- Research is needed to provide higher level of evidence on the effectiveness of continence promotion programmes to include:
  - Identification and understanding of barriers to help-seeking behaviours
  - Translation of promotion research into improved clinical practice and identification of methods by which this occurs.
  - Effectiveness and impact of consumer education initiatives.

CONTINENCE AWARENESS AND PROMOTION

6. Recommendations

Continence Promotion, Education and Primary Prevention

CONTINENCE ADVOCACY AND MODELS OF SERVICE DELIVERY

- There is a need to move beyond the theory and work on research about the practice of continence care delivery and education. We recommend a care delivery model based on a chronic disease approach.
- There needs to be an increased emphasis on non-physician models of care (nursing, nurse practitioner, continence advisor, physiotherapy, physician assistants, etc.).
- Despite the proliferation of guidelines, there is increasing evidence that they are not being followed by practicing clinicians. Implementation models should be developed on how to translate guidelines into practice.
- There still appears to be a shortage of physician specialists in continence care (urology, gynaecology, etc.) and this needs to be addressed. (Grade D)
- Research is needed on the activities or effectiveness of organisations that target consumers or the general public.

7. Increase emphasis on research into lower urinary tract and gastro-intestinal tract in HEIs through:
- greater representation on grant-funding agencies
- encouragement of submission to high impact-factor journals and recognition of research published in specialty journals
- more integrated teaching and training opportunities

6. Bring about a greater emphasis on the importance of research to medical trainees through:
- establishing research training as a core component of medical training
- increased access to support funds, especially scholarships and personal awards
- organisation of focused multidisciplinary research meetings, either stand-alone or as dedicated sessions during international conferences
- greater interaction between medical centres and Higher Education Institutions (HEIs)
- allow researchers-in-training better access to international meetings through reduced registration charges and travel grants
- Lobby research-funding organisations about the medical and social importance of LUT and GIT disorders.
There remains a need for rigorously evaluated continence education programmes which adhere to defined minimum standards for continence specialists and generalists, utilising web-based and distance learning techniques alongside audit and feedback, train-the-trainer models and leadership models as well as traditional methods.

Models of education content delivery (professional and patient education) are changing with technology with increased emphasis on internet, web modules, etc. There needs to be ongoing quality control that includes maintenance of accuracy, methods of delivery, etc.

There is a need for research on the most effective means to educate professional groups on continence issues to include:

- The effectiveness of innovative teaching methods in improving knowledge and practice.
- Translation of research into improved clinical practice and identification of methods by which this happens.
- Mechanisms for increasing professional motivation to acquire education and improve performance.

Models of education content delivery (professional and patient education) are changing with technology with increased emphasis on internet, web modules, etc. There needs to be ongoing quality control that includes maintenance of accuracy, methods of delivery, etc.

There is a need for research on the most effective means to educate professional groups on continence issues to include:

- The effectiveness of innovative teaching methods in improving knowledge and practice.
- Translation of research into improved clinical practice and identification of methods by which this happens.
- Mechanisms for increasing professional motivation to acquire education and improve performance.

Primary prevention studies should not be limited to individual interventions, but also test the impact of population-based public health strategies **(Grade C)**

More high quality randomised controlled trials are needed to strengthen the effectiveness of population-based primary prevention intervention.

---

### 7. Recommendations for Clinical Research Methodology

#### PART I: RECOMMENDATIONS ON STUDY CONDUCT AND STATISTICAL METHODS

The role of quality RCTs as providing the strongest level of evidence in incontinence research should be fully acknowledged by researchers, journal reviewers, and editors. **HIGH**

Careful attention to the planning and design of all research, especially RCTs, is of the utmost importance. **HIGH**

Appropriate expertise in biostatistics and clinical trial design should be employed at the design phase of a RCT and thereafter on an ongoing basis. **HIGH**

The design, conduct, analysis and presentation of RCTs must be fully in accordance with the CONSORT Statement. **HIGH**

The design, conduct, analysis and presentation of observational studies should follow STROBE guidelines. **HIGH**

The design, conduct, analysis and presentation of meta-analyses should follow QUORUM guidelines. **HIGH**

Reporting studies of diagnostic tests, including urodynamics, should follow the STARD statement guidelines. **HIGH**

#### PART II: RECOMMENDATIONS ON RESEARCH CONDUCT

Use correct terminology to describe the intervention. **HIGH**

Report details of ability to perform correct contraction, dose-response issues and adherence. **HIGH**

Use recommended outcome measures with high responsiveness, reliability and validity. **HIGH**

Compare new methods with the best available intervention. **HIGH**

Use power calculation in planning of the study. Avoid large sample sizes and weak (ineffective dosages) interventions. **HIGH**

For long-term follow-up studies report cross-over, co-interventions, recurrent and competing events, adherence in the follow-up period and loss to follow-up.
The safety and serious side effects of new operations must be completely defined with adequate follow-up so that risks can be weighed against efficacy. At a minimum, this requires more use of large scale, independent, prospective, multicenter cohort studies when RCTs are not practical. HIGH

Safety and serious side effects of incontinence devices must be completely defined with adequate follow-up, especially for use of implantable devices and biologic materials, so that risks can be weighed against efficacy. HIGH

Valid informed research consent is required in all trials of surgical interventions, which is separate from the consent to surgery. HIGH

We recommend ongoing research into the usefulness of pre- and post-operative predictive testing (such as urodynamics, ultrasound, MRI, etc) in surgical trials. HIGH

Reports of successful treatment should be limited to subjects with a minimum (not mean) of one year follow-up and should include a patient perspective measure. Specific assumptions about subjects lost to follow-up should be stated. HIGH

Randomisation for surgical trials should occur at the time of surgery to minimize drop-outs and switch of procedure. HIGH

Long-term follow-up of RCT cohorts in an observational cohort is recommended. HIGH

Cost analysis should be incorporated into clinical studies whenever possible (137). HIGH

Measurement of prostate size should be performed before and after treatment (at the same time as continence outcome measures where possible) whenever prostate size is considered to be a variable, or to change during the intervention and follow up. HIGH

Maximum free flow rate and measurement of post-void residual urine should be recorded pre-treatment and the effect of therapy on these parameters should be documented simultaneously with assessment of the primary outcome variables. HIGH

Participants should be stratified by prostate size at randomization when size is considered to be a potentially important determinant of treatment outcome. LOW

Specific information about menopausal status, hysterectomy, parity/obstetric history, and hormonal status should be included in baseline clinical trial data and controlled for in specified analyses in the research protocol. HIGH

High quality, symptom and bother scores (e.g., ICIQ-FLUTS, ICIQ-SM, KHQ, PISQ, ICIQ-FLUTSsex) validated in women should be employed when assessing outcomes. HIGH

Standardized assessment of pelvic organ prolapse should be performed before treatment and at the time of other outcome assessments in all research where prolapse and continence outcomes are being assessed. HIGH

Criteria for cure/improvement/failure from incontinence treatment should be defined in the protocol based on patient perception as well as objective and semi-objective instruments such as validated questionnaires, diaries and pad tests. HIGH

Assessment of the impact of treatment on sexual function should be performed with other outcome assessment when appropriate. MEDIUM

Long-term follow-up is of critical importance in the paediatric population in order to ascertain the effect of a treatment on normal growth and development. HIGH

Research is needed to develop standardised outcome measures including validated, age-specific symptom and disease-specific quality of life outcome measures. MEDIUM

Detailed urodynamic studies are recommended for classification of neurogenic lower urinary tract function.
disorders in research studies because the nature of the lower tract dysfunction cannot be accurately predicted from clinical data. Videourodynamic studies are preferred but are not mandatory. LOW

• An area of high priority for research is the development of a classification system to define neurogenic disorders. Relevant features could include the underlying diagnosis, the symptoms, more precise documentation of the neuromuscular lesion by clinical neurophysiologic testing, and the nature of the urodynamic abnormality. LOW

III: POPULATIONS AFFECTED BY BLADDER PAIN SYNDROME (INCLUDING INTERSTITIAL CYSTITIS)

• Broader entry criteria should be used to reflect the full spectrum of the BPS/IC patient population. MEDIUM

• The primary endpoint of BPS/IC trials should be patient driven and the Global Response Assessment is recommended. A wide spectrum of secondary endpoints will be useful in defining the effect of treatments. MEDIUM

IIIg: POPULATIONS AFFECTED BY PELVIC ORGAN PROLAPSE

• A validated standardised assessment of prolapse (eg POP-Q) should be used for baseline and outcome assessments. HIGH

• Complete reporting of outcomes including a validated assessment of anatomy, functional status, and complications is essential. HIGH

• Complications/adverse events (especially for mesh) must be explicitly and completely reported in any research. HIGH

• Long term outcomes (> 2 years) of intervention studies are needed. HIGH

IV. RECOMMENDATIONS FOR ETHICS IN RESEARCH

Continuity in clinical direction from design through authorship is mandatory. Investigators should be involved in the planning stage and a publications committee should be named at the beginning of the clinical trial. The Uniform Requirements for Manuscripts Submitted to Biomedical Journals, from the International Committee of Medical Journal Editors should be followed. Authorship requires:

• Substantial contributions to conception and design or acquisition of data or analysis and interpretation of data,
• Drafting the article or revising it critically for important intellectual content,
• Final approval of the version to be published

• Authors should provide a description of what each contributed and editors should publish that information.
• Authors should have access to all raw data from clinical trials, not simply selected tables Clinical trial results should be published regardless of outcome. The sponsor should have the right to review manuscripts for a limited period of time prior to publication but the manuscript is the intellectual property of its authors, not the sponsor.

• All authors should be able to accept responsibility for the published work and all potential conflicts of interest should be fully disclosed
The scientific committee which met at the end of the 1st ICI in 1998 supported the idea that a universally applicable questionnaire should be developed, that could be widely applied both in clinical practice and research.

The hope was expressed that such a questionnaire would be used in different settings and studies and would allow cross-comparisons, for example, between a drug and an operation used for the same condition, in the same way that the IPSS (International Prostate Symptoms Score) has been used.

An ICIQ Advisory Board was formed to steer the development of the ICIQ, and met for the first time in 1999. The project’s early progress was discussed with the Board and a decision made to extend the concept further and to develop the ICIQ Modular Questionnaire to include assessment of urinary, bowel and vaginal symptoms. The first module to be developed was the ICIQ Short Form Questionnaire for urinary incontinence: the ICIQ-UI Short Form. The ICIQ-UI Short Form has now been fully validated and published [2].

Given the intention to produce an internationally applicable questionnaire, requests were made for translations of the ICIQ-UI Short Form at an early stage, for which the Advisory Board developed a protocol for the production of translations of its modules. The ICIQ-UI Short Form has been translated into 30 languages to date. Two further, newly developed and fully validated, modules have been finalised since the third consultation and are now being incorporated into clinical practice and research, and translated accordingly for international use. The ICIQ-VS[7] provides evaluation of vaginal symptoms and the ICIQ-B [3] can be used to assess bowel symptoms including incontinence. Both questionnaires also provide assessment of the impact of these symptoms on quality of life (Table 1).

Where high quality questionnaires already existed within the published literature, permission was sought to include these within the ICIQ in order to recommend them for use. Eleven high quality modules have been adopted into the ICIQ which are direct (unchanged) derivations of published questionnaires (Table 1).

www.ICIQ.net provides details of the validation status of the modules under development for urinary symptoms, bowel symptoms and vaginal symptoms and provides information regarding the content of existing modules. Information regarding production of translations and the ICIQ development protocol is also available for those interested in potential collaborations to continue development of the project.
ICIQ-UI on Urinary Incontinence Questionnaire (short form)

Today’s date

Many people leak urine some of the time. We are trying to find out how many people leak urine, and how much this bothers them. We would be grateful if you could answer the following questions, thinking about how you have been, on average, over the PAST FOUR WEEKS.

1. Please write in your date of birth:

2. Are you (tick one):
   - Female
   - Male

3. How often do you leak urine?
   - (Tick one box)
     - never
     - about once a week or less often
     - two or three times a week
     - about once a day
     - several times a day
     - all the time

4. We would like to know how much urine you think leaks.
   - How much urine do you usually leak (whether you wear protection or not)?
   - (Tick one box)
     - none
     - a small amount
     - a moderate amount
     - a large amount
     - a very large amount

5. Overall, how much does leaking urine interfere with your everyday life?
   - Please ring a number between 0 (not at all) and 10 (a great deal)
   - 0
   - 1
   - 2
   - 3
   - 4
   - 5
   - 6
   - 7
   - 8
   - 9
   - 10

6. When does urine leak?
   - (Please tick all that apply to you)
     - never – urine does not leak
     - leaks before you can get to the toilet
     - leaks when you cough or sneeze
     - leaks when you are asleep
     - leaks when you are physically active/exercising
     - leaks when you have finished urinating and are dressed
     - leaks for no obvious reason
     - leaks all the time

Thank you very much for answering these questions.
## Table 1. Fully validated ICIQ modules and derivation

### REFERENCES

The ICS defines three types of Bladder Charts and Diaries which can be used to collect data:

**Micturition Time Chart**
- times of voiding and
- incontinence episodes

**Frequency Volume Chart**
- times of voiding with voided volumes measured,
- incontinence episodes and number of changes of incontinence pads or clothing.

**Bladder Diaries**
- the information above, but also
- assessments of urgency,
- degree of leakage (slight, moderate or large) and descriptions of factors leading to symptoms such as stress leakage, eg. running to catch a bus
- It is important to assess the individual’s fluid intake, remembering that fluid intake includes fluids drunk plus the water content of foods eaten. It is often necessary to explain to a patient with LUTS that it may be important to change the timing of a meal and the type of food eaten, particularly in the evenings, in order to avoid troublesome nocturia.

The micturition time and frequency volumes charts can be collected on a single sheet of paper (Fig. 1). In each chart/diary, the time the individual got out of bed in the morning and the time they went to bed at night should be clearly indicated.

Each chart/diary must be accompanied by clear instructions for the individual who will complete the chart/diary: the language used must be simple as in the suggestions given for patient instructions. There are a variety of designs of charts and diaries and examples of a detailed bladder diary are given. The number of days will vary from a single day up to one week.

### INSTRUCTIONS FOR COMPLETING THE MICTURITION TIME CHART

This chart helps you and us to understand why you get trouble with your bladder. The diary is a very important part of the tests we do, so that we can try to improve your symptoms. On the chart you need to record:
1. When you get out of bed in the morning, show this on the diary by writing ‘GOT OUT OF BED’.
2. The time, eg. 7.30am when you pass your urine. Do this every time you pass urine throughout the day and also at night if you have to get up to pass urine.
3. Each time you pass urine, collect the urine in a measuring jug and record the amount (in mls or fluid ozs) next to the time you passed the urine, eg. 1.30pm - 320 mls.
4. If you leak urine, show this by writing ‘W’ (wet) on the diary at the time.
5. If you have a leak, please add ‘P’ if you have to change a pad and ‘C’ if you have to change your underclothes or even outer clothes. So, if you leak and need to change a pad, please write ‘WP’ at the time you leaked.

6. At the end of each day please write in the column on the right the number of pads you have used, or the number of times you have changed clothes.

When you go to bed at the end of the day show it on the diary - write ‘Went to Bed’.

### INSTRUCTIONS FOR USING THE FREQUENCY VOLUME CHART

This chart helps you and us to understand why you get trouble with your bladder. The diary is a very important part of the tests we do, so that we can try to improve your symptoms. On the chart you need to record:
1. When you get out of bed in the morning, show this on the chart by writing ‘Got out of bed’.
2. The time, eg. 7.30am when you pass your urine. Do this every time you pass urine throughout the day and also at night if you have to get up to pass urine.
3. Each time you pass urine, collect the urine in a measuring jug and record the amount (in mls or fluid ozs) next to the time you passed the urine, eg. 1.30pm - 320 mls.
4. If you leak urine, show this by writing ‘W’ (wet) on the diary at the time.
5. If you have a leak, please add ‘P’ if you have to change a pad and ‘C’ if you have to change your underclothes or even outer clothes. So, if you leak and need to change a pad, please write ‘WP’ at the time you leaked.
6. At the end of each day please write in the column on the right the number of pads you have used, or the number of times you have changed clothes.

When you go to bed at the end of the day show it on the diary - write ‘Went to Bed’.

7. If you have a leakage please write in the column called ‘Comments’ whether you leaked a small amount or a large amount and what you were doing when you leaked, eg. ‘leaked small amount when I sneezed three times’.
8. Each time you change a pad or change clothes, please write in the ‘Comments’ column.
9. If you have a leakage please write in the column called ‘Comments’ whether you leaked a small amount or a large amount and what you were doing when you leaked, eg. ‘leaked small amount when I sneezed three times’.
10. When you go to bed at the end of the day show it on the diary - write ‘Went to Bed’.

b) Afferent Innervation of the Urethral and Anal Rhabdosphincters 202
5. REFLEX ACTIVATION OF URETHRAL AND ANAL RHABDOSPINDCTERS 202
6. INHIBITION OF URETHRAL RHABDOSPINDCTER (URS) REFLEXES DURING VOIDING 204
7. SUPRASPINAL ACTIVATION OF RHABDOSPINDCTERS AND PELVIC FLOOR MUSCLES 204
8. NEUROCHEMICAL ANATOMY OF RHABDOSPINDCTER MOTOR NEURONS 206
a) Pharmacology of Urethral and Anal Rhabdosphincters 206
9. LA AND RHABDOSPINDCTER NEUROPATHY 208
IV. AFFERENT PATHWAYS TO THE BLADDER 210
1. PREGANGLIONIC NEURONS 210
2. GANGLIA 210
3. TERMINAL NERVE FIBERS 211
4. TRANSMITTERS 212
a) Glutamate 212
b) Glycine/ gamma amine butyric acid 212
c) Serotonin 212
d) Adrenergic 212
e) Substance P 212
f) Purinergic 213
5. PELVIC ORGAN INTERACTIONS AT THE EFFERENT NEURAL LEVEL 213
a) Bladder and Outlet 213
b) Bladder and Bowel 214
c) Bladder and Prostate/Uterus 214
6. EFFERENT INHIBITION 214
7. PERIPHERAL EXCITATORY MECHANISMS 215
V. PONTINE-MIDBRAIN CONTROL OF BLADDER FUNCTION 216
1. AFFERENT PATHWAYS LINKING THE BLADDER AND URETHRA TO THE PONS AND MIDBRAIN 217
2. DEFINING THE CENTRAL CIRCUITY REGULATING BLADDER FUNCTION BY TRANSNEURONAL TRACING 218
3. BARRINGTON’S NUCLEUS: THE PONTINE MICTURITION CENTER (PMC) 218
4. BARRINGTON’S NUCLEUS, THE LOCUS COERULEUS AND CENTRAL RESPONSES TO BLADDER INFORMATION 220
a) Normal Function 220
b) Pathological Consequences 220
5. SUPRASPINAL INPUTS TO BARRINGTON’S NUCLEUS 222
6. DEFENSIVE STRATEGIES AND MICTURITION 223
7. COORDINATION OF BLADDER WITH OTHER PELVIC VISCERA BY BARRINGTON’S NUCLEUS 223
8. THE PONTINE CONTINENCE CENTRE (PCC) 224
9. NEUROTRANSMITTERS & MODULATORS WITHIN BRAINSTEM NETWORKS CONTROLLING BLADDER FUNCTION 224

VI. FOREBRAIN CONTROL OF BLADDER FUNCTION 225
1. BACKGROUND 225
2. ROLE AND IMPORTANCE OF CEREBRAL CONTROL OF VOIDING 225
3. CORTICAL AND SUBCORTICAL CENTRES INVOLVED IN BLADDER CONTROL. EVIDENCE FROM OBSERVATIONS OF LESIONS AND FROM FUNCTIONAL BRAIN IMAGING IN HUMANS 227
   a) Frontal Lobes 227
   b) Anterior Cingulate Gyrus (ACG), Supplementary Motor Cortex (SMA) and Insula 228
   c) Periaqueductal Grey (PAG) 232
   d) Hypothalamus 232
   e) Pons 232
   f) Other Regions 232
4. VOIDING 233
5. WORKING MODEL OF BRAIN / BLADDER CONTROL 233
   a) The Normal Continence Mechanism 235
   b) A Back-up Continence Mechanism 235
   c) Limbic or Paralimbic Circuits 235
   d) Voiding 235
6. CONCLUSION: CORTICAL CONTROL OF BLADDER FUNCTION 235

VII. ABNORMAL LOWER URINARY TRACT FUNCTION 236
1. ABNORMALITIES INVOLVING AFFERENT SIGNALING 236
   a) Bladder Pain Syndrome / Interstitial Cystitis (BPS/IC) 236
   b) Pelvic Organ Cross-talk 237
2. INVOLVING ABNORMAL URINE STORAGE 237
   a) Overactive Bladder / Detrusor Overactivity 237
   b) Stress Urinary Incontinence 239
3. INVOLVING ABNORMAL VOIDING 239
   a) Bladder Outflow Obstruction 239
   b) Co-Morbid Disorders 240

Pathophysiology of Urinary Incontinence, Faecal Incontinence and Pelvic Organ Prolapse

PREFACE 263
A. THE OVERACTIVE BLADDER 263
I. INTRODUCTION 263
II. MECHANISMS UNDERLYING INCREASED AFFERENT ACTIVITY 265
   1. THE UROTHELIUM-BASED HYPOTHESIS 265
   2. MYOGENIC HYPOTHESIS 266
   3. OTHER LOCAL FACTORS 267
      a) Ischaemia 267
      b) Inflammation 267
III. MECHANISMS INVOLVED IN ABNORMAL HANDLING OF THE AFFERENT SIGNALS IN THE BRAIN 268
   1. NEUROGENIC DETRUSOR OVERACTIVITY 268
      a) Suprapontine lesions 268
      b) Spinal cord lesions 268
   B. PREGNANCY, CHILDBIRTH AND THE PELVIC FLOOR 269
I. DAMAGE TO FUNCTIONS SUSTAINED BY THE PELVIC FLOOR 269
1. POSTPARTUM URINARY INCONTINENCE 269
2. ANAL INCONTINENCE 270
3. PELVIC ORGAN PROLAPSE 271
II. EFFECT OF PREGNANCY ON PELVIC FLOOR FUNCTION 272
   1. EFFECT ON THE COLLAGEN 272
   2. NATURAL HISTORY 272
   3. FAMILIAL PREDISPOSITION 273
III. PATHOPHYSIOLOGICAL MECHANISM OF BIRTH INJURY TO THE PELVIC FLOOR 274
   1. MUSCLE TRAUMA 274
   2. NERVE INJURY 276
IV. PERINEAL TRAUMA 276
   1. EPIDURAL ANALGESIA DURING LABOUR 276
   2. ROLE OF EPISIOTOMY 277
V. CONCLUSION AND RECOMMENDATION 279
C. PATHOPHYSIOLOGY OF STRESS INCONTINENCE IN WOMEN: URETHRAL STRUCTURE, SUPPORT AND FUNCTION 279
I. THE FEMALE UROGENITAL DIAPHRAGM: URETHRAL SPHINCTER LOCATION 280
II. EFFECT OF CHILDBIRTH, VAGINAL PROLAPSE AND URETHRAL POSITION ON URINARY CONTINENCE 282
   1. PUDENDAL NERVE 282
   2. CARDINAL AND UTERO-SACRAL LIGAMENTS 282
   3. THE VAGINA 282
   4. LEVATOR MUSCLES 282
III. EMERGING CONCEPTS OF URETHRA WEAKNESS AND ISD 283
IV. HYPERMOBILITY VS. ISD: FROM DICHOTOMY TO CONTINUUM 283
   1. DIRECT STUDIES OF URETHRAL FUNCTION 284
      a) Studies of urethral position 284
      b) Studies of urethral pressure and resistance 284
      c) Electrophysiological studies of urethral function 284
      d) Genetic factors 284
   2. ROLE OF ADVANCED IMAGING IN UNDERSTANDING PATHOPHYSIOLOGY 285
      a) Magnetic resonance imaging 285
      b) Real time ultrasonography 285
V. CONCLUSIONS 287
D. PELVIC ORGAN PROLAPSE 287
I. PATHOPHYSIOLOGY OF PELVIC ORGAN PROLAPSE 287
   1. INHERITANCE, GENETIC AND ETHNIC PREDISPOSITION 288
   2. ALTERATION OF COLLAGEN, ELASTIN AND SMOOTH MUSCLE OF THE VAGINAL AND SUPPORTIVE TISSUE 291
   3. NEUROLOGICAL FACTORS 293
   4. PREGNANCY AND PELVIC FLOOR MUSCLE REMODELLING 294
   5. CHILDBIRTH 294
   6. OBSTETRIC AND MATERNAL FACTORS 296
   7. AGE 297
   8. HORMONES 297
   9. OBESITY 297
   10. CONSTIPATION 297
   11. CHRONIC PELVIC FLOOR STRESS 298
   12. PREVIOUS OPERATIONS 298
   13. THE BONY PELVIS 298
   14. ASSOCIATED PELVIC FLOOR CONDITIONS 298
      a) Bladder function 298
      b) Anorectal function 300
      c) Sexual function 301
5. ABDOMINAL LEAK POINT PRESSURE 434

IV. TECHNOLOGICAL INNOVATIONS IN URODYNAMICS 434
1. AIR-CHANGED CATHETERS FOR PRESSURE MEASUREMENT 434
2. OBJECTIVE ASSESSMENT OF BLADDER SENSATION 434
3. NON-INVASIVE PRESSURE (& FLOW) MEASUREMENTS 435
4. URETHRAL RETRO-RESISTANCE PRESSURE 436
5. URETHRAL PRESSURE REFLECTOMETRY 437
6. ULTRASOUND IMAGING 437
B. URODYNAMICS: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE 437
I. REPRODUCIBILITY OF FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS 437
1. INTER-OBSERVER, TEST-RETEST AND PRACTICE VARIATION 437
2. SHORT-TERM (WITHIN-SESSION) REPRODUCIBILITY 438
3. INTERMEDIATE-TERM REPRODUCIBILITY 439
4. LONG-TERM REPRODUCIBILITY 439
5. REPRODUCIBILITY OF AMBULATORY URODYNAMICS 440
II. CYSTOMETRY: NORMAL VALUES 440
1. NORMAL VALUES: FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS 440
2. COMPLIANCE 441
3. NORMAL SENSATIONS AND BLADDER CAPACITY 441
4. DETRUSOR (OVER-) ACTIVITY IN NORMAL SUBJECTS 442
5. INFLUENCE OF CATHETER ON VOIDING 442
III. REPRODUCIBILITY, RELIABILITY AND NORMAL VALUES OF URETHRAL PRESSURE MEASUREMENTS 443
1. NORMATIVE AND COMPARATIVE DATA FOR MAXIMUM URETHRAL CLOSURE PRESSURE 443
2. RELIABILITY OF URETHRAL PRESSURE VARIABLES 443
3. AGING 443
4. OTHER PARAMETERS AFFECTING THE MEASUREMENT OF URETHRAL CLOSURE PRESSURE 443
IV. LEAK POINT PRESSURE 444
1. INTRODUCTION 444
2. RELIABILITY OF LEAK POINT PRESSURE MEASUREMENTS 444
a) Diagnosis 444
b) Treatment 445
c) Within-patient variability 445

V. DIAGNOSTIC PERFORMANCE OF FILLING CYSTOMETRY AND AMBULATORY MONITORING 446
1. SENSITIVITY AND SPECIFICITY OF FILLING CYSTOMETRY IN OVERACTIVE BLADDER SYNDROME 446
a) Detrusor overactivity incontinence 446
b) Detrusor overactivity alone 447
c) Overactive bladder syndrome and detrusor overactivity 447
d) Distinguishing or defining characteristics of detrusor overactivity 450
e) Provocative manoeuvres 451
2. AMBULATORY URODYNAMICS: SENSITIVITY AND SPECIFICITY 452
3. THE ADJUNCT USE OF IMAGING AND ELECTROMYOGRAPHY 453
VI. THERAPEUTIC PERFORMANCE OF FILLING CYSTOMETRY AND AMBULATORY MONITORING 453

1. PREDICTION OF TREATMENT RESPONSE 453
a) Filling cystometry 453
b) Ambulatory monitoring 453

C. CLINICAL APPLICATIONS OF URODYNAMIC STUDIES 454
I. PATIENT EVALUATION: WOMEN 454
1. INTRODUCTION 454
2. STRESS URINARY INCONTINENCE 455
a) Urethral pressures and severity of stress urinary incontinence 455
b) Aspects of urodynamic studies relevant to therapy for stress urinary incontinence 456
c) Prediction of failure of surgery 457
d) Voiding difficulties after surgery 457
e) Postoperative urgency 458
f) The role of urodynamic studies in predicting occult stress urinary incontinence in women due to be treated for pelvic organ prolapse 459
3. URGENCY URINARY INCONTINENCE 459
a) Pathophysiology and severity of urgency urinary incontinence 459
b) Prediction of treatment response 460
4. RECOMMENDATIONS FOR URODYNAMIC STUDIES IN WOMEN WITH URINARY INCONTINENCE 460
II. PATIENT EVALUATION: MEN 461
1. INTRODUCTION 461
2. URODYNAMIC TESTING OF DETRUSOR OVERACTIVITY AND OVERACTIVE BLADDER IN MEN 461
3. LOWER URINARY TRACT SYMPTOMS RELATED TO MALE LOWER URINARY TRACT DYSFUNCTION: DETRUSOR OVERACTIVITY AND BLADDER OUTLET OBSTRUCTION 462
4. POST-PROSTATECTOMY INCONTINENCE 463
a) General 463
b) Transurethral resection of the prostate and Open Prostatectomy for benign disease 464
c) Radical Prostatectomy and Radiotherapy 464
d) Artificial urinary sphincter and male sling 465
5. NEUROLOGICAL LESIONS RELATED TO MALE LOWER URINARY TRACT DYSFUNCTION 467
a) Nocturnal enuresis 467
b) Stroke 468
c) Parkinson’s disease 468
d) Diabetes Mellitus (DM) 469
e) Recommendations for urodynamic investigation for men suffering from nocturnal enuresis, stroke, Parkinson’s disease or DM 469
III. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION 470
1. INTRODUCTION 470
2. WHAT IS USUALLY EVALUATED? 470
3. SPECIAL TESTS 470
4. NEUROGENIC DETRUSOR OVERACTIVITY IN CONTINENCE 470
5. DETRUSOR-SPHINCTER DYSSYNERGIA 471
6. LEAKAGE ASSOCIATED WITH CHRONIC RESIDUAL/RETENTION OF URINE (‘OVERFLOW INCONTINENCE’) 471
7. REPRODUCIBILITY AND RELIABILITY OF TESTS 471
8. DOES URODYNAMIC TESTING HELP TO SELECT (OPTIMAL) TREATMENT? 471
IV. PATIENT EVALUATION: CHILDREN 472
1. INTRODUCTION 472
2. NEUROGENIC BLADDER DYSFUNCTION 473
a) Myelodysplasia 473
b) Occult spinal dysraphism 474
c) Sacral agenesis 475
d) Spinal cord injury 476
e) Cerebral palsy 477
f) Tumours 477
3. ANORECTAL MALFORMATION OR IMPERFORATE ANUS 477
4. ANATOMIC ABNORMALITIES 478
a) Posterior urethral valves 478
b) Bladder extrophy and persistent Cloacal anomalies 479
c) Ectopic ureterocoli 480
d) Vescoureteral reflux 480
e) Urethral strictu 481
f) Enuresis (nocturnal) 482
5. FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT 481
a) Diurnal incontinence 481
b) Stress urinary incontinence 486
6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS 483
V. PATIENT EVALUATION: FRAIL ELDERLY 484
1. INTRODUCTION 484
2. ROUTINE EVALUATION 485
a) Urinary urgency incontinence 485
b) Stress urinary incontinence 486
3. EVIDENCE FOR REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC TEST IN THE GERIATRIC OR FRAIL ELDERLY POPULATION 486
a) Filling cystometry 486
b) Post-void residual urine 486
c) Pressure-flow studies 486
4. EVIDENCE THAT PERFORMING URODYNAMIC TESTING IMPROVES CLINICAL OUTCOMES IN THE GERIATRIC POPULATION 487
5. THE PRACTICAL INDICATIONS FOR URODYNAMIC STUDIES AND WHICH TESTS ARE NEEDED 487
a) Post-void residual urine 487
b) Uroflowmetry 487
c) Pressure-flow studies 487
6. THE URODYNAMIC PARAMETERS IMPORTANT IN VARIOUS GERIATRIC CONDITIONS 487
a) Parkinson’s Disease 487

VI. MUSCARINIC RECEPTORS 630
B. Drugs used for treatment of overactive bladder symptoms/detrusor overactivity 632
I. ANIMUSCARINIC (ANTICHOLINERGIC) DRUGS 632
   1. ANIMUSCARINICS WITH "SPECIFIC" ACTION 635
      a) Atropine sulfate 635
      b) Darifenacin hydrobromide 635
      c) Fesoterodine fumarate 637
      d) Imidafenacin 638
      e) Propantheline bromide 639
      f) Solifenacin succinate 640
      g) Tolsunide tartrate 642
      h) Tosprim chloride 645
   2. ANIMUSCARINICS WITH "MIXED" ACTION 646
      a) Oxybutynin chloride 646
      b) Propiverine hydrochloride 649
      c) Flavoxate hydrochloride 651
   3. CLINICAL USE OF ANIMUSCARINICS 652
      II. DRUGS ACTING ON MEMBRANE CHANNELS 653
         a) CALCIUM ANTAGONISTS 653
         b) POTASSIUM CHANNEL OPENERS 654
   III. A-ADRENOCEPTOR (AR) ANTAGONISTS 655
   IV. B-ADRENOCEPTOR AGONISTS 656
   V. PHOSPHODIESTERASE (PDE) INHIBITORS 660
   VI. ANTIDEPRESSANTS 662
      a) IMIPRAMINE 662
      b) DULOXETINE 663
   VII. CYCLOOXYGENASE (COX) INHIBITORS 663
      VIII. TOXINS 664
         a) BOTULINUM TOXIN 664
            i) Mechanism of action of BONT 664
            ii) BoNT/A effects on bladder histology 665
            iii) BoNT/A injection protocol 666
            iv) Effect of Bont/A on NDO adult patients 666
            v) BoNT/A and UTI in adult NDO patients 668
            vi) BoNT/A in IDO patients 668
            vii) BoNT/A in children and elderly patients 670
            viii) Effect of BoNT/A on quality of life 671
i) Side effects of bladder wall injection of BoNT/A 672
j) Effectiveness of repeated injections in NDO and IDO patients 673
k) Cost-effectiveness of BoNT/A 674
l) Comparisons between different BoNT/A brands 674
m) BONT/B 674
n) BONT/A in IC/PBS 675

2. CAPSAICIN AND RESINIFERATOXIN (RTX) 676
a) Rationale for intravesical vanilloids 676
b) Intravesical capsaicin 676
c) RTX in NDO 676
d) RTX in IDO 676
e) RTX and urgency 677
f) Intravesical RTX and IC/PBS 677

IX. OTHER DRUGS 677
1. BACLOFEN 677

X. COMBINATIONS 678
1. Α1-AR ANTAGONISTS WITH ANTIMUSCARINICS 678
2. COMBINED ANTIMUSCARINICS 679
3. ANTIMUSCARINICS AND 5Α-REDUCTASE INHIBITORS 680
4. Α1-AR ANTAGONISTS WITH 5Α-REDUCTASE INHIBITORS 680

XI. FUTURE POSSIBILITIES 680
1. PERIPHERALLY ACTING DRUGS 680
2. CENTRALLY ACTING DRUGS 686
a) Gonadotropin-releasing hormone antagonists 686
b) Gabapentin 687
c) Tramadol 687
d) NK1-receptor antagonists 687

C. Drugs used for treatment of stress incontinence in women 688
I. Α-ADRENOCEPTOR AGONISTS 689
II. Β-ADRENOCEPTOR AGONISTS 690
III. Β –ADRENOCEPTOR ANTAGONISTS 690
IV. SEROTONIN-NORADRENALINE UPTAKE INHIBITORS 690
1. IMPRIMAINE 690
2. DULOXETINE 690

D. Stress urinary incontinence in men 693

5. OTHER LUTS

d) Does the addition of PFMT to other treatments add benefit? 1135

c) Is PFMT better than other treatments? 1129

b) Is one type of PFMT programme better than another? 1120

c) Is PFMT better than other treatments? 1129

d) Does the addition of PFMT to other treatments add benefit? 1134

5. OTHER LUTS

6. FACTORS AFFECTING OUTCOME

a) Age 1136

b) Other 1136

III. WEIGHTED VAGINAL CONES (VCS)

1. PREVENTION 1137

2. TREATMENT 1138

a) Are VCs better than no treatment, placebo or control treatments? 1138

b) Are VCs as effective as other treatments? 1138

c) Are VCs combined with PFMT better than PFMT alone? 1144

3. OTHER LOWER URINARY TRACT SYMPTOMS (LUTS)

4. FACTORS AFFECTING OUTCOME 1144

IV. ELECTRICAL STIMULATION (ESTIM)

1. PREVENTION 1152

2. TREATMENT 1152

a) Is ESTim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI? 1152

b) Is one type of ESTim better than another in the treatment of UI? 1154

c) Is ESTim better than other treatments for UI? 1154

d) Does the addition of ESTim to other treatments add any benefit in the treatment of UI? 1156

3. OTHER LUTS

4. FACTORS AFFECTING OUTCOME 1158

V. MAGNETIC STIMULATION (MSTIM)

1. PREVENTION 1160

2. TREATMENT 1160

a) Is MSTim better than no active treatment (placebo, control or no treatment)? 1160

b) Is one approach to MSTim better than another? 1163

c) Is MSTim better than other treatments? 1163

d) Does the addition of MSTim to other treatments add any benefit in the treatment of UI? 1166

VI. SCHEDULED VOIDING REGIMENS

1. PREVENTION 1165

2. TREATMENT 1165

a) What is the most appropriate bladder training (BT) protocol? 1166

b) Is BT better than no treatment, placebo or control treatments? 1167

c) Is BT better than other treatments? 1168

d) Can any other treatment be added to BT to add benefit? 1169

e) Does the addition of BT to any other treatment add benefit? 1170

f) Timed voiding 1171

3. OTHER LUTS

4. FACTORS AFFECTING OUTCOME 1172

2. PHYSICAL THERAPY 1605
3. STRESS REDUCTION 1606
4. DIETARY MANIPULATION 1606
IX. ORAL THERAPY 1606
1. ANALGESICS 1607
a) Amitriptyline 1608
b) Doxepin, desipramine, duloxetine 1608
2. ANTIDEPRESSANTS 1608
a) Amitriptyline 1608
b) Doxepin, desipramine, duloxetine 1608
3. ANTIHISTAMINES 1608
a) Hydroxyzine 1609
b) Cimetidine 1609
4. IMMUNOSUPPRESSANTS 1609
a) Cyclosporine 1609
b) Sulfasalazine 1609
c) Azathioprine and Chloroquine derivatives 1609
d) Corticosteroids 1609
5. SODIUM PENTOSANPOLYSULFATE 1609
6. OTHER ORAL MEDICATIONS THAT HAVE BEEN USED FOR BPS 1610
a) L-arginine 1610
b) Quercetin 1611
c) Antibiotics 1611  
d) Methotrexate 1611  
e) Montelukast 1611  
f) Nifedipine 1611  
g) Misoprostol 1611  
h) Tanezumab 1612  

X. INTRAVESICAL / INTRAMURAL THERAPY 1612  
1. DMSO (DIMETHYL SULFOXIDE) 1612  
2. HEPARIN 1612  
3. HYALURONIC ACID 1613  
4. CHONDROITIN SULFATE 1613  
5. PENTOSAN POLYSULFATE 1613  
6. VANILLOIDS (CAPSAICIN, RESINIFERATOXIN) 1614  
7. BACILLUS CALMETTE-GUERIN (BCG) 1614  
8. OXYBUTYNIN 1614  
9. LIDOCAINE 1614  
10. BOTULINUM TOXIN (INTRAMURAL) 1614  

XI. NEUROMODULATION 1615  

XII. PAIN EVALUATION AND TREATMENT 1616  
1. EVALUATION OF PAIN: PHARMACOLOGIC MANAGEMENT OF CHRONIC PELVIC PAIN 1617  
a) Non-acidic antipyretic analgesics 1617  
b) Acidic antipyretic analgesics 1617  
c) Neuropathic analgesics 1617  

XIII. SURGICAL THERAPY 1619  
1. HYDRODISTENTION 1620  
2. TRANSURETHRAL RESECTION 1620  
3. CYSTOLYSIS – PERIPHERAL DENERVATION 1620  
4. SYMPATHETIC DENERVATION 1620  
5. PARASYMPATHETIC DENERVATION 1620  
6. BOWEL SURGERY 1621  
a) Bladder augmentation-cystoplasty 1621  
b) Cystoplasty with Supratrigonal Resection 1621  
c) Cystoplasty with Subtrigonal Cystectomy 1621  
7. URINARY DIVERSION WITH OR WITHOUT TOTAL CYSTECTOMY AND URETHRECTOMY 1621  

XIV. CLINICAL SYMPTOM SCALES 1622

Research Methodology

I. INTRODUCTION 1865
1. LEVELS OF EVIDENCE 1865
2. PRIMARY GUIDING ETHICAL PRINCIPLES 1865

APPENDIX 1. Directory of continence organizations 1826
3. INFORMED CONSENT IS AN ETHICAL CORNERSTONE OF HUMAN SUBJECT RESEARCH. 1866

4. SPECIFIC INFORMED CONSENT IS REQUIRED FOR RESEARCH PARTICIPATION. 1866

5. THE INVESTIGATOR HAS AN ETHICAL RESPONSIBILITY TO TAKE RESPONSIBILITY FOR ALL ASPECTS OF THE RESEARCH. 1866

6. ENSURING PARTICIPANT SAFETY IS PARAMOUNT. 1866

7. HIGH QUALITY DATA MANAGEMENT IS KEY TO PROVIDING VALID AND ETHICAL RESEARCH RESULTS [41]. 1867

8. USEFUL WEBSITES. 1867

9. FINANCIAL CONFLICTS OF INTEREST. 1867

II. DEFINING THE RESEARCH QUESTIONS. 1867

III. EXPERIMENTAL STUDIES. 1867

1. RANDOMIZED CONTROLLED TRIALS. 1867
   a) Simple randomization. 1868
   b) Block randomization. 1868
   c) Stratified randomization. 1868
   d) Parallel Group Trials. 1868
   e) Crossover Trials. 1869
   f) Non-inferiority trials. 1869
   g) Equivalence trials. 1869
   h) Superiority trials. 1869

2. NON-RANDOMIZED CONTROLLED CLINICAL TRIAL(S). 1869

3. PRAGMATIC AND EXPLANATORY TRIALS. 1869

4. DRUG TRIALS ARE CATEGORIZED ACCORDING TO THE FOLLOWING DEFINITIONS [30, 50]. 1870
   a) Phase I studies. 1870
   b) Phase II studies. 1870
   c) Phase III studies. 1870
   d) Phase IV studies. 1870

5. BIAS, BLINDING AND EFFECTS ON VALIDITY. 1870
