INCONTINENCE

EDITORS
PAUL ABRAMS - LINDA CARDozo - SAAD KKhOuRY - ALAN WEIN

5th International Consultation on Incontinence, Paris February, 2012

5th Edition 2013
Accurate indications, adverse reactions, and dosage schedules for drugs are provided in this book, but it is possible that they may change. The reader is urged to review the package information data of the manufacturers of the medications mentioned.

The Publishers have made every effort to trace the copyright holders for borrowed material. If they have inadvertently overlooked any, they will be pleased to make the necessary arrangements at the first opportunity.

The great tragedy of science:
The slaying of a beautiful hypothesis by an ugly fact
Thomas Huxley (1825-1895)

The 5th International Consultation on Incontinence was held in Paris in February 2012, made possible by the generous support of the European Association of Urology. The four previous ICI Consultations were held as stand-alone meetings. However, by holding the 5th ICI during the annual meeting of EAU this made possible the attendance of a wider range of participants than had previously occurred.

The 23 committees included almost 200 experts from every corner of the globe: all selected according to their pre-eminence in their topic area within the overall subject in incontinence. The committees prepared their chapters making full use of modern technology and in particular email discussions. Hence they arrived at the 5th ICI with their committees’ work in final draft. The principle of the Consultation is to present the final draft to a wider audience and then to finalize the chapter following the discussions at the Consultation.

The 1st Consultation occurred in 1998 and since then the scope had gradually broadened so that, once again this year, the Consultation included faecal incontinence, pelvic organ prolapse, bladder pain syndrome and obstetric fistula.

Whilst some conditions afflict either men or women, many conditions affect both sexes. The ICUD also held a Consultation in 2012 on Male Urinary Tract Symptoms and consideration could be given to combining these Consultations in the next cycle. Both Consultations deal with functional pelvic disorders, usually of a benign nature, although some patient’s problems emanate from treatment of malignancy, for example, stress incontinence after a radical prostatectomy for prostate cancer. However, the principles of management are similar in both men and women, in most conditions. It is of interest that there is increasing discussion of a new speciality that combines female urology, urogynaecology and benign colorectalology.

This book, produced by the huge efforts of the 23 committees has once again vigorously examined and summarised the latest scientific evidence, and remains a unique publication and reference source. The reference source is invaluable to all those who commit their professional lives to men and women suffering from these often miserable conditions. The conditions we deal with are not “glamorous” medicine and remain “Cinderella” subjects. However, we have seen the emphasis move towards measuring outcomes by assessing improved quality of life. As the population ages then maintaining or improving quality of life in the latest stages of all our lives will attract greater attention. Hence the work of the ICI remains vitally important to the many millions of women and men who suffer from these conditions.

Paul Abrams, Chairman of the 5th International Consultation on Incontinence.
November 2012
MEMBERS OF THE COMMITTEES
(Alphabetical order - Chairmen in bold print)

---
EVIDENCE – BASED MEDICINE OVERVIEW OF THE MAIN STEPS FOR DEVELOPING AND GRADING GUIDELINE RECOMMENDATIONS.

INTRODUCTION

The International Consultation on Urological Diseases (ICUD) is a non-governmental organization registered with the World Health Organisation (WHO). In the last ten years Consultations have been organised on BPH, Prostate Cancer, Urinary Stone Disease, Nosocomial Infections, Erectile Dysfunction and Urinary Incontinence. These consultations have looked at published evidence and produced recommendations at four levels; highly recommended, recommended, optional and not recommended. This method has been useful but the ICUD believes that there should be more explicit statements of the levels of evidence that generate the subsequent grades of recommendations.

The Agency for Health Care Policy and Research (AHCPR) have used specified evidence levels to justify recommendations for the investigation and treatment of a variety of conditions. The Oxford Centre for Evidence Based Medicine have produced a widely accepted adaptation of the work of AHCPR. (June 5th 2001 http://minerva.minervation.com/cebmi/docs/levels.html). The ICUD has examined the Oxford guidelines and discussed with the Oxford group their applicability to the Consultations organised by ICUD. It is highly desirable that the recommendations made by the Consultations follow an accepted grading system supported by explicit levels of evidence.

The ICUD proposes that future consultations should use a modified version of the Oxford system which can be directly ‘mapped’ onto the Oxford system.

1. 1st Step: Define the specific questions or statements that the recommendations are supposed to address.

2. 2nd Step: Analyse and rate (level of evidence) the relevant papers published in the literature.

The analysis of the literature is an important step in preparing recommendations and their guarantee of quality.

2.1 What papers should be included in the analysis?

• Papers published, or accepted for publication in the peer reviewed issues of journals.

• The committee should do its best to search for papers accepted for publication by the peer reviewed journals in the relevant field but not yet published.

• Abstracts published in peer review journals should be identified. If of sufficient interest the author(s) should be asked for full details of methodology and results. The relevant committee members can then ‘peer review’ the data, and if the data confirms the details in the abstract, then that abstract may be included, with an explanatory footnote. This is a complex issue – it may actually increase publication bias as “uninteresting” abstracts commonly do not progress to full publication.

• Papers published in non peer reviewed supplements will not be included.

An exhaustive list should be obtained through:

I. the major databases covering the last ten years (e.g. Medline, Embase, Cochrane Library, Biosis, Science Citation Index)

II. the table of contents of the major journals of urology and other relevant journals, for the last three months, to take into account the possible delay in the indexation of the published papers in the databases.

It is expected that the highly experienced and expert committee members provide additional assurance that no important study would be missed using this review process.

2.2 How papers are analysed?

Papers published in peer reviewed journals have differing quality and level of evidence.

Each committee will rate the included papers according to levels of evidence (see below).

The level (strength) of evidence provided by an individual study depends on the ability of the study design to minimise the possibility of bias and to maximise attribution.

is influenced by:

• the type of study

The hierarchy of study types are:

- Systematic reviews and meta-analysis of randomised controlled trials
- Randomised controlled trials
- Non-randomised cohort studies
- Case control studies
- Case series
- Expert opinion

• how well the study was designed and carried out

Failure to give due attention to key aspects of study methodology increase the risk of bias or confounding factors, and thus reduces the study’s reliability.

The use of standard check lists is recommended to insure that all relevant aspects are considered and that a consistent approach is used in the methodological assessment of the evidence.

The objective of the check list is to give a quality rating for individual studies.

• how well the study was reported

The ICUD has adopted the CONSORT statement and its widely accepted check list. The CONSORT statement and the checklist are available at http://www.consort-statement.org

2.3 How papers are rated?

Papers are rated following a «Level of Evidence scale».

ICUD has modified the Oxford Center for Evidence-Based Medicine levels of evidence.

The levels of evidence scales vary between types of studies (ie therapy, diagnosis, differential diagnosis/symptom prevalence study).

The Oxford Center for Evidence-Based Medicine Website: http://minerva.minervation.com/cebmi/docs/levels.html

3. 3rd Step: Synthesis of the evidence

After the selection of the papers and the rating of the level of evidence of each study, the next step is to compile a summary of the individual studies and the overall direction of the evidence in an Evidence Table.

4. 4th Step: Considered judgment (integration of individual clinical expertise)

Having completed a rigorous and objective synthesis of the evidence base, the committee must then make a judgement as to the grade of the recommendation on the basis of this evidence. This requires the exercise of judgement based on clinical experience as well as knowledge of the evidence and the methods used to generate it. Evidence based medicine requires the integration of individual clinical expertise with best
available external clinical evidence from systematic research. Without the former, practice quickly becomes tyrannised by evidence, for even excellent external evidence may be inapplicable to, or inappropriate for, an individual patient; without current best-evidence, practice quickly becomes out of date. Although it is not practical to lay our “rules” for exercising judgement, guideline development groups are asked to consider the evidence in terms of quantity, quality, and consistency; applicability; generalisability; and clinical impact.

5. 5th Step: Final Grading
The grading of the recommendation is intended to strike an appropriate balance between incorporating the complexity of type and quality of the evidence and maintaining clarity for guideline users.

The recommendations for grading follow the Oxford Centre for Evidence-Based Medicine.

The levels of evidence shown below have again been modified in the light of previous consultations. There are now 4 levels of evidence instead of 5.

The grades of recommendation have not been reduced and a “no recommendation possible” grade has been added.

6. Levels of Evidence and Grades of Recommendation Therapeutic Interventions
All interventions should be judged by the body of evidence for their efficacy, tolerability, safety, clinical effectiveness and cost-effectiveness. It is accepted that at present little data exists on cost-effectiveness for most interventions.

6.1 Levels of Evidence
Firstly, it should be stated that any level of evidence may be positive (the therapy works) or negative (the therapy doesn’t work). A level of evidence is given to each individual study.

• Level 1 evidence (incorporates Oxford 1a, 1b) usually involves meta-analysis of trials (RCTs) or a good quality randomised controlled trial, or ‘all or none’ studies in which no treatment is not an option, for example in vesicovaginal fistula.

• Level 2 evidence (incorporates Oxford 2a, 2b and 2c) includes “low” quality RCT (e.g. < 80% follow up) or meta-analysis (with homogeneity) of good quality prospective ‘cohort studies’. These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts, where those with the condition in the first group are compared with those in the second group.

• Level 3 evidence (incorporates Oxford 3a, 3b and 4) includes:

good quality retrospective ‘case-control studies’ where a group of patients who have a condition are matched appropriately (e.g. for age, sex etc) with control individuals who do not have the condition.

good quality ‘case series’ where a complete group of patients all, with the same condition/disease/therapeutic intervention, are described, without a comparison control group.

• Level 4 evidence (incorporates Oxford 4) includes expert opinion were the pinion is based not on evidence but on ‘first principles’ (e.g. physiological or anatomical) or bench research. The Delphi process can be used to give ‘expert opinion’ greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of ‘options’; the options are serially ranked; if a 75% agreement is reached then a Delphi consensus statement can be made.

6.2 Grades of Recommendation
The ICUD will use the four grades from the Oxford system. As with levels of evidence the grades of evidence may apply either positively (do the procedure) or negatively (don’t do the procedure). Where there is disparity of evidence, for example if there were three well conducted RCT’s indicating that Drug A was superior to placebo, but one RCT whose results show no difference, then there has to be an individual judgement as to the grade of recommendation given and the rationale explained.

• Grade A recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. However, there will be occasions where excellent evidence (level 1) does not lead to a Grade A recommendation, for example, if the therapy is prohibitively expensive, dangerous or unethical. Grade A recommendation can follow from Level 2 evidence. However, a Grade A recommendation needs a greater body of evidence if based on anything except Level 1 evidence.

• Grade B recommendation usually depends on consistent level 2 and or 3 studies, or ‘majority evidence’ from RCT’s.

• Grade C recommendation usually depends on level 4 studies or ‘majority evidence’ from level 2/3 studies or Delphi processed expert opinion.

• Grade D “No recommendation possible” would be used where the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Delphi.

7. Levels of Evidence and Grades of Recommendation for Methods of Assessment and Investigation
From initial discussions with the Oxford group it is clear that application of levels of evidence/grades of recommendation for diagnostic techniques is much more complex than for interventions.

The ICUD recommend, that, as a minimum, any test should be subjected to three questions:

1. does the test have good technical performance, for example, do three aliquots of the same urine sample give the same result when subjected to ‘stix’ testing?

2. Does the test have good diagnostic performance, ideally against a “gold standard” measure?

3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

For the third component (therapeutic performance) the same approach can be used as for section 6.

8. Levels of Evidence and Grades of Recommendation for Basic Science and Epidemiology Studies
The proposed ICUD system does not easily fit into these areas of science. Further research needs to be carried out, in order to develop explicit levels of evidence that can lead to recommendations as to the soundness of data in these important aspects of medicine.

CONCLUSION
The ICUD believes that its consultations should follow the ICUD system of levels of evidence and grades of recommendation, where possible. This system can be mapped to the Oxford system.

There are aspects to the ICUD system that require further research and development, particularly diagnostic performance and cost effectiveness, and also factors such as patient preference.

Epidemiology of Urinary Incontinence (UI) and other Lower Urinary Tract Symptoms (LUTS), Pelvic Organ Prolapse (POP) and Anal Incontinence (AI)

IA N M ILSOM
D. ALTMAN, R. CARTWRIGHT, M.C. LAPITAN, R. NELSON, U. SILLÉN, K. TIKKINEN

A. INTRODUCTION

In this report we focus on the epidemiology (distribution and determinants) of urinary incontinence (UI) and other lower urinary tract symptoms (LUTS), pelvic organ prolapse (POP) and anal incontinence (AI). We also discuss important topics such as differences between epidemiological and clinical approaches to health problems, help seeking behaviour, and methodological issues for this research.

We have included a section on overactive bladder and nocturia which are commonly occurring LUTS. A worldwide estimation of the current and future number of individuals with LUTS [1,2] including UI and overactive bladder (OAB) is also included at the end of this chapter.

The epidemiological population under study for this review will mainly be community dwelling non-institutionalised persons. The review will include discussion of the prevalence, incidence, natural history, and presence of racial and ethnic differences. We also review correlates and potential risk factors that have been revealed in epidemiological studies. Progress has clearly been made during the 4 years since our previous report when the 4th International Consultation on Incontinence (4th ICI) was published. Some new important areas have been studied with increasing regularity and quality. We have searched the literature for relevant new articles, thus reviewing a large number of high-quality and population based studies, as well as clinical trials that might include relevant epidemiological data. Because of an abundant number of studies, only a small fraction can be presented in a text like this. Other studies not presented here may have equally useful information, but lack of space precluded their inclusion.

Summary points:

- This review includes discussion of the prevalence, incidence, natural history, and presence of racial and ethnic differences in the epidemiology of UI, OAB, nocturia, POP and AI.
- Correlates and potential risk factors that have been revealed in epidemiological studies are also reviewed.

B. BASIC EPIDEMIOLOGICAL CONSIDERATIONS

Epidemiology is the scientific study of the distribution and determinants of disease in people. Descriptive epidemiology is the description of disease prevalence, incidence, (and mortality) by persons, place and time, while the term analytical epidemiology describes the search for determinants of disease risk. The discovery of risk factors and protective factors may then in turn lead to primary or secondary prevention.

In order to collect knowledge about risk factors or natural history, observational studies are needed. Cohort studies and case-control studies are the most common. However, caution is always needed when interpreting the results from such studies, as associations found in epidemiological studies may not be the same as causes. Longitudinal study designs and appropriate control for confounding factors are preferred, as these increase the validity of epidemiologic studies. For practical and ethical reasons, experimental designs are seldom used.
Recommendations and conclusions should always be based on the best available evidence. Studies of interventions, and studies of risk factors generally cannot be randomised because they relate to inherent human characteristics or practices, and exposing subjects to harmful risk factors is unethical. No uniform guidelines for assessing the results of observational studies exist, and the level of evidence for risk factors from observational studies should be judged on the soundness of the exclusion of alternative explanations by statistical and other controls. But some initiatives for how to report meta-analyses of observational studies have been taken [3].

Studies of disease frequency should rely on a very specific definition of the condition under investigation. The absence of unifying definitions for the conditions reviewed here is a fundamental problem which has not been resolved. Definitions used and problems associated with them are discussed in the subsections for the particular populations below.

Prevalence is defined as the probability of experiencing a symptom or having a condition or a disease within a defined population and at a defined time point. The concept is important for establishing the distribution of the condition in the population and for projecting the need for health and medical services.

Incidence is defined as the probability of developing the condition under study during a defined time period. Incidence is usually reported for one-, two- or five-year time intervals.

Even in many of the recent studies reviewed analyses are very simple. Often only proportions or percentages are used to describe differences in different subgroups. Many analyses do not control for confounders (by stratification or multivariate analysis techniques). There is an obvious need for more advanced epidemiological analyses of risk factors and comorbidity using multivariable techniques, and strength of associations should be determined by relative risks and odds ratios.

The relative risk (RR) estimates the magnitude of an association between exposure and a condition, and indicates the likelihood of having the condition in the exposed group relative to those who are not exposed (e.g. do not have the risk factor). A RR of 1.0 indicates that the rates in the exposed and non-exposed groups are identical and thus that there is no association between the exposure and the condition in that specific dataset. A value greater than 1.0 indicates a positive association or an increased risk. A RR of 2.5 for UI indicates that there is a 2.5 times increased risk or that the persons in question are 150 percent more likely to have incontinence than those without the risk factor.

The odds ratio (OR) is the odds for having a risk factor in persons with a condition divided by the odds among those without the condition. An OR of 2.5 for UI my be interpreted as meaning that in this sample the odds in favour of having incontinence are 2.5 times higher among those with the risk factor than among those without.

For a condition with high prevalence, like UI or POP, OR and RR will not be identical, but in practice the results can be interpreted similarly. Results should always be given with a 95% confidence interval (CI).

Words like well established and established may be used about risk factors and findings with a high level of evidence in the literature. For less documented findings words like "indications of" or "data are suggestive" may be used.

Summary points:
- Descriptive epidemiology reports disease incidence, prevalence (and mortality) by persons, place and time.
- Analytical epidemiology searches for determinants of disease risk. There is a need for good longitudinal cohort studies.
- Variations in definitions and measurement issues are fundamental, and lead to problems with assessing the findings in epidemiological studies.
- There is a need for more advanced epidemiological analyses of risk factors and comorbidity using multivariable techniques, and strength of associations should be determined by relative risks and odds ratios.

C. EPIDEMIOLOGY OF ENURESION AND UI IN CHILDREN

I. GENERAL COMMENTS AND DEFINITIONS

The International Children’s Continence Society (ICCS) has issued new recommendations regarding terminology of bedwetting or nocturnal enuresis (NE) [4]. NE is now the term for all urinary incontinence during sleep taking place in discrete episodes, regardless of the presence or absence of concomitant daytime symptoms. Mono-symptomatic nocturnal enuresis (MNE) denotes bedwetting without any other LUTS symptoms, and non-mono-symptomatic nocturnal enuresis (NMNE) should be used for those with any concomitant LUTS.

NE is caused by relative nocturnal polyuria [5] and/or nocturnal bladder over-activity [6], combined with the lack of arousal at the time when the bladder needs to be emptied. The most important cause is, of course, the lack of arousal, otherwise the child would have had nocturia.
Any other leakage of urine in children during both the day and night is referred to as UI, just as it is in the adult population. UI with no obvious cause, i.e. without neurological or congenital anatomic alterations, is often seen together with other urinary symptoms such as frequency, urgency and infections. Altogether these symptoms are referred to as functional LUT dysfunction, which is the term used to describe the entire spectrum of functional filling-voiding disturbances. Several sub-classifications have been used for children who present with varying degrees of “functional” urinary symptoms. Some are based on urodynamic patterns, others on clinical presentation.

According to recent definitions by the ICCS [4], based on symptoms and flow-residual studies rather than invasive urodynamic investigations, incontinence as a result of a filling-phase dysfunction, is in most cases due to an OAB, which can also be referred to as “urgency syndrome” and “urge incontinence”. Children with OAB usually have detrusor overactivity, but this label cannot be applied to them without cystometric evaluation. When incontinence is the result of a voiding-phase dysfunction, the diagnosis is often dysfunctional voiding (DV), which is induced by increased activity in the sphincter and pelvic floor during voiding. It is subdivided into staccato and fractionated voiding, and the terms cannot be applied unless repeat uroflow measurements have been performed. Voiding postponement (VD) is another common LUT dysfunction causing UI in children, but differs from the other since it is induced by a habitual postponement of voiding and not a LUT dysfunction per se.

NE and UI due to functional LUT dysfunction are the wetting problems addressed in this chapter. Both can be either primary (the child has not been dry for more than six months) or secondary (the wetting has recurred after a dry period lasting more than six months). If the complaints are secondary, they may signify psychological, neurological or even structural anomalies and therefore require careful consideration.

The healthy infant is socially incontinent but physiologically continent, because micturitions (about once every hour) are discrete and there is no leakage of urine between micturition [7]. Bladder control develops during the first four to six years of life and is a highly complex process, which is still not fully understood. Most children are toilet trained by the age of three years, although there is huge social and cultural variation. By the age of five years, the child is normally able to void at will and to postpone voiding in a socially acceptable manner [8]. By this age, night-time and daytime involuntary wetting becomes a social problem and a cause for therapeutic intervention.

II. PREVALENCE OF NOCTURNAL ENURESIS (NE)

As bladder control is something that develops over time, longitudinal studies are the best way of defining the dynamics of this process. Studies giving us the prevalence for all children between five and 15 years of age, for example, are not appropriate, as all the developmental stages are clustered together. It is therefore better to give the prevalence for an age cohort, such as seven-year-olds. Furthermore, random sampling should preferably be used in order to be able to say anything about the population. These problems associated with understanding epidemiology were summarised by Krantz [9], who also reviewed the epidemiological studies that had been published by 1993.

One explanation for the variation in prevalence in different studies is the fact that some studies include only monosymptomatic enuresis (MNE), whereas others also include what is defined as non-monosymptomatic enuresis (NMNE). Another explanatory factor is that the frequency of enuretic episodes differs or is not taken into account in some studies. Moreover, most epidemiological studies link primary and secondary enuresis together.

1. PREVALENCE OF ALL NIGHT WETTING (MNE+ NMNE) ACCORDING TO AGE

Longitudinal cohort studies should be the ideal when analysing epidemiology in childhood NE, as there is a successive reduction in prevalence. Only a few of these studies are available [10-15] and cross-sectional studies at different ages therefore have to be used.

Most studies investigate cohorts of children in an age span of six to 12 years of age, for example, and give the prevalence for the entire group. Some of them also give the age-related prevalence [13, 16-26] which is summarised in Table 1. Cross-sectional studies of a specific age are also included [27-31] in Table 1.

In most studies (Table 1), the prevalence for seven-year-olds was between 7% and 10%. In two studies, the prevalence was higher; 15.1% and 16.4% for Turkish [20] and Korean [18] children respectively, despite the fact that the inclusion criteria were very similar in all the studies dealing with seven-year-olds (NE=night wetting once/month or more), apart from the studies by Hellström [27] (once/3 months or more) and Järvelin [28] (once/6 months or more). The prevalence of more frequent wetting (once/week or more) was lower compared to the prevalence for all wetting (once/month or more) by age, which have been illustrated in Figure 1.

In nine studies at age seven years [12,16,19,21-24,27-28], (Table 1) the numbers of both non-enuretic and enuretic children were given and the definitions
for enuresis were similar (MNE and NMNE, wetting once/1-3 months or more). A prevalence of 10% was obtained by meta-analyses of these studies (cohort of 14372 seven-year-old children, of whom 1422 were enuretic). Only four studies included groups of children that were chosen at random from the population [16,21,24,28].

At age 11-12 years, the prevalence of NE had decreased and from the studies shown in Table I the prevalence varied between 1.7% and 4.7%. In seven of the studies, the number of non-enuretics and enuretics were available and the definition of NE was similar (once/month or more), apart from Swindenbank’s [30] study (once/3 months or more). In these studies, the total number of children included was 8947, while the number of children with NE was 278, giving a prevalence of 3.1%. So, of those children with NE at age seven years, almost 15% spontaneously grow out of the wetting every year. In a recent Japanese study a higher resolution rate was reported in children with MNE compared to NMNE in children 7 to 12 years of age (21% and 15%, respectively) [22]. Similar results were found in a study from Hong Kong in which the proportion of children with NMNE was significantly greater in adolescent boys than in boys aged 5-10 years (32% vs 14.6%), even if the total prevalence of NE was decreasing as in other studies [24].

The variation in the prevalence of NE at 11-12 years between the studies is less than that seen at age seven years. The highest prevalence is no longer found in Turkey or Korea, as was the case at age seven years, but instead comes from a non-randomised cross-sectional study of 11- to 12-year-old schoolchildren (n=1145) in the UK (4.7%). It can therefore be suggested that the high prevalence seen in the studies from Turkey and Korea at age seven is not due to differences in genetic predisposition, but rather to phenotypic differences, such as the age of toilet training and the subsequent attainment of bladder control, socioeconomic status, or cultural differences.

At age 16-17, three cross-sectional studies show a further reduction in prevalence to 0.5-1.7%. Two of the studies re-investigated children who had

Figure 1. Prevalence of nocturnal enuresis (NE) by frequency of enuretic episodes and age. The data were obtained from metaanalyses of the epidemiological studies included in table III.1. NE>1 episode/6months: at 7 years [16, 19, 21-25, 27-28,], 11-12 years [16, 19, 21-24, 30] and 16-17 years [24, 29, 31]. NE>1 episode/week: at age 7 years [23, 24, 27, 28], 11-12 years [23, 24, 30] and 16-17 years [24, 29].
previously been studied; at age seven years [29] and 11-12 years [30] respectively. The prevalence when the cohorts were added together was 1.3% (cohort=3819, NE=51) [24,29,31], which gives a spontaneous cure rate of 11% a year among those who wet at age 11-12 years.

In a study of 13,081 adults randomly sampled in the Netherlands [32], an overall prevalence of NE of 0.5% was found. There was no significant difference between age groups. Primary NE was reported by 50% of the men and 19% of the women, indicating that a small group of the enuretic children remain enuretic as adults.

2. PREVALENCE OF MONOSYMPTOMATIC ENURESIS (MNE)

Very few studies make a distinction between MNE and NMNE and it is therefore difficult to obtain relevant figures for MNE (Table 2). In two studies from Scandinavia dealing exclusively with seven-year-olds, there was agreement between the studies; 6.4% [28] and 7.4% [27]. Recently, a Japanese study gave similar figures for MNE; 6.2% at age 7 years. In this latter study MNE corresponded to approximately 60% of all NE in ages from 7 to 12 years [19]. When it comes to studies in which all ages were mixed (5-12 years), four studies were identified in which those without daytime voiding problems could be identified.

However, the difference in prevalence of MNE varied in these studies; 3.5% [17], 6.9% [33], 9.4% [21] and 15% [34].

3. PREVALENCE OF NE VERSUS GENDER

Almost all epidemiological studies of NE report a higher prevalence in boys than in girls, with a ratio of 2:1 in western countries [16-23,26-28,30,33-35]. It appears that the gender difference diminishes with age and becomes less visible and less proven among older children [29,31,36] (Figure 2).

4. PREVALENCE OF NE VERSUS ETHNICITY

In a study from The Netherlands [18], a higher prevalence was reported in the Turkish/Moroccan group (14%) than in the Dutch children (6%) (OR 3.76 (95%CI 1.98-7.12)). An equally high prevalence was found in a Turkish study of children with NE [20] at age seven years (15.1%). In a study from Korea [18], the same high prevalence at age 7 years was identified (16.4%). However, other studies from South-East Asia had comparable [19,22,24] or even lower levels of prevalence to those in western countries. In fact, two Chinese studies have shown a low prevalence of nocturnal enuresis [17,37], 3.6% and 4.3% for children aged 4-12 and 6-16 respectively, which they attribute to earlier nocturnal urinary control in Chinese children, due to earlier toilet training.

5. PREVALENCE OF NE VERSUS FREQUENCY OF WET NIGHTS AND AGE

Yeung et al [24] showed in a large epidemiological study that the relative proportion of subjects with frequent bed-wetting increased with age. Overall 82% of the adolescents had >3 wet nights/week versus enuretic children aged 5-10 (42%) (Figure 3). Such a relationship is also evident in figure 1, in which the proportion of children with severe NE increase with age, even if the total number decreases. Further support for severe NE to remain in a higher proportion as compared to children with infrequent bedwetting was shown in a recent study [15]. Findings in epidemiological studies also show a correlation between severity of the NE and NMNE [15-16,38], meaning that NE in adolescents often are combined with LUT dysfunction.

III. POTENTIAL RISK FACTORS FOR NE

Several risk factors have been established or suggested by epidemiological studies and the most important ones will be discussed here.

1. DAYTIME UI AND LUT DYSFUNCTION

Daytime UI, a symptom of LUT dysfunction, has in epidemiological studies been shown to be the strongest predictor for NE (OR 4.8 (2.9-7.9)) and has been identified in a third of the patients (NMNE) [38]. However, poor concordance was revealed (kappa 0.25), which confirmed the two to be separate entities that should be evaluated and treated separately.

2. FAMILY HISTORY

NE is a hereditary disorder and this has been demonstrated in many studies (for example, [16,17,20,28,33,34,39]). The mode of inheritance appears to be autosomal dominant. Järvelin [28]

showed that, if both parents were enuretics as children, the RR (95% CI) for the child to have NE was 16 (6.3-20.1), while if only one was enuretic, the RR was 7.8 (5.1-9.8). It has recently been shown that the risk for the child to have hereditary NE is increased with the severity of the enuresis. Children with severe NE (>2 episodes/week) were combined with odds ratio for maternal NE 3.63 (2.56-5.14), whereas mild and moderate NE (<2 episodes/week) had 2.14 (1.74-2.64) [40]. The association with paternal NE was less pronounced, but a similar increased association to severe NE was observed. Using molecular genetic methods, foci have been found on chromosomes 13, 12, 8 and 22 [41-42]. A picture of pronounced heterogeneity for both genotype and phenotype emerges [43].

3. PSYCHOPATHOLOGY

There are evident connections between childhood enuresis and mental well-being [13-14,37,39,44-47]. Evidence is accumulating to show that psychological consequences are probably caused by the enuresis and not a cause of primary NE, which has
been thought for a long time [45]. The findings presented by Feehan [14] support this latter statement, as he only found an association between psychopathology and secondary NE, while children with primary NE did not display a connection of this kind.

4. DEVELOPMENTAL DELAY AND ADHD

Children with developmental delay and mental retardation have been shown to have a higher prevalence of NE [12,18,28,48]. Spee-van der Wekke [18] found that children who were given special education in school, including both those with and without mental retardation, had an OR of 3.74 (95% CI 2.32-6.03) for NE.

Perinatal events such as toxaemia and low birth weight, possibly involving an increased risk of minor neurological dysfunction, have also been shown to be associated with NE [12,28,39]. A connection between NE and minor neurological dysfunction of this kind has also been shown by Lunsing [49] in 12-year-old enuretic children. Furthermore, children with attention deficit hyperactivity disorders (ADHD) and tardation have been shown to have a higher prevalence at 7 years, 11-13 years and 15-17 years [17,20-23,37,57] at early ages in different parts of the world are probably partly due to socio-cultural differences and not to differences in genetic predisposition [18]. It has been suggested that socio-economic status correlates with NE in some studies [16,46], whereas in others no correlation was found [12].

5. SLEEP AND AROUSAL

The main pathology behind NE in children is the inability to wake up to the sensation of a full bladder. Parents often say that their enuretic child “sleeps very deeply”. Some recent studies support this view. By using auditory signals [53], computerised EEG [54] or questionnaires [33], a defect in arousal has been largely validated. In the study by Neveus [33], the odds ratios were significantly high for a high arousal threshold (2.7), favour nocturnus (2.4) and confusion when awoken from sleep (3.4). Computerised EEG energy analysis has indicated both greater depth of sleep and impaired arousal in enuretics [55]. Difficult arousal from sleep has also been shown in children with NE compared to children with isolated day-wetting problems and controls, by using a scoring system in a questionnaire [56].

6. SOCIO-CULTURAL FACTORS

Differences in the prevalence of NE [17,20-21,37,57] at early ages in different parts of the world are probably partly due to socio-cultural differences and not to differences in genetic predisposition [18]. It has been suggested that socio-economic status correlates with NE in some studies [16,46], whereas in others no correlation was found [12].

7. OTHER RISK FACTORS

Obstructive sleep apnoea (OSA) has been associated with enuresis in some patients [58]. In an epidemiological study association between severe OSA and NE in girls was shown [26], but when including both sexes and all forms of OSA no difference was seen. In another study dealing with OSA patients versus controls, a significant correlation between NE and OSA was found (OR 5.1 (2.4-10.7) [59]. Removal of large adenoids or tonsils causing upper airway obstruction in children with NE significantly reduced or cured NE [60]. Constipation (see co-morbidity below) may cause secondary NE or make primary NE persist [58]. Enkopresis was shown as a risk factor for NE in an epidemiological study (OR 2.7 (1.6-4.4)), while no association with constipation could be identified [38]. Sexual abuse must also be included among the factors that may lead to NE [62]. Organic conditions such as infravesical obstruction and neuropathic bladder may also present as NE. In most cases, however, additional symptoms are present to make detection possible. Type 1 diabetes was reported to be a risk factor for secondary MNE due to the polyuria seen at presentation [63].

IV. PREVALENCE OF FUNCTIONAL INCONTINENCE IN CHILDREN

In children with functional LUT dysfunction, OAB is far more common than dysfunctional voiding. In a urodynamic study of 1,000 patients with functional LUT dysfunction, approximately two-thirds had an OAB and one-third had dysfunctional voiding [64]. Based on clinical information, another study comprising 226 children revealed that 76% were considered to have an OAB and only 1% dysfunctional voiding. The difference illustrates that different inclusion criteria influence the rate of prevalence [65].

When considering the total prevalence of UI (all frequencies of UI included) (Table 3), there was a variation between 3.2% and 9% in different studies at the age of seven years. In the earliest studies the prevalence was lower (3.2%-5.0%), whereas the studies performed later in the 2000 [21, 23, 66-68], the prevalence was higher 6.3%-9.0%. One explanation for the difference was probably an increased recognition of the problem in the population through information via media etc. At 11-13 years the reported prevalence varied between 1.1% and 12.5%. Switchenbank’s study [30] showed a very high prevalence (12.5%) and differed most from the rest (1.1%-4.2%). The difference could probably partly be explained by different limits for frequency of UI (occasionally [30] vs once/month or more). The fact that the studies were performed in different parts of the world was also a possible explanatory factor (UK and Korea).

The frequency of UI decreased with age (Table 3), which was clearly demonstrated in the subjects with frequent episodes of UI (>1/week) (figure 4). The prevalence at 7 years, 11-13 years and 15-17 years was 2.6%, 1.1% and 0.3% respectively. There were only two authors who investigated the same cohort of children on two occasions; Hellström [27, 29] in Sweden and Switchenbank [27, 28] in the UK.

</table>
| Episodes of UI: 1>1/6 months, 2>1/3 months, 3> 1/ month, 4>1/2 weeks, 5 occasionally

According to the studies by Hellström, the reduction from seven years to 17 years was 0.2% per year in those with wetting at least once a week and 0.3% when including all kinds of wetting. Swithinbank reported a far higher frequency for all kinds of wetting at age 11-12 years but not at 15-16 years and the reduction in his cohort of children was therefore approximately 2% per year.

UI was more common in girls in most studies, especially in the older age groups (Table 3, figure 4). From the prevalence found in the different studies, daytime UI could be suggested to be 1.5 times more common in girls than in boys at age seven years, whereas at age 16 years the difference was even more pronounced: 5-10 times more common in girls than in boys (Table 3). Overall in a population based study of 2856 children between 4.8-12.8 years, female gender was an independent risk factor for UI (OR 5.4 (2.6-11.1), [69].

1. PREVALENCE OF OVERACTIVE BLADDER (OAB)

In a Japanese study [66], the prevalence in children between 7 and 12 years of age, OAB was seen in 17.8%, with no significant difference between boys and girls. There was a gradual decrease in prevalence from 19.8% at the age of 7 years to 12.8% at 12 years.

2. COMORBIDITY:

a) Prevalence of NE

NE in combination with UI is denoted as NMNE as mentioned above. NE has been identified as an independent risk-factor for day-UI (OR 7.2 (3.4-15.2)) [69]. Association of NE to day UI was more often reported in children with frequent UI (≥ 2 episodes/week), as compared to infrequent UI (< 2 episodes/week) at 7.5 years [68]. In boys NE was seen in 70-80% of those with frequent day UI compared to about 50% in those with infrequent. Corresponding figures for girls was about 55% and 30%, respectively.

b) Prevalence of Bowel problems

Urinary and faecal incontinence often coexist in different combinations. Constipation in childhood is a very common condition and when functional faecal incontinence is seen, constipation is often the cause. The term encopresis can be used synonymously with functional faecal incontinence. An increasing number of epidemiological studies reporting the frequency of bowel problems are accumulating, either in terms of constipation or functional faecal incontinence, in children with daytime wetting. Table 4 shows that the prevalence of bowel problems in day-wetting children approximately corresponded to a third of the children (21%-35%) [23,56,66-67,69-70], with even higher prevalence in the subgroup with dysfunctional voiding (43%) [70]. A significant association between day-wetting and bowel problems was shown [23]. These results support the new treatment concept of day-wetting children, with treatment of bowel problems as the first step. MNE, on the other hand, seldom have bowel problems (0%-1%), whereas in NMNE it is more common (16%-24%) [56,70].

In an epidemiological study from Japan including 5282 children, ages between 7-12 years, 81.5% were reported to have daily bowel movements. A significant higher prevalence of NMNE was found in those with constipation, compared to those with regular daily bowel movements (3.4% vs 2.2%) [22].
1. FAMILY HISTORY

Day wetting, also including those subjects with mixed day and night wetting, has been shown to be correlated with hereditary factors, in parallel to what is known about children with NE. However, the number of studies is limited (Table 5). Like for NE hereditary factors have been shown to be more pronounced in those with severe UI (>2 episodes/week), especially when paternal day UI is present (table 5) [40].

Table 4. Comorbidities. The prevalence of concomitant bowel problems in children with day-wetting and nocturnal enuresis.

2. PSYCHOPATHOLOGY

Children under stress as a result of marital separation, for example, have a higher incidence of diurnal or mixed UI, according to some authors [16,39,71]. Moreover, psychopathology investigated by Järvelin [39] using the Children's Apperception Test (CAT) revealed a significant increase in the signs of repression, including an inability to express one's emotions and feelings (p=0.027), when comparing day wetting children with controls. Neveus [33] found that day-wetting children had more difficulty falling asleep (OR 2.4, CI 1.4-4) and he interpreted them as "anxious children". Lettgren [72] found a significant increase in attention problems and delinquent behaviour in a certain form of day-wetting children (voiding postponement) using the Child Behaviour Check List (CBCL, Achenbach). In a recent paper [73] similar results were found with the highest rate of psychiatric comorbidity in children with UI due to voiding postponement and the lowest in children with MNE. In the group with encopresis 65% were considered to have severe behavioural problems [70], meaning that children with both wetting and bowel problems are at the highest risk for psychopathology.

In a population-based study investigating psychological problems associated with day UI, 8213 children were included of whom 643 suffered from daytime wetting at median age 7.5 years [67]. Overall the results indicated a rate of psychological problems that was twice the rate reported for children with no daytime wetting, particularly notable was the increase in externalising problems. After adjustment for developmental delay, gender, stressful life events, variables associated with family socio-demographic background and soiling, there was still an independent association of daytime wetting and behaviour problems.
can also be suggestive of minimal brain dysfunc
to studies by Järvelin [28]. Perinatal events, which
increased (OR 1.9 and 4 respectively), according
to studies by Järvelin [28]. Perinatal events, which
found that children of mothers who had suffered
from toxaemia had RR of 8.5 (CI 4.4-51.9) for day UI.

3. MINOR NEUROLOGICAL DYSFUNCTION
AND DEVELOPMENTAL DELAY

Children with minor neurological dysfunction have
also been shown to have an increased rate of day
wetting. Duel [50] found that children with ADHD are
time three times more likely to have day UI than controls
(p<0.0005). Also in children with delayed maturation
or with mental retardation, the risk of day wetting is
increased (OR 1.9 and 4 respectively), according
to studies by Järvelin [28]. Perinatal events, which
also be suggestive of minimal brain dysfunction,
have also been shown to be over-represented
in day-wetting children. For example, Järvelin [39]
found that the children of mothers who had suffered
from toxaemia had RR of 8.5 (CI 4.4-51.9) for day UI.

4. OTHER RISK FACTORS FOR DAY UI

Sometimes, functional day UI is difficult to distinguish
from UI due to organic anomalies. The most promi-

*Only children with mixed day and night wetting, **compared with 45% in dry children

(OR 2.04, CI 1.67-2.51). In another epidemiological
study UI was found to be associated with parenteral
concerns about the child’s social behaviour (OR 3.4
(1.4-8.3)), [69]. It is not clear whether the behavioural
problems described in these studies are a cause or a
consequence of daytime wetting.

3. MINOR NEUROLOGICAL DYSFUNCTION
AND DEVELOPMENTAL DELAY

Children with minor neurological dysfunction have
also been shown to have an increased rate of day
wetting. Duel [50] found that children with ADHD are
three times more likely to have day UI than controls
(p<0.0005). Also in children with delayed maturation
or with mental retardation, the risk of day wetting is
increased (OR 1.9 and 4 respectively), according
to studies by Järvelin [28]. Perinatal events, which
also be suggestive of minimal brain dysfunction,
have also been shown to be over-represented
in day-wetting children. For example, Järvelin [39]
found that the children of mothers who had suffered
from toxaemia had RR of 8.5 (CI 4.4-51.9) for day UI.

4. OTHER RISK FACTORS FOR DAY UI

Sometimes, functional day UI is difficult to distinguish
from UI due to organic anomalies. The most promi-

In many papers, UTI is regarded as a risk factor
for day UI. Järvelin [39] found RR of 8.6 (2.3-32.3)
for UTI in day UI children. Neveus [33] was able to
demonstrate similar connections; OR 2.3 (1.3-3.9)
and similar results were seen in the Sureshkumar
study [69]; OR 5.6 (2.0-15.6). However, these in-
fected should probably be regarded as a conse-
quence of the functional bladder disturbance with
UI and not the other way round as a cause of the UI.

VI. SUMMARY POINTS

Nocturnal enuresis (NE)

- The prevalence of NE at age 7 seems to be around
  10% for most countries, at age 11-12 years around
  3% and at age 16 around 1.3%.
- The spontaneous resolution rate seems to be
  around 15% annually between 7 and 12 years,
  and between 12 and 17 years 11%.
- In an adult population the prevalence of NE seems
to be 0.5%. The prevalence was 0.1% when includ-
ing only those with a history of NE during childhood.
  Thus the risk for NE as adult if having the condition
  at 7 years of age can be calculated to 1%.
- Potential risk factors for NE in children include
  OAB, polyuria, family history, psychopathology,
  developmental delay, mental retardation, socio-
  cultural factors, sleep and arousal problems, sleep
  apnoea,  constipation,  sexual  abuse  and  organic
  conditions such as infravesical obstruction.

Functional incontinence

- Children who are and remain dry in the day seem
to attain their diurnal continence between age 4
  and 5 years.
- Diurnal UI, or combined diurnal and nocturnal UI,
in children is caused by overactive bladder in the
  great majority of cases.
- Prevalence of functional UI decreases with age.
  At age 7 years prevalence figures vary between
  3.2% and 9%, with the highest prevalence in re-
cent studies. At age 15-17 years the correspond-
ing prevalence is 1.2-3%.
- Variation in prevalence figures is mainly depend-
ant on differences in frequency of incontinence
  episodes in the studies.
- Potential risk factors for diurnal UI in children in-
clude bowel problems such as constipation and
  functional faecal incontinence, family history,
  psychopathology, socio-cultural factors, minor
  neurological dysfunction, developmental delay,
  organic anomalies such as infravesical obstruction
  in boys and sexual abuse.
D. EPIDEMIOLOGY OF UI IN WOMEN

I. GENERAL COMMENTS AND DEFINITIONS

In this section we address the epidemiology of female UI, including its common subtypes, stress UI, urgency UI, and mixed UI. Current terminology for female UI is drawn from the 2010 IUGA/ICS joint terminology report [2] but in most instances is entirely compatible with current terminology for men [1], and children [4]. In considering the epidemiology of female UI, we mainly address the epidemiology of the symptom of UI, defined as complaint of involuntary loss of urine. There remains a paucity of work at a population level concerning either the sign of UI, defined as observation of involuntary loss of urine on examination, or on the formal diagnoses of urodynamic stress incontinence or detrusor overactivity.

A large majority of epidemiological studies have either not considered subtypes of UI, or only reported on stress UI (complaint of involuntary loss of urine on effort or physical exertion or on sneezing or coughing), urgency UI (complaint of involuntary loss of urine associated with urgency), and mixed UI (complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing). A small number of studies have reported prevalence and risk factors for adult nocturnal enuresis (complaint of involuntary urinary loss of urine which occurs during sleep). With a lack of validated questionnaire items for less common subtypes, the current literature is almost silent regarding the population prevalence and risks for postural incontinence, continuous incontinence, insensible incontinence, and covert incontinence, although they are sometimes grouped as “other incontinence”.

The validity of urinary symptom questionnaires employed in epidemiological research is considered in detail in Chapter 5. Most questionnaires were initially developed using secondary care samples, with criterion validity demonstrated in comparison to bladder diaries, pad tests, or urodynamic diagnoses. Quite widely varying terminology is used in the items assessing stress incontinence and urgency incontinence in different questionnaires and some items do not capture all aspects of the standardised definitions. Even the surrounding context for the items is known to strongly affect prevalence estimates [74], and small variations in terminology from different questionnaires may have similar effects.

The optimal assessment of incontinence subtype remains controversial [75-76], but it is clear that self-report of symptoms differs systematically from detailed clinical evaluation. In particular, for women mixed incontinence is more common than would be expected by chance using questionnaire evaluation [77], and is reproduced less frequently using urodynamics [78-79]. Stress and urgency incontinence have different treatment options, and are presumed to have different underlying pathophysiology. Caution is therefore needed when comparing epidemiological studies that either do or do not report a separate mixed incontinence subgroup, and when generalising from population level data on mixed incontinence to clinical practice.

Self-report of incontinence symptoms should reflect the woman’s own experience of incontinence, but may bear little relationship to expressed need for treatment. Across multiple measures, incontinence severity is shown to be only a moderate predictor of incontinence specific quality of life impairment [80-81]. It is important therefore to characterise both the severity of symptoms, through frequency of leakage and/or quantity of loss, and the perceived bother or impact on activities. Most questionnaires in contemporary use, including the ICIQ-SF, ICIQ-FLUTS and DAN-PSS, therefore ask patients to report both the frequency of UI, and its perceived bother. Cautious interpretation should be made of high prevalence rates obtained with case definitions that do not incorporate a measure of symptom bother.

Incontinence is a stigmatising condition in many populations [82], which creates a high risk for respondent bias in incontinence epidemiology [83-84]. Perhaps because of stigma, incontinence is also associated with low rates of presentation for care. Surveys assessing incontinence may therefore also be highly prone to both medical surveillance bias and Berksonian bias. In this section we therefore focus on community or population based samples with high response rate. To further minimise differential effects of such biases, where possible we report outcomes stratified by age, by type of incontinence, and by major subgroups of interest.

The majority of work reviewed in previous editions of this chapter, originated from developed countries. There have been many recent studies from both developing and developed countries [85], which are now reviewed. Subsequent discussion excludes however the epidemiology of obstetric vesico-vaginal fistula, which is covered in a later chapter.
Among general population studies included in previous ICI editions, crude prevalence estimates for the most inclusive definitions of UI (‘ever’ ‘any’ or ‘at least once in the past 12 months’) have ranged from 5% to 69%, with most studies reporting a prevalence of any UI in the range of 25% to 45% (Table 6). This enormous variation between studies is seen both within and between countries, with few studies reporting age standardised rates, largely precludes meaningful comparison between countries. If there is variation in true prevalence rates between countries, it is obscured by cultural differences in the perception of UI and willingness to report UI, as well as methodological differences [86], including in the wording of questionnaire items, in the method of administration of questionnaires, and perhaps most importantly, with differences in case definitions employed [87-88].

Only four studies have used the same survey tools and methods to report female UI general population prevalence in more than one country (Table 7). Three studies have attempted to assess the relative prevalence in western nations [89-91]. Across all countries surveyed, all these three studies find that SUI is the most common subtype, followed by MUI, and then UUI. Hunskaar and colleagues surveyed 29,500 women in France, Germany, the UK and Spain [89]. By demonstration of similar age trends across all countries, they suggested both lower overall prevalence of incontinence in Spain, and a relative excess of urgency incontinence in France. The EPIC and EpiLUTS studies [90-91], used similar questionnaire items explicitly based on standard definitions. However, there was inconsistency between studies. The EpiLUTS study found similar prevalence of each UI subtype in the US, UK, and Sweden, while the EPIC study reported a more than 3-fold variation in prevalence between countries, with Sweden having a prevalence of 29.5% and Italy only 9.3%. The disparity in results could be explained by differences in sampling methods, or different response rates (58%, 33% and 59% respectively). A further recent study set in Senegal, Mauritania, and Chad, reports substantial variation in prevalence across countries, even after age stratification [92].

The lack of consistency in between country comparisons, even for large surveys set in western nations, makes it impossible to assess the extent of true variation between countries. It remains difficult to establish stable, meaningful prevalence rates for female UI, when there is no consensus about what constitutes significant UI. Again, extreme caution is needed in making direct comparison of crude prevalence rates.

Although between study comparisons of female UI prevalence are largely unrewarding, we can meaningfully compare within study distributions of UI by age and UI subtype. Table 8 summarises prevalence estimates by age for female UI from community or population based studies with response rate >60%, over the period January 2008 through December 2011. Again a 10 fold variation in crude prevalence is evident between studies, so where available, overall prevalence rates are given by UI subtype, while age trends are depicted with sparklines.

As in the studies comparing prevalence between countries, although absolute prevalence rates vary widely in recent cross-sectional work, the distribution of UI subtypes is consistent. Isolated stress incontinence accounts for approximately half of all incontinence, with most studies reporting 10-39% prevalence. With few exceptions mixed incontinence is found to be next most common, with most studies report 7.5-25% prevalence. Isolated urgency incontinence is uncommon, with 1-7% prevalence, and where recorded at all, other causes of incontinence occur with approximately 0.5-1% prevalence.

In summary, current data provide very disparate estimates of population prevalence for UI in women. Approximately 10% of all adult women report leakage at least weekly. Occasional leakage is much more common, affecting 25%-45% of all adult women. Prevalence rates from cross-sectional studies uniformly demonstrate an association with age, which is explored in more detail in the section on risk factors.

</table>
remission. Even non-differential misclassification bias, can have devastating consequences both for estimates of absolute cumulative incidence, and relative incidence risk, and such effects are largest for conditions such as UI, with high prevalence and low incidence [119].

Other methodological differences may also cause wide variation. Questionnaires that use different recall periods (e.g. any leakage in last week, any leakage in last year, any leakage ever), will produce different estimates of incidence and remission. Due to changes in standard definitions, many studies also use different case definitions at baseline and follow-up. Finally, although loss to follow up itself is very variable between studies, differential loss to follow-up is observed in almost all studies, and must substantially decrease generalisability.

Annual incidence rates for broad definitions of UI (“monthly” or “any”) range from 0.9% to 18.8%, while rates for weekly UI show less variation at 1.2-4.0% (Table 8). There is a significant negative correlation between the length of a study and its reported annualised incidence rate, suggesting that short studies of 1-2 years overestimate incidence due to a dominating effect of misclassification.
Limiting comparisons to studies with >5yr follow up suggests incidence of 1.3-4.9% even for inclusive definitions of UI. Fewer studies have reported remission rates, and again estimates vary widely between 1.2 and 42%. Again limiting comparisons to longer studies of >5yrs suggests rates of 2.1 to 5.0%. Overall these results are compatible with findings from cross-sectional studies, with modest increases in UI prevalence across the whole female population of 0.5-1% per year. Although the extent of cohort effects has rarely been reported, current data suggests that earlier cohorts are less likely to report incontinence, consistent with evidence of increased care seeking among later cohorts[111,120],

IV. RISK FACTORS

In this section we summarise the most important reported demographic, social, environmental, and lifestyle correlates of urinary incontinence in women. Genetic risk factors for incontinence and prolapse are considered together in a later section. While a majority of previously cited studies have reported associations with incontinence, some caution is again needed in judging whether these may be causal risk factors.

As already seen, a large majority of studies are cross-sectional in design, providing limited evidence of causation, since the temporal association of the putative risk factor and the onset of incontinence cannot be assessed. Where possible we therefore try to focus on risk factors for incident UI, from longitudinal studies. Again though, with the exceptions of mode of delivery, menopause hormone therapy, and weight loss, there remains a dearth of interventional studies. Even the highest quality observational studies may suffer from residual or unmeasured confounding.

1. AGE

The age distribution for incontinence of all causes reported in the widely cited EPINCONT study[144], depicts a steady increase in moderate and severe incontinence throughout the adult lifespan, but with a distinct peak in slight incontinence around the time of the menopause. Other large studies have however, reported a steady increase in prevalence for both slight and severe UI, without a distinct menopausal peak[145]. The timing and causes of a fifth and sixth decade peak have been explored in a number of high quality longitudinal studies of menopausal transition, discussed subsequently. Where such a peak is identified from cross-sectional studies, it is most pronounced for stress incontinence[89,146]. Across most cross-sectional studies isolated stress incontinence declines into old age, as mixed incontinence becomes relatively more common[144,147]. Besides methodological differences, disparity in age ranges, severity thresholds, and proportion of each subtype of incontinence probably therefore explains the differences in age trends seen in Table 3. These age trends from cross-sectional studies may in any case be biased by cohort or period effects.

While most cross-sectional studies find an increase in crude prevalence into old age, some recent studies identify a peak in all causes of incontinence, with a decline in the eighth and ninth decade. Such a large disparity might be explained by sampling strategies that include or exclude institutionalised adults. The epidemiology of UI in this vulnerable group deserves special attention. Only one study provides data from more than one country, allowing cross-border comparisons. From a population of 279,191 elderly people in care homes, from Denmark, France, Iceland, Italy, Japan, Sweden, and the US, the prevalence of female urinary incontinence was relatively stable at 42.0-72.5%[148], with much of that variation accounted for by differences in age structure, and proportion of residents with functional or cognitive impairment. Indeed variability in prevalence estimates for female care home residents across the entire literature is much less than for the general population[149], ranging from 42.0% in Japan [78] through to 78.4% in the US (using a much more inclusive definition) [150]. Urinary incontinence is associated with nursing home admission from the community [151]. This may in part explain the apparent steeper increase in prevalence with age in nursing homes compared to community dwelling samples [150]. Loss to follow up certainly limits our ability to accurately assess age trends in the elderly from cross-sectional studies.

Given the difficulties in establishing robust incidence estimates, most longitudinal studies do not provide good evidence of age trends in incidence. Many studies have either reported no change in incidence with age, or a stable incidence in middle age, with a sharp increase in old age. However, the large Nurse's Health Study cohort [145], provided good evidence of a decrease in incidence of stress UI following the menopause, which has more recently been explored in analyses of the SWAN study[152], the 1946 British Birth Cohort[146], and the Hordaland Women's Cohort [142,153]. All these studies provide consistent evidence of a peak in incontinence at the time of the menopause, with pre and peri-menopausal status being associated with increased incidence of UI and decreased remission of UI compared to post-menopause. As will be discussed in the section on menopausal replacement therapy, part of this peak may be iatrogenic. Consistent with evidence from cross-sectional studies [89,144], the peak is attributable mainly to slight stress incontinence.
While the association between age and female UI is clearly important for planning healthcare resource allocation, in many studies this is not an independent association. Other risk factors associated with age, including parity, co-morbidities, and BMI attenuate the association with UI [145], and additional adjustment for relevant co-morbidities typically eliminates the association [97]. Confounding factors adequately explain the association between age and UI, and therefore UI in women should not be considered as an intrinsic consequence of the aging process itself.

2. OBESITY AND ADIPOSITY

Perhaps even more than age, obesity is the most clearly established risk factor for UI in women. There is a wealth of cross-sectional, longitudinal, and interventional data demonstrating a positive association between BMI and UI, which has recently been subject to two systematic reviews [154-155]. Across a wide range of studies obese women have approximately double the risk of UI. A typical pattern of association, taken from the large Nurses’ Health Study II [156], (n=83,355) is demonstrated in Figure 5. The ORs for UI by severity are plotted against BMI, from underweight through to obese. Although the Nurses’ Health Study II is limited to middle aged women, such findings are consistent across all age groups, both within studies[157], and between studies[154]. This association is quite minimally attenuated by adjustment for other risks for UI.

Data from the EPINCONT survey also demonstrate the same positive association between BMI and more severe incontinence. Additionally they indicate that such associations hold for the major subtypes of incontinence (Figure 6), but are most pronounced for mixed UI, and relatively modest for UUI. Similar findings were reported for data from HERS [158], and the 1946 British Birth Cohort[159], with the associations with BMI being greater for stress or mixed UI compared with urgency UI.

The temporal association between BMI and UI is also established with data from the 1946 British Birth Cohort [161], SWAN [128], MRC Incontinence [125], and the Nurses’ Health II studies [162], demonstrating that earlier onset of obesity is associated with increased risk for UI in middle age[161], and that both higher BMI and greater weight gain are associated with increased risk of incident UI [125,128,162]. Although again it is hard to compare between studies, it appears that BMI may be a greater risk factor for incident UI than for prevalent UI adding credence to its causal association [128]. As for cross-sectional studies, the association is stronger for incident stress UI and mixed UI, compared with incident urgency UI [125, 128].

There is adequate evidence [163-164], that obesity increases intraabdominal pressure, predisposing to stress incontinence, while coexisting

![Figure 5. Associations between BMI and UI severity from [156].](image-url)
metabolic syndrome predisposes to urgency incontinence [165-168]. Consistent with this hypothesis waist circumference and waist to hip ratio appeared to be associated only with stress UI, and not with urgency UI in the SWAN [128] and HERS studies [158]. More recent data from BACH [159] and KNHNES [170] indicate that measures of central adiposity are also correlated with urgency UI.

Finally, intervention studies for weight reduction have reported that even modest weight loss is associated with improvement or resolution of both stress and urgency UI, with the probability of resolution correlated to the degree of weight loss [163,171-174]. Despite the complex interplay between weight and other risk factors for UI, we therefore have very robust evidence to support a causal role of BMI in the development of UI.

3. PARITY, PREGNANCY AND MODE OF DELIVERY

Parity is considered by the laity as among the most important risk factors for UI. This is reflected in almost all large cross-sectional surveys (Figure 7). Some early studies reported a threshold effect at one delivery and little or no additional risk with increasing parity [175-177], but in most subsequent work, increasing parity is associated with increased risk of UI. A single delivery is typically associated with adjusted OR of around 1.3-1.6 for UI, and further deliveries linearly increasing the risk up to an adjusted OR of 1.5-2.0 [128,145,156,178]. As expected these effects are strongest in the third and fourth decades, with substantial attenuation through middle age, and in many studies no persistent effect in old age [157,178-180], as other risk factors come to dominate. Although the EPINCONT [178] and SWAN [128] studies reported only association between parity and stress or mixed UI, other studies have suggested, a reduced but significant association with urge UI also [181-182].

There is a substantial difference in effect between vaginal delivery and caesarean delivery, that has also been subject of a systematic review [183]. Meta-analysing data from four large cross-sectional studies [184-187], suggested a significant protective effect of caesarean on stress UI (OR 0.56) and mixed UI (OR 0.70), consistent with data both from more recent cross-sectional [179,181], and longitudinal studies [188-191]. While the existing interventional studies remain significantly underpowered, even in aggregate, a trend towards protective effect of caesarean is still seen [192].
Pregnant women, and those in the early post-partum period are typically excluded from population-based studies of UI, but a large body of work considers the specific epidemiology of UI in and around pregnancy. A recent systematic review including 33 population based studies, each with response rate over 50% [193], concluded that the prevalence of UI in the first three months post-delivery was 30%, and with infrequent stress UI being most common. As demonstrated in Table 9, there is a gradual decrease in prevalence during the first post-partum year. The difference in UI rates between women delivering vaginally and those delivering by caesarean is evident immediately after delivery.

Despite the protective effect of caesarean, for many women the onset of incontinence is during pregnancy itself. Point prevalence of UI is low in the first trimester, rising rapidly in the second trimester and increasing slightly in the 3rd trimester [204-205]. In the population based Norwegian Mother and Child Cohort Study, (n=43,279), the prevalence of stress incontinence from before to during pregnancy, rose from 9% to 31% in nulliparous women, and from 24% to 42% in parous women. In contrast, mixed incontinence showed a similar rise in both groups (from 6% to 16% and from 8% to 20%, respectively). Urge incontinence remained virtually unchanged in both groups at less than 5%. In follow up of these women, onset of incontinence during pregnancy was strongly predictive of post-partum UI, with little modification by mode of delivery. Such an effect seems to persist even into long term follow up [189-190, 206-207], even for women who return to full continence in the immediate post-partum period. It seems that the temporary physiological changes during pregnancy may reveal women with a predisposition to incontinence in later life, in a manner analogous to gestational diabetes.

There are other suggested potentially modifiable obstetric risk factors, including induction of labour, forceps delivery, and use of episiotomy. Regardless of conflicting observational evidence of an effect of episiotomy (for example [195,203,208-209]), there are a large number of interventional studies that have not shown either harm or benefit [210]. Similarly while forceps delivery has conflicting evidence from observational studies (for example [199,209,211-212]), within the context of the second stage of labour, maternal urinary incontinence is of secondary importance in decision making regarding choice of delivery instrument [213]. In a similar vein, while induction and augmentation of labour, and use of epidural anaesthesia have each been identified as being associated with both early postpartum and persistent UI [198,214-216], it is doubtful whether this should have any effect on current obstetric practice.

Many other suggested obstetric risk factors, including age at first delivery, and birth weight, are perhaps not meaningfully modifiable. Several studies have suggested that older age at either first or last birth is associated with UI [159,217-219], although more recent data from the RRISK study suggested a U shaped distribution [216], with very young mothers also at increased risk. Inadequate adjustment for

---

36
Socio-economic class may explain all these effects. Numerous studies have suggested that greater birth weight at a single delivery, or maximum weight of infant across all deliveries may also be associated with UI [177,179,201,216,220], but again randomized interventional trials of elective caesarean are needed before making clinical recommendations.

4. ETHNICITY AND RACE

With wide variations in UI prevalence between studies, comparison by race and ethnicity can be made only where such data have been reported within one study. Almost all population-based studies comparing the prevalence of UI among women from one or more racial or ethnic groups originate from the US, which may limit generalisability of conclusions. Results are summarised in Table 10. In general, across all studies, white women have a higher prevalence of UI, and in particular stress UI than all other groups.

The starkest and most consistent contrast is in rates of stress UI for black and white women. In most studies, black women have half the prevalence of stress UI compared to white women, with differences persisting after adjustment for age, parity and BMI. In comparing prevalence of mixed and urge UI for white and black women, there is less consistency. Most studies suggest similar prevalence of urge UI and mixed UI, however, the recent BACH survey found very high rates of mixed UI [27] among black women, while the EPI study reported very high rates of pure urgency UI [221]. (Table 10) These cross-sectional data are supplemented by longitudinal studies. In SWAN [128], black women were at half the risk of incident stress UI, but nearly double the risk of incident urgency UI. In the Nurses Health Studies [222], black women had lower risk of both overall UI, and stress UI after adjustment. The consistency of this difference across both cross-sectional and longitudinal studies, employing different case definitions suggests a real difference in prevalence rather than simply reporting bias.

Typically smaller groups of east Asian or Hispanic women have been included in these studies, which precludes clear conclusions. Broadly though, Asian women report lower prevalence of both stress and urgency UI. There is less consistency in comparisons of Hispanic and non-Hispanic white women, with some studies reporting higher, and others lower overall prevalence. This heterogeneity may be explained, at least in part, by differences in prevalence among sub-populations, with Mexican-American women being at higher risk than other Hispanic women [226], or differences in extent of adjustment for covariates.

5. MENOPAUSAL REPLACEMENT THERAPY

Menopausal oestrogen replacement therapy was widely prescribed as a treatment for urinary incontinence during or after menopause, on the basis of rather heterogenous data from clinical trials [231] and inconsistent associations in cross-sectional studies [215,232]. While current evidence overall continues to support prescribing of topical oestrogen [233], the Nurse’s Health Study [234], the Heart Estrogen/Progestin Replacement Study (HERS) [235], and Womens’ Health Initiative (WHI) Hormone Replacement Trial [165] all provided strong evidence that oral oestrogens, with or without combined progesterones were associated with increased incident UI. In the placebo controlled HERS trial, women randomized to conjugated oral oestrogen plus medroxyprogesterone were more likely to experience worsening of their incontinence over 4 years (39% vs 27%, p<.001) [164]. In the randomized WHI trial, continent women receiving oestrogen, with or without progesterone, were approximately twice as likely to have developed stress incontinence at 1 year (16% vs 9%, p<.0001) [236]. The risks of mixed and urge incontinence were also significantly increased, though more modestly. Further trials including oestrogen arms have subsequently been reported during development of selective oestrogen receptor modulators (SERMs), confirming these findings [237]. Some SERMs, have themselves been associated with an increased risk of UI [238] although raloxifene appears safe.

6. HYSTERECTOMY

Hysterectomy is among the most common major procedures performed for women in Western nations. Many women date the onset of incontinence to a hysterectomy, but uncontrolled case series and small randomised trials produced conflicting results. Evidence from large population based observational studies has increasingly suggested a causal link, although the underlying pathophysiological mechanism is poorly understood.

Among a sample of 1,517 Taiwanese women aged 65+, hysterectomy was associated with OR 1.8 for UI, with no difference by hysterectomy route [239]. Earlier trials had however suggested either no effect [121,135] or rather more modest effects [240]. Where an association is found, it is strongest with case definitions consistent with “severe UI” [136,156,185], perhaps reflecting high rates of mild UI in controls. Using a sample of more than 900,000 women from the Swedish Population Register, abdominal hysterectomy for benign disease was associated with hazard ratio 2.1 for subsequent stress UI surgery, while vaginal hysterectomy for prolapse was associated with hazard ratio 6.3 [241]. Similar results were observed comparing hysterectomy and endometrial ablation in the Scottish Morbidity Returns database [242]. Recent data from a randomised trial of levonorgestrel-IUS versus hysterectomy [243] does confirm this effect. In follow up of 236 women, increased incidence of both stress UI (OR 1.83) and urgency UI (OR 1.48) was first noticed only at 10 years, with corresponding higher rates of treatment.

Overall hysterectomy by any route appears to be associated with development of subsequent incontinence symptoms, and particularly with need for stress UI surgery. The data from observational studies should still be considered cautiously, as findings may be influenced by both healthy responder bias and medical surveillance bias, the latter of which may also affect unblinded interventional studies.

7. DIET

Studying diet as a risk factor for UI remains challenging. While some dietary constituents such as coffee, alcohol or carbonated beverages have been suspected as worsening UI, there is little theoretical reason to suspect other dietary constituents as causing, or protecting from, UI. Dietary data are difficult to obtain reliably. Studies of dietary factors must adjust for confounders, notably age and body mass, and should consider the trade-offs made with other constituents. Finally, women may change dietary intake in response to UI, making cross-sectional studies of diet and UI difficult to interpret.

Several studies have examined the consumption of coffee as a risk factor for UI. While some studies report a positive association with an increased risk of UI [131,244-245], others have either reported no association [246], or a protective effect [125,247]. Even within the large EPINCONT study there appeared to be conflicting findings with a positive association with mixed UI, but a negative association with stress UI [160]. The WHI study demonstrates a dose-dependent positive association between caffeinated coffee and urgency UI, but not for decaffeinated coffee or other UI subtypes [248]. The overall picture is therefore unclear.

The EPINCONT study suggested a positive association between tea drinking and stress UI or mixed UI [160], while analysis of the Swedish Twin Registry Cohort showed an association only with overactive bladder [247]. The Leicester MRC Incontinence study is one of two studies to have used food frequency questionnaires, and found no association with tea [125]. It is unclear whether tea consumption contributed significantly to the overall association between UI and dietary caffeine in the WHI study [248]. A positive association between alcohol consumption and UI has been reported by some studies [249], but is found to be either protective [125,250], or of no significance [160] in other studies.

The most comprehensive assessment of diet as a risk factor for UI comes from the Leicester MRC study [125]. Besides effects reported above, this study also found an increased incidence of stress UI with carbonated drinks, and reduced incidence of overactive bladder with bread, potato and vegetable consumption. While these effects certainly provide interesting avenues for further research, there is a concern that they may be surrogates for other unidentified socioeconomic risks, rather than truly causal. Overall there is a lack of consistency in reports of dietary associations with UI that most likely reflects methodological limitations rather than differences between populations.

8. SOCIOECONOMIC STATUS

Socio-economic status (SES) is strongly correlated with many of the other risk factors for UI including parity, BMI, diabetes, depression, smoking and timing of menopause. Higher SES is consistently associated with increased care seeking for UI, but there is conflicting evidence of association between SES and UI prevalence, or bother. While many studies do include some measure of SES as a potential confounder, its effect is frequently not reported. Table 11 summarises some of the major studies that have reported associations, to highlight inconsistencies both by SES definition and UI definition. In the table a positive association is cited where women of higher SES, i.e. higher income, more education, report a greater prevalence of UI.

9. SMOKING

Data from observational studies on smoking are again quite inconsistent. It has been reported to be an independent risk factor for UI in women in some cross-sectional studies [108,156,160,225,256] but not in many others [96-97,110]. Within studies that do find an association, former smokers have a risk intermediate between never smokers and current smokers, and some dose response effect is evident, adding plausibility.

However, with one exception longitudinal studies have consistently failed to find a significant association between either past or current smoking and incident UI in multivariate analysis [125,128,131,135,257]. Only in the Leicester MRC study [125] was current smoking associated with increased risk for incident stress UI. The conflicting data from cross-sectional studies and lack of association between smoking and incident UI in most prospective studies suggests that smoking is probably not a causal risk factor for UI.

10. PHYSICAL ACTIVITY

Evaluating associations between physical activity and incontinence remains complex. It is clear that high impact exercise such as gymnastics [258-259] or trampolining [260-261], is a direct cause of stress UI, with a dose dependent deleterious effect. However, women who suffer from UI, and particularly stress UI, may feel less able to engage in such sports [262]. Furthermore with increasing interest in core training as a treatment for UI [263], there are theoretical reasons to believe that low impact exercise might have a direct therapeutic effect. With these competing mechanisms at play, unsurprisingly cross-sectional studies have again
produced conflicting evidence (see for example [97,264-265]). However, among cross-sectional studies, comparison of low impact and high impact exercise is suggestive that, as hypothesised, high impact sports might be harmful, while low impact sports might be protective [160,266].

Evidence from longitudinal studies overall suggests that exercise does have a protective effect against incident UI, but perhaps only mediated via an effect on weight. In the Leicester MRC study, women who reported that they exercised less frequently were at increased risk for both incident stress UI and OAB in a model that adjusted for physical functioning, although notably this association was eliminated in a full model, adjusting for obesity[125]. In a study of 4,291 older women exercise at baseline was not associated with incident UI at 10 year follow up after multivariate adjustment [131]. Perhaps the strongest evidence comes from the Nurses’ Health Study [267]. In this population of US nurses aged 54-79, a higher level of physical activity across 14 years of follow-up, was associated with a reduced risk of UI overall, and specifically stress UI, although after adjustment for BMI and other factors, the overall effect was small.

### 11. COMORBIDITIES: DIABETES, UTI, COGNITIVE IMPAIRMENT, ISCHAEMIC HEART DISEASE, PHYSICAL IMPAIRMENT AND DEPRESSION

In cross-sectional studies many different comorbidities have been associated with UI in univariate analysis [232,255,268]. However, in most cases these have no explicable power, being neither a cause nor consequence of UI, but only associated with other known or unknown mediators of UI, or differentially diagnosed due to medical surveillance bias. In this section, we therefore concentrate on studies that are able to adjust for a wide range of confounders, and give priority to associations of incident UI.

Many, though not all, cross-sectional studies have reported urinary incontinence to be more common in women with either type 1 or type 2 diabetes than among women with normal glucose levels even after extensive adjustment for known risk factors [128,135,185,258,269-271]. There are conflicting data regarding a dose dependent association [270,272]. Longitudinal evidence is also conflicting. In the Nurses’ Health Study cohort, diabetes was a slight but significant predictor of incident UI.

Table 11. Selected studies reporting associations between socioeconomic status and UI in women.
Acute urinary tract infection (UTI) is a direct cause of transient UI [273], but caution is required regarding a causal association with chronic UI. UTIs are often diagnosed and treated based on symptoms alone, and there may therefore be a risk of misclassification between exposure and outcome. Many cross-sectional studies have found that women with UI are more likely to report having had one or more lifetime UTIs [221,246,274-275], and longitudinal data suggest both that UI can cause UTI, and that UTI can lead to UI. Two recent prospective studies found that baseline UI was a risk for incident UTI [273,276], among middle aged and elderly women, and in the Leicester MRC study, a history of cystitis was associated with both incident stress UI (OR 1.9) and incident OAB (OR 2.1) in women aged >40.

Prevalent UI has a clear dose dependent association with dementia [277-278], but until recently longitudinal studies did not identify an association with incident UI. One longitudinal study of 6,349 community dwelling women found that a decrease in mental functioning as measured by the modified mini mental status exam (MMSE) was not associated with increased frequency of UI over 6 years, but did predict a greater impact [279]. Despite strong associations with baseline UI in the Canadian Study of Health and Aging, moderate or severe cognitive impairment, again defined by the modified MMSE, was not associated with incident UI over 10 years [131]. However, in a sample of 12,432 women aged 70-75, followed up for 9 years, the Australian Longitudinal Survey of Women’s Health did demonstrate a strong longitudinal association with diagnosed dementia (OR 2.34) [134]. In 9 year follow up of 1,453 women aged 65+ enrolled in a US HMO diagnosed dementia was strongly associated with incident diagnosis of UI (RR 3.0) [280]. Given the strength and consistency of associations with prevalent and incident UI, and given that treatment for reversible dementias can improve UI [210,211], a causal role seems certain.

Ischaemic heart disease is associated with many risk factors for UI, but perhaps because of Neyman’s bias, cross-sectional studies have often failed to identify an association with UI itself even in univariate analysis [227,232]. The BACH study reported a strong association only among Black participants (OR 2.52) in multivariate analysis [97]. In the Leicester MRC study [268], a history of ischaemic heart disease was associated with baseline stress UI and OAB only in univariate analysis, and with no association with incident symptoms. In contrast, the Nurses’ Health Study found that coronary heart disease was associated with incident weekly UI (OR 1.46), and incident severe UI (OR 1.79) [135]. If ischaemic heart disease is a risk factor for incident UI, its effects might be mediated by cardiac failure [280], or polypharmacy [283-284].

Several cross-sectional studies have documented an association between depression and incontinence [128,185,224,229,240,285]. It seems plausible both that the stigma of UI leads to depression (for example by reducing a woman’s social network), and depression is likely to increase the bother of UI symptoms. In the SWAN study, depression was not associated with incident UI, but in the UAB Study of Aging, in a sample of 490 women aged 65+, baseline depression was weakly associated with incident UI (OR 1.2) over 3 years of follow-up [130]. Similarly in the Health and Retirement Study confounders (n=5,820), major depression was a modest predictor of incident UI (OR 1.46) over six years of follow-up, and including extensive adjustment for confounder. Baseline incontinence did not predict incident depression in the same study. Follow up of women aged 65+ enrolled in an HMO, diagnosed depression was also associated with incident diagnosed UI over 9 years (OR 1.6) [280].

Functional impairments, particularly mobility limitations, a history of falls, arthritis, dizziness, need to use walking aids, and poor lower extremity strength, have been correlated with UI in many community-based and nursing home studies [97,224,229,230,278]. In the Nurse’s Health Study osteoarthritis and functional limitations were plausibly associated only with incident urgency UI (RR 1.86 and 2.10), not with incident stress UI or mixed UI [135]. In a study of 2,025 older women improvement in ADLs was associated with remission of urge UI at 3 year follow up [224]. Other longitudinal studies have shown similar findings [130,279]. It remains unclear whether UI is a direct consequence of difficulties in getting to the bathroom and/or removing clothing, or whether mobility limitations and UI may both be consequences of general frailty in older age or of an underlying systemic illness.

V. SUMMARY POINTS

1. The estimated prevalence of UI in middle-aged and older women in the general population appears to be in the range of 30% to 60% (increasing with age); while the prevalence of daily UI ranges from 5% to 15%, rising to over 15% in women over age 70 who are institutionalised. Some studies have found prevalences outside these ranges, demonstrating that there remains a large variation in the estimated prevalence of
urinary incontinence in women, even after taking into account differences in definitions, ascertainment, and demographic characteristics. At least part of this variation is likely to be due to the sensitivity of the subject and subtle differences in the conduct of studies. (LE 1)

2. Multiple observational studies have confirmed that White, non-Hispanic women have a substantially higher prevalence of stress UI than Black or Asian women that is not explained by differences in known risk factors for UI. (LE 1)

3. Pregnancy, labour and vaginal delivery (vs Caesarean section) are significant risk factors for later UI, but the strength of this association diminishes substantially with age. (LE 1)

4. While several specific parturition factors such as instrumental delivery and birth weight are risk factors for UI in the post-partum period, their association with UI in later life is weak or non-existent, suggesting that changes in birthing practices in developed countries are unlikely to affect UI in older age. (LE 2)

5. Additional evidence has now established body mass as an important, modifiable risk factors for UI. (LE 1)

6. Physical function also appears to be an independent risk factor for UI in older women. Whether improvement in physical function leads to a reduction in UI remains to be established. (LE 2)

7. Evidence from 2 blinded, randomised controlled trials indicate that oral oestrogen, with or without progestogen, is a significant risk factor for UI in women age 55 and older (LE 1).

8. Diabetes is a risk factor for UI in most studies. While diabetic neuropathy and/or vasculopathy are possible mechanisms by which diabetes could lead to UI, no mechanism has been established, nor is it clear whether prevention or treatment of diabetes, separate from weight reduction, will reduce the risk of UI. (LE 2)

9. Menopause, as generally defined, does not appear to be an independent risk factor for stress UI. (LE 2)

10. Hysterectomy remains a possible risk factor for later UI, but the evidence is inconsistent. (LE 2)

11. Moderate to severe dementia in older women is a moderate to strong independent risk factor for UI (LE 2). Whether interventions to maintain or improve cognitive functioning also reduce UI has not been evaluated.

12. Mild loss of cognitive function in community-dwelling women, separated from physical function and other factors, increases the risk of UI slightly if at all, but may increase the impact of UI. (LE 2)

13. Data from twin studies suggests that there is a substantial genetic component to UI. (LE 1)

14. Other potential risk factors, including smoking, diet, depression, constipation, UTIs, and exercise, while associated with UI, have not been established as aetiological risk factors and are in fact difficult to study with observational data because of the potential for unmeasured confounding and questions of direction of the association. (LE 3).

VI. FUTURE DIRECTIONS

Since the 4th ICI in 2009, the quantity and quality of epidemiological studies of UI has continued to increase. Most notable are the availability of prospective data from several studies that can examine risk factors for incident incontinence and a growing number of studies comparing the prevalence and incidence of UI among Caucasian, Black, Asian and Hispanic women using population-based samples and multivariate analysis. Below are several suggestions for research over the next 5 years.

- Obesity is now an established, modifiable risk factor for UI. Investigation and dissemination of strategies to reduce the risk of UI through weight control or reduction should be a priority.

- Poor physical function is a consistent risk factor for incontinence, particularly in the elderly. Whether or not it is modifiable is not clear. Intervention studies are needed to assess the impact of improvement of physical function on prevention or reduction of UI in frail elderly.

- Moderate to severe dementia is also a consistent risk factor for incontinence. Studies aimed to maintain or improve cognitive functioning should assess change in UI as an outcome variable.

- The higher prevalence and incidence of UI, particularly stress UI, among Caucasian women, compared to Black or Asian women remains unexplained. Further studies are needed to identify additional exposures or biological factors that could explain these differences.

- Determining the role of genes and identifying specific genes that increase the risk of UI is a daunting challenge. Nonetheless, laboratory and epidemiological studies are needed to investigate this area.

- While the role of oestrogen in the aetiology of UI has been rendered largely moot due to the move away from estrogen use because of concerns about increased risk of breast cancer and cardiovascular disease, the use of other medications for control of menopausal symptoms and the introduction of selective oestrogen receptor modulators (SERMs) is growing. Their impact on UI
needs to be studied. Add something about the role of vaginal oestrogens.

- More is now understood about the prevalence of and factors affecting treatment seeking among women with UI. However, more work needs to be done to identify women who would benefit from treatment, but who do not seek, or who do not receive, treatment and to develop interventions to help these women.

E. EPIDEMIOLOGY OF UI IN MEN

I. GENERAL COMMENTS

The epidemiology of UI in men has not been investigated to the same extent as women. However, progress has been made during recent years, particularly in the reporting of population-based studies of urinary incontinence among men and more specifically, of urinary incontinence associated with prostatectomy. In addition, more reports have been published on the risk factors for the development of UI in men.

In almost all community based studies, the prevalence rates of UI continue to be reported to be less in men than in women by a 1:2 ratio. The type and age distribution of UI appear to be different between the sexes, and risk factors, although less investigated in men, seem to be different from women. It is also important not to consider UI as an isolated problem in men, but rather as a component of a multifactorial problem. Often other urogenital symptoms (LUTS) such as weak stream, hesitancy, and dribbling, or erectile dysfunction, coexist.

Post-prostatectomy incontinence has been studied and reported with increasing regularity in the last few years. Since radical prostatectomy is being performed with increased frequency, and incontinence is one of the main complications of the procedure, a specific review of UI in the postprostatectomy patient population is presented in this section. In addition to epidemiological studies, we included clinical trial data on postprostatectomy incontinence.

II. PREVALENCE

Several surveys from the general population have been conducted to determine the prevalence of UI in men (Table 12). Prevalences ranging from 1 - 39% have been published. The wide span of results may be explained by the variation in the population studied, the definition of incontinence used and the methods used in the surveys. A systematic review of 21 studies reported a prevalence of UI in older men ranging from 11-34% (median = 17, pooled mean = 22%), while that among middle-aged and younger men was from 3% to 5% (median = 4%, pooled mean = 5%). In the same review, the prevalence of daily UI in men ranged from 2-11% (median = 4%, pooled mean = 5%) [286]. A more recent systematic review of 69 prevalence studies on UI in community-dwelling men showed pooled overall prevalence rates from 4.81% to 32.17%, with prevalence increasing with age. [333]. A wide definition of UI, older age, inclusion of institutionalised men, and the use of self-reporting methods tend to result in higher prevalence rates [286-287].

For any definition of UI, there is a steady increase in prevalence with increasing age (Table 13).

1. TYPES OF INCONTINENCE

Due to differences in anatomy and pathophysiology of UI in men and women, there is a different distribution in incontinence subtypes. Recent studies confirmed our previous reports of the predominance of urgency incontinence (40-80%), followed by mixed forms of UI (10-30%), and stress incontinence (<10%) [322]. The pooled prevalence rates in a systematic review confirmed that such distribution pattern across the different types of UI is consistent across the different age groups [333]. (Table 14).

The higher percentages of urgency and mixed types of incontinence are more significant in studies involving older people. In fact, the increasing prevalence of any UI by age in men is largely due to the contribution of urgency incontinence rather than stress incontinence. One study demonstrated an increasing rate of urge UI from 0.7% between age 50-59, 2.7% between 60-69 and 3.4% for 70 years and older respondents. Stress UI was steady at 0.5%, 0.5% and 0.1% for the above groups respectively [295]. A similar trend of increasing proportions of urgency and UI with increasing age is demonstrated in a large population-based study in the US [313], and a smaller population-based Canadian study [336]. On the other hand, Maral and coworkers [292] reported increasing prevalence also of SUI with age, from 0.9% between age 35-44, to 1.2% between 45-54, 3.8% between 55-64, and 4.9% at age 65 and older [292].

Most studies report a significant fraction of other/unclassified types of urinary incontinence. One study reported that a majority of men with UI had overflow and functional types of incontinence [293], while another found constant dribbling in 7% of their respondents [319]. Terminal dribbling or postvoid dribbling is another type of leakage in men that is difficult to assign to the conventional subtypes of UI. In an Australian survey, 12% of respondents reported frequent terminal dribbling [337].

2. SEVERITY OF INCONTINENCE
When it comes to severity, the distribution in men follows that of the women. Estimates for severe UI in older women tend to be about twice as high as for older men [322].

3. RACE/ETHNICITY
Very few studies have included the impact of race or ethnicity on the prevalence of UI among men. A four-country study presented lower prevalences of reported UI among men from Korea (4%) and France (7%) than in men from Britain (14%) and Denmark (16%) [288]. On the other hand, unpublished data from the MESA study did not indicate differences in prevalence among white male respondents compared to African American respondents. Similarly, the National Health and Nutrition Examination Survey did not find any difference in prevalence of UI by racial/ethnic group [308].

4. INCIDENCE AND REMISSION
Literature on the incidence of male UI is very scarce. The MESA study [322] found a one-year incidence rate for men older than 60 years of 9-10%. In a population-based survey in the UK among men over 40 years of age, the one-year incidence of UI was noted to be 3.8% [303]. A review of a health organisation database of males at least 65 years old revealed an UI incidence of 23.8 per 1000 person years. Malmsten [299] analysed the age of onset of UI for each age cohort. Mean debut age for all men was 63 years. The mean duration was about 8-10 years in the cohorts. A longitudinal population based study in Sweden showed that 8.6% [212/2471] of those without UI at the initial survey were found to have UI at the survey done 11 years later [344].

Substantial remission rates for UI in males were noted by the MESA study, higher among men (27-32%) than women (11-13%) [322]. A similarly high one-year remission rate of 39.6% was noted among British males [303]. In the Swedish longitudinal study, 47.8% (55/115) of those found to have UI at the initial survey did not present with the problem at the time of the follow up survey 11 years later [344].

One possible explanation for the difference in the published incidence and remission rates in men compared to women, is the predominance of urgency type incontinence among men, and its close relation to overactive bladder with and without incontinence. Another factor is the close association between urgency UI and prostate gland disease, infections, or bowel dysfunction, all of which are relatively amenable to treatment or may improve even without treatment.

III. POTENTIAL RISK FACTORS FOR UI
There is relatively little research concerning conditions and factors that may be associated with UI in men, and clear risk factors are more seldom scientifically documented. However, a few available studies have identified potential risk factors, which are described below.

1. AGE
As in women, increasing age is correlated with increasing prevalence of UI. Multivariate analysis in several studies has shown that age
2. LOWER URINARY TRACT SYMPTOMS (LUTS) AND INFECTIONS

In postal and telephone surveys of community-living incontinent men, a majority had experienced a variety of other medical conditions, many of which may cause or aggravate UI. LUTS like urgency, nocturia, feeling of incomplete voiding and reduced flow are typically associated with UI [291,314,320,343]. In one study, UI was reported by 15% of men without voiding symptoms, frequency or urgency and by 34% of those with such symptoms [314].

Studies have also reported that urinary tract infections and cystitis are strongly associated with male UI [295,319], with an odds ratio of 3.7 for UI in men reporting cystitis [295] and an odds ratio of 12.5 among men with recurrent infections [293]. The metaanalysis of 5 studies including the previously mentioned studies showed a significantly higher risk of UI among men with UTI, with a pooled odds ratio of 3.6 (95% CI 2.17-6.00) [333]. It should be noted that most reports indicating a positive association between UTI and incontinence involved men aged older than 60 years.

3. FUNCTIONAL AND COGNITIVE IMPAIRMENT, PHYSICAL ACTIVITY

Mobility problems such as use of a wheelchair or aids to walking, as well as diagnosed arthritis or rheumatism or having a fall the last year, were
significantly greater among incontinent than continent men [319,345]. The Canadian National Population Health Study involving 25,400 men found that those afflicted with arthritis were more likely to have UI with an odds ratio of 1.59 (95% CI 1.07-2.38) [310]. The same study demonstrated that men with back problems were 2x more likely to have UI (OR 2.1, 95%CI 1.50-2.93). A Japanese study on community dwelling men noted that UI is more likely among men whose activities of daily living (ADL) are impaired, specifically those who are unable to change clothes and unable to walk outside, with odds ratio of 17.4 and 4.36 respectively [295]. A Canadian study found odds ratios of 1.8 and 6.4 for partially and totally immobile men aged 65+, respectively, for daily UI compared to those with normal ambulatory function [343]. Similarly, the Silver Network Home Care project among the frail older persons in Italy showed that those with higher ADL scores (i.e., greater functional impairment) had 2-4x higher odds of having UI. A survey of nursing home residents in Wisconsin identified dementia and poor ADL as risk factors for the occurrence of UI [339]. In general, most studies find similarities between men and women (see subsection on women) for functional and cognitive impairment as risk factors for UI.

Corollary to this, the association between physical activity and UI has been studied by Kikuchi and co workers among the elderly, community-based population in Japan [340]. They found that middle level physical activity in men was associated with a lower UI prevalence compared to those with low level physical activity, with an odds ratio of 0.38 (0.17-0.78). High level physical activity showed similar relations but was not statistically significant.

4. NEUROLOGICAL DISORDERS

Many specific neurological diseases may lead to UI [341]. Detrusor hyper-reflexia is seen commonly in meningomyelocele patients and in spinal injuries, Parkinson’s disease and multiple sclerosis. Areflexic bladder dysfunction due to a cauda equina lesion or diabetes might cause overflow or a paralysed pelvic floor and hence stress incontinence. A meta-analysis of 5 studies showed that men who suffered stroke were at an increased risk for UI with a pooled odds ratio of 2.68 (95% CI 1.31-5.45) [333]. Men who had suffered a stroke were at increased risk for incontinence with an odds ratio of 7.1 [295]. The Canadian National Population Health Survey showed that stroke in men increased their odds of having UI by 8x (OR = 8.26, 95%CI 3.63-18.8) [310]. In a study of 235 stroke patients, the occurrence of UI correlated with motor weakness (OR 5.4), visual defects (OR 4.8, and dysphagia (OR 4.0) [342].

5. DIABETES

Several reports have not found diabetes to be a factor significantly associated with UI in men. This includes the Canadian population-based study involving more than 25,000 men showing no increased risk for UI among men with diabetes [310]. However the pooled analysis of 6 studies showed that diabetic men were significantly more likely to have UI with an odds ratio of 1.36 (95%CI 1.14-1.61) [333].

IV. FACTORS OF UNCLEAR ASSOCIATION WITH UI IN MEN

A 9 year study of Janssen [323] showed increasing rates of UI with increasing BMI among the older men and women. However, multivariate analysis failed to show increased BMI (overweight and obese levels) as an independent risk factor for the development of UI.

In a study including a younger population in Australia, obesity was noted to be associated with UI with an odds ratio of 3.2 (1.2-9.0) [338]. In this study, however, being merely overweight was not associated with UI.

Several studies in older persons have shown an association between physical activity and UI among women that is not seen among men [288,340].

V. SUMMARY POINTS:

- The epidemiology of UI in men has not been investigated to the same extent as for women. But it appears that UI is at least twice as prevalent in women as compared to men. There seems to be a more steady increase in prevalence with increasing age than for women.
- Most studies find a predominance of urgency incontinence, followed by mixed forms of UI and stress incontinence the least. Most studies have a large fraction of other/unclassified types.
- Literature on incidence and remission of male UI is still very scarce.
- Clear risk factors are more seldom scientifically documented, but several medical correlates have been reported. Established risk factors predisposing men to UI include increasing age, presence of lower urinary tract symptoms (LUTS), urinary tract infections, functional and cognitive impairment, diabetes, neurological disorders, and prostatectomy.
- Substantial gains have been achieved on the study of the epidemiology of UI in men compared to the previous years. The conduct of more population-based prevalence studies permitted a better understanding of the problem of UI among men.
1. GENERAL COMMENTS AND DEFINITIONS

Overactive bladder (OAB) and nocturia have been neglected topics in the medical literature [392-394], with early epidemiological research on urinary symptoms focused either on lower urinary tract symptoms (LUTS) suggestive of benign prostatic hyperplasia (BPH) in men or on urinary incontinence in women [4]. However, there has been increased research interest in OAB and nocturia during the last decade [393-396].

OAB can be bothersome [397-399], and is associated with increased comorbidity [400], impaired quality of life [8], and reduced emotional well-being and work productivity [401]. Nocturia is a common cause of sleep maintenance insomnia [402-404]. Nocturia can be bothersome [405-412] and is associated with impaired mental and physical health [413] and impaired quality of life [412, 414]. Both OAB and nocturia have been reported to be associated with increased risk of falls and fractures [415-422] and nocturia also with mortality [421,423-425].

Generally, the definition of any condition is a critical factor in evaluating its epidemiology, and OAB and nocturia are no exception to this rule [394, 426]. To facilitate discussion and research related to LUTS, the International Continence Society (ICS) has produced standardisation reports. The ICS revised and re-revised its Standardisation Report of lower urinary tract function terminology in 2002 [427] and 2009 [428]. We will use the ICS definitions as basis of this chapter. However, we acknowledge that these definitions are not perfect and we encourage further discussion [396,428-431].

OAB is a term to describe the clinical problem of urgency and urgency incontinence from a symptomatic rather than from a urodynamic perspective. Previously various terms, such as ‘irritable bladder’ or ‘unstable bladder’ have been used. According to the ICS, OAB is a symptom-defined condition characterised by urinary urgency, with or without urgency urinary incontinence, usually with increased daytime frequency and nocturia [427,428]. The ICS defines urinary urgency as sudden compelling desire to pass urine, and the term OAB is appropriate if there is no proven infection or other obvious pathology [427].

For a long time, it has been known that among healthy people urine production is lower during the night than during the day [432]. Urologists have traditionally defined nocturia as frequency of urination at night without reference to urine amount, while internists have assumed that nocturia results from an increased amount of urine produced with less focus on other urinary symptoms [433]. By the ICS definitions, nocturia refers to waking at night one or more times to void, and nocturnal polyuria (NP) to the production of an abnormally large volume of urine during sleep [434]. Nocturnal urinary incontinence or nighttime bed wetting (enuresis) differs from nocturia.

According to the ICS, as stated earlier, nocturia is also a component of OAB. However, there is an ongoing debate on the definitions, especially regarding urinary urgency and OAB [396, 430-431, 435-445].

Sometimes OAB has been divided into ‘OAB wet’ (OAB with urgency urinary incontinence) and ‘OAB dry’ (OAB without urgency urinary incontinence). In this part of the chapter we focus on the epidemiology of OAB – without distinction between OAB ‘wet’ and ‘dry’ – and nocturia. ‘OAB wet’ (i.e., urgency urinary incontinence) is covered separately in urinary incontinence sections (Epidemiology of UI in Women and Epidemiology of UI in men).

2. PREVALENCE OF OVERACTIVE BLADDER

Prevalence estimates from as low as 2% [446] up to 53%[447] have been reported. Most studies on OAB have reported prevalence estimates between 10% and 20% [448-455], and the most cited articles estimate a prevalence of between 12% and 17% [448,450, 455].

In Table 15, we have reviewed all population-based studies assessing prevalence of OAB in adults of both sexes. To identify these studies [398, 448, 450, 452, 455-465], a Medline search [English-language articles published before January 2012] was carried out on with the search strategy (((Overactive bladder.mp) or (OAB$.mp)) and ((prevalence.mp)). Non-population-based (i.e. based on doctor attendances or similar) studies or studies not conducted among both sexes are not included in Table 15.

Among these population-based studies identified, different populations, different sample selection and different data collection methods were often used (Table 15). Sample size varied between 913 and 162,906, median being 2,005 individuals. Three (20%) out of 15 studies did not report any response proportion. Among those which reported, as many as seven (58%) studies had response proportion less than 50%. There was significant heterogeneity in symptom assessment, exclusion criteria, case definitions (some studies used grading of symptom severity whereas others did not), and in the time period during which the occurrence of symptoms was asked (Table 15). Hence, dissimilarities in study
Table 15. Overview of published population-based studies assessing prevalence of OAB in both sexes (PubMed indexed English-language articles before January 2012 in chronological order).

a In the European study, in five out of six countries, telephone interview was used (excluding Spain, where direct interviews were conducted due to lower proportion of households with telephone). Study sample was obtained from telephone number listings (except Spain, where electoral census data was used).
b Out of 11,740 participants (of 17,231 households contacted), 5,539 were considered ineligible. To calculate response rate, the number of respondents was divided by eligible participants (the former response rate). If same proportion of non-participants, as there were ineligible among participants (47%), were also considered ineligible, response rate was greater (the latter response rate). c Out of 7487 individuals, 3239 completed the questionnaire (response proportion 43.4%).
d Invitation to complete email survey was sent to 88,150 members of the Internet-based panel. Of the members, 51,546 responded but 7,947 were excluded due to high rates of missing or inconsistent data, or discontinuation of the survey. Finally, 30,000 participants were randomly selected from the pool of respondents with completed surveys.
e ICS, International Continence Society; OAB, overactive bladder; UTI, urinary tract infection.
f Cut-off point (threshold) used for normal vs. abnormal symptom occurrence. Reviewed only for studies using current ICS definition of OAB.
g Time period during which the occurrence of symptoms was asked.

Procedures likely explain the differences in prevalence estimates. Overall, prevalence rates varied between 6% and 32% (Table 15). However, estimates of the prevalence of OAB have actually been smaller in many recent studies compared to earlier estimates (Table 15).

Only very few population-based studies have evaluated OAB prevalence using the ICS definition and reported bother. Assessing perceived bother associated with OAB drastically decreases the prevalence estimates. In the FINNO Study (conducted in Finland among people aged 18-79) [399], as many as 54% of men and 57% reported any (at least rarely) urinary urgency. However, prevalence of at least moderate bother from urgency was 7% for men and 9% for women. Overall, more than 96% of individuals with rare urgency reported no or small bother from it whereas 65% of individuals with urgency often and more than 70% with urgency always reported moderate or major bother (scale: none-small-moderate-major) [399]. These results are in concordance with two international studies [397-398]. In the EpilUTS study (conducted in the US, UK and Sweden among people aged 40–99) [398], 22.4% of men and 35.7% of women reported urinary urgency at least sometimes (in scale: never - rarely - sometimes - often - almost - always). However, prevalence estimates were substantially lower when bother was taken into account. Only 6% of men and 12% of women reported “quite a bit” or more bother from urgency (in scale: not at all a little bit-somewhat-quite a bit-a great deal) [398]. Bother analysis from the EPIC Study [397] showed also that infrequent urinary urgency is not considered as very bothersome by most individuals. Out of OAB cases, 46% did not report symptom bother from it [397]. All these results suggest that bother measurement is essential in estimating the clinically relevant prevalence of OAB [396-398].

3. INCIDENCE OF OVERACTIVE BLADDER

The natural history of OAB has been systematically reviewed quite recently [English articles published between January 1, 1990, and September 20, 2009] [466]. Authors identified 7 longitudinal studies
of OAB. OAB incidence varied between 3.7% and 8.8%; and included studies provided evidence for dynamic nature of OAB [466]. The authors also noted that the variations in symptom definitions and methods used across studies prevent statistical determinations of overall incidence rates. Overall, longitudinal studies have confirmed that OAB prevalence increases with age but also that OAB is a dynamic condition [467-471]. In a population-based study (conducted between 1991 and 2007 in Gothenburg, Sweden) [469], the number of women with OAB with urgency incontinence (“OAB wet”) increased from 6% to 16%, however, the proportion of women with OAB without UUI (OAB dry) did not differ significantly (11% vs. 10%). Among women with OAB dry in 1991, 23% remained OAB dry, 28% reported symptom progression to OAB wet and approximately half reported remission of OAB by 2007, supporting the concept of the dynamic nature of OAB. The rate of remission OAB symptoms was greater for women who were OAB dry (49%) compared with those who were OAB wet (26%). Similar findings were recently reported in an Austrian study. The authors concluded that “OAB is a dynamic disease with long-lasting stable disease courses as well as remissions and progressions” [471].

4. RISK FACTORS FOR OVERACTIVE BLADDER

The causes and risk factors of urinary urgency and/or OAB are not well studied. Available studies, that have identified potential risk factors, are summarised below.

**a) Age**

In numerous cross-sectional studies older individuals reported more OAB than younger ones [448, 450, 452, 455-456, 458-462, 464]. Furthermore, longitudinal studies have confirmed that OAB increases with age [466]. However, while OAB is age-related, it may not be age-dependent. In some studies, OAB was not associated with age after adjustment for other factors/ confounders [400, 472-473]. Besides increasing age, also having urgency in childhood predicts having urgency in later life [474-475].

**b) Gender**

In Table 15, we summarised population-based studies assessing prevalence of OAB among both sexes. In most studies OAB was more common among women [398, 448, 450,455-462, 464-465]. In only two (13%) out of 15 studies, men reported more OAB than women. However, these two studies [452, 463] did not include younger age groups, and typically OAB is more common among women especially in younger ages [448, 455-456, 458-462, 464].

**c) Obesity**

In a British, prospective study, obesity was a risk factor for the onset of OAB (OR 1.5, 1.0-2.1) in women [400] but not among men [468]). In a Kaiser Permanente study among women aged 25-84, obesity was associated with three-fold risk of OAB [476]. In a population-based study conducted among women in Southern Sweden [477] and in a Japanese study among elderly people [478], OAB was associated obesity. Similarly, among obese women, increasing obesity was associated with OAB after adjustment for age, mode of delivery, and parity [479]. Furthermore, among type 2 diabetic patients, increased waist circumference was associated with prevalence of OAB [480]. Among non-care seeking women (enrolled at one site in a randomised trial) [481], obesity was associated with increased OAB in univariate analysis, but the association did not remain significant after adjustment for confounders. Although OAB seems obesity-related, in many studies, incomplete adjustment for all relevant confounders was possible.

**d) Life style**

In a prospective study among British women, neither alcohol, coffee nor tea consumption were risk factors for the onset of OAB (defined as having either urgency, UUI, or a combination of these) but drinking carbonated drinks was [400]. Among men, neither tea, coffee nor wine consumption were associated with onset of OAB onset, but a negative association between beer intake at baseline and subsequent OAB onset was found [468]. However, this may be explained by a systematic misclassification error (individuals decrease or cease alcohol consumption due to ill health) [482-483], residual confounding (moderate drinkers have many other favouring lifestyle factors) [484-485], or direct biological effects. In a Swedish population-based study in young female twins [486], tea (but not coffee) drinking was associated with an increased risk for both OAB and nocturia. However, after controlling for confounders (including zygosity of twins) these associations did not remain significant. Concurring with these studies, among non-care seeking women [481], coffee or alcohol consumption was not associated with OAB. In a population-based study among women in Southern Sweden [477], OAB was not associated with alcohol consumption.

In a prospective British study, smoking was a risk factor for the onset of OAB (defined as having either urgency, UUI, or a combination of these) in women [468] but not in men [468]. In a population-based study among Finnish women aged 18-79 [487], urgency was approximately three times more common among current and twice as common among former than never smokers. Parallel associations for urgency with smoking intensity suggested a dose–response relationship [487]. Other supporting findings have also been reported [473, 488-490]. However, some other studies did not find smoking to be a risk factor for urgency [463, 478, 486].

A prospective study among British men did not provide evidence of any specific dietary patterns as
a risk factor for onset of OAB [468]. Furthermore, physical activity was not significantly associated with OAB onset in men [468]. Contradictory results were found among non-care seeking women [481] where physical activity was associated with decreased OAB.

e) Race/ethnicity and socioeconomic status

Evidence regarding the role of race/ethnicity on OAB prevalence is limited. In a small Taiwanese study [491], higher prevalence of urgency (7.7% vs. 4.3%, p=0.02), was found in indigenous women than in non-indigenous women. In the US part of the EpiLUTS study [473], OAB was reported by 26% of White, 33% of Black, 27% of Asian and 28% of Hispanic men. In the multivariate analysis, OAB was significantly more common among African-American (OR 2.0, p<.001) and Hispanic (OR 1.7, p<.001) male participants. The authors noted no statistically significant differences among women after multivariate analysis, despite wide variation in crude prevalence (27% for Asian women, 43% for White, 46% for African-American and 42% for Hispanic) [473]. Hospital-based studies have reported no difference in the prevalence of OAB by race/ethnicity [492-493].

f) Reproductive factors and pelvic surgery

Urinary urgency is a common symptom during pregnancy [494]. In a Taiwanese study [495], only 1% of women reported having urgency before pregnancy, whereas corresponding estimates were 16% in the first, 25% in the second, and 31% in the third trimester. Other studies have also found increasing prevalence of urgency with advanced gestational age [496-497]. However, in a Nigerian study, women in 3rd trimester did not report more urgency than women in 2nd trimester [498]. Although one quarter of pregnant women reported urgency, it was associated with moderate or severe bother for only 5% of symptomatic women [498].

The association between parity and urinary urgency is controversial. Some studies reported no association for parity with urgency or OAB [400, 481, 499-500], whereas others found increased prevalence of urgency among parous women [472, 491, 501-503]. However, there were substantial differences in methods between these studies. Regarding delivery mode, most studies demonstrated no effect on prevalence of urgency, urgency incontinence or OAB [463, 499 502-505]. On the other hand, contrary findings have also been reported [506-507]. In a Swedish prospective study, weekly urgency was reported in late pregnancy by 2.6% of women in the elected vaginal delivery and by 2.7% of the women in the elected cesarean section group [506]. Corresponding figures were 7.9% for vaginal delivery and 2.7% for cesarean section groups at 9 months postpartum [506] concurring with the results of a cross-sectional US study [507]. In a recent US study [99], for women with a history of at least one operative vaginal birth, the adjusted odds of OAB was more than quadrupled (OR 4.9, 95% CI 2.2-11; women who had delivered all their children by pre-labor cesarean as reference).

The association of the postmenopausal years with increased urgency or OAB has been reported in several studies [465, 472, 502-503, 508-509]. The impact of hormone therapy on OAB is unclear. The Cochrane Incontinence Group review of urinary incontinence and oestrogens (urgency or nocturia not as the primary objective of the study) found that there were less nocturnal voids and urgency episodes among women treated with local (but not systemic) oestrogen [510]. There were no significant differences in OAB prevalence among women using either oral contraceptives or a levonorgestrel-releasing intrauterine device, in comparison to non-contraceptive users in a population-based study among young, Swedish women [511].

Radical hysterectomy is related to increased prevalence of pelvic floor problems [512]. For instance, patients treated for cervical cancer reported urgency 2-3 times more commonly than the matched controls: 36% of those with history of radical hysterectomy and pelvic lymph node dissection, 49% of those with surgery and adjuvant radiotherapy, and 48% of those with primary radiotherapy reported experiencing urgency [513]. However, the relationship between urgency and hysterectomy for benign indications is less clear. Many studies did not find a significant association between hysterectomy and urgency [499-500, 514-519]. However, some studies reported less [509, 520-523] and some more [463, 472, 501, 524] urinary urgency after hysterectomy. No differences according to the route of hysterectomy on urgency have been found [509, 523, 525-526]. Both prolapse surgery and stress incontinence surgery are associated with a risk of (de novo) urgency or urgency incontinence in both hospital based, and population based studies [489, 500, 527-528].

g) Specific conditions

There is a paucity of studies concerning conditions and co-morbidities that may be associated with OAB, and clear causal risk factors are even more seldom documented. Few available studies have identified potential risk factors, which are described below.

1. Benign prostatic hyperplasia. Instead of OAB/urgency, observational, clinic-based studies have assessed the relationship between detrusor overactivity and benign prostatic hyperplasia/obstruction. Although patients with detrusor overactivity are less likely to get symptom improvement after BPH surgery than those without detrusor overactivity, many patients report less urgency after BPH surgery [529]. Similar findings were reported following a prostatectomy study among men aged 47-85,
Other conditions.

2. Pelvic organ prolapse. In community-based studies [476, 533-535], pelvic organ prolapse was associated with 2-6 times higher risk of having urgency incontinence. Concurrent with this finding, hospital based studies have also found pelvic organ prolapse to be a risk factor for urgency incontinence, and in interventional studies urgency incontinence is often (but not always) relieved [536].

3. Mental health. In the BACH survey [537], urinary frequency, urgency, and nocturia were associated with previously experienced sexual, physical, and emotional abuse for both genders and for all ethnic groups in the study (White, Black, Hispanic). Concurring results were found in a German, clinic-based study where 31% of women with OAB reported almost twice as often earlier physical or sexual abuse as did the women with stress urinary incontinence (18%) or women without urinary symptoms (18%) [538]. In an Iranian study, individuals with OAB had a higher prevalence of anxiety (28.2 vs. 8.8%; p=0.001) and depression (38.2 vs. 18.2%; P = 0.02) [453] concurring with finding from multinational EpILUTS study where increased depression and anxiety scores were found among individuals with OAB [148]. Furthermore, postpartum depression has also been reported to be associated with urgency incontinence [540].

4. Other conditions. In the BACH survey [541], urgency was associated with almost double the risk of hypertension and heart disease in women and with more than double the risk of diabetes in men. However, In a Japanese study among the elderly, OAB was not associated with diabetes or kidney disease but was associated with depression, alcohol use, and increasing BMI [478]. In a UK prospective cohort study within a random sample of 19,241 women aged 40 or more identified from Health Authority lists of 108 general practices [400], predictors of OAB included faecal urgency, imbalance, osteoporosis, ankle swelling, diabetes, DVT and cystitis [9]. Urgency/OAB has also been reported to be common among patients with diabetes [542], stroke [543] and asthma [463].

II. NOCTURIA

1. PREVALENCE OF NOCTURIA

Most earlier studies assessing the prevalence of nocturia have been conducted among elderly men [544-552]. They consistently found that nocturia 1) is a very common symptom and 2) increases with age. These finding have recently been confirmed in comparative studies conducted in both sexes [405-406, 411, 424, 455, 461, 553-558] (Figure 8).

We have reviewed all population-based studies assessing prevalence of nocturia in adults of both sexes. To identify these studies, a Medline search [English-language articles published before January 2012] was carried out on with the strategy ((nocturia.mp) and ((prevalence.mp)). Non-population-based (i.e. not based on doctor attendances or similar) studies, studies not conducted among both sexes of adults, studies with narrow age range (less than 40 years), or studies with percentage data unavailable are not shown in Figure 8.

In the FINNO Study (individuals aged 18 to 79), approximately one out of eight men and women reported at least two voids per night, in addition one third reported one void per night [557]. Young women reported more nocturia than young men, prevalence of nocturia in men and women equalized only in the sixth to seventh decade of life, and in older age groups men had more nocturia than women. Many other recent studies have supported these findings: higher prevalence of nocturia among young women than young men, and an equalisation of prevalence in middle age [411, 414, 455, 461, 561-562]. As the gender difference has been found across different continents (Europe, Asia, Australia and North America) it probably is not due to the specific country, lifestyle or cultural factors (Figure 1) [394, 411, 414, 455, 461, 557,559-562]. The reasons for the excess of nocturia among older men remain unknown, but prostatic enlargement is likely to be the predominant factor.

The Krompen study (conducted in the Netherlands among elderly men) [563] is one of the few studies where nocturia was assessed by frequency-volume charts). One and a half or more voids/night (average of information on two to three nights) was present in 60% of men aged 70-78 years, whereas at least 2.5 voids per night was present in 20%, respectively. These estimations are comparable to questionnaire studies: most elderly people void at least once per night [564] (Figure 8).

2. INCIDENCE OF NOCTURIA

There remains a paucity of studies on the incidence and natural history of nocturia [565]. This is not only due to the fact that longitudinal studies are more difficult to perform than cross-sectional studies but also due to the youth of “nocturia research” [434], uncertainty not only about “incidental nocturia” definition [566-569] but also about the appropriate time interval for repeated sampling [570].

In a US community-based study among adults over 60 [571], nocturia was ascertained during the baseline and
first and second year follow-ups. Of the 738 individuals with no nocturia at baseline, 34.6% reported having nocturia (2 or more) at follow-up, or an incidence rate of 213/1,000 person-years. Of the 357 individuals who had 2 or more episodes at baseline, 66.3% reported 1 or fewer at follow-up, for a remittance rate of 497/1,000 person years. These estimates were not calculated with adjustment for age- or gender, and the exact number of days between date at baseline and date at follow-up were not determined [568].

In a study conducted among elderly men in a Finnish county, questionnaires were mailed in 1994, 1999 and 2004 [572]. The crude incidence of nocturia for men from zero to one or more was 75 new cases per 1000 person-years during the first 5-year period and 126 during the second period. The younger cohort had a lower incidence than the two older cohorts (50-, 60-, 70-year old: 61, 91, 93 cases/1000 person-years, respectively). Interestingly, for all age cohorts the rate of incidence during the second five year period (102, 168, and 167 per 1000 person-years) was higher than during the first. The incidence of nocturia to 3 or more times (from 0 or 1-2 times) was less across all age groups (3, 12 and 16/1000 person-years, respectively for the age cohorts). However, this study is difficult to compare to other studies as no information on incidence of nocturia from <1 episode to >2 or more is available [572].

In a study conducted in the city of Gothenburg, Sweden questionnaires were mailed in 1992 to 10,456 men (aged 45-99) [470]. Follow-up was performed in 2003 when 3,257 men replied (3,000 men had died and 691 had emigrated or were no longer available in the register). The authors presented prevalence data at two time points. Nocturia prevalence increased from 12.8% to 50.1% (2 or more voids/night) among this study [470].

In the Krimpen study [563]. The overall incidence and remission rates (nocturia defined as ≥2 voids/night) were 23.9% and 36.7% after 2.1 years [563]. The incidence was highest among the oldest and lowest among the youngest men. As the absolute number of men with incident nocturia was higher, the prevalence rate increased over time. The authors concluded that “due to this fluctuation it is almost impossible to provide reliable incidence rates for nocturia in community dwelling older men” [563]. Overall, these longitudinal studies have shown that although nocturia increases with age it also has fluctuating character. However, the extent to which lack of reliability of the questionnaires has obscured true incidence or remission estimates remains unknown.

3. RISK FACTORS FOR NOCTURIA

The causes and risk factors of nocturia are not well understood [426, 565]. Available studies, that aimed to identify potential risk factors, are summarised below.

a) Age

There have been numerous studies showing that elderly subjects have more nocturia than younger
people (Figure 8) - age is one, if not the most important correlates of nocturia. For instance, in a community-based US study, less than 5% of those aged 18-24 reported two voids per night while the corresponding figures were approximately 15% and 25% for those aged 45-54 and 65-74 respectively [406]. Besides increasing age, also childhood nocturia predicts nocturia in later life [474].

b) Gender

Although there is no remarkable difference in overall prevalence of nocturia between genders, in more detailed age specific analyses differences have emerged between the genders (Figure 1). Many studies found higher prevalence of nocturia among young women than young men, and an equalisation of prevalence in middle age [411, 426, 455, 461, 557, 561-562]. Prostatic enlargement has been suggested as a predominant factor for potential excess of nocturia among elderly men [564].

c) Obesity

Several studies have shown the relation between overweight/obesity and nocturia. Obesity was associated with more than three-fold risk of nocturia in a Swedish study among middle-aged women [573], and with more than two-fold risk in the FINNO Study [557]. Confirmatory findings have been reported in numerous studies [574-577]. In the longitudinal TAMUS study among men aged 50 or more [578], obese men had double the risk for nocturia compared with normal weight men. The frequency of nocturia at baseline did not increase the incidence of obesity at follow-up [578].

d) Life-style

Most studies have not found an association between nocturia and either alcohol [405, 556, 568, 576, 579-580] or coffee/caffeine [552, 573, 578, 580-581] consumption. In some studies moderate alcohol consumers had less nocturia than abstainers [578, 582, 583]. However (as discussed earlier in ‘Risk factors of overactive bladder’), these findings may be due to systematic misclassification error or residual confounding [482-485].

Most studies have not found an association between nocturia and smoking [424, 552, 576, 578-581, 584]. Some conflicting results have also been reported: in a Swedish study [573] smoking was associated with increased nocturia but in Austrian [405] and Japanese [556] studies, with decreased nocturia.

Physical activity has been reported as being protective against LUTS in men [585-587], and against nocturia in women [573]. In an Austrian study [405], no relation was found between nocturia and physical activity. However, exercise programme has been shown to improve nocturia in a non-randomised trial [588].

e) Race/Ethnicity and socioeconomic status

In several US studies, African Americans were approximately twice as likely to report nocturia as other groups [574, 577, 589-591]. This effect was attenuated, although remained significant [577, 590], with adjustment for socioeconomic status and comorbidity. Furthermore, care-seeking black women also reported nocturia more commonly than other groups [592-593]. Conflicting results were found in a Kaiser Permanente study [594]. Less is known about the relationship between ethnicity and nocturia outside the US. In small studies in Taiwan [491, 595] and Scotland [596], associations between nocturia and ethnicity have been found. In the Scottish study, nocturnal polyuria was more common in Caucasian men compared to Asian men.

f) Reproductive factors and pelvic surgery

Nocturia is a very common symptom during pregnancy. In all studies most pregnant women report nocturia at least weekly, in many studies most women report having nocturia every night [494-498, 503, 597-598]. Typically the occurrence of nocturia increases during pregnancy. In an Indian study [598], nocturia (defined as more than one void per week) was reported by 50.6% of women before pregnancy (retrospective information), by 58.6% of those in the first, 71.9% in the second and 77.0% in the third trimester. In a Finnish study among women aged 18-79 [500], parous women reported slightly more nocturia than nulliparous women, contradicting earlier reports (conducted among perimenopausal women) of no association [501, 599]. The relationship of nocturia between parity has been suggested to be more likely to be due to pregnancy itself than trauma to the urinary tract during delivery [600] supported by the finding of no difference in nocturia between primiparous and multiparous women in the same Finnish study [500] and by a finding of no difference between vaginal delivery and caesarean section in a Swedish prospective study [506]. In these studies, the postpartum period was also associated with increased nocturia [500, 506].

In a population-based Swedish study among young women, no difference in nocturia was found among oral contraceptive users and non-users, however, levonorgestrel-releasing intrauterine device (compared with non-contraceptive users), reported less nocturia (OR 0.53, 95% CI 0.32-0.89) [511].

Danish and Finnish population-based studies have reported more than double the risk of nocturia after the menopause [500, 501], consistent with other studies [508, 599]. One study attributed this to aging rather than to menopausal transition [601]. In these Finnish and Swedish studies, there were indications of increased nocturia among women using menopausal hormone therapy, but the findings were statistically insignificant [500, 599]. In a small randomised trial [602], there was
no difference in nocturia among those with menopausal hormone therapy or placebo. Similar findings were reported in a randomised trial of vaginal oestradiol and placebo after sling surgery [603].

The relationship between nocturia and hysterectomy is unclear, with hysterectomy being protective factor [515, 520, 522], risk factor [501], or not associated with nocturia [500, 509, 516]. Surgery for stress urinary incontinence was not associated with nocturia in a population-based study [500].

g) Specific conditions

1. Benign Prostatic Hyperplasia And Prostate Cancer. Benign prostatic hyperplasia (BPH) constitutes a well-recognised risk factor for nocturia [563, 580, 604]. In the FINNO Study [580], half of the subjects with physician-diagnosed BPH reported at least two voids per night; however, only a third of the men with nocturia reported BPH. However, nocturia is the least specific LUTS associated with BPO and medical treatment to relieve BPO has less effect on nocturia than on other LUTS [605-606]. Furthermore, nocturia has been reported as one of the most persistent LUTS following prostate surgery [530, 607], and in a study of men with bothersome LUTS, those receiving finasteride had an effect indistinguishable from placebo [608]. Many men with LUTS express a fear of prostate cancer [609], however, whether LUTS (including nocturia) are suggestive of prostate cancer is not clearly established [610]. In the large HUNT-2 study [611], LUTS severity was positively associated with the subsequent diagnosis of localised prostate cancer but not with advanced or fatal disease. More than 70% of men with physician-diagnosed prostate cancer reported at least two voids/night, while 7% of men with nocturia reported prostate cancer in the FINNO Study [580]. Whether men with nocturia are more likely to be diagnosed with prostate cancer (due to use of prostate-specific antigen), prostate cancer causes nocturia, or nocturia is a side-effect of various prostate cancer treatments remains unclear [412, 612]. Impact of radical prostatectomy on nocturia has been neutral or negative (i.e. increased nocturia) [613-615].

2. Nocturnal polyuria. The ICS defines nocturnal polyuria as an increased proportion of the 24-hour output of urine volume occurring at night [427]. However, there is a paucity of studies providing reference values. The Krimpen study authors suggested that nocturnal urine production exceeding 90 ml/hr is abnormal [563, 584] but concluded that “nocturnal urine production as an explanatory variable for nocturnal voiding frequency is of little value.” [584]. The fundamental pathogenesis of nocturnal polyuria remains largely unknown.

3. Overactive bladder. Urinary urgency was a clear risk factor for nocturia in the FINNO Study (OR 7.4, 95% CI 4.5-12 for men, and OR 4.9, 95% CI 3.2-7.7 for women) [580]. However, while half of subjects with urgency also reported at least two voids per night, only one in three with nocturia reported urgency [459]. The finding that most people with nocturia do not report frequent urinary urgency (Figure 9), has also been reported in the EPIC and EpilUTS studies [398, 455].

4. Diabetes. An association between diabetes and nocturia has been noted in most [556, 574, 576, 580, 583, 604, 616-619], but not all reports [555, 563, 568]. In the BACH Survey [574] and in a Danish study at ages 60-80 years [576], nocturia was associated with double the risk of diabetes. In these surveys [574, 576], it remained unreported whether there were gender differences. In the FINNO Study [580], diabetes was associated with nocturia after adjustment for other factors only in women.

5. Hypertension. It has been suggested that essential hypertension and nocturnal polyuria are part of the same pathophysiological process [620]. In Japanese [556] and US [568, 577] studies, hypertension was associated with nocturia, although effect sizes were modest (ORs between 1.5 and 1.6). However, in studies conducted in Europe [555, 563, 580], neither nocturnal polyuria nor nocturia were associated with hypertension. In a secondary analysis from the BACH survey [621], monotherapy with calcium channel blockers in women, and combination therapy with loop diuretics in men was associated with nocturia but no other associations for nocturia with any other antihypertensive was found [621]. While the treatment for hypertension may cause [395, 621-622] or alleviate nocturia [623] in some cases, appropriate methods are of particular importance when trying to assess the relationship between hypertension and nocturia.

6. Coronary disease. Earlier (male) studies [164, 165, 172] did not find a relationship between nocturia and cardiac disease. However, in these studies [555-556, 563], an association between cardiac symptoms/disease and nocturia was found in the preliminary analyses before multivariate modelling. In more recent studies [424, 574, 580, 583] coronary disease has been shown to be associated with nocturia.

7. Depression. In Swedish and US population-based studies [414, 624], depression and antidepressant use were both associated with increased prevalence of nocturia whereas in a Finnish study a relationship was found only among men using antidepressants after adjustment for other factors [580]. In another Finnish study (among men aged 50 or more), those with depressive symptoms at study entry were at almost triple risk for moderate or severe nocturia than those without depressive symptoms but nocturia had no effect on depressive symptoms during 5-year follow-up [625].
8. Sleep apnoea and snoring. In clinic-based studies [618, 626-628], nocturia was associated with sleep apnoea. In US studies conducted among community-dwelling older adults, subjects with increased apnoea-hypopnoea index had greater mean nocturia episodes, nighttime urine production and atrial natriuretic peptide excretion [629-630]. Snoring was one of the three most important nocturia population-level risk factors for both sexes in the FINNO Study [580] concurrent with a Swedish urology clinic study [631].

9. Neurological diseases. Most patients with multiple sclerosis have bladder dysfunction, which may also lead to nocturia [632-633]. Nocturia was also associated with stroke and cerebrovascular disease [583, 616]. Moreover, in a study among Parkinson’s patients, severity of disease was also associated with increased nocturia [634]. Furthermore, a relationship between nocturia with restless legs syndrome was recently reported [580].

4. SUMMARY POINTS

- Overactive bladder (syndrome) (OAB) has been defined as urinary urgency, with or without urgency urinary incontinence, usually with increased daytime frequency and nocturia (in the absence of infection or other obvious pathology).
- Prevalence of OAB has been estimated from as low as 2% up to 53%.
- Recent population-based studies have shown that less than 10% of people have OAB with at least moderate bother suggesting that bother measurement is essential in estimating the clinically relevant prevalence of OAB.
- Longitudinal studies have shown that OAB increases with age, and that OAB is a dynamic condition, with not only substantial progression but also remission rates.
- OAB has been suggested to be associated with an increased risk of falls, fractures, and impaired quality of life.
- While age is a clear risk factor for urinary urgency and/or OAB, other risk factors have not been that well studied.
- Individuals with benign prostatic hyperplasia, pelvic

Figure 9. Age-standardised prevalence of nocturia, urinary urgency (with or without urgency incontinence) and urinary frequency among Finnish people aged 18–79 years.

The red circle represents individuals with urinary urgency (often or always in scale: never-rarely-often-always) without urgency incontinence (often or always in scale: never-rarely-often-always) excluding the area of the red oval representing individuals with urinary urgency with urgency incontinence. The blue circle represents individuals with urinary frequency (defined as more than eight voids/day) and the green circle nocturia (defined as at least two voids/night). Age-standardization performed using the age structure of Finland. Pelvic organ prolapse (POP) refers to loss of support for the uterus, bladder, colon or rectum leading to prolapse of one or more of these organs into the vagina. Prolapse is thus a continuous condition when measured by visual inspection of the vaginal wall during valsalva. For clinical purposes, the degree of POP is commonly described as above the introitus, at the introitus, or beyond the introitus with or without valsalva. The International Continence Society first developed a standardised definition for the condition of POP in 1996 [635]. The ICS Pelvic Organ Prolapse Quantification (POPQ) examination defines prolapse by measuring the descent of specific segments of the reproductive tract during valsalva strain relative to a fixed point, the hymen. The POPQ system describes the anatomic findings of pelvic organ prolapse without consideration for symptoms and bother perceived by the woman. Validation of this system has shown it to be highly reliable [636]. The stages of prolapse severity are arbitrarily defined, and there is no clear differentiation between normal anatomic variation and mild POP. For research purposes there is consensus for use of the POPQ system until further evidence might clarify the distinction between normal variation and mild prolapse [637].

Determining POP based on self-reported symptoms is difficult because of the lack of specificity and sensitivity of most symptoms attributed to pelvic organ prolapse [638] and the fact that prolapse above the level of the hymeneal ring is usually asymptomatic [639]. The only exception appears to be a sensation of bulging into the vagina [640], which is most strongly associated with prolapse at or below the hymeneal ring [641-642]. A recent study of 110 women found that a question asking about a feeling of something bulging in or dropping out of their vagina had a sensitivity of 84% and a specificity of 94% for POP at or beyond the hymeneal ring on examination [639]. Seeing prolapse would presumably be even more specific, but is too uncommon to be useful as a definition.

Since the 4th ICI several additional studies have reported the prevalence of POP in a general population [643-648]. Reports from the Women’s Health initiative (WHI) Oestrogen Plus Progestin Trial, and randomised controlled trial, have been included [643,645-646]. While not actually population-based, the women in the trial were recruited from the community rather than from women seeking gynaecological care, and provide important information on the prevalence of POP based on pelvic examination.

The prevalence of POP based on a sensation of a mass bulging into the vagina was remarkably consistent, ranging between 5 and 10 percent (Table 16). The study by Eva et al., which reported a substantially higher prevalence included in the definition of POP, pelvic heaviness or digital pressure on the perineum or in the vagina to aid with defaecation [649]. The prevalence of observed prolapse in women enrolled in the WHI trial is similar to the
Table 16. Prevalence of pelvic organ prolapse (POP) defined by symptoms or observed on pelvic examination in the general population.

prevalence found in the one population-based study that also used pelvic examination [650], although the prevalence of each type of prolapse was higher in the WHI study [642]. In both studies, prolapse occurs most frequently in the anterior compartment, next most frequently in the posterior compartment, and least in the apical compartment.

Two studies that examined prolapse by race found that the Black women had the lowest prevalence and Hispanic women the highest after controlling for multiple other factors in multivariate analysis [642,648]. The study reported by Rortveit et al based on symptoms found adjusted odds ratios of 0.4 (95% CI=0.2-0.8) for Black and 1.3 (95% CI=0.8-2.2) for Hispanic women, with White women as the referent group [556]. Hendrix et al reported adjusted odds ratios of 0.6 (95% CI=0.5-0.8) for Black and 1.2 (95% CI=1.0-1.5) for Hispanic women compared to White women for POP based on genital examination [643].

III. INCIDENCE

Only two studies could be located that reported the incidence of new POP. Both studies were done on sub-groups of women enrolled in the WHI Oestrogen Plus Progestin Trial. The first study of 412 women enrolled at the University of California, Davis site, used a standardised pelvic examination repeated every 2 years over 8 years [643]. The incidence of new cystocele, rectoceles and uterine prolapse was 9%, 6% and 2%, respectively. Annual rates of remission from grade 1 (prolapse to above introitus) was relatively common for each type of POP (24%, 22% and 48%, respectively) but less common from grade 2 or 3 (prolapse to or beyond the introitus) (9%, 3% and 0%, respectively). In a second study of 259 postmenopausal women with a uterus who were examined using the POP-Q at baseline and annually for 3 years. POP was defined as prolapse to or beyond the hymeneal ring. The incidence of new POP was 26% at 1 year and 40% at 3 years, with remission rates of 21% at 1 year and 19% at 3 years [645].

Several studies have reported the annual incidence of surgery for POP in the US and at least one in the UK. A longitudinal study of over 17,000 women in the UK, age 25 to 39 at baseline, reported an annual rate of prolapse surgery of 0.16% [653]. This rate is consistent with the rate of approximately 0.2% per year reported in the US [654-655]. One US study reported an annual incidence rising with age from 0.05% in women age 30-39 to 0.5% in women age 70-79 with an estimated lifetime cumulative risk of surgery from prolapse of 7% to 11% [656]. A recent US study reported similar surgical rates: 0.07% for women 18-39, 0.24% for women age 40-59, and 0.31% for women age 60-79 [657]. Surgical rates drop substantially after age 80 [656-657]. Estimating rates of prolapse surgery has the advantage of use of hospital discharge data on procedures, which is highly accurate for the procedure performed, but less accurate for the indications for the procedures, particularly when a procedure may have more than one indication.

IV. POTENTIAL RISK FACTORS

1. BOWEL DYSFUNCTION AND PELVIC ORGAN PROLAPSE

Women who seek urogynecological care report a high prevalence of bowel symptoms [658]. However, bowel dysfunction is highly prevalent among women in general and it has been estimated that up to 27% of the female population in industrialised countries is affected by constipation [659]. The overall prevalence of constipation and associated symptoms in women with pelvic organ prolapse ranges between 20-53% depending on the definition of disorders [660-662]. Although definitions of disease differ between studies it is widely acknowledged that bowel dysfunction is a complex condition with a multifactorial aetiology. Bowel dysfunction comprises a wide variety of symptoms including constipation, rectal emptying difficulties, incomplete defaecation, manually assisted defaecation, faecal urgency and irritable bowel syndrome (IBS). Neurophysiological assessments have shown that damage to the pelvic floor musculature and nerve supply can occur as a result of chronic constipation [663]. Other predisposing factors comprise low socio-economic status, pelvic floor surgery, depressive disorders, thyroid dysfunction, physical disability and inactivity, and food habits [664].

Current epidemiological evidence on the association between bowel dysfunction and pelvic organ prolapse are at odds. A number of studies suggest that women with pelvic organ prolapse are significantly more likely to experience constipation and other symptoms of bowel dysfunction, [662,665-668] whereas others show a weak or non-existent association [661,669-671]. In a case-control study, manually assisted defaecation was present in 19.7% of women with prolapse compared to 4.4% of control subjects (p<0.001) [662]. In a randomly selected population based study, irritable bowel syndrome and constipation were both strongly associated with pelvic organ prolapse (OR 2.8 95% CI 1.7-4.6, and OR 2.5 95% CI 1.7-3.7 respectively) [667]. Varma et al., [668] suggested that among randomly selected women, having symptomatic pelvic organ prolapse more than doubled the risk for obstructed defaecation (OR 2.3 95% CI 1.5-3.7). A retrospective questionnaire based survey of women with and without prolapse concluded that constipation as a young adult was an important factor in the development of uterovaginal prolapse[665]. In a case-control study, women with prolapse were at increased risk for constipation also after adjustment...
In the cross-sectional Women’s Health Initiative (WHI), cysto- and rectocele was only weakly associated with constipation (OR 1.1 95% CI 1.0-1.2) [669]. Similar weak associations between prolapse and bowel dysfunction have been observed in other large cross-sectional studies [661,670-671]. Overall severity and prevalence of bowel dysfunction has shown poor correlation with findings of pelvic organ prolapse at radiological imaging [672-674]. Also at clinical examination, increasing vaginal descent and prolapse severity, show a generally weak (or absent) association with symptoms related to bowel dysfunction [660,675-678]. In a study to the WHI, no specific bowel symptom was associated with increasing loss of pelvic organ support in any vaginal compartment [671]. When considering compartment-specific pelvic floor defects, most studies suggest that increasing posterior vaginal wall prolapse and perineal descent are correlated to more symptoms of obstructive defaecation [661,674,676]. In a cross-sectional study of 260 women with pelvic organ prolapse, women with posterior vaginal wall prolapse were more likely to incomplete emptying (41% vs 21%, P=0.003), straining at defaecation (39% vs 19%, P=0.002), and splinting with defeca
tion (36% vs 14%, P<0.001) compared with women without posterior vaginal wall prolapse. But there was no significant association between bowel symptoms and increasing severity of prolapse [679].

The association between bowel dysfunction other than specifically obstructive symptoms and pelvic organ prolapse has been poorly investigated. In a random population-based study of 2109 racially diverse women women with IBS (prevalence =9.7%) had higher odds of reporting symptomatic pelvic or
gan prolapse (OR 2.4; 95% CI, 1.4-4.1) compared to those without IBS [680]. It has also been suggested that anal sphincter dysfunction such as para
doxical anal sphincter reaction is more common in patients with rectocele as compared to women without rectocele at defaecography [681].

### 2. PELVIC SURGERY AND POP

Even though the notion that hysterectomy increases the risk for pelvic organ prolapse has wide acceptance, longitudinal studies confirming a temporal association are few and previous studies do not of
ten differentiate between various types of hysterecto
tomy. A number of cross-sectional and retrospective studies implicate hysterectomy as an independent risk factor for pelvic organ prolapse. However, due to a delay of onset, large population samples and a sufficiently long duration of follow-up are required to determine an association with adequate certainty.

In a nationwide cohort study, Altman et al. [682]. reported that 3.2% of women with hysterectomy had pelvic organ prolapse surgery, compared with 2.0% in non-hysterectomized controls, corresponding to a risk of 1.7 (95% CI, 1.6-1.7). In this Swedish study, vaginal hysterectomy had the highest risk for sub
sequent prolapse surgery (HR 3.8, 95% CI, 3.1 to 4.8) in comparison to non-hysterectomised controls. These results were corroborated by Cooper et al. in a large study from Scotland showing an increased risk for prolapse surgery among women after hys
terectomy, compared to endometrial ablation [683]. These register-based data are largely in agreement with the longitudinal Oxford Family Planning Asso
ciation study by Mant et al. [684] reporting increased overall incidence rates for prolapse surgery following hystere
tomy. Although not separating various hys
terectomy techniques, Mant el al. determined that the risk of prolapse following hysterectomy was 5.5 times higher (95% CI 3.1-9.7) in women whose hy
terectomy was performed for prolapse as opposed to other benign conditions. A history of hysterectomy has also been identified to increase the risk for pro
lapse in several cross-sectional and retrospective studies [685-686].

Specific risk factors for posthysterectomy prolapse have been assessed in two case-control studies. Both Dällenbach et al. [687]. and Forsgren et al. [688]. reported that pelvic floor surgery before hys
terectomy was the strongest risk factor for develop
ing posthysterectomy pelvic organ prolapse (OR 7.9, 95% CI 1.3-48.2 and OR 2.8, 95% CI 1.0-7.7 re
spectively). The risk of prolapse repair was 4.7 times higher in women whose initial hysterectomy was indicated by prolapse [687]. Vaginal vault prolapse involves the loss of vaginal apical support and may per definition only occur after hysterectomy [689]. Marchionni et al. reported a 4.4% overall incidence of vaginal vault prolapse after hysterectomy but in women where uterine prolapse was the indication for hysterectomy the incidence was 11.6% [690]. In a register-based study Forsgren et al. showed that the greatest risks for prolapse surgery (HR 4.9, 95% CI 3.4-6.9) were observed subsequent to vaginal hysterectomy for pelvic organ prolapse but having a vaginal hysterectomy also for other indications signif
cantly increased the risk for subsequent pelvic organ prolapse surgery compared to other modes of hysterectomy [691]. Similar observational results were shown by Cooper et al. [683].

It has also been suggested that pelvic surgery other than hysterectomy may predispose women to sub
sequent genital prolapse including: rectopexy for rectal prolapse (OR 3.1; 95% CI 1.4-6.9) [692]; gynaecological surgery in general (OR = 3.9, 95% CI 1.8-8.8) [693]; and retropubic colposuspension procedures are associated with a near 30% risk of subsequent vaginal vault and posterior vaginal pro
lapse at long-term evaluations [694-695]. In a pro
spective cohort study of 374 women, the 10-year re-operation rate was 17% after traditional prolapse or incontinence surgery[696]. Having undergone pelvic organ prolapse or incontinence surgery prior
to the index operation increased the risk of re-operation to 17% compared with 12% for women who underwent a first procedure (p=.04) [696].

3. OBSTETRIC FACTORS AND POP

For ethical and practical reasons, randomised controlled trials to study the causal effects of vaginal and caesarean delivery on the pelvic floor will never be performed. Observational studies will therefore most likely remain the main source of knowledge on this subject. Nonetheless it is widely accepted that childbirth is a significant risk factor for pelvic organ prolapse, presumably due to overt or occult pelvic floor tissue trauma. Controversy does, however, remain with regard to the protective effect of caesarean section and if specific obstetric events should be considered as risk modifiers. Due to a delayed onset of pelvic organ prolapse in relation to giving birth, studies on the subject need a long duration of follow-up as well as large study populations to be able to elucidate the possible causative events. Therefore, the majority of studies on the subject are typically designed as cross-sectional surveys or retrospective cohort or case-control studies. It is, however, encouraging that long term longitudinal data are starting to emerge.

Pregnancy itself has been identified as a risk factor for stress urinary incontinence. With regard to pelvic organ prolapse, the association is less substantiated. In a clinical case-control study, all 21 nulliparous non-pregnant women had POP-Q stage 0 or 1, whereas 47.6% of 21 nulliparous pregnant women had pelvic organ descent corresponding to stage II (p<0.001) [697]. Overall POP-Q stage was higher in the third trimester than in the first (p=0.001). Also Sze et al. [698] found that in 94 nulliparous women evaluated at the 36 with antepartum visit and six weeks postpartum, POP-Q staging increased.

A large number of studies identify childbirth as one of the strongest predictors for developing pelvic organ prolapse later in life [667,669,684-685,699-703]. It is also a recurrent observation that the number of deliveries is associated with the risk of prolapse although there are data to suggest the contrary [705]. In the prospective Oxford Family Planning Association study, [684] childbirth was the single strongest risk factor for developing prolapse in women under 59 years of age and the risk increased by every delivery. Similar findings derived from the WHI, [669] where a parity of one conveyed an overall two-fold risk increase for prolapse compared to having no children, after which each additional childbirth added a 10-20% risk increase. In a case-control study, Tegerstedt et al. [703] found that the risk for symptomatic pelvic organ prolapse increased with the number of deliveries and were 3.3-times higher among mothers of four than among mothers of one. Similarly, Rortveit et al. [667] found that the risk of prolapse increased in women with one (OR 2.8 95% CI 1.1-7.2), two (OR 4.1, 95% CI 1.8-9.5), and three or more (OR 5.3, 95% CI 2.3-12.3) vaginal deliveries compared with nulliparous women. In a questionnaire based cross-sectional study among 2,640 middle-aged women the number of vaginal deliveries was a risk factor for past or present symptomatic prolapse [704].

Whether or not caesarean section provides sufficient protection to the pelvic floor, thereby preventing loss of pelvic organ support, is controversial. Several studies suggest that elective caesarean does indeed protect women from developing pelvic organ prolapse later in life [699,700-703]. In 4,458 randomly selected women, vaginal childbirth increased the risk of prolapse by 1.82 (95% CI 1.04-3.19) [701] In a nested case-control study, Uma et al. [702] found that caesarean section was associated with a significantly reduced risk of pelvic floor surgery compared with spontaneous vaginal delivery (OR 0.16, 95% CI 0.05-0.55). In a case-control study, Chiaffarino et al. [706] found that women who were delivered by caesarean section were at significantly lower risk of prolapse (OR 0.3 95% CI 0.1-1.0). Other investigators suggest that in the long term, caesarean delivery does not provide a significant risk reduction in pelvic floor morbidity compared with vaginal delivery [707-708]. In a cohort study of women having their first and all subsequent deliveries by caesarean (n = 33,167), and an age-matched sample of women only having vaginal deliveries (n = 63,229) between 1973 and 1983, Leijonhufvud et al. found that women only having vaginal deliveries had increased overall risk of subsequent prolapse surgery (hazard ratio, 9.2; 95% CI 7.0-12.1) compared with women only having cesarean deliveries [709]. Among women with vaginal deliveries only the incidence rate for prolapse surgery increased steadily, reaching its peak close to three decades after first delivery. In women with cesarean deliveries only the incidence rate for POP surgery showed very little variation over time and being notably lower compared to the vaginal delivery cohort 10 years after first birth for the duration of the observational period. These observational data suggest that cesarean section conveys a long-term protective effect with regard to the development of pelvic organ prolapse (Figure 10).

A number of specific obstetric events and interventions have been implicated as risk factors for the development of pelvic organ prolapse. In one study, maternal age and use of epidural analgesia was associated with an increased need for pelvic organ prolapse surgery [700]. A case-control study found no significant association with maternal age, instrumental delivery (forceps or vacuum), or length of delivery when comparing women with prolapse to randomly selected controls [703] However, Handa et al. [710] found that operative vaginal birth significantly increased the risk for all pelvic floor disorders and pelvic organ prolapse in particular (OR 7.5, 95% CI 2.7-20.9). In a case-control study, Chiaffarino et al.
[706] found that after forceps delivery women had an OR of 3.6 (95% CI 1.0-13.5) for developing pelvic organ prolapse, but after adjustment for vaginal delivery the odds were no longer significant (OR 1.3 95% CI 0.6-3.1). Also Moalli et al. [693] concluded that forceps delivery posed a risk for prolapse. On the other hand, Uma et al. [702] found no significant association between pelvic organ prolapse and forceps delivery (OR 0.9, 95% CI 0.7-1.2); infant birthweight >4.0 kg (OR 0.9, 95% CI 0.5-1.7); episiotomy (OR 1.46, 95% CI 1.0-2.10); and labour prolonged >12 hours (OR 1.51, 95% CI 1.00, 2.27). The inconsistency and wide variety in the magnitude of the risk estimates suggest that most studies so far lack sufficient statistical power for valid conclusions.

4. MISCELLANEOUS RISK FACTORS AND POP

A wide variety of risk factors for pelvic organ prolapse, others than those addressed above, have been identified in the literature. Most of these have been investigated as part of larger multivariate analyses based on cross-sectional surveys or retrospective case-control studies. Overall, these associations are largely of level III-IV evidence and further research is needed to disentangle the effects and interactions of environmental risk factors for prolapse.

Several somatic risk factors for pelvic organ prolapse have been identified. Generalised connective tissue disorders such as Ehlers-Danlos disease and Marfans syndrome [711-712] have been linked to an increased risk for pelvic organ prolapse. In a community-based study of prolapse in rural West Africa, chronic anaemia was the strongest risk factor for prolapse after parity and age (OR 2.1 95% CI 1.1-3.4). [713] and chronic obstructive pulmonary disorders. Skeletal abnormalities such as thoracic kyphosis, lumbar lordosis and pelvic dimension changes have been associated with an increased risk for prolapse [713-715]. Women with joint hypermobility have a significantly higher prevalence of genital (and rectal) prolapse in comparison to women with normal mobility[716-717] Weak associations have also been shown for osteoporosis and rheumatoid arthritis [707] Obesity may be associated with increased pelvic floor symptoms and more severe symptomatic prolapse [704,718-719] yet increasing body mass index and obesity have not consistently been identified as risk factors for prolapse as compared to stress urinary incontinence [720-721] Other factors that have not convincingly demonstrated any significant linkage to prolapse include the presence of chronic obstructive pulmonary disease and diabetes mellitus [685,721] Pulmonary impairment has been shown to more common in women with loss of pelvic organ support compared to those without [722].

A low educational level (OR 2.16, 95% CI 1.10-4.24) [723] and low annual income, [724] are socio-economic factors which have been associated with an increased risk for pelvic organ prolapse. In 21,449 non-hysterectomised Italian women, higher education was associated was a protective factor for uterine prolapse [708]. However, despite significant differences in educational level, smoking habits, alcohol consumption, and socio-economic indices, the prevalence of pelvic organ prolapse did not differ between

---

**Figure 10. Rate of pelvic organ prolapse surgery in relation to mode of delivery and time from first childbirth[709].**
Kroatiaburban and rural women [725] Interestingly, risk factors for pelvic floor disorders including pelvic organ prolapse among women in developing countries were similar to those in industrialised countries (increased age and parity). In a review study across 16 low-income and lower middle-income countries the mean prevalence for pelvic organ prolapse was 19.7% (range 3.4-56.4%) but risk factors were similar to those described in studies from more affluent countries but additionally pelvic organ prolapse and other pelvic floor disorders were associated with other factors including poor nutrition and heavy physical work [726].

A physically strenuous occupation has also been shown to influence the risk for pelvic organ prolapse. In a register based study of 28,000 Danish assistant nurses exposed to repetitive heavy lifting, the risk for prolapse was higher among the nurses compared to controls (OR 1.6 95% CI 1.2-2.2) [727]. Women who were labourers/factory workers had significantly more severe prolapse than other job categories (p < 0.001) in a cross-sectional study of women presenting for routine gynecological care [724]. Also, hard physical training may increase the risk for prolapse as women attending paratrooper training, were more likely to present stage II prolapse compared to controls (RR=2.7 95% CI 1.4-5.4) [728].

V. SUMMARY POINTS

• Most studies have used a cross-sectional design and there are limited longitudinal data to suggest a causal relationship between symptoms of obstructed defaecation and pelvic organ prolapse or vice versa. Posterior vaginal wall prolapse and perineal descent are the specific pelvic defects most frequently associated with symptoms of obstructive defaecation.

• Current evidence suggest that hysterectomy increases the risk for subsequent pelvic organ prolapse in general.

• Vaginal hysterectomy and hysterectomy performed for pelvic organ prolapse are the strongest risk factors for having secondary pelvic floor surgery.

• Childbirth is associated with an increased risk for pelvic organ prolapse later in life and increasing number of deliveries is positively associated with the risk.

• Longitudinal long-term data suggest that caesarean section decreases the risk for surgically managed pelvic organ prolapse and most studies indicate that caesarean is associated with a decreased risk for subsequent pelvic floor morbidity in comparison to giving vaginal birth.

• There is a deart in the understanding of how specific obstetric events and the process of labour and delivery affect the risk for pelvic organ pro-

H. THE GENETIC EPIDEMIOLOGY OF UI AND POP IN ADULT WOMEN

The existence of both acquired and inherited risk factors for incontinence has been recognised for more than 150 years [729]. Although recent advances in formal genetics have quantified the relative contribution of environmental and genetic variation, we still have very limited understanding of the molecular genetics of these conditions. In this section we consider the evidence for genetic predisposition from family studies, twin studies and segregation analyses, and then consider in detail efforts to identify causal variants from linkage studies, candidate gene association studies, and the first reported genome wide association study for pelvic organ prolapse.

I. FAMILY STUDIES

Family studies have classically been considered the first step in establishing the genetic basis of any disease. However, familial aggregation provides limited evidence of heritability, since it fails to control for the effects of shared environmental factors. For pelvic floor disorders, exposures to all major lifestyle risk factors are likely to be at least partly determined by socio-cultural values that are shared within families. Such effects are at least plausible for family size, smoking, socio-economic status, care seeking behaviour, physical exercise, dietary and drinking habits, and toilet training. Both incontinence and prolapse are considered stigmatising in many populations, which places family studies at high risk of differential misclassification bias. This might be expected to have particular impact on the validity of estimates obtained from studies employing the family history method, and any study with non-random sampling of families, for example those relying on probands recruited in secondary care, or those recruiting volunteers via advertisement. Finally, while age correction of risks is possible to account for increasing disease prevalence with age, this has typically not been employed in family studies of pelvic floor disorders.

Although family studies may not provide robust evidence, there have been many studies that
examined prevalence of incontinence (Table 17) among relatives of women with incontinence [730-735]. Despite considerable variation in case ascertainment and sampling methods, all studies demonstrate increased risks for urinary incontinence among first degree relatives of probands. This appears to apply for all subtypes of urinary incontinence, and to have a plausible biological gradient, with higher risks among relatives of women with severe incontinence.

In the only study to attempt adjustment [732], it appears that these familial risks are attenuated but not eliminated by classic risk factors for incontinence including age, parity, and BMI. At least three studies have also assessed family history as a risk factor for incident post-partum incontinence, with conflicting findings [737-739].

There is also a large body of evidence regarding familial transmission of pelvic organ prolapse. With wide variation in prolapse rates with different cases definitions?, uncontrolled studies have produced disparate estimates of the proportion of prolapse patients with a family history of prolapse [740-742]. Reports from controlled studies (Table 18) have however consistently demonstrated increased risks [743-746], with unadjusted OR of 2-3 for prolapse among first-degree relatives of prolapse sufferers. These risks are attenuated but not eliminated by adjustment for other risk factors [743-745].

Note: unadjusted risks generally higher across all outcomes, indicative of substantial concordance/correlation in age, BMI, and parity between family pairs.
In summary, family studies have consistently demonstrated familial aggregation of both incontinence and prolapse. A family history of incontinence or prolapse is associated with approximately double the risk of developing either condition. Such an effect appears to hold for all subtypes of incontinence, and prolapse in all compartments. There is plausible evidence that family history is associated with both earlier onset, and more severe phenotype. These effects are partly explained by known environmental risk factors, and family studies cannot exclude the risk of further unmeasured confounding from shared environmental risks. For this we should consider evidence from classical twin studies.

### II. TWIN STUDIES

Twin studies compare the concordance in a trait or condition between monozygotic (MZ) twins and same-sex dizygotic (DZ) twins, to estimate heritability. For genetically determined traits higher concordance is observed in MZ twins compared to DZ twins, while for entirely environmentally determined traits, concordance should be the same in both types of twin pair. This simple idea is illustrated by consideration of a fully penetrant autosomal single gene disorder, which will display 100% concordance in MZ twins, while in DZ twins will have only 50% concordance for a gene with dominant mode of inheritance, or 25% concordance for a gene with recessive mode of inheritance. A fundamental assumption of these analyses is that both types of twin pair share equal environment. This assumption is clearly violated both pre-natally, and in later life. This bias can be partially compensated for either in studies of twins reared apart, or in adoption studies, but these designs have not been applied to the study of incontinence or prolapse.

Three major twin resources have been used to assess genetic influences on incontinence or prolapse: the US Twins Days festival, the Danish Twin Registry, and the Swedish Twin Registry. The Twins Days festival relies on volunteers, and the resulting recruitment bias is likely to overestimate concordance for many traits for both MZ and DZ twins. In the sample of 1,764, predominantly MZ, middle-aged twins from Twins Days, concordance of symptomatic stress urinary incontinence was 79.5% for MZ and 78.6% for DZ twins [748]. Such a result suggests no significant genetic contribution to stress urinary incontinence at all.

Among a sample of 2,336 twins surveyed as part of four surveys from the Danish Twin Register, concordances for both MZ and DZ twins were much lower.

---

Incontinence, there again seems to be a plausible biological gradient [744], with anatomically more severe cases of prolapse being more likely to have a positive family history. This is consistent with the suggestion of an earlier onset of prolapse among familial cases [742]. Only one study has used direct anatomic ascertainment, in a study based on sib-pairs discordant for parity [747]. There familial concordance was observed not only for overall prolapse stage, but also by compartment. Where it has been tested, there also appears to be shared familial risk between prolapse and incontinence [744-745], although this overlapping propensity may be explained by known shared environmental risk factors, rather than common genetic predisposition.
not only for stress urinary incontinence, but also for urgency and mixed incontinence [749]. With separate cohorts for middle-aged and elderly women, heritability was calculated separately in each age group. As in the Twins Day sample, genetic factors were not significant for stress incontinence in middle-aged women, but rose to a heritability of 39% in the elderly women. Similarly, heritability increased with age for urgency incontinence (42% rising to 49%), and mixed incontinence (27% to 55%).

Women participating in the Swedish Twin Register have provided relevant data as part of two separate analyses [750-751]. Treatment codes corresponding to stress incontinence and prolapse surgery from a nationwide surgical register were used to estimate heritability for a sample of 16,886 twins aged >50. As might be expected for such a strict phenotype definition, concordances for surgical treatment were low, but produced heritability estimates of 41% for stress incontinence surgery, and 43% for prolapse surgery. Similarly for female twins aged 20-46 from the same register (evaluable sample 4,550), using questionnaire based phenotyping, produced an estimate of 34% heritability for stress incontinence. From the same survey heritability was estimated for urgency incontinence (37%), mixed incontinence (18%), “any” incontinence (51%), nocturia (48%), and urinary frequency (40%). It should be noted that because of sample size limitations, an absence of genetic effects cannot be entirely precluded for stress, urgency, or mixed incontinence.

The mechanism of these probable genetic effects has been explored in analyses of joint hypermobility and pelvic floor mobility in twins [752-753]. These data suggest heritability of 59% for oblique bladder neck descent on Valsalva in nulliparous twins aged 18-24, with a shared genetic component to both pelvic floor and elbow mobility.

In summary, twin studies to date have suggested significant heritability for stress incontinence, urgency incontinence, and pelvic organ prolapse, with genetic variation potentially contributing up to half of population phenotypic variation. Heritability appears to be highest for urgency incontinence, with apparent heritability increasing with age as environmental factors reduce in importance. This is consistent with our understanding of childbirth as a major environmental determinant of both incontinence and prolapse. Genetic predisposition to incontinence and prolapse may manifest at a preclinical stage in pelvic floor hypermobility. Together with data from family studies this provides strong evidence of genetic risk factors for incontinence and prolapse.

III. SEGREGATION ANALYSES

Despite the large number of family studies for incontinence and prolapse in adults, there have been few studies to examine segregation among extended pedigrees. Studies of families affected by nocturnal enuresis [754], have however included some adults affected by urgency incontinence. Analysis of different enuretic families has usually suggested autosomal dominant inheritance with high penetrance, but low penetrance and autosomal recessive modes have also been reported. In the only segregation analysis reported to date of 10 families affected by prolapse [742], a dominant mode of inheritance was again proposed. These findings could be a consequence of selection or ascertainment bias. In contrast results from more recent association studies strongly suggest that polygenic inheritance is most likely across the population as a whole.

IV. LINKAGE STUDIES

Again, many linkage studies have been conducted using families of children affected by nocturnal enuresis [754], but only two studies have considered uniquely adult symptoms. In a family including 6 women with early onset prolapse across three generations, 10 putative loci were suggested, but none approached genome wide significance [755]. Allen-Brady and colleagues [785] genotyped women from 32 families, including 70 patients needing surgical treatment for prolapse. There was strong overlap with other pelvic floor disorders including a high prevalence of treatment for both stress and urgency incontinence. Using a set of 27,157 markers from a larger Illumina array, they observed a genome wide significant peak at 9q21, and further suggestive peaks at 9q31 and 1q42.

V. GENE ASSOCIATED STUDIES

Currently reported candidate gene studies have assessed polymorphisms of 10 different genes for incontinence (Table 19), and 15 genes for prolapse (Table 20). To allow comparisons across all studies, we extracted all genotype counts, and recalculated the allelic test. As a check on study quality we also recalculated the power of the study for an OR of 2.0 between cases and controls based on observed minor allele frequencies, and finally rechecked Hardy-Weinberg Equilibrium for cases, controls, and the overall population. We assessed the credibility of associations using the interim Venice criteria [756].

Polymorphisms in COLIA1, ADRB3, HTR2A, LOXL1, MMP1, MMP3, CYP17, CYP19, ESR, and AR, have been tested for an association with incontinence, or one of its subtypes. There is little uniformity in case definitions, with a mixture of urodynamic, clinical, and questionnaire based inclusion criteria used, and frequently inadequate matching between cases and controls for age, parity, or prolapse stage. In most cases we found significant

</table>
deviation from Hardy-Weinberg Equilibrium for controls, or both cases and controls, highly suggestive either of genotyping error, or problems with population stratification. In addition to the high risk of bias introduced, these studies are all underpowered other than for extremely large genetic effects, and in most cases fail to account for multiple comparisons in their primary analyses.

Despite this multiplicity of methodological problems, there remains tentative evidence of replicated effects for two different polymorphisms. The rs1800012 polymorphism of collagen type I alpha1 (COLIA1), has been associated with a two-fold increased prevalence of stress incontinence in separate European populations [758,767]. The rs4994 polymorphism of the beta 3 adrenoceptor (ADRB3) has been associated with almost 2.5 fold increased risk of overactive bladder in separate studies of Japanese and Brazilian samples [30,31]. Other polymorphisms tested in more than one study include rs6313 in the 5-HT2A receptor, and rs1799750 in matrix metalloproteinase-1. In each case there are however inconsistent findings, with a high risk of genotyping error, and or population stratification.

Candidate gene studies for prolapse are at an equally nascent stage. Here polymorphisms have been tested in COLIA1, COL3A1, LOX-L1, LAMC, MMPs 1, 2, 3, 8, 9, 10, 11, TIMP1, TIMP3, ESR, and PGR. In comparison to incontinence, investigators have used the POPO system as standard. However, other methodological problems are common. We again found many underpowered studies, frequent significant deviation from Hardy-Weinberg Equilibrium, and many instances of failure to consider the impact of population stratification in samples. Although many of the primary studies report significant results, our reanalysis suggests that there are no consistently replicated associations in any populations.

With these disappointing results in mind we can consider findings from the first reported genome wide association study in this area. The discovery cohort comprised 115 familial cases of prolapse identified as having had surgical treatment (and frequently also stress or urgency incontinence treatment) with 2,976 controls. In the discovery cohort 6 individual SNPs approached or exceeded genome wide significance (p<5x10-8), but in Manhattan and Regional Association Plots no evidence was seen to support a wider associated locus. Correspondingly, after correction for multiple comparisons none of the 6 SNPs (rs1455311 rs1036819 rs430794 rs8027714 rs1810636 rs2236479) were successfully replicated in a sample of 76 Dutch familial cases. Given the failure of the candidate gene approach, genome-wide association studies are urgently needed, but will require much larger samples of cases for reliable identification of significant loci.

**VI. SUMMARY POINTS**

Family studies and twin studies have provided convincing evidence of genetic predisposition to incontinence and prolapse, with genetic variation contributing up to half of population phenotypic variability in elderly women. Despite a large research effort, the candidate gene approach has not produced consistent results. Only the rs1800012 polymorphism of collagen type I alpha1 (COLIA1), and the rs4994 polymorphism of the beta 3 adrenoceptor (ADRB3) have been replicated. Despite an urgent need for genome-wide association studies to discover susceptibility genes for these conditions, initial results from the genome-wide approach have been fruitless. Future progress will likely be made through collaboration between large scale population based cohorts phenotyped for these conditions.

**I. EPIDEMIOLOGY OF ANAL INCONTINENCE**

Faecal Incontinence (FI) is the involuntary loss of faeces – solid or liquid. Anal Incontinence (AI) includes these events as well as the involuntary loss of flatus, which is felt by many patients to be an equally disabling disorder.

The discussion below will therefore focus on the broader definition: AI. A third cause of soiling or embarrassment is anal mucoid seepage, a troubling condition that cannot be deferred by an able sphincter and intact cognition, most often caused by an organic colonic disease or dietary sensitivity, and more rarely by faecal impaction. This is the loss of fluid, sometimes faeculent, often following a normal continent defaecation. This is an important condition to distinguish from other manifestations of incontinence because most authors that report very high prevalence rates of AI include leakage in their questionnaires and thus may include these individuals with this very common symptom. However in these individuals there is often no detectable sphincter abnormality [786]. It is not treatable by any of the standard therapies for incontinence of faeces: such as sphincter repair, neormuscular re-education or even faecal diversion. It is in fact why we wear underclothes. Not really true for women.

**1. ASCERTAINMENT OF ANAL INCONTINENCE**

Older reports of AI prevalence have come from single institutions, and the patients described therein have been subject to referral bias when demographics and aetiology are discussed. The accuracy of AI
prevalence estimates may also be diminished by difficulty in ascertaining those figures due to the common underreporting of AI and patients' reluctance to report symptoms or to seek treatment [787-788]. It has been shown that women are more willing to report AI than men [789]. In addition, the character (incontinence of solid faeces, diarrhoea, or flatus, or merely anal seepage) and frequency (daily versus episodic) of reported AI varies greatly in each report, and indeed between individuals. So, prevalence depends heavily on the definition of AI.

The variation in prevalence of AI seen in a sampling of surveys in Table 21 further demonstrates how difficult the ascertainment of AI is. The border between occasional dyschezia which may be associated with minor illness, travel or diet and a disabling disease that requires intervention to return a patient to acceptable function is not clearly drawn. Many questionnaires have been developed and "validated" for the detection of AI, at least three published since the last update of this book. No systematic review of these many questionnaires has yet to be published. The most insightful of prevalence studies has recently been published from New Zealand [790]. The authors studied adults, not excluding those in custodial care. Acknowledging the difficulty in prevalence estimation, they used three different questionnaires: the first simply asking if the participant had incontinence and if they were troubled by it, the second a well known quantitative instrument and the third a qualitative instrument specific to faecal incontinence. In the cohort examined there were those who were totally continent, those that exceeded thresholds in all three instruments and were incontinent and those who had positive responses on only one or two of the questionnaires (Figure 11). The authors surmised the two out of three positive responses constituted clinical AI, though the threshold for the quality of life instrument was very high (i.e. perhaps too sensitive). From Figure 11 it can be seen that the prevalence of AI varied from 12.6% to 26.8% for each individual instrument, 4.6% were positive for all three and 13.2% were positive for two of three, which was the authors' definition of AI.

2. DATA SOURCES AND LEVEL OF EVIDENCE

Since ICI 4 new studies were sought using Medline and EMBASE using the search terms faecal, faecal, anal, incontinence, epidemiology. In addition systematic reviews were specifically sought in Medline, EMBASE and the Cochrane Library.

II. PREVALENCE

Because therapeutic interventions are not the subject of this chapter, and so the epidemiology is descriptive and not derived from randomised clinical trials (aside from the antenatal intervention described below), the level of evidence will be at best 2, and the strongest evidence will come from systematic reviews in which there was a predefined search strategy and application of quality assessment tools that were designed specifically to minimize bias in referral or ascertainment.
1. ADULTS

In an effort to resolve the widely varying reported prevalence figures (Table 21) two systematic reviews of the published frequencies have been reported of community dwelling adults (above age 15 in the second). A summary frequency was not calculated in the first because of the marked clinical heterogeneity between reports. The three reports that the authors judged most free of potential biases had frequencies between 11% and 15%, although only one of these three used a validated assessment instrument [791]. The degree of disability present in these 11%-15% is not known, nor even if a portion of them had only anal seepage. These high prevalences were obtained in surveys that employed anonymous self-administered questionnaires, which may not allow objective confirmation of AI or assessment of degree of disability associated with AI. The second systematic review found a range of solid and liquid anal incontinence of 0-15.2%, with an average across both genders and all age groups of 4.3% [462]. The prevalence in a more recent and rigorous study is discussed above under Ascertainment [790].

2. CHILDREN

The reported prevalence of AI in children can be broadly divided into two facets: in those children born with congenital anomalies of the anus and rectum – either congenital aganglionosis (Hirschprung’s Disease) or imperforate anus – and those children without congenital anomalies. Among those children and adults who were born with defects, despite surgical correction of the defect, life long defaecation difficulties are common, occurring in roughly half of affected children [792-794]. Problems with psychological health and development because of the defaecation disorder is also common in this group, as is a generally depressed quality of life [795]. These disorders are not horribly rare, occurring in 3 to 5 per 10,000 live births [796]. Among children without congenital defects of the anal canal, bowel control has been found to be complete in one Swiss cohort in 33% by age 1 year, 75% by age two and 97% by age three. Nevertheless in this longitudinal study, a quarter of the boys and one tenth of the girls had a major period of incomplete bowel or bladder control between the ages of 6 and 18. At least annual encopresis occurred in 2-3% of these children, boys more frequently than girls [797]. In the Wisconsin Family Health Survey the prevalence of AI in children from the ages of 5 and 16 years was 12/1367 (0.88%) with the gender distribution being 7 boys and 5 girls (Wisconsin Family Health Survey: unpublished data). The common disorder for all children and then adults in this discussion is faecal retention with overflow.

III. INCIDENCE

Clinical trials have provided incidence data after a therapeutic intervention, but usually without a preliminary continence assessment. This is best seen in two Cochrane reviews of therapy for anal fissure.

Figure 11. Co-occurrence of fecal incontinence in each of 3 diagnostic measures. FISI = Fecal Incontinence Severity Index; FIQLS = Fecal Incontinence Quality of Life Scale
1. **AGE**

Two systematic reviews have analyses of the association of age and anal incontinence and found age to be the most significant of all assessed associations [800-801].

2. **GENDER**

Most discussions of the aetiology of AI have been based upon the assumption that women, particularly for individuals under the age of 65 years, are far more at risk for AI than men. Injury to the pudendal nerve or sphincter muscle from prior obstetric trauma is described as the primary risk factor [802-804], followed by irritable bowel syndrome (a disease thought to be more prevalent in women) [805], and other aetiologies such as diabetes a distant third [806]. Yet each population based-survey of the prevalence of AI has shown a surprisingly high prevalence in males (Table 21) [788-789, 807-838].

Of the two systematic reviews that looked specifically at prevalence, only one assessed the role gender played and in that review gender was not associated with incontinence in any age group [800]. In the search for this updated review, 26 publications assessed prevalence of AI, two in both genders and 24 only in women. Clearly, aetiologies other than childbirth must be sought. This represents a rather gross imbalance in research on this topic.

3. **OBESITY**

Four reports have demonstrated an increased risk of AI in obese women, a Kaiser cohort, a cross sectional survey in a specialty clinic and two case control studies [839-842]. One longitudinal study found a reduction in anal leakage (again not necessarily a direct correlate with incontinence) in women after bariatric surgery and weight loss, though other factors including diet and activity change may have been responsible for the improvement [843].

4. **CHILDBIRTH AND MODE OF DELIVERY**

A meta-analysis of published reports that assessed anal sphincter integrity after vaginal delivery and correlated this with continence stated that 77%-83% (depending on parity) of anal incontinence in parous women was due to sphincter disruption [844].

Another systematic review that looked only at post partum factors in prospective cohorts found that the only predictor of AI was 3rd-4th degree sphincter rupture during birth [845]. Three things are implied by the conclusion or the first review: first, that incontinence in men, children, of elderly onset (or even in middle aged women) and in nulliparous women, or women having Caesarean section has a completely different cause than in women who have ever delivered vaginally. There is scant epidemiological evidence that this is the case [846]. Second, it is implied that sphincter repair would be effective treatment for anal incontinence in almost all parous women. Yet repair of disrupted sphincter has less than a perfect track record. Even more importantly, there is a reported rapid decay in function after repair that is far too great to be explained by age alone [847-854]. Third, if direct trauma to the anal sphincter (and not intra-pelvic nerves) were the major cause of anal incontinence, then Caesarean section should be effective in preventing incontinence. However a systematic review has shown that this is not the case [801] (Figure 12). Twenty-one reports have been found eligible for inclusion in the review, encompassing 31,198 women having had 6,028 Caesarean deliveries and 25,170 vaginal births as index events prior to anal continence assessment. Only one of these reports demonstrated a significant benefit of Caesarean section in the preservation of anal continence. In that report AI rates exceeded 39% in both groups, suggesting a problem with ascertainment. The greater the quality of the report, the closer its Odds ration approached 1.0. Among the seven reports that passed all quality criteria (age adjustment, parity adjustment, no previous vaginal delivery in the Caesarean section group, continence assessment more than 4 months post partum) the odds ratio for faecal incontinence was 0.98 (0.79-1.21. 

In reports that allowed comparison of vaginal delivery with elective Caesarean section there was also no significant difference in AI risk (OR=0.73; 0.52-1.03. Figure 13) There was no difference incontinence preservation in women have emergency versus elective Caesarean section (OR= 1.09; 0.89-1.34. Figure 14). Among the seven best studies, the NNT is 339, i.e. 399 Caesarean sections would have to be performed to prevent a single case of faecal incontinence. Pregnancy with delivery of any kind was found to be only a marginal risk factor for faecal incontinence (OR= 0.86; 0.73-1.01. Figure 15 though there is significant statistical heterogeneity in this analysis (p=0.05, I2=62%).

But why doesn’t Caesarean section prevent anal incontinence, especially when associating perineal trauma with loss of bowel control is not just intuitive, but sometimes visibly obvious? Certain aspects of vaginal delivery are clearly causally related to anal

[798-799]. AI incidence rates varied widely from 0% to 30%, to flatus only, and the duration was unspecified in the trials. Medical therapy was less likely than surgery to cause AI (0.23, 0.02-2.1), and certain operations (anal stretch) were more likely to cause AI than others (sphincterotomy) (4.2, 1.9-9.4). None of these trials reported rigorous ascertainment of continence before the onset of disease or therapy.

**IV. RISK FACTORS**
incontinence: significant laceration, forceps, and some episiotomies [855-856]. However this review demonstrates that other factors need to be explored. So one must look to pregnancy and not just labour and delivery as an initiating factor. Further evidence in favour of this comes from the sphincter repair literature cited above. The rapid decay in function suggests that another defect is present besides a gap in the sphincter that remains after the early effects of sphincter repair wear off. What this is, is not yet known, doesn’t make sense although trauma at the pelvic inlet during pregnancy or in early labour [857] seems likely. Sphincter dysfunction has been demonstrated in women who have had Caesarean section [858]. Further indirect evidence for the possibility that injury higher in the pelvis may be related to AI in pregnant women can be found in the association between hysterectomy and AI, an association seen more prominently with abdominal hysterectomy (TAH) than vaginal hysterectomy (VH), and for flatus only [859] (Odds Ratio of TAH vs. VH for faeces: 1.2, 0.3-4.7, Odds Ratio for gas: 18.9, 1.1-327). Pelvic nerve injury during surgery is the postulated reason for this difference.

5. NURSING HOME RESIDENCE

The most prominent association with AI by far is nursing home residence. Whereas the prevalence of AI is probably around 2% to 5% for community-dwelling persons, and may rise with increasing age to greater than 10%, among nursing home residents the prevalence approaches 50% [832-834]. This is partly explained by FI being one of the most common reasons for nursing home admission. In a large survey of 18,000 Wisconsin nursing home residents, risk factors for faecal incontinence (FI) were directly observed by nursing home personnel [833]. Urinary incontinence (UI) was the greatest association with FI (OR = 12.6, 11.5-13.7), followed by the loss of ability to perform daily living activities (6.0, 4.7-7.7), tube feeding (7.6, 5.6-10.4), physical restraints (3.2, 4.7-7.7), diarrhoea (3.3, 2.7-4.2), dementia (1.5, 1.4-1.7), impaired vision (1.5, 1.4-1.7), constipation (1.4, 1.3-1.6), faecal impaction (1.5, 1.1-2.1), stroke (1.3, 1.2-1.5) male gender (1.2, 1.1-1.3), age and body mass index. Inverse associations were noted with heart disease, arthritis and depression.

6. DIARRHOEA

The importance of diarrhoea of liquid stool in FI cannot be overemphasised [842]. One case series noted that 51% of individuals with chronic diarrhoea were incontinent [787]. In the Wisconsin Family Health Survey of AI [789], 10 of the 25 subjects with FI lived in Milwaukee when the city experienced an outbreak of waterborne disease [860]. Non-infectious causes of diarrhoea must also be considered, such as inflammatory bowel disease [861] and those initiated by sports activities such as running [862-863].

7. SURGERY

AI originating from surgery would seem fairly insignificant in the general population, since previous anal surgery has not been an apparent risk factor in the larger surveys. Several operations nonetheless can frequently result in AI. Examples are midline internal sphincterotomy, lateral internal sphincterotomy, fistulectomy, fistulotomy, ileo-anal reservoir reconstruction, low anterior rectal resection, total abdominal colectomy, and

---

Figure 13. Systematic review of Efficacy of Cesarean Section in Preventing Faecal Incontinence: Vaginal Delivery versus Elective Cesarean Section

Figure 14. Systematic review of Efficacy of Cesarean Section in Preventing Faecal Incontinence: Elective vs. Emergency Cesarean Section

Figure 15. Systematic review of Efficacy of Cesarean Section in Preventing Faecal Incontinence: Nulliparous women versus Any Form of Delivery
urinary incontinence. The risk of lateral internal sphincterotomy for anal fissure causing AI was previously thought to be insignificant when compared to midline sphincterotomy, but a recent re-appraisal of this operation has shown an AI risk may be 8% [864]. The risk of AI after fistulotomy has been reported to be as high as 18% to 52% [865]. New approaches to fissure and fistula have recently been developed specifically to lower this risk [865-866]. However incontinence after haemorrhoidectomy has also been reported to be as high as 33%, an operation in which no sphincter is divided [867]. This suggests either that division of the anoderm, not the sphincter may be affecting continence, or that the method of ascertainment used in published surveys is not accurate. Mixing urine and stool has been found to have a predictable effect on anal continence control, as does diarrhoea, in patients having uretero-sigmoidostomy after urinary bladder resection [823]. Patients with rectal cancer form a special group in whom cancer issues often mute the continence disturbance after urinary bladder resection [823]. Patients with rectal cancer form a special group in whom cancer issues often mute the continence disturbance that may result from rectal resection [868] or radiotherapy [869].

8. SPECIFIC NEUROLOGICAL AND OTHER DISEASES

Several specific diseases have been anecdotally associated with AI in case series, and mechanisms to explain the associations have been investigated [870]. Examples are diabetes [825], stroke [871-872], multiple sclerosis, Parkinson’s disease, systemic sclerosis, myotonic dystrophy, amyloidosis, spinal cord injury, imperforate anus, Hirschsprung’s disease, retarded or interrupted toilet training, procidentia, and any illness causing diarrhoea (HIV, IBD, radiation, infection). Many of these conditions directly affect patient mobility and ability to perform daily living activities or they cause diarrhoea or faecal impaction.

9. CONSTIPATION

Constipation may alternate with diarrhoea in irritable bowel syndrome making defaecation chaotic and often very urgent. Just as often retained faeces lead to anal seepage that cannot be held. In the New Zealand survey [790], the 2 of 3 rule for categorising an individual as incontinent excluded constipated patients, which was also assessed in their survey, the positive rate fell from 13.2% to just over 9%. This further demonstrates the frequent coexistence of constipation and AI, similar to the frequent coexistence of urinary incontinence and AI.

10. COHORTS INITIATED BEFORE CLINICAL AI ASSESSED FOR SUBSEQUENT DEVELOPMENT OF AI

Because of a paucity of clinical trials that specifically address risk factors and prevention of AI, the strongest available data to identify risk come from cohorts that collected data on potential risk factors prior to the onset of incontinence. Prospectively collected risk assessments for FI have occurred in three nursing home cohorts. Porell combined UI and FI into a single outcome variable and found many positive associations in a cohort of 60,000 nursing home residents in Massachusetts [873]. Age, African American race, cognitive and ADL impairments, predicted the outcome, although specific relative risks for incidence are not presented. Chassange followed 234 previously non-FI residents in France for 10 months, during which 20% had FI episodes, but only 7.5% developed long lasting FI [874]. The others had acute episodes due to diarrhoea or impaction. The factors associated with the development of long lasting FI were urinary incontinence (UI) (2.9, 1.8-4.6), decreased mobility (1.8, 1.1-3.0), and cognitive defects: either as seen in an MMSE score <15 (2.5,1.4-4.4) on history of dementia (2.1, 1.2-3.5). Neither gender nor age were risk factors. Nelson reported, in a cohort of 18,000 nursing home residents in Wisconsin, a subgroup of 3,850 continent of both urine and faeces in 1992 who were assessed one year later [875]. 15% developed FI. Positive associations were seen for ADL loss (3.4, 2.4-4.5), trunk restraints (2.5, 1.7-3.6), dementia (1.7, 1.4-2.0), African American race (2.1, 1.3-3.4) and age (1.02, 1.0-1.0). UI was not investigated as a risk factor because it was felt to be a co-morbid condition. In a broadly based cross sectional survey, it was apparent that factors that affect an individual’s general health or physical capabilities, independent of age and gender, place that individual at greatest risk for AI [805], though all four are significantly associated with AI [789]. Among obstetric patients age has also been a consistent association, with less consistent associations noted for chronic bronchitis (OR =6.5, 1.1-38), symptoms of pelvic organ prolapse (5.0, 3.0-8.7) and obesity (3.0, 1.0-3.4) [876]. Defaecatory dysfunction has also been assessed in antenatal women [877-879], found to be prevalent which has led to an important preventive strategy for post partum AI described below.

V. PREVENTION

This discussion is by necessity descriptive, so preventive measures are only relevant insofar as they provide insight into the aetiology of incontinence. By far the most frequently applied preventive measure is Caesarean delivery, discussed above. Its lack of effectiveness in preventing anal incontinence provides a valuable insight into the relationship between pregnancy and AI – that the focus may need to be more on the pregnancy rather than the delivery and how it
affects defaecation afterwards. A decision analysis study suggests specific obstetric indication for elective C. section that may be cost effective [880]. Another study related to birth trauma randomised mothers to immediate post-partum anal ultrasound with repair of occult defects in the sphincter and continence assessed in follow-up, demonstrating an improved outcome with this intervention [881]. Antenatal intervention with pelvic floor exercises has been assessed in a number of randomised trials [882-883] for the purpose of diminishing post partum AI. One Cochrane review found this strategy effective [882]. Sixteen studies were included in the analysis in which 6,181 women participated. Those without prior urinary incontinence were randomised to either pelvic floor training or standard care. At 12 months postpartum the intervention group were half as likely to have AI (RR= 0.52; 0.31-0.87). A subsequent report has not shown this benefit, and has yet to be included in the Cochrane review [883].

The AHRQ recently published a monograph on the prevention of incontinence, although the strategies listed for AI were therapies for existing AI, such as pelvic floor exercises and retraining, rather than established mechanisms for prevention [884].

**VI. SUMMARY POINTS**

- Anal and urinary incontinence commonly coexist, particularly in the elderly and in nursing home residents (LE 1).
- The prevalence of anal incontinence increases with age, but is present in all age groups and both genders varying from 1.5% in children to more than 50% in nursing home residents (LE1).
- AI is almost as common in men as in women (LE 2).
- Mode of delivery does not seem to be a significant factor in the development of obstetric anal incontinence, i.e., AI develops after Caesarean delivery as often as after vaginal delivery (LE 2).
- Obesity is perhaps the most modifiable risk factor for AI (LE 2). Intrapartum pelvic floor education can decrease the risk of subsequent development of post partum AI (LE 1).
- As populations age, co-morbid disease becomes a significant component of faecal incontinence risk. Surgery, neurological diseases, and stroke are examples.
- Cognitive and ADL impairment are associated with faecal incontinence.
- More population based prevalence surveys have been published.

**VII. FUTURE NEEDS**

- More analyses comparing AI after Caesarean section and vaginal delivery have been published.
- Systematic reviews of prevalence, including the role of age and gender, Caesarean delivery and decision analyses for the application of Caesarean delivery in macrosomia have been published, providing needed aggregation of data with quality assessment of existing literature.
and this might contribute to the wide range of reported prevalence estimates. The former ICS definition of UI – as a condition in which involuntary loss of urine is a social or hygienic problem and is objectively demonstrable - included objective demonstration of urine loss as one critical component. This aspect limited the ICS definition for community based epidemiological investigations, because objective demonstration of UI is difficult to achieve outside of the clinical setting, and studies which were able to include this aspect in their assessment might have produced different prevalences. In addition, a social or hygienic aspect of the definition was problematic in epidemiologic studies because it added a subjective aspect to an objectively defined condition and therefore confounded the investigation of prevalence, incidence, and risk factors. In our previous report we argued for reconsideration of the definition of UI, and we emphasized that the core of the definition should be "any involuntary loss of urine". In accordance with this view, ICS changed its definition in 2003 to UI being "the complaint of any involuntary leakage of urine".[1]

The new definition makes epidemiological research easier. But three consequences should be addressed:

1. Epidemiological studies should not be based on this definition alone, and all studies should include a minimal additional data set, standard confounders, and questions specific to the aim of the study. This is discussed in the Section on Recommendations for further research.

2. The number of persons fulfilling the definition will increase. This should not be interpreted as an increase in the number potential of patients.

3. Public awareness, case finding of health care personnel, and help seeking behaviour may be affected of a new and more extensive definition.

Studies have used different severity levels and time frames for defining UI. A further factor complicating the conceptualisation and measurement of UI in epidemiological studies lies in the nature of the condition. UI is a chronic condition (or set of conditions) that often starts slowly and comes and goes for a considerable time period before it become fully established. If people get used to their UI or notice it less, this can interfere with valid assessment.

Ideally self-report measures are validated by clinical evaluations. However, clinical and even urodynamic investigations should be regarded as other measures, not necessarily as gold standards, because it is known to be difficult to demonstrate all urinary symptoms in the clinical setting.

Holteidahl calculated prevalence estimates using different definitions of UI for the same sample of 50 to 70 year old women. The prevalence of any self-reported leakage was 47%. Self-reported regular UI with or without objective demonstration was found for 31% of women, regular incontinence according to the former full ICS definition for 19%. Another study found prevalences of 69% and 30% for any UI and the former ICS definition, respectively. The results indicate that the former ICS definition was rather restrictive.

Low response rates may further bias prevalence estimates. Known differences between responders and non-responders can be compensated during the analysis. The major problems is unknown differences in response rates and other characteristics. Incontinent women may not answer (or deny UI) because of embarrassment or related handicaps. But incontinent women may also find the subject particularly relevant and therefore respond to a greater extent than continent women. At present, we do not know much about how these factors may affect the comparison between incontinent and continent women.

One paper explored the problem of underreporting incontinence and how it can be altered with the use of an introduction to the incontinence questions and probing. Another paper explored the issue of selection bias in mailed surveys. The first wave had higher prevalence of incontinence than follow-up mailings, and thus individuals with UI tended to respond on the first wave. In an English mailed survey on incontinence and other urinary symptoms, a sample of non-responders were traced, and those eligible were asked questions from the survey. Compared with the responders, the non-responders overall showed little differences in reporting of urinary symptoms. However, non-responders >70 tended to be of poorer general health, and they reported certain urinary symptoms more frequently.

III. SUMMARY POINTS:

• The lack of epidemiological data from populations underrepresented in research limits the world wide application of the present information.

• Many investigations are plagued by sampling and non response issues, by self selection and attrition. Many early studies were obtained from sampling patients seeking care.

• A major problem is the use of different definitions of incontinence. The new ICS definition makes epidemiological research easier.

• There are large methodological challenges to research in the field of UI. Unless the scientific community deals with these issues, progress will be difficult to make.
K. HELP SEEKING BEHAVIOUR

I. URINARY INCONTINENCE

A majority of people with UI have not sought help, and this is confirmed also in recent publications. [454-455, 469-470] Reasons given by people for not seeking help include: not regarding incontinence as abnormal or serious, considering incontinence to be a normal part of ageing, having low expectations of treatment and thinking they should cope on their own. Some studies also confirm the notion that embarrassment may be an important reason for not seeking help [332-334] There is an association between help seeking and condition-specific factors like duration, frequency and amount, and people’s perceptions of the impact of incontinence, but other more personal characteristics like individual health care behaviour and attitudes may also play a role.

In a Norwegian study 4.4 % of all women >20 years old in a community consulted their general practitioner for UI during a 3 year period. But mentioning the symptoms to a physician may not be enough. There are reports of doctors not responding, either by ignoring the statement of symptoms or by providing a dismissive explanation, and people interpreting a lack of response from the doctor as an indication that no treatment is available. In a study of management of incontinence in general practice, 30% of the women who had told their doctor about their symptoms perceived that they were offered no help. It is probable that many primary health care providers lack confidence in managing UI, and that this contributes to under treatment in those seeking help [338].

Only a small proportion of incontinent community-residing women have had surgery, medication, or exercise regimens. In addition to seeking help from the formal health care system, common responses to symptoms of illness are self-management and self-treatment behaviour. The major method of actively managing UI among community residents is the use of absorbent products.

It is obvious that millions of men and women suffer from their UI, and that for many of them good treatment options are available. However, for many persons with very mild or occasional UI it is probably adequate not to seek help from the health care system. Others are satisfied with just information and understanding about the causes and in many cases self care may be quite appropriate. A Danish study has shown that simple information and advice was adequate “treatment” for 23% of the women attending an open access incontinence clinic. A Swedish study found that among 136 women with UI, 36% wanted clinical evaluation, and only 24% subsequently started treatment.

Both epidemiological and qualitative research in this field should be encouraged in order to understand cultural, religious, and personal factors for help seeking behaviour world wide. Specifically, other than condition-specific factors should be further explored, e.g. persons’ health care behaviour, perceptions and attitudes.

II. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

There are indications of underreporting also of FI and patients’ reluctance to report symptoms or to seek treatment.[787-788, 820] It has been shown that women are more willing to report FI than men. For POP we have no information.

III. SUMMARY POINTS:

- Recent publications confirm that a majority of people with FI, UI, and POP have not sought help.
- Only a small proportion of urinary incontinent community-residing people have had surgery, medication, or exercise regimens.
- Increasing severity, increasing duration, and urgency/mixed type of UI are related to consulting a health care provider.
- Associations other than condition-specific factors should be further explored in future research, e.g. persons’ health care behaviour, perceptions and attitudes.
- Health care personnel should be encouraged to approach those at risk for FI, UI and POP. People with such symptoms should be assessed so services and treatment can be offered and targeted. The patient’s view of management, even denial, should be respected.

L. EPIDEMIOLOGY AND CLINICAL WORK: FROM RESPONDENT TO PATIENT

We have emphasised some major and important differences between epidemiology and clinical work. These differences may have several implications. A selection process is most often accomplished first by self-selection (help seeking), then a referral system, which provides specialist physicians to a patient population with higher prevalence of disease, more severe disease, and often skewed type distribution, thus obtaining
In order to effectively plan health care resources it is necessary to estimate the prevalence and incidence of illnesses to know to what extent resources require to be allocated to a specific illness health care condition. This chapter has dealt with three major global problems, urinary and faecal incontinence as well as pelvic organ prolapse, that affect women and men throughout the world. Irwin and coworkers [885] have published data estimating the current and future worldwide prevalence of lower urinary tract symptoms.

The objective of the study was to estimate the current and future number of people with LUTS, including overactive bladder (OAB) and Urinary Incontinence (UI) utilising the current ICS definitions. Age- and gender-specific prevalence rates from the EPIC study[455] were applied to the worldwide over 20 year old population (4.2 billion) with males and females stratified into five-year age groups (20-24 to 80+). Projected population estimates for all worldwide regions were based on the United States Census Bureau International Database (IDB).

Estimates were presented for 2008, 2013 and 2018 and are summarised in Tables 22 and 23. Table 22 summarises the estimated number of individuals with certain LUTS symptoms by year and sex in the world population and Table 23 describes the estimated number of individuals of LUTS and OAB over 10 years across the world regions.

Estimates and projections featured in this analysis were based on prevalence rates of LUTS described in the EPIC study – based primarily on a European population. The prevalence rates featured in the EPIC study are similar to other prevalence rates of LUTS that were found in others studies across other countries [452,461]

The projections in this report assume the prevalence rates of LUTS will remain throughout the year 2018 for all age and sex groups

Prevalence of LUTS will also increase as other factors related to LUTS, such as obesity, increases (Figures 16 & 17). The estimated number for present and future years are not true numbers but are based on a projected population configured by the International Database (IDB). The IDB’s estimates and projections are drawn by Census Bureau demographers and are based on reviewed censuses, surveys, and vital statistics provided by

### Table 24. Summary of major findings

- 46% of the 4.2 billion of the adult world population (≥20 and over) experience any LUTS
- 455 million individuals or 11% of the world population estimated to experience OAB symptoms
- 346 million individuals or 8% of the world population estimated to experience some type of UI
- SUI is the most common type of incontinence in 2008 and 2018 (Figure 1)
- 136 (3%) and 164 (4%) million individuals are estimated to experience SUI in 2008 and in 2018 respectively
- 49 (1%) and 60 (1%) million individuals are estimated to experience UUI in 2008 and in 2018 respectively
- 53 (1%) and 65 (1%) million individuals are estimated to experience MUI in 2008 and in 2018 respectively
- 108 (3%) and 131 (3%) million individuals are estimated to experience Other Incontinence in 2008 and in 2018 respectively
- Assuming LUTS prevalence rates remain stable for the next ten years, 2.3 billion individuals are estimated to experience LUTS by the year 2018
- An increase of 18% from 2008
- Storage symptoms has the highest burden in both the male and female population than other LUTS (Figure 2)
- Male: estimated 597 million in 2008, 713 million in 2018
- Female: estimated 760 million in 2008, 901 million in 2018
- Asia region is estimated to carry the highest burden of LUTS. Estimated 1.2 billion individuals in Asia regions may experience any LUTS
Figure 16. Estimated number of individuals with UI 2008, 2013 and 2018 grouped according to type of incontinence.

Figure 17. Estimated number of individuals with LUTS 2008, 2013 and 2018 grouped according to gender.
National Statistics Offices9. Data on international migration and refugee movements, public health efforts, socio-political circumstances, and historical events such as natural disasters and conflict are all considered when the IDB calculates the estimates and projections.

It is anticipated that with the overall aging of the population the prevalence of LUTS will also increase.

It has been shown that LUTS are burdensome to individuals [397,539] and the likely increase in the number of individuals experiencing. LUTS has implications on healthcare resources and overall health burden. This analysis is an estimate of the number of individuals with LUTS based on a conservative prevalence rate, and so the future number of those with certain LUTS may surpass those of this report.

II. SUMMARY POINTS

- The spectrum of severity of anal and urinary incontinence, as well as pelvic organ prolapse, and the symptom profile of patients referred to specialist centres do not necessarily reflect the spectrum of disease seen in the community.
- The selection and referral process may introduce bias into research and hamper the ability to generalise hospital-based research back to primary care populations.
- One should be very careful with calculating numbers of patients in need of therapy based on epidemiological data.

M. RECOMMENDATIONS FOR FURTHER RESEARCH

Much biomedical research is observational and the reporting of such research is often inadequate which hampers the assessment of its strengths and weaknesses and of a study’s generalisability. The STROBE (Strengthening the Reporting of OBservational studies in Epidemiology) statement was introduced [661]. It is a checklist of items that should be addressed in articles reporting on the three main study designs of analytical epidemiology: cohort, case-control, and cross sectional studies. The use of this checklist is highly recommended.

I. URINARY INCONTINENCE

It is recommended that more sustained research on measurement of UI should be performed including, its types and severity to move the research ahead. Longitudinal study designs are needed to estimate incidence of UI and describe the course of the condition and its different forms and to investigate its risk factors and possible protective factors.

There is still little knowledge with regard to prevalence, incidence, and other epidemiological data in developing countries. It is recommended that fundamental research regarding prevalence, incidence and other epidemiological data in developing countries should be encouraged, and tailored to the cultural, economic and social environment of the population under study.

Crude prevalence studies (descriptive epidemiology) from USA and Europe are abundant, and further studies should be done only with recommended and validated questionnaires or in order to combine data from the prevalence study with studies of co-factors and predictors (analytical epidemiology). Control for confounders, stratification, and multivariate techniques should be increasingly used because of the need for more advanced epidemiological analyses of risk factors and comorbidity. Strength of associations should be determined by relative risks and odds ratios, and confidence limits should be given. We still have very little knowledge of the absolute and relative importance of several risk factors, and almost no information about the attributable risk of the factors in the society.

Some potential risk and protective factors deserve more attention. For example, the role of pregnancy and childbirth in the development of UI must be studied in a fashion that links population-based methods to clinical assessment of pregnancy, delivery and the birth trauma and follows women over many years. Such a design is necessary because the effect of pregnancy and childbirth may become clear only years later when the woman is older and because the woman will not be able to report the exact nature of the tear or episiotomy, etc. There should be more emphasis on the associations between UI and specific diseases like stroke, diabetes, psychiatric disease and genital prolapse. Genetic components should be investigated.

Primary prevention is the main goal in the management of human disease. An important strategy would thus be to identify the individuals at risk, and then take measures to reduce the risk among those individuals or in certain risk groups. Based on current knowledge there are no well documented efforts that can be done in order to avoid the occurrence of UI in large populations. Primary prevention studies should be encouraged, but the epidemiological basis for choosing appropriate interventions is weak.
In surveys based on questionnaires or interviews symptoms can be registered. There are convincing data suggesting that the different types may reflect quite different pathologies and risk factors. Differentiating the types in future research might therefore prove very fruitful. Methodological work has still to be done in this area, but typical type descriptions should be included in new studies. Likewise, studies of risk factors should include important and known confounders such as age, parity, and weight.

Variations in definitions and measurement issues are fundamental and lead to problems with assessing the findings in epidemiological studies. We need to improve epidemiological studies by including variables that better characterise UI, so that more advanced and informative analyses may be conducted. It is therefore recommended that all epidemiological studies include a minimum data set (Table 25), including elements of screening question, frequency measure, quantity of urine loss, duration, type, and severity. In addition, it is recommended that validated measures of bother/quality of life and urinary symptoms other than UI should be included. We here also refer to the chapter from the committee on symptom and quality of life assessment.

In addition, it is recommended that validated measures of bother/quality of life and urinary symptoms other than UI should be included.

II. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

In these areas there is a need for more epidemiological research in all areas; prevalence, incidence, and risk factors. Many of the fundamental methodological issues relevant to UI discussed above are highly relevant to the fields of FI and POP.

The committee emphasises that uniform definitions of FI and POP should be used in studies, and there should be a move towards a standardisation of measurement instruments in community surveys that can be used worldwide. Developing definitions is a scientific process requiring careful conceptualisation of the condition in light of its many clinical presentations and underlying mechanisms. This will require a multi-method approach and consideration of issues such a reliability and validity.

**Table 25. Elements in a minimum data set recommended for all epidemiological studies**

- Screening question for any involuntary urine loss.
- Frequency measure. For example, classification into categories of none, less than once a month, one/several times a month, one/several times a week, every day/night, all the time.
- Quantity of urine loss for a typical episode. For example, classification into categories of none, drops, small amounts, moderate amounts, much/a great deal.
- Duration. For example months, years.
- Type. Based on typical description; stress, urge, mixed and other.
- Severity. Either by combining existing questions or by a validated index.

The four years between this and the 4th report* on Cell Biology as part of the International Consultation on Incontinence has seen enormous advances in our understanding of the physiology and pathophysiology of the urinary tract. In addition, different aspects of lower urinary tract physiology have come to the forefront of research, which offers new and exciting avenues to understand and manage LUT dysfunctions such as overactive bladder syndrome (OAB) and detrusor overactivity (DO). This is reflected in the major topics chosen for this report. An understanding of the pathophysiology of detrusor smooth muscle remains essential to understand OAB and DO and a significant portion of the report is devoted to spontaneous contractile activity. However, the key role exerted by the mucosal layer of the bladder (the urothelium and suburothelium) is becoming recognised and the myogenic basis of spontaneous activity, although still important, is more complex than initially recognised. The urothelium is also appreciated not just as a relatively inert lining of the inner wall of the bladder, but as an active metabolising structure that releases transmitter molecules due to chemical and mechanical stresses that in turn influence adjacent nerves and smooth muscle. Another important cellular structure is the interstitial cell, a ubiquitous structure throughout the lower urinary tract whose functions are likely to be various, and about which we are only now becoming familiar. This is not a homogeneous cell type but a series of related cells that probably serve different functions within various regions. In addition, our knowledge of other regions of the lower urinary tract, in particular the complex outflow tract, is also increasing and a separate section is devoted to this region. The lower gastro-intestinal tract remains important in this report. Less attention through research is devoted to this tract but the clinical and social problems are no less important and probably no less prevalent. Finally, consideration is given to the search for potential new targets to manage lower urinary and gastro-intestinal tract disorders, as our knowledge of the basic science concerned with these regions increases so does our opportunity to identify new drug targets. Allied with this search, is one for better biomarkers of LUT dysfunction, ranging from physical methods to chemical markers. In all a series of relatively new topics that reflects the flux of research in this key area of academic medicine.

Cells resembling the Interstitial Cells of Cajal (ICC) in the G-I tract have been described in several other organs. In the bladder they have been termed Interstitial Cells (IC), ICC, ICC-like cells and myofibroblasts. Although a recent international meeting on Interstitial Cells advocated the use of the term “Interstitial Cell of Cajal-like Cells” [1], the less contentious term IC will be used to describe these cells in the bladder: this does not imply that they have similar functional properties as the ICC in the G-I tract. The IC represent a family of cells that demonstrate specific electron microscopic features: numerous mitochondria, a prominent endoplasmic reticulum, a Golgi apparatus producing secretion granules, thin and intermediate filaments and a basal membrane which may be discontinuous [2,3]. Electron microscopy permits detailed studies of cell structures and cell interactions, and is considered the gold standard for identifying IC [4]. However most studies aiming at the identification and characterization of interstitial cells have been performed by fluorescence microscopy using antibodies against specific epitopes. By combining different antibodies IC have been characterized in the bladder of a number of species. It should be pointed out that immunohistochemical proof for one or another receptor does not imply they exert any function within the cell. Given the problem of histochemical specificity, concepts or hypothesis based on histochemical findings will have to be verified with functional experiments.
1. IMMUNOHISTOCHEMICAL MARKERS USED TO CHARACTERIZE BLADDER INTERSTITIAL CELLS

c-Kit is a proto-oncogene that encodes a membrane tyrosine kinase receptor Kit, or CD117, which is expressed on the surface membrane of hematopoietic stem cells, mast cells, skin melanocytes, and IC [5]. Antibodies against c-Kit are considered the most reliable marker to identify IC in smooth muscle preparations as Kit receptors are not found on smooth muscle cells (SMC), nerves or fibroblasts [6]. c-Kit positive cells have been described in the bladder by many authors [7-11], but others have been unable to reproduce these observations. Whilst c-Kit positive cells were not found in the urinary bladder of the mouse they have been in the upper urinary tract [12]. Furthermore, c-Kit immunoreactivity (IR) has not been found in the mouse urinary bladder although cells were described that showed a rise in cGMP after NO stimulation, which was considered to be an identifier of IC [13]. Davidson & McCloskey identified a network of vimentin positive cells below the urothelium, of which many, but not all, cells were c-Kit positive. The reasons for these discrepancies remain unknown, but difficulties have been reported using anti-Kit consistently to label bladder cryosections [6]. Furthermore c-Kit has a role in the maturation of IC [3] and it is unknown whether Kit receptor expression remains stable during cell maturation. It has been suggested that it might be that some cells that have fully differentiated from mesenchymal cells lose their reactivity to c-Kit [14], which could explain why part of the vimentin positive cells show negative Kit immunofluorescence.

Vimentin is a member of the intermediate filament family of proteins, which is a general marker for mesenchymal stem cells. Vimentin is found in IC and other cells of mesenchymal origin like fibroblasts, but not in smooth muscle [2]. Vimentin antibodies can therefore be used to visualize potential IC, although fibroblasts cannot be excluded. However the expression of prostaglandin receptors EP1-IR, EP2-IR [15,16], the muscarinic receptor M3-IR [17], and COX I-IR [18] suggest that these vimentin positive cells are not merely fibroblasts, but may have a role in a complex communication system. Figure 1 shows vimentin labelling in various ICs.

The CD34 molecule is a cluster of differentiation molecules present on certain cells within the human body. It is a cell surface glycoprotein and functions as a cell-cell adhesion factor. Cells expressing CD34 are found in the umbilical cord and bone marrow as hematopoietic cells, endothelial progenitor cells, endothelial cells of blood vessels, mast cells, a sub-population of dendritic cells. A subtype of IC’s located between muscle bundles in the bladder that show immunoreactivity for the CD34 molecule have been identified [19,20].

![Figure 1. Vimentin immunoreactivity in interstitial cells. A: Vimentin positive sub-urothelial interstitial cells (SU-ICs) directly below the urothelium (green). Below this layer are vimentin-positive lamina propria interstitial cells (LP-ICs; green). COX-I immunoreactivity (IR) is visible in red. The basal urothelial layer shows strong COX I IR. A subset of the LP-ICs show IR for COX I. B: SU-ICs vimentin (red) and EP2 IR (green). Colocalization of vimentin and EP2 is seen in SU-ICs (yellow). Note also the strong labelling of the urothelium (uro) for EP2. Vimentin IR in the SU-ICs is visible in green. C: Co-labelling of SU-ICs for vimentin (green) and the M3 receptor (red). D: vimentin IR in LP-ICs (red). E: shows vimentin IR in muscle ICs (red). A subset of these cells also label for c-Kit (yellow). Nuclei are visible in purple. CD44 is a cell-surface glycoprotein involved in cell-cell interactions, cell adhesion and migration and is a receptor for hyaluronic acid. CD44 participates in a wide variety of cellular functions including lymphocyte activation, recirculation and homing, haematopoiesis, and tumour metastasis. Transcripts for this gene undergo complex alternative splicing that results in many functionally distinct isoforms; however, the full-length nature of some of these variants has not been determined. CD44 is expressed on cells in the interstitial space, and are possibly interstitial cells [21]; however the function of CD44 in these cells is not known.

PDGFRα (PDGF receptor-α) is a marker located on fibroblast-like and interstitial cells at many locations and has been proposed as mediator of normal and pathological cellular remodelling [22,23]. In the G-I tract, like c-Kit, PDGFRα as mutations are associated with most gastrointestinal stromal tumours [24,25]. PDGFRα on G-I tract interstitial cells has also been proposed to have a physiological function by transducing inputs from enteric motor neurons [26]. PDGFRα labelling has also been identified on mouse bladder interstitial cells in both the muscle and suburothelial layers and found to be associated closely with nerve fibres [27]. This implies that, as in the GI tract, they may have a neuromodulatory function.

An overview of the immunohistochemical reactivity with respect to the location of the ICs is presented in table 1.

2. STRUCTURAL IMMUNOHISTOCHEMICAL MARKERS USED TO IDENTIFY INTERSTITIAL CELLS

a) Suburothelial interstitial cells

Suburothelial-ICs (SU-IC) are described as a distinctive zone directly below the urothelium [28-30]. All layers consist of long spindle-shaped cells with branches that apparently form a network [6,8,12,31-33]. Depending upon the region, this zone varies from two cell layers in the dome up to five cell layers in the lateral wall. SU-ICs contain bundles of fine cytoplasmic filaments, dense bodies, linear arrays of subsurface vacuoles, and an interrupted basal lamina. Figure 2.

Table 1. Immunohistochemical reactivity to different types of ICC. SU-ICC: sub urothelial ICC; SM-ICC: surface muscle ICC; IM-ICC: intra-muscle ICC; MC-ICC: muscle coat ICC

Be visualized after NO stimulation [6,29,31,35-38], which resemble the vimentin positive cells initially described by Smet et al. [39]. As the urothelium releases substances such as NO [40], these SU-IC’s would be ideally situated to respond to and transmit signals from the urothelium either to underlying smooth muscle cells or adjacent nerve fibres.

Furthermore, acetylcholine [41,42] and prostaglandins [44-47] are also released by the urothelium, endogenously and augmented after different stresses. Both M2 and M3 muscarinic acetylcholine receptors have been reported on SU-IC’s [17,48,49], which suggests that these cells can respond to muscarinic stimulation. Although muscarinic receptors play an important role in the mediation of bladder contractions, their role on SU-IC’s is unknown. Electron microscopy shows close interaction between SU-IC and unmyelinated axonal varicosities of presumably cholinergic sensory nerves, containing a mixture of clear and large dense-core vesicles, or clear vesicles alone [50]. The identification of these vesicles indicates the release of acetylcholine alone (clear vesicles) or acetylcholine and ATP (dense-core vesicles) [50]. Purinoreceptors have also been identified
on SU-ICs. The most readily-labelled purinoceptor is P2Y6, with weak labelling of P2X3, P2Y2 and P2Y4 [30,51]. Activation of a P2Y receptor by ATP results in an intracellular Ca\textsuperscript{2+} transient and generates transient depolarisations. This suggests that purinoceptors on SU-ICs may play a role in regulating the excitability of the SU-IC, which may then modulate the non-voiding bladder activity.

To increase the complexity of this suburothelial cell layer, prostaglandin EP1 and EP2 receptor immunoreactivity has also been shown on vimentin positive SU-IC [16]. Furthermore some of these SU-ICs were also immunopositive for COX 1 [37]. Additionally, some of the SU-IC’s show immunoreactivity for the vanilloid receptor-1 [52]. Vanilloids are thought to block selectively C-fibres by desensitization, decreasing bladder activity, although the relationship between the vanilloid receptors on the SU-IC’s and C-fibre desensitization is unclear. Further research is necessary in order to understand the role of the vanilloid receptor on the SU-ICs.

The SU-ICs appear to be inter-connected through connexin-43 containing gap junctions [8,9,14,30,33,53]. The role of the connexin-43 positive SU-ICs is unknown but their coupling by gap junctions implies that they have the capacity to form a functional syncytium in the suburothelial space. Double labelling with the nerve marker PGP 9.5, showed that the SU-ICs are in close contact to each other, but also to nerves [6,50]. E-cadherins are located on SU-ICs, at areas where SU-ICs come in close contact with each other [21,54]. Cadherin-11 most probably plays an important role in the intercellular physical coupling of SU-ICs [54]. SU-ICs also label for CD44, a cell-surface glycoprotein which is also involved in cell-cell interactions [21]. CD44 participates in a wide variety of cellular functions including lymphocyte activation, recirculation and homing, haematopoiesis, and tumour metastasis. The function of CD44 on the SU-ICs is not known.

b) Surface muscle interstitial cells

Surface muscle (SM) ICs are described as cells located on the edge of smooth muscle bundles. A sub-population of the SM-ICs are c-Kit positive [6,7,9,12,19,34,55,56]. They contain lateral branches that run in parallel with the muscle bundles [6,7,8,12,55,57]. Contrary to the SU-ICs the elongated SM ICs appear not be interconnected [1], but connect adjacent muscle bundles and also connect to the muscle coat interstitial cells (MC-ICs) [31]. A close association between enteric nerves and SM-ICs has been described [6-8]. The SM-ICs contain nuclei, with clumped peripheral heterochromatin, and a dilated rough endoplasmic reticulum with a moderately electron dense amorphous content and prominent Golgi complexes [55]. EP1 receptor expression was found on SM-IC’s, of which some also showed COX I-IR in different parts of their processes. Furthermore, processes expressing the EP1 receptor lay very close to processes of other IM-SCCs showing the presence of COX I [15]. This could suggest the presence of a signal propagation network. The outer muscle SM-ICs react to NO with a rise in cGMP [13,31,36,58,59], while this was not the case for the inner muscle SM-ICs. This suggests further heterogeneity in these cells. A subset of SM-ICs showed immunoreactivity to the vanilloid receptor 1 and nNOS [52,60]. Also positive staining for CD34 has been reported [19]. These CD34 positive cells showed no c-Kit immunoreactivity.

c) Intramuscular interstitial cells

IM-ICs are located throughout the smooth muscle bundles [55]. They have a stellate-like morphology [6,53,55] and are in close contact with cholinergic nerve fibres [58]. Ultrastructurally the IM-ICs are comparable to the SM-ICs as they have nuclei with clumped peripheral heterochromatin, a dilated rough endoplasmic reticulum with a moderately electron dense amorphous content, and prominent Golgi complexes [55].
c-Kit immunoreactivity has been described in IM-ICs [19,34,55,56], although c-Kit negative IM-ICs in mice have been described [13]. Another study reported that a subset of IM-ICs stained for c-Kit while another subset was c-Kit negative [6]. Similar to SM-IC, IM-IC also express EP1 receptor immunoreactivity, with a similar distribution [15]. The IM-ICs of the outer muscle show an increased cGMP-IR after NO stimulation, a feature not shown by the inner muscle IM-ICs [6,31,58,59]. Surprisingly, immunohistochemical staining for choline acetyltransferase (ChAT) showed immunoreactivity in a subset of the IM-ICs [58]. Currently little data are available on other neurotransmitter receptors on this subtype of IC’s. Labelling done with an antibody to CD34 showed positive results in a subset of these cells [19].

d) Muscle coat interstitial cells

Muscle coat (MC)-ICs are located on the boundary of the outer muscle layer. It has been reported that, in a number of species, these cells react to NO with an increase of the outer muscle layer. It has been reported that, in a number of species, these cells react to NO with an increase of cGMP-IR after NO stimulation, a feature not shown by the inner muscle IM-ICs [6,31,58,59]. Surprisingly, immunohistochemical staining for choline acetyltransferase (ChAT) showed immunoreactivity in a subset of the IM-ICs [58]. Currently little data are available on other neurotransmitter receptors on this subtype of IC’s. Labelling done with an antibody to CD34 showed positive results in a subset of these cells [19].

3. FUNCTIONAL CHARACTERISTICS OF INTERSTITIAL CELLS

a) Suburothelial interstitial cells

Similar to the gut, the bladder exhibits rhythmic small transient contractions during the filling phase. The origin of this “autonomous” or “non-voiding” activity is still unknown. It is contentious if detrusor myocytes initiate this activity as there are different reports about their ability to generate spontaneous action potentials, despite the fact that they are electrically excitable [61,62]. SU-ICs are also electrically active and at least a fraction of them show spontaneous transient inward currents with increases in intracellular Ca$^{2+}$ concentration and spontaneous depolarization [63,64]. They also respond to exogenous ATP and low pH, a response that is augmented when SU-ICs make physical intercellular contact [65]. The observation that SU-IC may be electrically activated by exogenous agents or physiological interventions known to influence bladder activity suggests that these cells could participate in a sensing network between urothelium and afferent nerves. The immunohistochemical observation of the expression of muscarinic [17,48], purinergic [30,51] and prostanoid [16] receptors on the SU-IC would make them ideal substrates to process and converge signalling from physiological pathways or mechanisms. Figure 3 shows electrical responses from isolated SU-IC, the first panel shows spontaneous electrical activity from a relatively negative resting potential. The depolarisations never overshoot the zero potential consistent with the observation that the major charge-carrying conductance mechanism is by Cl$^-$, who have a reversal potential around -20 to -30 mV [64]. The remaining panels show responses to different interventions that could represent stimuli associated with increased bladder filling and exposure to urine itself; low pH, high osmolality and exogenous ATP. Each generated a large inward ionic current that would generate significant transient depolarisations.

In dysfunctional bladders, morphological and/or functional changes in the SU-IC population occur. In the initial stages following spinal cord injury in rats the bladder develops an overactive phenotype and is associated with an increase of SU-IC number [66], figure 4. At longer times after injury the bladder develops a high compliance state, demonstrating only small rises of intravesical pressure. At this time the SU-IC network is markedly reduced and cell processes appear retracted or lost [67]. Following outflow obstruction in the guinea pig, there is not necessarily an increase of SU-IC number, but cells were more uniformly distributed across the lamina propria compared to the control bladders [48,68]. Bladder dysfunctional states were associated with an increase of M2 and M3-receptor immunoreactivity [49]. A further consideration of how SU-IC number correlate with pathological bladder function is described in section 3.

b) Interstitial cells in the detrusor layer

Muscle IC that lie at the boundary of muscle bundles are spontaneously active and respond electrically to cholinergic stimulation by generating electrical activity and Ca$^{2+}$ transients [7,11] the latter observation is absent in SU-IC. This has led to the speculation that they might function as pacemaker or modulator cells initiating or regulating “non-voiding” activity. However, spontaneous Ca$^{2+}$ transients appear to be independent of those of smooth muscle even when synchronous Ca$^{2+}$ waves sweep across muscle bundles [56]. These findings have formed basis for the hypothesis that the muscle IC have more a role in mediating the propagation of action potentials along the bundles rather than generating them [56,61,69]. Similar to SU-IC, after the generation of a hyper-compliant bladder after spinal cord injury in rats, the IC network is similarly damaged and connections with nerves also impaired [66]. Following outflow obstruction in the guinea pig, there is an up-regulation of muscle IC number, with an altered distribution into clusters and formation of type-3 muscarinic immunoreactivity [48]. In men with overactive detrusor, IC are also more numerous than in the normal bladder [10]. The functional impact of these changes is still unknown as there are currently no cellular studies that have evaluated any changes to IC spontaneous activity or response to exogenous agents that may elucidate their role in altered bladder behaviour associate with lower urinary tract dysfunction.

Studies using Glivec (imatinib mesylate), a specific c-Kit receptor inhibitor, have suggested a possible role for the IC in pathophysiology. In guinea pigs,
Figure 3. Electrical recordings from isolated guinea-pig suburothelial interstitial cells. A: Spontaneous variations of membrane potential. The spontaneous depolarisations never overshoot (i.e. become greater than 0 mV) but tend to limit near the Cl- equilibrium potential for the cell. B-D: inward currents from isolated suburothelial interstitial cells held under voltage-clamp at -60 mV. Responses are shown on exposure to: B, hyper-osmotic solutions; C, 100 µM ATP; D, low pH (CH Fry, C Wu, GP Sui, unpublished data).

Figure 4. Connexin43 labelling in rat bladder suburothelium. A: Normal bladder. B: Bladder from a spinal cord injured animals. Connexin43 (green), DAPI (nuclei, blue). Connexin43 labelling is prominent below the urothelium layer, observed as the invaginated, dense nuclear density regions. x200 magnification (CH Fry, AJ Kanai, unpublished data).
administration of Glivec reduced spontaneous electrical and mechanical activity in isolated bladder tissues [10,70]. It also reduced spontaneous bladder activity, improved bladder capacity and compliance in cystometric studies in guinea pigs, and inhibited detrusor contractions in biopsy samples from human overactive bladders [10]. Current data point to a more prominent role for IC in dysfunctional bladders than in normal bladders. Their role in normal bladders is unclear. Do they merely fine-tune smooth muscle activity or do they have a role as primary relay or processing stations between urothelial cells, nerves and muscle cells [4]?

III. THE UROTHELIUM – STRUCTURE AND FUNCTION

The outer layer of the bladder facing the urine is a composite of the urothelium and an underlying suburothelium. The whole structure is termed the mucosa by some authors and will be used in this report: however this does not imply a vigorous secretion of mucus as with the gastro-intestinal tract for example. Different terminologies have been employed for its two faces. When using preparations of whole bladder wall the terms mucosal and serosal faces have been used to refer to the sides facing the lumen of the urinary tract and the underlying tissues of the body, respectively. When preparations of isolated tissues mucosa and urothelium are used these terms become more confusing and their faces may be termed apical and basolateral respectively, by analogy to polarised epithelium membranes. In this report the terms apical and basolateral will be used.

Interest in the functional properties of the mucosa has increased recently as its different physiological functions are increasingly characterised. The barrier properties have been described in detail in previous reports [71] and more recent aspects will be included in the Committee 3 report. Moreover, the mucosa has a sensory function, responding to several external stresses generally associated with bladder filling, to influence the activity of mucosal afferent fibres as well as underlying smooth muscle. Different aspects of these functions will be considered in this and Committee 3 reports; here the release of ATP and acetylcholine; mucosal electrophysiological properties and the functional interaction between mucosa and smooth muscle will be discussed. A summary of the important relationship between different cellular layers and factors that have been shown to influence the release of important transmitters is shown in Figure 5.

Figure 5. A schematic diagram of transmitter release by the urothelium. Urothelial cells are shown in grey, above which are examples of physical and chemical stresses that may cause transmitter (e.g. ATP, acetylcholine (ACh), nitric oxide (NO) or prostaglandin (PG) release. Deformation of the bladder wall, as in bladder filling, can also limit blood flow and generate a local ischaemia with accompanying acidosis and hypoxia. Transmitters may act on suburothelial cells, interstitial cells or afferent nerves and/or influence directly underlying detrusor smooth muscle.
1. RELEASE OF TRANSMITTERS

The epithelial lining of the urinary tract releases a number of agents into the extracellular space when subjected to many alterations of the physical and chemical external environment. These agents may be released across either the apical or basolateral surfaces [43,71-73]. This phenomenon is common [74-78], but not ubiquitous [79], to epithelia of many tissues, such as the G-I tract and airways, as well as the endothelium of blood vessels and is considered to be a sensory process that allows external stimuli to be transduced to a chemical signal. The fate of these signalling molecules and factors that regulate their release will be considered below.

a) Stimuli for release

Different experimental paradigms have been used to generate release of chemicals from the mucosa including: lateral stretch [80-82]; changes to trans-mucosal pressure [43,83], although responses are reported to be different if pressure is raised on the apical or basolateral face [84]; stroking with hairs [79]; electrical stimulation to increase tension (stress) within the bladder wall [80,81]; hypotonic solutions to cause cell swelling [41,85]; and application of chemical agents such as acid solutions, prostaglandins or ATP itself [80,86-88]. Whether these interventions are equivalent on transmitter release is unclear and data derived from these different paradigms will be combined. In particular, changes to transmural pressure are analogous to equivalent alterations in the intact bladder during filling with urine and experimentally cause lateral strain to the mucosal membrane. Application of hypotonic extracellular solutions causes cell swelling as water enters the cell under osmotic forces. Although easy to use in an in vitro setting, care must be taken that any subsequent effects are not due to changes of the ionic composition of the extracellular and intracellular spaces, per se.

b) Transmitter chemicals, ATP

ATP has been the transmitter most extensively studied in response to stretch. It has been measured, in preparations ranging from intact bladders to cultures of urothelial cells, in the bladder lumen and in the basolateral compartment. The function of ATP release into the bladder lumen is unclear. It may have a direct effect on bladder function as ATP infused into the bladder causes contraction [89]. In addition, it can represent a useful biomarker for different bladder conditions where the amount of ATP that is released is variable [90]. ATP released across the basolateral face can have several functions: it may excite (depolarize) afferent nerve endings in the suburothelium through ionotropic P2X2/P2X2/3 receptors, thus providing a direct link between bladder filling and afferent activation [91]. Evidence in support of this hypothesis was gained from P2X2/3 knock-out mice in which the micturition reflex attenuated, with lower frequency of afferent firing on filling and a greater intravesical volume before voiding was initiated [71,92,93]. Alternatively, ATP may first excite, via P2Y receptors, a network of interstitial cells that have been observed in the suburothelium [14,63,64]. These cells in turn may excite afferent nerve fibres with which they make intimate connections [50]. Finally, ATP may diffuse directly to the smooth muscle layer and thus depolarize the myocytes, via P2X1 receptors, cells leading to their contraction [94].

Several important questions pertain to ATP release from the urothelium: the cellular routes that mediate release; factors that control release; and alteration to ATP release associated with lower urinary tract dysfunction. Several lines of evidence indicate that ATP release requires a rise of intracellular \([\text{Ca}^{2+}]\) as a result of \(\text{Ca}^{2+}\) release from intracellular stores, i.e caffeine, acetylcholine and prostaglandin E2 increase ATP release and heparin, acting as an IP3 receptor inhibitor, reduced release [95,96]. However, extracellular \(\text{Ca}^{2+}\) reduces ATP release and this occurs also by agents believed to reduce store-operated \(\text{Ca}^{2+}\) entry, although others have contradicted this effect of extracellular \(\text{Ca}^{2+}\) using cultured urothelial cells [97]. The opposing effects of these \(\text{Ca}^{2+}\) sources may be related to their occupation of different micro-domains within the cell and hence the activation of different cellular pathways, but does provide a negative feedback control to prevent excessive ATP release. Several routes for \(\text{Ca}^{2+}\) entry into urothelial cells including: TRPV4 channels [97]; TRPV1 channels [98]; TRPV2 channels [99]; and Gd3+-sensitive stretch activated channels [100]. The routes for ATP efflux from urothelial cells is less clear, although there is evidence for ATP accumulation in vesicles and release by exocytosis [101]. However, other routes are possible, such as through anion channels [102] that have been characterised in urothelium [103].

Several factors provide a physiological regulation of ATP release. Purinergic regulation provides positive and negative feedback as extracellular ATP itself generates further ATP release [88] whilst its breakdown product, adenosine, attenuates stretch-induced release [104]. Acetylcholine receptor antagonists also reduce stretch-induced release [105], suggesting a positive feedback effect by acetylcholine, as well as an explanation for how clinical antimuscarinic agents may reduce lower urinary tract symptoms associated with filling. In addition transmitter release is dependent on the magnitude of the potential difference across the urothelium (the transepithelial potential, TEP), such that abolishing TEP prevents stress-induced ATP release and increasing TEP in the absence of other external interventions increases ATP release.
Several lower urinary tract disorders are associated with augmented stretch-activated ATP release and this has been used to hypothesise that there is a causal link between the two phenomena. Urothelial tissue from animals and patients with interstitial cystitis or painful bladder syndrome and inflammatory conditions exhibits greater release [85,88,106,107]. This enhanced release was normalised by botulinum toxin-A suggesting a therapeutic mode of action for the neurotoxin [107]. A potential mediator of enhanced release of ATP is pituitary adenylate cyclase activating polypeptide (PACAP) that exhibits upregulation in dorsal root ganglia and the urothelium with inflammation induced by cyclophosphamide and acts to enhance ATP release from cultured urothelial cells [108].

Enhanced ATP release has also been measured using mucosa samples from patients with idiopathic and neuropathic bladder overactivity, or in animals with bladder obstruction following spinal cord injury [80,90,109]. Of interest was that with the human specimens from patients with neuropathic bladder overactivity most of the enhanced increase was abolished with the neurotoxin, tetrodotoxin [80], suggesting it had a neuronal origin. Table 2 summarises factors that have been shown to alter the extent of ATP from urothelium.

c) Transmitter chemicals, acetylcholine

Stretch also generates acetylcholine (ACh) release from bladder wall preparations that is greater with an intact mucosa. Release is independent of tetrodotoxin and increases with the age of the patient from whom biopsies were obtained [110-111]; however a positive feedback control, as with ATP release, seems to be absent for ACh release [41]. Cultured urothelial cells contain the machinery to synthesise ACh, with positive expression of a high affinity choline transporter (CHT1) and the synthetic enzymes choline acetyltransferase and carnitine acetyltransferase. Release may be via a cation transporter, but not by vesicular exocytosis as it is independent of brefeldin [41].

2. UROTHELIAL ION TRANSPORT AND PERMEABILITY

a) Urothelial ion transport

The urothelium is a tight epithelium with a high specific resistance [112,113] due mainly to uroplakin [114] proteins on apical umbrella cells limiting membrane transport and effective tight junctions between cells [115,116]. Because of the high resistance ion transport that does occur can generate a significant transepithelial potential that is linked to other urothelial functions, such as transmitter release. Therefore an understanding of those factors that regulate ion transport and urothelial resistance will provide insight into the regulation of transmitter release.

\[
\text{Na}^+ \text{ transport across the urothelium is similar to that across many epithelia with an apical route that allows } \text{Na}^+ \text{ to enter the cell down a concentration gradient, accompanied by basolateral expulsion through a Na}^-\text{K}^+\text{ ATPase. In the case of the urothelium a significant fraction of Na}^+ \text{ influx is by an amiloride-sensitive epithelial Na}^+ \text{ channel (ENaC),}
\]
which is increased when the apical hydrostatic pressure is raised as in bladder filling [117, 118]. Na+ transport is modulated by a number of hormones including aldosterone [119], arginine vasopressin [120] and atrial natriuretic peptide [121].

ATP release from urothelium is itself dependent on ENaC activity providing a direct linkage between transmitter release and ion transport [43]. What remains unclear is whether the TEP itself, generated by Na+ transport, or the transported ions themselves regulate ATP release. One hypothesis is that an increase of intracellular Na+, when ENaC activity is raised, increases intracellular Ca2+ through Na+-Ca2+ exchange [100] that leads to release of the transmitter. K+ transport across the urothelium is also modulated by stretch and several K+ channels have been identified including: an amiloride-sensitive non-specific cation channel [122]; Ca2+-activated K+ channels sensitive to charybdotoxin and apamin; and an inward rectifying channel (Kir2.1) [123]. Their particular roles remain to be identified.

In addition, channels of the TRP family have been identified on urothelium including: TRPV1, TRPV2, TRPV4, TRPM8, TRPA1 [124-128] and may be involved in transduction of stimuli as diverse as stretch, acidosis, altered local osmolality and temperature [129]. Their mode of action is also unclear but their characteristic to act as non-specific cation channels means that their activation will result in an increase of intracellular Na+ and Ca2+.

b) Urinary tract infections

A significant component of the clinical morbidity associated with urinary tract infections, in particular by Escherichia coli, is believed to be due to a reduction of the barrier properties of the urothelium. This would allow fractions in urine to interact more easily with underlying tissues and generate inflammatory responses associated with such infections. Acute exposure of mucosal membranes to E. coli reduced the transepithelial resistance. This effect was attributed to a degradation of tight junction integrity with a consequent increase of paracellular permeability and associated with a loss of the tight junction protein ZO-1 [130]. Flagellin in the bacterial wall most likely interacts with Toll-like receptors to mediate the host response [131]. The causative agents remain unclear but E. coli infection is associated with generation of several cytokines such as IL-6, IL-8, IL-15 and TNF-α [130,132,133]. These have not just a pro-inflammatory action but also modulate urothelial permeability, in the case of IL-6 and IL-15 urothelial integrity can be restored [130,134].

3. FUNCTIONAL INTERACTIONS WITH THE DETRUSOR LAYER

The urothelium exerts direct control over the contractile function of the bladder wall in several different ways: it may release chemical agents that diffuse to the detrusor layer and influence the contractility of muscle; it increases spontaneous contractile activity; and it may itself have intrinsic contractile activity. All of these modalities will influence the overall contractile output of the bladder and could represent targets for the modulation of such function.

a) Urothelium-derived relaxing factors

The in vitro contractile responses of bladder wall preparations from the dome and trigone to electrical field stimulation and agonists is reduced if the mucosa is left intact on the smooth muscle [135-139]. However, not all agonist responses are equally affected: those to carbachol, histamine and electrical field stimulation are depressed, but those to phenylephrine and raised KCl are not; the response to neurokinins has been reported as being reduced or unaffected [135,138]. A similar depressant response has been reported in the ureter where the presence of the mucosa attenuated spontaneous contractions and those evoked by high-KCl, neurokinin-A, vasopressin, carbachol, bradykinin and angiotensin-II [140]. This has led to the concept of a urothelium-derived inhibitory factor generated by the mucosa. However, if only the urothelium was removed from bladder preparations, leaving an intact suburothelium, smaller contractions evoked by carbachol, ABMA (a P2X1 agonist) or electrical field stimulation are also measured. One explanation is that the urothelium has a potentiating action on detrusor contractility, whilst the suburothelial layer has an inhibitory effect [141].

The nature of these agents is unknown, but they are probably diffusible and do not rely on cell-to-cell contact, as the contractility of a mucosa-denuded detrusor preparation is reduced if a second mucosa-intact preparation is placed in its vicinity [136]. Thus, these agents may be produced constitutively or in response to agonists and directly modulate muscle contractility, alternatively they may inactivate contractile the contractile agonists. The latter possibility is unlikely as presence of mucosa modifies responses to several different agonists, as well as contractions to electrical field stimulation. Control of their release may be mediated by purinergic receptor agonists, as ATP mimicked the effect of the urothelium in modulating carbachol contractions [142].

The inhibitory agent, at least, is unlikely to be nitric oxide, a cyclo-oxygenase product, a catecholamine, adenosine, GABA or a mediator of TEA- or apamin-blocked K+ channels [135,136]. However, one study did show that in mucosa-intact preparations carbachol responses were increased by L-NAME (to limit NO production) and the cyclo-oxygenase inhibitor indomethacin [143], although their direct effect on muscle function cannot be excluded.

b) Contractile activity of the mucosa.

In vitro preparations of mucosa dissected from the detrusor layer generate small spontaneous contractions and responses to agonists such as carbachol and neurokinin-A [144] as well as to electrical field...
stimulation [145]. The frequency of spontaneous contractions are similar to that generated by detrusor muscle preparations – see figure 6.

These contractions may originate from small smooth muscle bundles, muscularis mucosa, at the base of the suburothelial layer or from contractions of interstitial cells that are abundant throughout the suburothelium and which form a network of cells connected by gap junctions formed from connexin43 (Cx43) [14]. Evidence for contractions arising from the muscularis mucosa is poor as the magnitude of contractions is independent of the amount of smooth muscle in isolated preparations from which experiments were made [144]. Moreover, as seen below, the profile of contractile responses to many agonists is differs in several respects from bladder smooth muscle. The spontaneous activity is independent of tetrodotoxin and NO-synthase or cyclooxygenase inhibitors and carbachol responses are mediated by M3 receptors [146]. Of interest was that NO-donors did depress contractile function suggesting that there is no endogenous production of NO by the tissue under resting conditions.

The other possibility that contractions may be generated by the interstitial cells remains to be fully investigated. In the bladder suburothelium, interstitial cells have a phenotype typical of myoﬁbroblasts [147], which have a contractile phenotype, contain smooth muscle actin and label for vimentin [14,144,148,149]. Their ability to form norm a functional syncitium through gap junctions means that chemical and electrical signals can propagate to a signiﬁcant extent over several millimetres and produce a co-ordinated contractile response [33]. Sub-urothelial interstitial cells generate large intracellular Ca²⁺ transients and inward currents to ATP, through P2Y receptors, and to a reduction of pH [64,65]. The ability of such agents to increase spontaneous activity in preparations of mucosa will lend support to a role for suburothelial cells in generating signiﬁcant contractile responses.

Figure 6. Spontaneous contractions generated by preparations of isolated mucosa and detrusor (guinea-pig). Upper trace: spontaneous contractions from isolated mucosa, the preparation was exposed to a low-pH solution when shown. Lower trace: spontaneous contractions from isolated detrusor preparations, a similar exposure to a low-pH solution is also indicated.

c) Interaction between mucosa and detrusor

When the mucosa is left attached to in vitro detrusor preparations there is an increased prevalence of spontaneous contractile activity and the magnitude of prevailing contractions is greatly enhanced [65,150]. Thus, the character of such activity changes from small amplitude, high frequency contractions to larger, more prolonged and less frequent phenomena. This is especially the case in bladders showing an overactive phenotype resulting from, say, spinal cord injury [66]. This augmented activity may result from: i) spontaneous contractions within the mucosa itself, as discussed above; ii) the mucosa, through either cell-to-cell interaction or release of diffusible agents, inﬂuences detrusor function.

It is unlikely that mucosal contractions are the sole explanation as they are of relatively low amplitude. They are however of similar frequency and it is possible that they may inﬂuence additional activity in the detrusor. Propagating waves of depolarisation and intracellular Ca²⁺ have been demonstrated that originate in the suburothelium, propagate initially throughout this layer and to the urothelium, and then after a delay of several hundred milliseconds to the detrusor [151]. This extent and propagation speed of this interaction between mucosa and detrusor is increased by: exogenous agents such as P2Y agonists (Figure 7); small (50 nM) concentrations of carbachol; and mechanical distension. Such interaction is similarly augmented in the bladder wall from spinal cord injured rats, in which there is a large increase of suburothelial IC number and Cx26 expression in the urothelium [152], as well as the enhanced spontaneous contractile activity, described above. Several lines of evidence suggest that ICC contribute to increased spontaneous contractile activity with an intact mucosa:

ICC form an electrical syncitium in the suburothelium as observed from their expression of the gap junction
protein Cx43 and cable calculations based on their electrical properties [14,63,64]; from their A role for interstitial cells in signalling is suggested by several observations:

ICC number; the intensity of Cx43 labelling; and Ca^{2+}/depolarisation wave propagation speed are all increased in overactive bladders [152].

P2Y agonists generate excitatory responses in ICC and increase spontaneous contractile activity [64,65,153], whereas they reduce the contractility of detrusor muscle itself [154,155].

The first two of these arguments are consistent with a cell-to-cell interaction, however, it is unknown if there is a significant diffusion of excitatory agents between the mucosa and detrusor. Certainly the increase of stretch-induced mucosal ATP release, coupled with reduced extracellular ectoATPase activity in idiopathic detrusor overactivity [80,156] would provide such a substrate, but definitive experiments remain to be done.

### IV. DETRUSOR SMOOTH MUSCLE CONTRACTILE ACTIVATION

#### 1. SMOOTH MUSCLE CELLS

Smooth muscle (SM) cells are the major component cells of the walls of visceral organs and the vascular wall, and their ability to contract and relax is the hallmark of the physiological function of these organs. These mesoderm-derived (mesenchymal) cells have common characteristics, although cells in various regions of the body are heterogeneous in regard to their ability to express contractile proteins, contract spontaneously, and their responses to hormonal/neuronal stimulation. SM cells are elongated with tapering ends, and their length varies from 20 µm in certain small blood vessels to 500 µm or more in the gestational uterus [157]. There are three layers of SM aligned in a complex orientation in the bladder wall. The middle layer is the most prominent, but the other layers, a muscularis mucosa below the suburothelium and a thin layer below the serosa, may not
always be identified in a random histological section. In the trigone, the SM cells orient around the opening of the urethra.

The arrangement of the SM cells in the muscle bundle or sheet is staggered, with the broad nuclear region of one cell lying opposite to the narrow tapered end of an adjacent cell. At various points, adjacent cells form an intimate association, called a nexus or gap junction, where electrical coupling is facilitated. The cytoplasmic organelles of the myocytes, which include mitochondria, Golgi apparatus, rough endoplasmic reticulum, and free ribosomes, are abundant in the conical perinuclear region. The remainder of the cytoplasm is occupied by contractile filaments, which form the contractile machinery, and cytoskeletal filaments, which help maintain the cellular shape. The contractile apparatus of the SM cell is composed of thick (15 nm) myosin filaments and thin (7 nm) actin filaments [158,159]. Thin filaments, although composed mainly of actin, also contain actin-binding proteins, such as tropomyosin (Tm), caldesmon (CaD), and calponin, all of which are arranged in a specific manner and molar concentration. These proteins are also thought to be involved in regulation of the actin-myosin interaction that occurs during force generation. The filaments that form the cytoskeletal structure consist of intermediate filaments with a diameter of 10 nm. These filaments, which are connected to the dense bodies, are composed of desmin and vimentin. In addition, microtubules composed of tubulin and actin-containing thin (7 nm) microfilaments that are not part of the contractile apparatus also contribute to the cytoskeletal structure.

2. CONTRACTILE PROTEIN ISOFORMS AND THE CONTRACTILE MACHINERY

a) Myosin

Myosin in SM is mostly class II (myosin II) and contains two heavy chains (MHC, 200-204 kDa) that constitute the globular head (NH2-terminal) and the tail (carboxyl-terminal) domain. Thus, myosin II has two heads and a rod portion that is composed of a coiled-coil region. The ATPase and actin-binding sites reside in the head portion, whereas the ability of myosin to form filaments is due to properties that arise from the rod portion of the molecule. Myosin II also contains four light chains (i.e. two per head) that weigh 20 (MLC20) and 17 (MLC17) kDa. These bind to the heavy chains in the “neck” region between the head and the tail. MLC20 is also known as the regulatory light chain and actively participates in muscle contraction. Two MLC20 isoforms are found in SM and encoded by different genes [160], but only one isoform participates in contractility [161]. MLC17 is known as the essential light chain. Its exact function is unclear, but it is believed that it, along with MLC20, contributes to the structural stability of the myosin head. Two variants of MLC17 (MLC17a/b) exist due to the alternative splicing of the MLC17 gene [162].

Alternative splicing of the MHC pre-mRNA at the 5'-end produces SM-A and SM-B isoforms, whereas splicing at the 3' end of this mRNA produces SM1 and SM2 heavy chain isoforms that differ in molecular size (204 kDa for SM1 vs. 200 kDa for SM2) [163,164]. The SM-B isoform includes a 21-nucleotide exon that encodes a seven-amino acid insert in the N-terminal region near the ATP-binding site. This is the major isoform found in visceral SM and small muscular arteries. On the other hand, large arteries, such as the aorta and pulmonary artery, mainly express the SM-A isoform [165]. Compared to the SM-A isoform, the SM-B isoform has higher ATPase activity and moves actin filaments faster in an in vitro motility assay [166]. Detrusor smooth muscle (DSM) contains nearly 100% SM-B myosin isoform, which hydrolyzes ATP faster than the SM-A isoform. DSM is a phasic SM with a maximum velocity of contraction (Vmax) higher than that of tonic smooth muscles that are composed primarily of the SM-A isoform [165]. DSM from obstructed bladders with severe dysfunction shows an upregulation of the SM-A isoform [167,168] and exhibits tonic-type contractions, characterized by slow force generation and high force maintenance. These results suggest that bladder outlet obstruction produces a muscle that develops higher levels of force but greatly reduced cross bridge cycling rates [169]. Along with these changes in myosin heavy chain isoforms, hypertrophied tissue also showed a doubling in the relative expression of the basic isoform of the 17 kDa (MLC17b) myosin light chain. A relative increase of the MLC17b isoform is associated with a lowered ATPase activity [170]. Comparative studies have shown that muscles with a high MLC17b content have a lower shortening velocity [171] and a higher affinity for ADP-analogues [172,173].

The ratio of the C-terminal isoforms SM2 and SM1 in the DSM switches from ≈1:7:1 in a normal rabbit bladder to ≈1:1 in a decompensated bladder [174,175]. Increasing the SM1/SM2 ratio in the bladder has a significant effect on contractile function [176], possibly by the stabilization of the thick filament through the tail region interaction with the head of an adjacent myosin molecule [177]. SM2 homozygous knockout (SM2−/−) mice die within 30 days of birth and show pathologies that include segmental distention of the alimentary tract, retention of urine, distension of the bladder, and development of end-stage hydronephrosis [178]. In contrast, heterozygous (SM2+/−) mice appeared normal and reproduced well. In SM2−/− bladder SM, loss of SM2 myosin was accompanied by a concomitant down-regulation of SM1 and a reduced number of thick filaments.

Virtually nothing is known about the transcriptional regulation of myosin isoform expression in both normal and pathological SM. A better understanding would help target mechanistic steps that regulate the alternative splicing of the pre-mRNA that generates
the SM-B and SM-A mRNAs and could shed light on the differences between SM in normal and obstructed bladders. The recently established human bladder SM cell line that expresses the SM-B isoform should be helpful in gaining insight into the factors that regulate the expression of the various myosin isoforms [179].

SM cells also express non-muscle myosin. In humans, non-muscle myosin heavy chain (NMMHC) isoforms NMMHC-A and NMMHC-B are expressed. The mRNAs encoding NMMHC-A and NMMHC-B are products of different genes, localized to chromosome 22q11.2 and chromosome 17q13, respectively [180]. Obstruction-induced hypertrophy is associated with an increase in NMMHC-B, primarily in interstitial fibroblasts [181].

b) Actin isoforms

Vertebrates express at least six different actin isoforms in a tissue-specific manner and multiple actin isoforms are found even in the same cell [182,183]. Differentiated SM cells typically contain a mixture of muscle (α,γ) and cytoplasmic (β,γ) actin isoforms. The muscle isoforms are associated with contractile filaments, whereas the cytoplasmic isoforms form the non-contractile cytoskeleton. The amount of different isoforms in a muscle cell varies according to the source of tissue. The dominant type of actin in SM of mammalian visceral organs (chicken gizzard, uterus, intestine, urinary bladder) is γ-SM actin, whereas the major actin type in vascular SM is α-SM actin [182].

Bladders from SM α-actin−/− mice tended to generate less force than those from wild-type mice in response to electrical field stimulation (EFS) with or without prior treatment with carbachol and atropine. However, their bladders appeared to function normally with no gross or histological abnormalities [184]. DSM SM α-actin protein and mRNA are not altered in response to obstruction-induced bladder hypertrophy [185]. In addition there was a decrease in β-cytoplasmic actin and a small increase of SM γ-actin. Hence, the composition of the actin isoforms in bladder SM is altered in response to obstruction-induced hypertrophy.

c) Actin-associated proteins in the thin filaments

Caldesmon (CaD) is a Ca^{2+}/calmodulin-binding protein thought to play a role in the Ca^{2+}-dependent regulation of both SM and non-muscle contraction [186]. Two CaD isoforms have been identified, h-CaD (high Mr form), expressed predominantly in differentiated SM cells, and l-CaD (low Mr form), widely distributed in non-muscle cells [187,188]. The expression of CaD is tightly associated with the phenotypic modulation of SM cells, as the CaD isoform switches from the l- to h-form during differentiation [189]. Therefore, CaD is a useful molecular marker for the study of the phenotypic modulation of SM cells. Whether the h- or l-CaD isoform is expressed depends on the unique selection of two 5′-splice sites within exon 3 [190]. Another important molecular event is the upregulation of CaD expression during SM cell differentiation [189]. DSM cells from obstructed bladders over-expressed l-CaD; in the compensated phase h-CaD was also increased [191].

Tropomyosin (Tm) is a rod-like helical protein that dimerizes and binds to actin and stabilizes actin contractile filaments. The four Tm genes produce many isoforms (>40) as a result of alternative exon usage. Most isoforms are found in non-muscle cells, but there are some specific to either striated or SM. Only two isoforms appear to be specific to mammalian SM, one from the β-Tm gene, and the other from the α-Tm gene. α-SM Tm contains the unique exon 2a, whereas β-SM Tm uses exon 2b, the exon used in the other muscle isoforms [192]. There is no specific antibody against either of the two SM isoforms of Tm. Antibodies that detect both isoforms also detect non-muscle and/or striated muscle isoforms and thus SM cannot be labelled specifically. Thus, Tm in SM has not been widely studied, especially in comparison to actin and myosin. Tm cooperatively turns on actin-activated ATP hydrolysis by myosin ATPase [193-195], thus it is considered to be important for thin filament-mediated regulation of smooth muscle.

3. CONTRACTILE ACTIVATION OF SMOOTH MUSCLE

The previous consultation [196] considered in more detail the signalling pathways that generate contraction or relaxation through muscarinic, nicotinic, adrenergic, purinergic, nitricergic and neuropeptide-mediated mechanisms. This report will provide a brief overview of receptor-mediated activation (4.3.1) and updates on electrical activity in detrusor smooth muscle (section 4.4) and the cellular and tissue basis of spontaneous contractile activity in detrusor (section 4.5).

a) Receptor-mediated activation of detrusor smooth muscle

The relaxed state of the bladder in filling and the generation or wall tension to effect emptying are regulated by external neuronal, hormonal, and central systems. Neurotransmitters released from nerves act on receptors located in the DSM, the functionally most important of which are muscarinic, M3, and purinergic, P2X1, receptors. However, the contributions of these receptors and their subtypes differ between species, age and bladder pathologies. With the stable bladder the predominant contractile regulator are muscarinic receptors. The main route for detrusor relaxation is the adenyl cyclase-cyclic adenosine monophosphate (cAMP) pathway, activated by the β3-receptor in humans [197].

Muscarinic receptors are coupled to G-proteins. The M1, M3, and M5 receptors are considered to preferentially couple to Gq/11, which leads to phos-
phospholipase C and the subsequent mobilization of intracellular Ca$^{2+}$ by generation of inositol trisphosphate (IP$_3$) [198]. M2 and M4 receptors couple to pertussis toxin-sensitive Gi/o, which results in the inhibition of adenyl cyclase activity thereby blocking Ca$^{2+}$ channels in the SR or cell membrane as well as activating K$^+$ channels and modulating rho-kinase pathways [199]. Acetylcholine-induced contraction is mediated by stimulation of M3 receptors and finally IP$_3$ release [200]. However, other signaling pathways are probably also involved in muscarinic stimulation of detrusor contraction. Contractions elicited by the muscarinic agonist bethanechol were abolished by inhibition of rho-activated kinase (ROK) in combination with a non-selective cation channel inhibitor [201]. Carbachol-induced contractions in human bladder SM are mediated by M3 receptors and largely dependent on Ca$^{2+}$ entry through nifedipine-sensitive channels and activation of the ROK pathway [202]. Thus, it has been proposed that the main intracellular pathways for detrusor activation by M3 receptors are Ca$^{2+}$ influx via L-type Ca$^{2+}$ channels and increased Ca$^{2+}$ sensitivity to the contractile machinery via phosphorylation of myosin light chain phosphatase (MLCP), thus maintaining myosin light chain (MLC20) in a phosphorylated state [203]. The latter is achieved by ROK-mediated phosphorylation and binding of a 17 kDa protein kinase C-potentiated myosin phosphatase inhibitor, CPI-17. The calcium sensitization pathway is described in more detail below.

b) Molecular mechanisms for activation of the contractile machinery.

Contraction of DSM is initiated by an increase of the free [Ca$^{2+}$] [204]. Free Ca$^{2+}$ bind to calmodulin (CaM) and the Ca$^{2+}$-CaM complex bind to calmodulin (CaM) and the Ca$^{2+}$-CaM complex activates myosin light chain kinase (MLCK) [205], which catalyzes phosphorylation of at serine-19 [206]. MLC20 phosphorylation is a prerequisite for actin-induced activation of myosin Mg ATPase activity of myosin [207,208] and the development of force [209,210]. During force maintenance, utilization of ATP is very low, and myosin cross-bridges cycle slowly, if at all [209,210] – the “latch” mechanism. In addition to MLCK, other kinases (PKC, ZIP kinase and integrin-linked kinase) can phosphorylate MLC20 under certain conditions [211].

c) Role of the Ca$^{2+}$-sensitization pathway in the regulation of the myosin-mediated pathway for smooth muscle contraction.

MLCP activity is also regulated by ROK, which in turn is activated by the small GTPase RhoA. ROK phosphorylates the regulatory subunit (MYPT1) of MLCP at Thr697 and Thr855 [212]. The phosphorylation activity of MLCP is decreased by this phosphorylation, thereby increasing the level of

![Figure 8: Schematic of signal transduction mechanism that activates the Ca$^{2+}$-sensitization pathway in smooth muscle. Cross-bridge cycling and force development in smooth muscle require phosphorylation of the myosin regulatory light chain (MLC20). The level of MLC20 phosphorylation is determined by MLCK and myosin phosphatase activities. At low Ca$^{2+}$ concentration, MLCK is not activated, but the myosin phosphatase is inactivated by Rho-kinase-mediated phosphorylation of the MYPT1 subunit of myosin phosphatase. The CPI-17, when phosphorylated by PKC, binds to myosin phosphatase and this also lowers the phosphatase activity. Thus, PKC signaling through CPI-17 phosphorylation and Rho-kinase-mediated phosphorylation of myosin phosphatase maintains the myosin in the phosphorylated form, which helps to maintain muscle tone at the basal Ca$^{2+}$ concentration.](image-url)
MLC20 phosphorylation. This causes the muscle to contract at low (basal) [Ca\textsuperscript{2+}] (Ca\textsuperscript{2+} sensitization). This mechanism plays an important role in maintaining and modulating normal tone of SM [212,213]. A second signalling pathway regulates calcium sensitization, particularly in tonic SM and involves CPI-17, which is phosphorylated at Thr38 by protein kinase C (PKC) [214,215]. The phosphorylated CPI-17 binds strongly to MLCP and inhibits the catalytic subunit of MLCP [216]. Cross-talk between these two mechanisms in the regulation of phosphatase activity has been proposed [217]. The Ca\textsuperscript{2+} sensitization mechanism is important for the retention of resting tone in viscous organs, including the bladder during filling. ROK expression is enhanced in DSM from obstructed bladders that are dysfunctional [218]. Furthermore, MLCP activity is decreased, and the maintenance of force by the detrusor of a decompenated bladder is inhibited by a ROK inhibitor. Thus, the RhoA/ROK cascade appears to regulate the force maintenance (tone) of DSM in a decompenated bladder.

d) The role of thin filament-mediated regulation of contraction.

Although myosin-mediated (via MLC20 phosphorylation) regulation is the major mechanism that activates myosin ATPase and generates force, there is sufficient evidence that a thin filament-mediated regulatory mechanism modulates the MLC20 phosphorylation-dependent regulation. One likely candidate is the thin filament-associated protein caldesmon (CaD).

The CaD molecule has two irregular domains in the C- and N-terminal regions and an elongated central space region that consists of a highly charged repeat sequence of 150 amino acids. The isoform I-CaD lacks this space region. The C-terminal region is rich in aromatic amino acids, whereas the N-terminal and central regions contain relatively high proportions of acidic amino acids [219]. SM CaD is elongated (75 nm in length) and interactions between CaD and Tm when both are bound to actin filaments induce changes in Tm [220], although it is not known if these conformational changes are caused by direct contact between CaD and Tm or are indirectly mediated through actin. If a labelled antibody specific for CaD is incubated with SM, it binds along the actin filaments in register with Tm, as labelling is repeated every 40 nm along a thin filament. This indicates that the CaD molecules bound to each actin strand are staggered by the length of one tropomyosin molecule [220-221]. There is general agreement that actin-activated ATP hydrolysis mediated by myosin is inhibited by CaD [222-224]. Tm enhances CaD-induced inhibition of actin-activated ATP hydrolysis [222] and CaD inhibits the cooperative induction of SM heavy meromyosin by tropomyosin and actin [194,222,225]. CaD tethers myosin to actin by through binding of the N-terminal region of CaD to the S-2 region of myosin and the CaD C-terminal region to actin. This is thought to be important for the stability of SM myosin filaments in the presence Mg\textsuperscript{2+}-ATP and has been suggested as a plausible mechanism for force maintenance [226-227].

The “tethering” of CaD to actin decreases the in vitro motility of actin filaments and requires both the myosin-binding and the actin-binding domains of CaD [228]. When myosin is fully phosphorylated tethering is negligible, i.e. when actin-activated ATPase activity is high as in force generation when cytosolic Ca\textsuperscript{2+} is also raised. Thus, “tethering” is believed to play a role in maintaining muscle tone with very low ATP hydrolysis, useful for force maintenance in tonic muscle, e.g. aorta and sphincter muscles. The biochemical basis of basal SM tone and force maintenance (the “latch” phenomenon) is not understood but may involve some variation in Ca\textsuperscript{2+}-dependent phosphorylation in which force is maintained at very low levels of ATP utilization and slow myosin cross-bridge cycling. Thus, the thin filament-associated protein CaD is thought to play a role in the maintenance of force at low levels of phosphorylation and cross-bridge cycling. The phosphorylation of CaD itself might also be important as a regulatory mechanism, although evidence is weak. Nonetheless, CaD phosphorylation, catalysed by extracellular signal-regulated kinase (ERK), is involved in non-muscle cell migration [229]. Other data supporting a role for CaD in the regulation of contraction has come from studies of conformational changes induced by CaD on the actin filaments in “ghost fibres,” which contain actin filaments in their native organization but lack all other muscle proteins [230]. The binding of CaD to actin filaments changes the conformation of actin to the weak-binding (“off”) state and prevents the transition of actin filaments in muscle fibres to the strong-binding (“on”) state, which occurs when myosin heads bind to actin. Indeed binding of actin and CaD leads to a change in the conformation of actin filaments from the “on” to the “off” state [195]. The removal of CaD from chemically “skinned” SM increases the Ca\textsuperscript{2+} sensitivity of force development, and the addition of the C-terminal fragment of CaD to a skinned fibre inhibits contraction, indicating that CaD suppresses the force [231]. The use of antisense oligodeoxynucleotides designed to bind CaD mRNA decreased CaD expression and increased basal cross-bridge cycling rates [232].

e) Smooth muscle relaxation.

During urine storage, the bladder outlet is closed and DSM is relaxed and the increase of intravesical pressure is small over a wide range of bladder volumes. During voiding, DSM contracts, and the smooth and skeletal muscles in the urethra and internal sphincter relax, which raises the intravesical pressure. This is followed by relaxation of DSM due to either removal of the contractile stimulus or the direct effect of a substance that stimulates inhibition of the contractile mechanism.
(e.g. β-adrenergic stimulation). Regardless of the relaxation mechanism, there is a decrease of the intracellular \([\text{Ca}^{2+}]\) which leads to a subsequent decrease in MLC activity and increase in MLCP activity (Figure 8) [233]. The removal of cytosolic \(\text{Ca}^{2+}\) involves the sarcoplasmic reticulum (SR) and plasma membrane ATPases and a membrane Na\(^+-\text{Ca}^{2+}\) exchanger. There are several pharmacological agents that disrupt the Mg\(^{2+}\)-dependent SR Ca\(^{2+}\)-ATPase (SERCA), such as vanadate ions and thapsigargin [234]. The SR also plays important roles in buffering \(\text{Ca}^{2+}\) influx and the phasic component of DSM contraction [235]. Phosphorylation of phospholamban by multifunctional \(\text{Ca}^{2+}/\text{CaM}\)-stimulated protein kinase (CaMK II) activates SERCA, increasing both the \(\text{Ca}^{2+}\) clearance from the myoplasm and the frequency of localized \(\text{Ca}^{2+}\) release from intracellular stores [236]. SR function changes during bladder development and in bladder hypertrophy and hence will modify the magnitude and duration of the contraction [237,238].

The intracellular \([\text{Ca}^{2+}]\) is also controlled by a plasma membrane Ca\(_{\text{Mg}}\)-ATPase (PMCA) [239]. This enzyme is regulated by phosphorylation through a membrane-bound CaM kinase, which stimulates \(\text{Ca}^{2+}\) sequestration and muscle relaxation [240]. In addition, the plasma membrane contains a Na\(^+-\text{Ca}^{2+}\) exchanger (NCX), which decreases intracellular \(\text{Ca}^{2+}\). These low-affinity antiporters are closely coupled to intracellular \(\text{Ca}^{2+}\) levels and play a role in the regulation of DSM \([\text{Ca}^{2+}]\) [241]. Further evidence for a role of NCX in regulating intracellular \([\text{Ca}^{2+}]\) in DSM comes from transgenic mice over-expressed with the exchanger when contractions elicited by a number of processes were reduced compared to DSM from control bladders [242].

f) Alterations to contractile and regulatory proteins in lower urinary tract dysfunction.

The precise molecular mechanisms underlying the pathophysiology of the bladder dysfunction associated with bladder outflow obstruction (BOO) is not understood. However, outlet obstruction induces molecular, cellular and structural alterations in the SM cells in the bladder wall, leading to an impaired ability of the bladder to store and empty urine. Although the initial events that lead to detrusor SM remodeling are not understood, evidence from recent studies clearly shows that BOO induces molecular events that cause bladder wall SM to undergo hypertrophy, a compensatory response to increase detrusor pressure and maintain flow in the face of increased outflow resistance [243]. Despite detrusor hypertrophy, some obstructed bladders continue to remain dysfunctional (decompensated bladders) and show increased frequency of voiding, low void volume, and decreased intravesical (micturition) pressure [244]. The DSM from decompensated bladders over-express the non-muscle isoform of caldesmon [191,245]. The role that the overabundance of l-CaD in DSM cells has in contractile dysfunction of a decompensated bladder is unknown. However, the reversal of outlet obstruction and the regression of hypertrophy lead to decreased l-CaD expression and the return of bladder function to a near-normal state. Downregulation of CaD has been shown to affect the cytoskeletal structure of cultured cells [246].

In addition to the changes in thin filament-associated proteins, studies from several laboratories [18,108] have demonstrated that overexpression of the C-terminal myosin isoform SM1 is associated with the detrusor hypertrophy induced by BOO [175,247]. In a rabbit model of BOO, although DSM from normal bladders expressed the SM myosin heavy chain isoform SM-B and LC17a almost exclusively, detrusor muscle from severely dysfunctional bladders expressed as much as 75% SM-A and 40% LC17b (both are associated with a decreased maximum velocity of shortening) [167].

DSM from dysfunctional bladders also exhibited tonic-type contractions, characterized by slow force generation and high force maintenance. Immuno-fluorescence microscopy showed that the decreased SM-B expression found in dysfunctional bladders was not due to the generation of a new cell population that lacked SM-B. Metabolic cage monitoring revealed that decreased void volume and increased voiding frequency were correlated with overexpression of SM-A and LC17b [167]. The upregulation of the low ATPase-activity myosin isoform in the remodelled DSM caused the detrusor to develop force slowly but with low utilization of ATP and a more economical generation of force. Myosin isoform expression and bladder function returned close to normal upon removal of the obstruction, indicating that the level of expression of these isoforms is a marker of BOO-induced bladder dysfunction.

4. SPONTANEOUS ACTIVITY

Spontaneous contractions are observed in whole bladders, bladder strips and isolated detrusor myocytes [62,248,249] from animal models and man, Figure 9A. Such spontaneous activity is, however, not common to all strips [249,250] or all areas of the bladder [251] at any given time. Likewise, only a proportion of smooth muscle cells sampled by intracellular recording exhibit spontaneous action potentials [252] and the basis of such heterogeneity is yet to be established. The function of spontaneous contractions is likely to be in maintaining bladder tone during filling and enabling rapid elevation in intravesical pressure when micturition is required [250]. Pathologies such as OAB and BOO are characterised by increased spontaneous activity and fused tetanic contractions [250,253,254], making its study pertinent.

a) The origin of spontaneous activity

Spontaneous contractions in physiology and pathophysiology are resistant to TTX, atropine and α,β-methylene ATP suggesting they are not due to acti-
Figure 9. Spontaneous activity contractile activity. A: Spontaneous contractile activity from isolated strips of human detrusor smooth muscle from a patient with OAB (upper trace) and a stable bladder (lower trace). B: Spontaneous contractile activity from isolated strips of human detrusor smooth muscle with the mucosa intact (upper trace) and with the mucosa removed (lower trace).

vation of parasympathetic fibres [249,250]. Activity is, however, abolished by agents that limit transmembrane Ca²⁺ influx, such as L-type Ca²⁺-channel blockers, and by a reduction of extracellular Ca²⁺ [255], suggesting an origin within the bladder itself. Several hypotheses have been put forward to account for the origins of spontaneous activity but those most often described – the myogenic hypothesis [250] and neurogenic hypothesis [256] – concern origins in pathology, not physiology. This review will give a brief overview of these hypotheses but will aim to focus mainly on hypotheses bridging physiology and pathophysiology.

Prostanoids. In the rabbit, at least, spontaneous contractions are likely to result from prostanoids binding to EP receptors on detrusor smooth muscle. Spontaneous contractions can be abolished by inhibiting the production of prostaglandins (PGs) through non-selective or receptor-specific antagonism. Likewise, spontaneous contraction amplitude is increased by PGs or their mimics [257,258]. The origin of the PGs that cause spontaneous contractility is yet to be established as detrusor smooth muscle [45] and the urothelium [259] can produce PGs; and ICs show cyclo-oxygenase (COX) immunoreactivity [18,257]. Given an up-regulation of COX1 and COX2 expression and PG synthesis in disease states such as BOO and chronic ischemic bladder, [260-262], the possibility of NSAID treatment seems attractive. The few published studies are, however, equivocal in their findings [263-265]. Further studies are required to describe the role of PGs in the spontaneous contractions of human detrusor.

Nitric oxide. Nitric oxide (NO), derived from neuronal nitric oxide synthase (nNOS), contributes to spontaneous activity in mice [266] and guinea-pig [267]. The frequency of spontaneous action potentials was lower in nNOS⁻/⁻ mice than their wild-type (nNOS⁺/+⁴) siblings and their frequency could be restored by the addition of the NO donor, NONOate [266]. As with the role of PGs underlying spontaneous activity in rabbit detrusor, it remains to be established what role NO plays in other species. Furthermore, it is yet to be established whether the role of NO is up- or down-regulated in pathology.

Acetylcholine. In rat and guinea-pig there is a spontaneous TTX-resistant release of acetylcholine (ACh) from autonomic nerves which at least partly underlies bladder spontaneous contractions [268]. It is not known, however, whether such spontaneous release of ACh occurs and contributes to spontaneous contractions in man; an inhibition of ACh breakdown, resulting in increased resting tone and inducing spontaneous contractions was only observed in OAB patients – not in asymptomatic patients [269], implying the origins of spontaneous contractions in man may differ between physiology and pathophysiology.

Unknown agent(s) released by the mucosa. In many species, spontaneous activity is increased if the mucosa (comprising urothelium and suburothelium/interstitium/propria lamina) is left intact, Figure 9B.

Optical imaging experiments of bladder cross-sections show that spontaneous activity often arises in the suburothelium and spreads to the detrusor layer [151]. Using bladder sheets with the urothelial surface uppermost, optical imaging measurements show propagating Ca²⁺ waves over the sheets, but only in those sections where the mucosa had not been removed [65]. This aspect of spontaneous activity was considered above in more detail (section 3.3.3) but overall it consistent with the hypothesis that spontaneous activity can originate in the suburothelial layer of interstitial cells and then propagate to the detrusor where spontaneous contractions are generated. The increase of suburothelial interstitial cells in overactive bladders is consistent with their greater incidence of spontaneous activity.

b) The myogenic hypothesis

Central to the theory of a myogenic basis for OAB is: denervation and/or reduction of parasympathetic activation causing an increase in smooth muscle cell excitability and coupling [250]. There is evidence for increased smooth muscle cell excitability in isolated cells from overactive bladder samples [62]. The origin of this activity may reside in altered Ca²⁺ channel populations. Both L-type and T-type Ca²⁺ current can be recorded from detrusor muscle. However, the proportion of T-type current is increased in cells from overactive bladders [270], as T-type channels are opened at more negative membrane potentials, an increase in density would increase spontaneous electrical activity [271]. Evidence for increased coupling is compelling in animal models of disease; with consistent increases
in the gap junction proteins connexin43 [66,272-276] and connexin26 [152,272] associated with BOO and spinal cord injury. By contrast, evidence from human tissue is equivocal for connexin45 [e.g. 14,277] and connexin43 [14,278].

c) The neurogenic hypothesis

The neurogenic hypothesis [256] concerns how damage to the neural circuits in the brain and spinal cord that regulate storage and periodical voiding might result in OAB through: a reduction in the suppression or enhancement of the parasympathetic excitatory outflow; sensitisation of peripheral afferent terminals; emergence of bladder reflexes that are resistant to central inhibition. This aspect will be considered in the report of Committee 3.

5. ELECTRICAL ACTIVITY AND ION CHANNELS

How the electrical activity of detrusor smooth muscle is regulated by the movement of ions, and how receptor modulators affect excitability is the subject of the previous consultation [196] and other reviews [279-281]. The focus shall therefore be on channels that influence spontaneous activity and therapeutics; other channels, such as TRP and ligand-gated channels are included in Section 6.4.

K+ channels. Detrusor myocytes possess several types of K+ channel, including large (BK) and small (SK) Ca2+-activated channels as well as voltage-sensitive K+ (Kv) and ATP-sensitive (KATP) channels. The spontaneous contractility of human detrusor strips is dependent on both BK and SK channels, as blockade increases activity [282,283]. Openers of Ca2+-activated K+ channels (e.g. NS-9541) reduce spontaneous contractility in tissue from asymptomatic patients [284], making them potential candidates for the treatment of pathologies in which spontaneous contractility is elevated, such as OAB. But there is a reduced role for BK channels in contributing to spontaneous contractions in NDO patients; whilst a BK opener (NS-1619) reduced spontaneous contractions and a BK antagonist (iberiotoxin) increased activity in control patients, neither agent had an effect in strips from NDO patients. BK channels were unaffected in NDO patients, as apoptosis increased spontaneous contracture, in both groups [285]. Clearly there is a great need for experiments on pathological human tissue; animal studies are poor models in this case [286,287]. KATP openers offer some promise as pinacidil and ZD0947, for example, relax carbachol-contracted human detrusor [288]. KNCQ (Kv7) channels contribute to the resting membrane potential and excitability of several cell types and mutations in genes encoding for the channel have been implicated in contributing to abnormal activity in several tissues [289]. Their recent identification in detrusor interstitial cells [290] implies they may contribute a similar role. The KNCQ channel opener retigabine increased micturition volume and voiding intervals and reduced overactive bladder behaviour from capsaicin installation when the agents was infused into the bladder [291]. Recent understanding of many of the functions regulated by K+ channels has been recently summarised [292].

Isolated detrusor myocytes display an ability to generate spontaneous action potentials, especially in cells isolated from overactive bladders [62]. The more frequent spontaneous activity is associated with an increase of T-type Ca2+ channel activity, which is activated at more negative membrane potentials [270,293]. Ca2+ influx through T-type channels has been proposed to have a dual role: to contribute to action potential generation and also to stabilise the resting membrane potential through its close association with SK channels [294]. Mibebradil is a Ca-antagonist with a more selective action on T-type Ca2+ channels than other antagonists and one suggested use has been for the management of atrial fibrillation [295]. However, its ability to reduce contractions elicited by electrical field stimulation and high-KCl solutions was less than that achieved by more selective L-type Ca2+ channel antagonists [296,297]. It would be of interest to characterise the action of this agent on tissue from overactive bladders.

Cl- are not at thermodynamic equilibrium across the cell membrane of most smooth muscles [298] and thus opening a Cl- selective channel will result in membrane depolarisation. The role of Ca2+-activated K+ currents in the regulation of normal and overactive detrusor function has been well-reviewed (section 6.4, 196). The contribution of Ca2+-activated Cl- channels is less clear but has been identified in both detrusor and urethral smooth muscle [299,300]. The expression of Ca2+-activated Cl- channels is increased in tissue from overactive bladders and hence may contribute to transient inward currents and an increase of cell excitability [299,301]. Ca2+-activated Cl- current is blocked by agents such as niflumic acid and DIDS [302], but the true contribution of the current to spontaneous activity, especially in the overactive bladder, remains to be evaluated.

V. THE OUTFLOW TRACT

1. TRIGONE

The trigone consists of the triangular region between the ureteral orifices and the bladder outlet that aids bladder emptying and helps prevents ureteral reflux. Along with the bladder neck, it forms the base of the bladder that provides support for the bladder dome and transition to the urethra. The trigone contracts during bladder filling to help keep the ureteral orifices open and the bladder neck closed, and relaxes during micturition to help funnel urine into the outlet and prevent ureteric reflux [303]. The tone of the trigone muscle is predominately under adrenergic control [304] and as such this regions exhibits higher frequency spontaneous activity in comparison to detrusor smooth muscle [249]. This is believed to be mediated by L-type Ca2+ currents and Ca2+-activated Cl- fluxes, the propagation and
coordination of which is mediated by gap junction coupling [303]. It has been suggested that trigone spontaneous activity is initiated by peristaltic waves originating in the ureters but this has not yet been experimentally confirmed. The trigone is also heavily innervated and is the region where the majority of the fibres from the pelvic and hypogastric nerves enter the bladder wall [305,306]. This has made the trigone a target for the treatment of detrusor overactivity using botulinum neurotoxin type A (BoNT/A), as it is believed that it will be more effective due to the greater nerve density [307]. Figure 10 shows a diagram of the male lower urinary tract, i.e. with the additional presence of the prostate gland.

**a) Developmental origins of the trigone and insertion of the vesicoureteral junctions**

Trigone smooth muscle was originally believed to be formed from the mesodermal tissue of the ureters that project into the developing bladder, while the urothelium is formed from endodermal tissue [308]. Recent evidence, however, suggests that the trigone is mostly derived from bladder smooth muscle and that there are very few projections from the ureters [309].

The ‘ureteric bud theory’ of Mackie and Stephens suggests that the trigone develops from the ureters and the common mesonephric (Wolffian) ducts, independent of any contribution from the bladder [310,311]. This is reported to occur when the independently developing upper and lower urinary tracts connect at mid-gestation, when the ureters migrate from their initiation sites in the Wolffian ducts to form the trigone. The mechanism responsible for the precise location and angle of insertion of the ureters in the trigone is poorly understood but crucial for the proper functioning of the ureteric valves in preventing urine reflux and renal obstruction. Thus, this theory implies a common mesodermal origin for the trigone and ureterovesical junctions but it has not been tested experimentally [312-314].

An alternative ‘smooth muscle theory’ for the development of the trigone is based on recent studies utilizing cre-lox mice with fluorescently labelled epithelial cells in the ureters and Wolffian ducts. These studies confirmed the insertion of the common me-

Also shown is the prostate, its different regions, as well as the striated external urethral sphincter.*
sonephric ducts in the bladder wall. However, they also suggested that after insertion this tissue undergoes apoptosis and regresses and that the growth of the bladder smooth muscle moves the ureteral orifices to their final positions in the trigone [309,315]. This implies that the trigone is formed mostly from bladder smooth muscle with only a minor contribution from the ureters [308,309,316-318]. However, a role for both theories is suggested by findings from a recent transgenic mouse model with a primary defect in bladder smooth muscle differentiation that develops a megabladder and obstructive uropathy [319,320]. Although these mice completely lack detrusor smooth muscle they still develop a trigone, however the ureteric orifices insert incorrectly.

b) Superficial and deep trigone.

Superficial and deep trigone layers have been distinguished based on histological studies [321,322] where the former appears to function separately from the detrusor [323] but the origins of the different layers remain controversial. It has been suggested that the deep trigone is derived from the detrusor and the superficial layer from the ureters [324]. Recent studies, using optical mapping and mouse bladder sheets stained with a voltage-sensitive dye have demonstrated that the superficial trigone is electrically discrete from the underlying detrusor. Focal electrical stimulation of the superficial trigone in bladders from control mice resulted in membrane depolarization that did not spread beyond this region (figure 11A,B). However, in bladders from mice two weeks following T8-T9 spinal cord transection, stimulation of the superficial trigone initiated activity that spread to the detrusor (figure 11C). This enhanced spread of activity was reduced following desensitization of TRPV1 containing afferent nerves using capsaicin (figure 11D,E), suggesting that this is mediated by the morphological expansion of sensory nerves from the superficial trigone to the detrusor (i.e., sprouting). This enhanced afferent activity may be responsible, in part, for the neurogenic detrusor overactivity that occurs following thoracic level spinal cord injury and may help explain the therapeutic benefit of focal trigone injections of BoNT/A [307]. Note that capsaicin at 1 μM was able to activate transiently contractile activity before the preparation became desensitized (figure 11F).

2. THE URETHRA AND SPHINCTER MECHANISMS

a) Bladder-urethral coordination

There is neural regulation between the bladder and the outflow tract that facilitates the coordinated relaxation of the urethral sphincters and contraction of the detrusor smooth muscle. This allows for complete emptying of the bladder during micturition with a minimal increase in intravesical pressure.

The bladder base is a region of dual sympathetic-adrenergic and parasympathetic-muscarinic innervation [199,325] similar to that of the urethra. There is a higher expression of α1-adenoreceptors in the trigone and the bladder neck in comparison to the detrusor [199] with muscarinic receptor expression found predominantly in the superficial trigone [325,326]. Animal studies have shown that adrenergic stimulation via sympathetic nerves is active during the storage phase and induces contraction of the bladder base. Together with similar actions in the urethra it results in closure of the bladder base preventing incontinence [327]. Thus, the bladder neck

Figure 11. Optical mapping of membrane potential activity after electrical stimulation of the trigone: bladder-urethral sheets from control mice and mice with an upper spinal cord injury (SCI). A: Image of a preparation in the recording chamber to measure simultaneously tension and electrical activity. B: Electrical stimulation in control bladders resulted in a limited propagation of membrane activity within the region. C: Similar stimulation of bladders from mice with SCI – there is enhanced spread of activity beyond the trigone. D: desensitization of TRPV1 receptors with capsaicin (1 μM) reduced the spread of activity in normal bladders. E: desensitization with capsaicin (1 μM) in an SCI preparation also reduced the spread of activity in the preparation. F: Tension recordings demonstrating decreased force generation by the trigone following desensitization with capsaicin.
may represent a transitional region with functional characteristics of both the urethra and the bladder. In addition, parasympathetic innervation may act synergistically with sympathetic nerves as simultaneous activation of both systems produce a gain of function not seen if the two are activated independently [325]. This synergism may contribute to the prevention of reflux and increase in outflow closing pressure, and may explain the particular effectiveness of combination therapies utilizing both antimuscarinic and α1-adrenergic receptor antagonists.

Recent findings suggest that there is also intrinsic coordination between the bladder and the urethra mediated through intramural ganglia. Using optical mapping of bladder-urethral sheets propagation of action potentials were recorded in control and spinal cord injured mouse bladders (figure 12). In bladders from control and thoracic level injured animals (upper motoneurone lesion, UMN), focal electrical stimulation of the bladder dome caused signals to spread into the urethra (figure 12A,C). This spread was inhibited in the presence of a hexamethonium; a ganglion blocker (figure 12B,D). In bladders of mice with a lumbar-sacral level lesion (lower motoneurone lesion, LMN), signals were limited to the bladder (figure 12E,F). These finding suggest that pre-ganglionic parasympathetic nerves may innervate both bladder and urethral intramural ganglia to facilitate coordinated activation of the two structures (figure 13).

**b) The internal sphincter**

The presence of a single sphincter at the bladder base and proximal part of the urethra is a contentious subject. Several tissues of this region combine to generate a region that controls the flow of urine from the bladder and is often called the internal urethral sphincter. Because of the complex form and function of this region and the fact that an effective sphincter function is not due entirely to contraction of urethral smooth muscle, this mechanism will be termed ‘the internal sphincter’. By contrast, the incomplete ring of skeletal muscle that surrounds the more distal urethra forms a more recognisable sphincter mechanism, and will be described as an external urethral sphincter (section 5.2.3).

Urinary continence is maintained through the tonic contraction of the internal sphincter, which is further supported by the voluntarily controlled striated external urethral sphincter (EUS). The internal sphincter has two distinct longitudinal and circular muscular layers, a lamina propria and an epithelial lining (figure 14). During the storage phase, the circular smooth muscle contracts to maintain a high fluid resistance in this region and the longitudinal smooth muscle relaxes to facilitate closure. This occurs through the release of noradrenaline from sympathetic terminals and activation of α1-adrenoceptors on the circular muscle and β3-adrenergic receptors on the longitudinal fibres. Alternatively, during the emptying phase, the circular fibres relax and the longitudinal ones contract to lower fluid resistance and facilitate voiding [328]. This is believed to occur in response to nitric oxide and acetylcholine released from parasympathetic nerve terminals that activate guanylyl cyclase [329] and stimulate M2/3 cholinergic receptors, respectively [330]. Urethral smooth muscle cells from both layers also display intrinsic contractile activity that promotes urethral tone [328] and this is contributed by similar activity in smooth muscle cells of the bladder base. Mucus secreted from goblet cells on the luminal surface is believed to facilitate the passage of urine. Urethral closure may

---

**Figure 12.** Optical mapping of bladder-urethra sheets from control, upper motor neuron (UMN; T8-T9) and lower motor neuron (LMN; L4-L5) lesioned mice. Electrical activity maps show that in both control (part A) and UMN lesioned (part C) mice electrical stimulation of the dome resulted in activity that spread throughout the bladder and into the urethra. In LMN lesioned mice, there was disco-ordination, as electrical stimulation of the bladder evoked activity that did not spread into the urethra (part E). Hexamethonium inhibited propagation of signals from the bladder into the urethra in control (part B) and UMN lesioned (part D) mice, the blocker did not alter the signals from LMN-lesioned bladders (part F). These data suggest that bladder urethral coordination is mediated through intramural ganglia.
Figure 13. Hypothesis for the involvement of intramural ganglia in bladder-urethra coordination. Focally evoked electrical activity (O) spreads from the bladder to the urethra via intramural post-ganglionic parasympathetic axons (right side). Following a lower motor neuron (LMN) lesion, pre-ganglionic fibres degenerate (left side) resulting in disruption of coordination. Alternatively, coordination could be disrupted via chemical denervation using the ganglion blocker, hexamethonium.

Figure 14: Innervation of the internal sphincter. The circular and longitudinal smooth muscle layers are innervated by sympathetic, parasympathetic and nitricergic nerves. During the storage phase, sympathetic activity relaxes the longitudinal and contracts the circular muscles to close the urethra and maintain continence. During micturition, parasympathetic and nitricergic activity relaxes the circular and contracts the longitudinal muscles to open the urethra and promote voiding. NAd, noradrenaline; Ach, acetylcholine; GC, guanylyl cyclase.
be enhanced by the well-vascularized mucosa and submucosa that reduce the open space in the lumen.

Interstitial cells have been identified in the smooth muscle layers of the proximal urethra and show physiological characteristics similar to interstitial cells of Cajal found in the intestine [331-333]. It has been suggested that these cells may communicate with the smooth muscle cells to promote intrinsic contractile activity. However, this mechanism has not been elucidated and urethral smooth muscle appears to maintain intrinsic activity in the absence of interstitial cells [334]. Another cell type that may modulate contractility of smooth muscle in the internal sphincter is neuroendocrine cells or paraneurons. These are found on the luminal surface of the urethra scattered between epithelial cells. Neuroendocrine cells have microvilli that project into the lumen that can sense mechanical or chemical changes [335]. Urethral neuroendocrine cells also express transmitters such as chromogranin A, somatostatin and serotonin, which may be released in response to stimuli to regulate urethral tone [336].

c) External urethral sphincter (EUS)

The EUS or rhabdosphincter consists of striated muscle innervated by motoneurons through the pudendal nerves. The EUS facilitates voluntary regulation of micturition by maintaining outlet pressure during the storage phase and coordinating its relaxation with detrusor contraction for efficient voiding [337]. Prior to bladder contraction and EUS relaxation, there is a gradual rise of sphincter tone, as measured by electromyographic activity, referred to as the guarding reflex.

The EUS in both males and females forms a horseshoe shape surrounding the urethra. It covers the dorsal, lateral and a majority of the anterior urethra. In males the EUS surrounds a greater portion of the urethra; in females the uterus prevents further coverage of the urethra during development [338]. The less complete coverage in the female EUS may be a contributing factor to the higher incidence of stress urinary incontinence in women. In addition, women are more likely to experience damage to the EUS as a result of vaginal delivery. However, stress urinary incontinence also occurs frequently in men, where damage can result from radical prostatectomy, age-related degeneration of EUS muscle or neurodegenerative conditions. Sex hormones may also play a role in regulation of EUS function. Urinary dysfunction occurs more frequently in postmenopausal women and there has been evidence to suggest that decreased oestrogen levels can affect EUS function [339]. Fowler’s syndrome, an obstructive condition in women that occurs as a result of overactive urethral sphincters, is also believed to be influenced by hormones [340].

d) Consequences of EUS dysfunction and treatments

Disruption of neural regulation of the lower urinary tract can lead to severe impairment of EUS function. Thoracic level spinal cord injury can cause bladder-sphincter dyssynergia; a discoordination between contraction of the bladder and relaxation of the urethral sphincters during micturition. This can lead to further complications such as vesicoureteral reflux, hydronephrosis and potentially renal failure. There are a number of treatments for EUS dysfunction including, catheterization, BoNT/A injections, sacral neuromodulation, or in the most severe cases external sphincterotomy [341-343]. In the case of EUS damage (e.g., due to child birth or radical prostatectomy) a current treatment under investigation is the use of bone marrow derived mesenchymal stem cells to promote regeneration of the striated muscle. Several studies have indicated that this treatment improves sphincter function in rat models of stress urinary incontinence [344,345] and in clinical trials using autologous stem cell [346,347].

3. PROSTATE

a) Prostatic lobes and their cellular components

The human prostate consists of four lobes (figures 10 and 15). The anatomy varies between different species, and in particular between the human gland and that of small laboratory animals (Figure 15). The anterior lobe is mostly smooth muscle and constitutes approximately 10% of the prostate. The peripheral lobe, which is the site of most cancers, is mostly glandular cells and makes up about 60% of the organ. The central lobe is also mostly glandular cells and accounts for another 25% of the gland. The transitional lobe, which surrounds the urethra and is the site where benign prostatic hyperplasia (BPH) develops, constitutes the remaining 5% of the prostate.

The mammalian prostate is a fibromuscular (anterior lobe) and glandular (peripheral, central and transitional lobes) organ where the glandular lobes are composed of prostatic ducts that include an epithelial layer of basal, columnar secretory and neuroendocrine APUD (Amine Precursor Uptake and Decarboxylase) cells, and an underlying stromal layer made up of fibroblasts and smooth muscle, bound to one another by an extracellular matrix [348,349]. Together with the seminal vesicles and the bulbourethral (Cowper’s) gland it produces the bulk of the seminal fluid or ejaculate that is released during emission. Its secretions include acid phosphatase, citric acid, fructose, prostaglandins, proteolytic enzymes and zinc [348,350,351]. These factors provide nutrients and enhance sperm motility, viability and transport as they traverse the male and female reproductive tracts optimizing conditions for fertilization [352]. Emission results when the stromal smooth muscle contracts to propel these secretions from storage in the acini into the seminal fluid and the prostatic urethra to become part of the ejaculate.
b) Prostatic innervation and its role in seminal fluid secretion and emission

The growth, development and regulation of the mammalian prostate are under endocrine (androgen) and autonomic control and is densely innervated by hypogastric (sympathetic) and pelvic (parasympathetic) nerves. The distribution of nerves and pre- and post-synaptic receptor expression suggest that seminal fluid secretion is under cholinergic control with acetylcholine acting on postsynaptic M1-muscarinic receptors on the epithelium (figure 16). Emission is mediated by adrenergic control with noradrenaline stimulating postsynaptic α1-adrenergic receptors on stromal smooth muscle cells. Noradrenaline is also believed to contract the prostatic capsule [353]. β-adrenergic receptors on smooth muscle and epithelial cells are believed to be involved in stromal relaxation and epithelial protein synthesis, respectively. Presynaptic M1-muscarinic receptors on adrenergic terminals in the stroma suggest that acetylcholine may play a role in smooth muscle contractility [354]. Moreover, the co-localization of ATP [355], excitatory neuropeptides (e.g., vasoactive intestinal peptide, neuropeptide Y) [356-360] and nitric oxide [358] in cholinergic terminals also suggest that these transmitters play a role in prostate secretion and emission (figure 16). After castration, there is a marked loss of epithelial cells and atrophy that can be restored by exogenous administration of androgens demonstrating their importance in prostate growth and development [361]. This is the basis for the use of anti-androgenic 5α-reductase inhibitors (5ARIs) to shrink the prostate in patients with BPH [362].

Animal studies suggest that prostatic secretion is mediated mainly through parasympathetic nerves [306,363-365], but this has not been verified in humans. Dense cholinergic innervation has been demonstrated in both the prostate epithelium and stroma with M1-muscarinic receptor density exceeding that of α1-adrenergic receptors. However, these receptors are localized mainly to the epithelium and cholinergic agonists evoke only a small contractile response in the prostate [366], which may be mediated by activation of presynaptic M1-muscarinic receptors on sympathetic nerve terminals (figure 16).

Emission occurs when the testis/epididymis form and release sperm (~5% of the semen) into the vas deferens which contract peristaltically to propel the sperm into the ejaculatory duct. The seminal vesicles also release seminal vesicle fluid (~60% of the semen) into this duct, which passes through the prostate gland to enter the urethra at the seminal colliculus or verumontanum. The bulbourethral or Cowper’s gland also adds fluid (~5% of the semen) just below the prostate. Ejaculation, on the other hand, is driven by the somatic system and involves the rhythmic contractions of the periurethral striated muscle. The pre-prostatic urethral sphincter contracts during ejaculation to keep semen from entering the bladder. This is under adrenergic sympathetic control and the therapeutic use of α1-adrenergic receptor antagonists to treat BPH can allow semen to enter the bladder resulting in ‘retrograde’ ejaculations.

---

c) Benign prostatic hyperplasia (BPH), prostatitis and therapeutic approaches

As the prostate anatomically surrounds the urethra, inflammation and hyperplasia can lead to irritative and obstructive lower urinary tract symptoms. Although surgery is the gold-standard for alleviating these symptoms, there is considerable interest in three classes of drugs: α1-adrenergic receptor antagonists which reduce stromal smooth muscle tone by antagonizing the action of noradrenaline [367,368]; 5ARIs which are anti-androgenic and reduce the mass of the prostate [369]; and BoNT/A which inhibits neurotransmitter release at sympathetic, parasympathetic and sensory nerve terminals [370].

The prostate is the only accessory genital organ that often undergoes abnormal growth during later life. At puberty, the human prostate gland increases in weight from about 5 to 20 grams but sustains growth throughout life, which may contribute to its benign and malignant pathologies. BPH afflicts approximately 50% of men by their 5th decade and 95% of men by their 8th decade. African-American males develop BPH earlier in life than Caucasian men, often in their 4th decade, and Asian-Americans are less likely to develop it. While not known to be linked to BPH, prostate cancer develops in approximately 16% men during their lifetime with nearly 3% succumbing to the disease. As such, it is the second leading cause of cancer deaths in males in the United States next to lung carcinoma [371].

BPH is readily treated by excision or drug therapy. However, many men die with undiagnosed BPH and may have become impotent, experienced decreased sexual drive and developed urinary incontinence needlessly. The most common therapy is transurethral resection of the prostate (TURP). While TURP has long been the "gold standard" for the surgical treatment of BPH, intra-operative and postoperative side effects have led to the emergence of new surgical and pharmacological therapies. The complications of this therapy include excessive bleeding, urinary sepsis, transurethral resection syndrome and the development of long-term effects such as incontinence, urethral strictures, bladder neck contractures, and sexual dysfunction (retrograde ejaculation and erectile dysfunction). There are several different methods that are reported to be less invasive treatments for BPH, including transurethral laser ablation, transurethral microwave therapy (TUMT) [372], transurethral needle ablation, high intensity focused ultrasound, transurethral needle ablation and trans-rectal high intensity focused ultrasound. They are useful in certain groups of patients, but the evidence to justify the replacement of TURP is still insufficient [373].

Current guidelines recommend α-adrenoreceptor antagonists, to "relax" the prostate by reducing smooth muscle tone, and anti-androgenic 5ARIs, to reduce prostatic volume, either alone or in combination [374] as the preferred pharmacological treatments for BPH. However, these therapies can cause adverse sexual effects: α-blockers are associated with retrograde ejaculation and 5ARIs can cause reduced libido, erectile dysfunction and ejaculatory disorders. Prostatic injections of BoNT/A have also been proposed as a minimally invasive treatment for BPH and this approach is currently undergoing phase 2 clinical trials [375]. Preclinical animal studies have proposed several mechanisms of action for BoNT/A, with evidence of significant glandular apoptosis and pros-
tatic atrophy. It also may induce relaxation of smooth muscle tone through a reduction in the release of noradrenaline and stimulation of α1-adrenergic receptors, and decrease gland size by inhibiting the trophic effect of the autonomic nervous system. Other possible treatments include: phosphodiesterase type-5 inhibitors, luteinizing hormone-releasing hormone antagonists, vitamin D analogues and a proprietary protein with selective pro-apoptotic properties (e.g., NX-1207) [370].

Reliable animal models for studying the lower urinary tract symptoms due to BPH are limited to the chimpanzee [376,377], as unlike humans and chimps, dogs, rabbits, cats and rodents lack a prostatic capsule. Thus, prostatic hyperplasia does not compress the urethra to cause outflow obstruction [378-380]. Like humans and chimps, the dog spontaneously develops BPH but requires encapsulating the prostate in mesh to cause obstruction [379,380]. Transgenic mice that overexpress prolactin can undergo a 20-fold enlargement of the prostate [381], but outlet obstruction does not develop. Partial bladder outlet obstruction (PBOO) can be implemented in rabbits and rodents by tying a partially obstructing ligature around the urethra. However, this is an acute rather than a slowly developing obstruction and female animals are often used.

While BPH and prostatic cancer are more prevalent in older adults and aged men, prostatitis is the most common pathology during young adulthood (20 to 40 years of age). There are four classifications: acute and chronic bacterial prostatitis, which are usually caused by gram-negative bacilli; chronic prostatitis/chronic pelvic pain syndrome; and asymptomatic prostatitis. Acute bacterial prostatitis is an acute bacterial infection of the prostate gland and is typically treated with parenteral or oral antibiotics, depending on the severity of the disease. Chronic bacterial prostatitis is a persistent bacterial infection of the prostate lasting longer than three months. Antibiotics with good tissue penetration are usually recommended for treatment. Chronic nonbacterial prostatitis can be inflammatory or noninflammatory and may involve afferent nerve sensitization. The main symptomology is pain localized to the prostate without evidence of infection. Treatment options include α-adrenoreceptor antagonists and anti-inflammatory and antimicrobial medications. Other pharmacotherapies include 5ARIs, steroids and glycosaminoglycans. Asymptomatic prostatitis is diagnosed when inflammatory cells or leukocytes are noticed upon prostate or semen analysis, respectively, during the examination for other urological conditions. Treatment depends on the primary reason for evaluation. As prostatitis is multifactorial, there are a number of different animal models developed by exogenously administering α-adrenoreceptor agonists to male rodents to increase prostate size and promote inflammation [382], or by injecting inflammatory agents (capsaicin, Freund’s adjuvant, lipopolysaccharide, or Zymosan) directly into the prostate. The prostate can also be irritated through afferent cross-sensitization induced by irradiating the bladder. Different treatment paradigms that may be used to investigate prostatitis are shown in Table 3.

### VI. NOVEL MOLECULAR TARGETS FOR OAB AND DETRUSOR OVERACTIVITY

The importance of the urothelium and underlying suburothelium of the urinary bladder in mechanosensory control, and the role of afferent pathways including urothelium/ suburothelium/interstitial cell function in the pathophysiology for OAB is increasingly recognized [383-385]. This has revealed a greater variety of targets to manage OAB other than those concerned with smooth muscle contraction. This section will be concerned with identification of potential novel targets and the identification of biomarkers that can objectively measure the extent and progression of OAB.

The importance of the urothelium and underlying suburothelium of the urinary bladder in mechanosensory control, and the role of afferent pathways including urothelium/ suburothelium/interstitial cell function in the pathophysiology for OAB is increasingly recognized [383-385]. This has revealed a greater variety of targets to manage OAB other than those concerned with smooth muscle contraction. This section will be concerned with identification of potential novel targets and the identification of biomarkers that can objectively measure the extent and progression of OAB.
1. INTRODUCTION

Signal transduction mechanisms are subclassified into seven different categories (G-protein coupled receptors, ligand-gated ion channels, ion channels, nuclear receptors, catalytic receptors, transporters, and enzymes [386]). This report will focus on the first three of these categories from where most evidence has been derived, Table 4.

2. SEVEN TRANSMEMBRANE SPANNING RECEPTORS (7-TM, METABOTROPIC RECEPTORS)

a) Acetylcholine (ACh)-muscarinic receptors

The urinary bladder is profusely supplied with autonomic nerve fibres, which form a dense plexus among the detrusor smooth muscle cells. The majority of these nerves contain acetyl cholinesterase, and while they occur in profusion throughout the muscle coat of the bladder, some muscle bundles are more richly innervated than others. The majority of the autonomic nerves innervating the detrusor muscle is considered to be excitatory cholinergic [387], and contraction of the normal human detrusor is mediated almost exclusively through muscarinic receptor stimulation by released acetylcholine. Detrusor strips from normal human bladders produce little response to single stimuli and require repetitive activation of intrinsic nerves to induce a response that is absolutely abolished by atropine [249], suggesting that it is purely cholinergic. Molecular cloning studies have revealed five distinct genes for muscarinic ACh receptors in rats and humans, and it is now generally accepted that five receptor subtypes correspond to these gene products [388]. Muscarinic receptors are coupled to G-proteins; M2 and M4 are inhibitory (Gi); M1, M3 and M5 are facilitatory (Gq). The signal transduction systems of M1, M3 and M5 preferentially couple to phosphoinositide hydrolysis leading to mobilization of intracellular Ca\(^2+\), whereas activation of M2 and M4 receptors inhibits adenylylate cyclase activity. Hence, activation of either M2 or M3 subtypes elicits bladder contraction. Evidence suggests that the detrusor possesses both M2 and M3 receptors [389,390]. Although M2 receptors predominate in receptor binding studies, it is the M3 receptor that is thought to mediate contraction.

Desensitization of muscarinic ACh receptors is one mechanism to reduce the sensitivity of detrusor smooth muscle to incoming stimuli, and is mediated by phosphorylation of the receptor by guanosine phosphate binding protein-coupled receptor kinase (GRK) [391-393]. Protein expression of the GRK2 subtype was significantly decreased in obstructed bladder detrusor from patients with benign prostatic hyperplasia compared to that from normal bladders [393]. Failure of the desensitizing mechanism could contribute to detrusor overactivity with bladder outlet obstruction.

In addition to ACh released from peripheral nerve endings, non-neuronal ACh may also be present when released from bladder urothelium or suburothelium. This ACh fraction is increased by stretch of the bladder wall, and is increased with patient age [111]. At present its function is unknown but may contribute to the pathogenesis of OAB.

The principal treatment for overactive bladder (OAB) is the use of anticholinergic drugs that were initially believed to inhibit the effect of parasympathetic ACh on the detrusor. However, there is now evidence to suggest that anticholinergic drugs could interact with sensory pathways. Stimulation of muscarinic receptor pathways can depress sensory transduction by a mechanism independent of changes in bladder tone, suggesting that muscarinic receptor pathways and ACh could contribute to normal or pathological bladder sensations [394], however, there is no apparent evidence in the clinical setting. Recent studies have described muscarinic receptors on the mucosa as

well as the detrusor. The density and binding affinity profile of the muscarinic receptor population in the human bladder mucosa is similar to that of the detrusor muscle; mucosal M3 subtype density is similar to that in detrusor muscle but lower than in the parotid gland [395]. Furthermore, commonly-used and clinically-effective muscarinic receptor antagonists bind to receptors located on both the bladder mucosa and the detrusor, providing support for the hypothesis that muscarinic receptors in the mucosa may represent an important site of action for these agents in OAB [396].

b) Adrenergic β-receptors

With many animals, sympathetic nerve activity to the bladder increases during the urine storage phase, although this remains to be definitively shown in humans. In addition, there is both relaxation of bladder smooth muscle via an adrenergic β-receptor and contraction of urethral smooth muscle via adrenergic α1-receptors [397]. However, solabegron and other β-adrenoceptor agonists, such as isoprenaline, evoke potent concentration-dependent relaxation of isolated human bladder strips. There are three adrenergic β-receptor subtypes (β1, β2, β3) and relaxation of bladder smooth muscle has been regarded as mediated by the adrenergic β2-receptor [397,398] and the β3-receptor was thought to be related only to fat metabolism. In human bladder tissue it is regarded that the β3-adrenoceptor (β3-AR) is the most significant functional subtype with gene expression of the β3-adrenoceptor (β3-AR) and relaxation of human detrusor via this receptor have been reported [399-402]. In the near future, the role of the β3-AR will be important and several β3-agonists (KUC-7483, YM-178, FK-175) have been developed: YM-178 was launched in Japan in September 2011.

The β-AR is Gs-protein-coupled and its activation elevates intracellular cAMP; the pathway believed to be a key mediator in relaxation of smooth muscle. Downstream effectors activated via cAMP include plasma membrane K+ channels, such as the large-conductance, Ca2+-activated K+ (BK, Maxi-K) channel. β-AR-mediated relaxed mechanisms also include cAMP-independent signalling pathways, supported by numerous pharmacological and electrophysiological lines of evidence. In airway smooth muscle, direct activation of the Maxi-K channel by stimulation of β2-AR and Gsa is such a mechanism [403]. The β3-AR is recognized as an attractive target for drug discovery. On the other hand, activation of the β1- or β2-AR can cause undesirable side effects such as increased heart rate or muscle tremors. Consequently, a number of recent efforts in this field have been directed toward the design of selective agonists for the β3-AR [404]. GW427353, a novel β3 AR agonist, evokes bladder relaxation and facilitates bladder storage mechanisms in the dog [405]. The β3-AR agonist CL-316243 has also been shown to act on detrusor muscle and increase urine storage in spontaneously hypertensive rats [406]. The role of the urothelium in bladder responses to β-AR agonists is not yet clear. Masunaga et al. revealed that β3-ARs are involved in mediating inhibitory effects of β-AR agonists on detrusor contractions via the urothelium in pig bladder dome [407]. β3-AR mRNA has been found in the urothelium as well as the detrusor muscle and suggests multiple site of actions in the lower urinary tract [408].

c) Cannabinoids, GPR18, GPR55, GPR119

In recent years cannabinoids, the active components of Cannabis sativa linnaeus (marijuana) and their derivatives, are drawing renewed attention because of their diverse pharmacological activities such as cell growth inhibition, anti-inflammatory effects, and tumour regression [409-414]. The cannabinoid receptor has two subtypes, CB1 and CB2, which are both G-protein-coupled receptors [415]. Cannabinoid receptors are activated by endogenous ligands that include N-arachidonylethanolamine (anandamide) and N-homo-g-linolenylethanolamine, N-docosatetra-7,10,13,16-enylethanolamine and 2-arachidonoyl-glycerol [386].

CB1 was initially characterized in rat brains [416], and later cloned from rat cerebral cortex [417] and human testis [418]. CB1 is distributed mainly in the central nervous system, i.e. cerebellum, hippocampus, and cerebral cortex [419], as well as on peripheral nerves and in non-neuronal tissues including pituitary gland, adrenal gland, lung, testis, ovary, uterus, prostate, eye, and vascular tissue [419-423]. CB2 was cloned from rat spleen macrophages [424], and has also been found in the peripheral immune system tissues, such as spleen and tonsils, and particularly expressed on B-cells and natural killer cells [419]. CB1 is found expressed in human urinary bladder tissue from patients with hypersensitivity and over-activity disorders, and the amount correlates with changes of symptoms. CB1-immunoreactive nerve fibres were significantly increased in the suburothelium of patients with bladder pain symptoms (BPS) and idiopathic detrusor overactivity (IDO), and in detrusor layer in IDO patients, as compared with control. CB1-immunoreactive suburothelial nerve fibre density correlated significantly with pain scores on a visual analogue scale in PBS and urgency scores in IDO. Neurofilament-immunoreactive suburothelial nerve fibres were significantly increased in PBS and IDO. The results suggest that increased expression of CB1 on nerve fibres may be related to bladder pain in PBS and urgency in IDO and support clinical trials of CB1 agonists in bladder disorders [425]. A Cannabis sativa extract enriched in cannabidiol (CBD) and pure CBD reduced cholinergic-mediated contractility. This effect was modulated by transient receptor potential vanilloid type-1 (TRPV1) in rats but not in humans. If confirmed in vivo, such results
could provide a pharmacological basis to explain, at least in part, the efficacy of cannabis products in reducing incontinence episodes in patients with multiple sclerosis [426,427].

Agents named GPR18, GPR55 and GPR119 (a provisional nomenclature), although showing little structural similarity to CB1 and CB2 receptors, respond to endogenous agonists analogous to the endogenous cannabinoid ligands, as well as some natural/synthetic cannabinoid receptor ligands [386]. The expression of fatty acid amide hydrolase (FAAH), the endocannabinoid-degrading enzyme, was measured in human, rat and mouse bladders, as well as the effects of inhibition of FAAH. These data were compared to urodynamic measurements in awake rats using the FAAH inhibitor oleoyl ethyl amide (OEtA), rimonabant (CB1 antagonist) and SR144528 (CB2 antagonist). Bladder mucosa of all species expressed FAAH. Rat and human urothelium coexpressed FAAH and CB2. The FAAH inhibitor OEtA altered urodynamic parameters that reflect a sensory function for cannabinoids during the rat micturition cycle. This suggests a role for the endocannabinoid system in bladder mechano-afferent function of rats [428].

d) GABAB

Functional GABAB receptors are formed from the heterodimerization of two similar 7-TM subunits termed GABAB1 ENSG00000136928 and GABAB2 ENSG00000136928. Stimulation of spinal GABAergic mechanisms by intrathecal application of GABA and GABAB receptor agonists could be effective for the treatment of detrusor overactivity in spinal cord injured rats [429]. Fourteen of 31 patients with refractory OAB and nocturia improved with oral gabapentin. Gabapentin was generally well tolerated and can be considered in selective patients when conventional modalities have failed [430]. Gabapentin has also revealed efficacy in the treatment of DO of neurogenic origin. Preliminary results have shown significant modifications of urodynamic indexes, particularly of the DO, whereas the symptomatic score evaluation and the voiding diary data have demonstrated a significant lowering of the irritative symptoms [431]. These data support the rationale that DO may be controlled by modulating the afferent input from the bladder and the excitability of the sacral reflex centre and suggest a novel method with oral gabapentin to treat OAB patients.

e) Glutamate metabotropic receptors

Glutamate receptors consist of two major classes, the ionotropic receptors which form ligand-gated cation channels [432] and the metabotropic receptors (mGluRs) which are a family of G-protein coupled receptors activating distinct signal transduction pathways in neurons [433]. The former includes N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-lisoxazole-4-propionic acid (AMPA), and kainite receptors, and have an essential role in the control of micturition reflexes [434,435]. Less is known about the functional roles of mGluRs in the lower urinary tract. They comprise eight subtypes (mGluR1 to mGluR8), which are placed into three groups on the basis of sequence homology, transduction mechanism and agonist pharmacology: group I (mGluR1 and mGluR5), group II (mGluR2 and mGluR3) and group III (mGluR4, mGluR6, mGluR7, mGluR8).

Glutamate is involved in many CNS functions, and drugs acting on the different glutamate receptors may affect not only micturition [436]. Most previous work with lower urinary tract function has used ionotropic glutamate receptors, however the mGluRs should be of value to study further. The involvement of group I mGluRs in the micturition reflex of mice has been investigated. Wild-type female C57BL/6 mice and mGluR1 knockout mice under decerebrate, unanesthetized conditions were used for in vivo cystometry with 6-methyl-2-(phenylethynyl)pyridine (MPEP, 0.3-30 mg/kg i.p.), a selective mGluR5 antagonist. Inter-micturition interval was measured during continuous infusion cystometrograms. Blockade of mGluR1, mGluR5 or both increased bladder capacity and mGluR1 and mGluR5 additively interacted to transmit afferent signals from the bladder. Thus, a group I mGluR antagonist, which blocks both mGluR1 and mGluR5, would have a more beneficial effect than a drug targeting either mGluR1 or mGluR5 alone. This provides a further promising target to treat storage dysfunctions including OAB and urgency urinary incontinence [437]. Similar data has also indicated that glutamic acid has a transmitter function in bladder and somato-bladder reflex mechanisms and raises the possibility that mGluR5 may be a target for pharmacological treatment of lower urinary tract disorders [438,439].

f) Prostanoid receptors

Prostanoid receptors are activated by the endogenous ligands prostaglandin PGD2 (D), PGE2 (E), PGF2α (F), PGH2 (H), prostacyclin PG12 (I) and thromboxane A2 (T). Prostanoid actions are mediated by specific receptors on cell membranes, which include the DP, EP, FP, IP, and TP receptors that preferentially respond to PGD2, PGE2, PGF2, PG12, and TXA2, respectively. In turn, EPs are subdivided into four subtypes: EP2, EP2, EP2 and EP2 (Table 5) [440,441].

The signalling pathways vary. TP receptors signal via the Gq protein, activating Ca2+-diacylglycerol pathways, but also other G-proteins may be involved; EP1 receptors signal via IP3 generation and increase intracellular Ca2+; activation of EP2 and EP4 leads to an increase of cAMP; and EP3 activation inhibits cAMP generation via a pertussis toxin-sensitive Gi-coupled mechanism and may also signal via the small G-protein Rho. Prostanoids may affect excitation-contraction coupling in detrusor smooth muscle in two ways, directly by
effects on the smooth muscle, and/or indirectly via effects on neurotransmission.

The prostanoid receptor most important for detrusor function has not been established. Mice lacking EP1 receptors had normal cystometry, but did not react to intravesical PGE2 instillation, which caused detrusor overactivity in wild-type controls. Bladder outlet obstruction of EP1 receptor-knockout mice did not prevent the resulting gain of bladder weight, but prevented the increase of spontaneous non-voiding contractions [442]. PGE2 enhances the micrurition reflex through C-fibre afferents via EP1; thereby an EP1-selective antagonist may improve bladder storage function [443]. However, the prostaglandin EP1 receptor antagonist ONO-8359 failed to distinguish itself from placebo and was inferior to tolterodine, as reported at a late-breaking science session at the AUA 2011 meeting (http://www.medpagetoday.com/MedicalCoverage/AUA/26716). The urodynamic effects of an EP4 receptor antagonist (AH23848) in cyclophosphamide-induced OAB was evaluated in rats, and the results were favorable. Antagonists to the EP4 receptor may be a new target for treatment of patients with OAB [444]. The change in expression of each EP receptor subtype and the functional role of the EP4 receptor in bladder outlet obstruction was studied using a selective EP4 antagonist, EP4ONO-AE1-329. EP4 receptor mRNA and proteins have been detected in obstructed bladder detrusor smooth muscle and epithelium, as well as EP1-3 receptor mRNA in normal and obstructed bladders (Figure 17). ONO-AE1-329 (100 nM) significantly relaxed KCl-induced contractions of detrusor strips from rat bladder with outlet obstruction. A significant correlation was found between the relaxant effect of ONO-AE1-329 and bladder weight. Activation of EP4 receptors expressed in bladders with outlet obstruction may thus suppress detrusor muscle contraction and afferent activity (Figure 18, Table 6). This might be a compensatory mechanism to counteract the deterioration of storage function in bladders with outlet obstruction [445]. However, EP receptor distribution, and its implication, on human urinary bladder mucosa are not fully understood. EP2 and EP4 mRNA are over-expressed in the urothelium of obstructed human urinary bladder compared to non-obstructed bladder and significantly correlated with IPSS, especially storage scores. Hence, in contrast to previous mouse data, EP2 and EP4 may be promising receptor subtypes to treat OAB [446].

g) Tachykinins

Tachykinin receptors are activated by the endogenous peptides: substance P (SP), neurokinin A (NKA), neurokinin B, neuropeptide K and neuropeptide g (N-terminally extended forms of neurokinin A). The neurokinins (A and B) are mammalian members of the tachykinin family, which includes peptides of mammalian and nonmammalian origin containing the consensus sequence: Phe-x-Gly-Leu-Met. Marked species differences in pharmacology exist for all three receptors, in particular with nonpeptide ligands.

Figure 18. Representative traces to show the effect of the intravesically-infused EP4 selective agonist on the micturition reflex in a urethane-anesthetized BOO rat. Reflex voiding contractions were induced by continuous infusion of normal saline in control, saline with 10µM ONO-AE1-329 and normal saline recovery after ONO-AE1-329 washout at 2 ml per hour. Inter-contraction interval and peak pressure were reversibly increased by intravesical infusion of ONO-AE1-329.

B: Representative PCR result of EP4 receptor cDNA in agarose gel electrophoresis; Muc, mucosa. SM, smooth muscle.
The enogenous receptor for substance P is the G-protein coupled NK1 receptor. The hexapeptide agonist septide appears to bind to an overlapping but non-identical site to SP on the NK1 receptor [386].

Initial clinical trials revealed that Aprepitant, a NK1 receptor antagonist, may show efficacy for the treatment of OAB, suggesting that receptor antagonism may represent a novel therapeutic approach to treating OAB [447]. Cizolirtine citrate (cizolirtine) exerts an inhibitory influence on calcitonin gene-related peptide (CGRP) and substance P release by primary afferent fibres and/or dorsal horn interneurons at the spinal level, mediated through presynaptic serotonin and α2-ARs that are partly related to an increase of the descending noradrenaline pain inhibitory system [448-452]. A dose-finding study was performed as the first step in the clinical development of cizolirtine citrate. Its therapeutic potential at 400mg bid in OAB has been evidenced [453] and has provided further clinical evidence that modulation of tachykinins could be an effective way to treat OAB.

3. LIGAND-GATED ION-CHANNELS

Ligand-gated ion channels (LGICs) are integral membrane proteins containing a pore that allows the regulated flow of selected ions across the plasma membrane. Ion flux is passive and driven by the electrochemical gradient for permeant ions. The channels are opened, or gated, by a neurotransmitter binding to an orthoerteric site(s) that triggers a conformational change that results in a different conducting state. Among eight ligand-gated ion channels (5-HT3, nicotinic-ACh, GABAA, glutamate-ionotropic, glycine, P2X, and Zn2+-activated channel), only P2X channels will be discussed. P2X receptors have a trimeric topology with two putative transmembrane domains, where the endogenous ligand is ATP and gate primarily Na+, K+ and Ca2+, exceptionally Cl-. The native receptors may occur as either homopolymers (e.g. P2X1 in smooth muscle) or heteropolymers (e.g. P2X2:P2X3 in the nodose ganglion or peripheral afferents and P2X1:P2X5 in mouse cortical astrocytes). P2X2, P2X4 and P2X7 receptors form functional homopolymers which, in turn, activate pores permeable to low molecular weight solutes. The hemi-channel pannexin-1 has been implicated in the pore formation induced by P2X7, but not P2X2 receptor activation [386].

AF-792(5-(5-ethyl-2-isopropyl-4-methoxy-phenoxy)-pyrimidine-2,4-diamine, a novel selective P2X3 and P2X2/3 antagonist, 300 nM), inhibits micturition reflex activity significantly by increasing baseline contraction intervals. Afferent signals originating from the bladder are regulated by spinal P2X3 and P2X2/3 receptors and establish directly an endogenous central presynaptic purinergic mechanism to regulate visceral sensory transmission. P2X3 and P2X2/3 antagonists may therefore be promising to treat lower urinary tract dysfunction, such as OAB, and possibly other debilitating sensory disorders, including chronic pain states [454].

After bladder outlet obstruction with overactivity the expression of M2, M3 and P2X3 receptors is increased in rat urothelium, suggesting that changes in urothelium P2X3 receptor expression may mediating afferent sensory responses in the urinary bladder [455]. The P2X2 and P2X2/3 receptor antagonist A-317491 is effective at improving the signs of cyclophosphamide-induced cystitis in the rat, suggesting that the P2X2 or P2X2/3 receptor pathway is involved in the resultant bladder overactivity [456]. The exact mechanisms that underline mechanosensory transduction in bladder afferent terminals remain ambiguous; however, a wide range of ion channels (e.g. TTX-resistant Na+ channels, Kv channels and hyperpolarization-activated cyclic nucleotide-gated cation channels) and receptors (e.g. TRPV1, TRPM8, TRPA1, P2X2/3) have been identified at bladder afferent terminals and implicated in the generation and modulation of afferent signals. The expression and/or function of these ion channels and receptors may be altered in animal models and patients with overactive and painful bladder disorders. Some of these ion channels and receptors may be potential therapeutic targets for bladder diseases [457]. However, it has also been shown that with detrusor from idiopathic DO patients there was a selective absence of P2X3 and P2X5 that may impair control of detrusor contractility and contribute to the pathophysiology of urge incontinence [458].

4. ION-CHANNELS

Ion channels are pore-forming proteins that allow the flow of ions across either plasma membranes or those of intracellular organelles. Many ion channels (i.e most Na+, K+, Ca2+ and some Cl- channels) are voltage-gated, but others (i.e. certain K+ and Cl- channels, TRP channels, ryanodine receptors and IP3 receptors) are relatively voltage-insensitive and are gated by second messengers and other intracellular and/or extracellular mediators. Many ion channels, such as K+, Na+, Ca2+, HCN and TRP channels, share several structural similarities. Others, such as Cl- channels, aquaporins and connexins, have completely different structural properties. At present, ion channels (including ligand-gated ion channels) represent the second largest target for existing drugs after G protein-coupled receptors. However, the advent of novel, faster screening techniques for compounds acting on ion channels suggests that these proteins represent promising targets for the development of additional, novel therapeuetic agents [386]. The recent demonstration that the urothelium is sensitive to both mechanical and other stimuli, and responds by releasing signalling molecules (NO, ATP) makes this tissue an attractive additional target to detrusor smooth muscle. One or multiple mechanosensitive ion channels play a role in transduction of hydrostatic pressure changes, which supports the view that not only tissue stretch or tension, but also pressure is an important parameter for mechanosensing bladder fullness [459]. A survey of interesting potential targets follows.
a) Acid-sensing (proton-gated) ion channels (ASICs)

Acid-sensing ion channels (ASICs) are members of a Na\(^+\) channel superfamily that includes the epithelial Na\(^+\) channel (ENaC), the FMRF-amide activated channel (FaNaC) of invertebrates, the degenerins (DEG) of Caenorhabitis elegans, channels in Drosophila melanogaster and ‘orphan’ channels. ASIC subunits contain two transmembrane domains and assemble as homo- or hetero-trimers to form proton-gated, voltage-insensitive, Na\(^+\) permeable, channels. (Table 7) ASIC1 is the dominant subunit expressed in bladder epithelium, whereas both ASIC1 and ASIC2 are expressed in detrusor smooth muscle. ASIC3 expression was much less abundant, but localized in the subepithelial region. In the mucosa, the ASIC1 gene is more highly expressed in male than in female mice, whereas the expression level of ASIC2 in the bladder muscle is higher in female than in male mice [460] (Figure 19).

Urothelial cells express multiple TRP and ASIC channels, whose activation elicits ionic currents and Ca\(^{2+}\) influx. These “neuron-like” properties might be involved in transmitter release, such as ATP, that can act on afferent nerves or smooth muscle to modulate their responses to different stimuli [461]. Indeed, capsaicin (acting on TRPV1) and acid (acting on TRPV1 and ASIC) induce ATP release from the rat bladder urothelium and highlights the importance of both ATP and H\(^+\) as signalling molecules in modulating bladder function [81]. Intravesical administration of 100 µM capsazepine (TRPV1 antagonist) showed no effect on bladder irritation by acetic acid (Table 8) and implies the two systems are independent. Urinary bladder inflammation induced by cyclophosphamide alters ASIC2a and ASIC3 expression in the rat urinary bladder; ASIC1 transcript expression is not altered [462]. Several ASIC subunits are expressed in human bladder and urothelial cells, in which levels are regulated during urothelial differentiation. Up-regulation of ASIC2a and ASIC3 in patients with bladder pain syndrome suggests involvement in increased pain and hyperalgesia. Down-regulation of TRPV1 mRNA might indicate that a different regulatory mechanism controls its expression in the human bladder [463].

b) Epithelial sodium channels (ENaC)

ENaCs are responsible for Na\(^+\) reabsorption by the epithelia lining the distal part of the kidney tubule, and fulfill similar functional roles in some other tissues such as the alveolar epithelium and the distal colon. This reabsorption of Na\(^+\) is regulated by aldosterone, vasopressin and glucocorticoids, and is one of the essential mechanisms in the regulation of Na\(^+\) balance, blood volume and blood pressure. The degenerin ENaC family has been proposed as a transducer of sensory stimuli in several species [464-467] and seem to be mechanosensitive. In the rabbit urinary bladder, ENaC can change Na\(^+\) transporter properties after alterations to hydrostatic pressure [465]. The ENaC in the renal pelvic epithelium of rats participates in the activation of afferent renal mechano-sensitive neurons by increased renal pelvic pressure [468]. Thus, ENaCs are likely to be involved in mechanotransduction in the bladder, and may be related to the pathophysiology of changes to sensory nerve function by ENaC upregulation in the bladder urothelium or afferent nerve terminals. cAMP stimulates the insertion of ENaC channel into the apical membrane of the rabbit bladder epithelium [469]. ENaC is expressed in the mammalian bladder urothelium and is the main route of amiloride-sensitive Na\(^+\) transport [470].

In human tissue the α, β- and γ -subunits ENaC proteins and mRNA are well-expressed in urothelium from patients with and without BOO and the amounts are positively associated with the storage symptom score [471]. In rat bladder the intravesical infusion of 1 mM amiloride (to block ENaC) significantly reduced the frequency of reflex voiding during bladder filling and increased bladder capacity, without any effect on the amplitude of micturition pressure. Stretch (50%) induced significant increase in the ATP release from whole layer bladder strips, but only a slight increase in muscular layer strips without epithelium. Amiloride suppressed stretch-evoked ATP release from rat urinary bladder epithelium [472].

c) K\(^+\) channels

K\(^+\) channels are fundamental regulators of excitability; they control the frequency and shape of the action potential waveform, the secretion of hormones and neurotransmitters and the cell membrane potential. Their activity may be regulated by transmembrane voltage, intracellular Ca\(^{2+}\) and neurotransmitters. They consist of a primary pore-forming α-subunit often associated with auxiliary regulatory subunits. The three main families are the 2TM (two transmembrane domains), 4TM and 6TM families [386].

1. The 2TM family of K\(^+\) channels

The 2TM domain family of K\(^+\) channels are also known as the inward-rectifier K\(^+\) channels. This family includes the strong inward-rectifier K\(^+\) channels (Kir2.x), the G-protein-activated inward-rectifier K\(^+\) channels (Kir3.x) and the ATP-sensitive K\(^+\) channels (Kir6.x, which combine with sulphonylurea receptors (SUR)). The pore-forming α-subunits form tetramers, and heteromeric channels may be formed within subfamilies (e.g.Kir3.2 with Kir3.3).

2. The 6TM family of K\(^+\) channels

The 6TM family of K\(^+\) channels comprises the voltage-gated KV subfamilies, the KCNQ subfamily, the EAG subfamily (which includes herg channels), the Ca\(^{2+}\)-activated Slo subfamily (actually with 7TM) and the Ca\(^{2+}\)-activated SK subfamily. The pore-forming α-subunits also form tetramers and heteromeric channels may be formed within subfamilies (e.g. KV1.1 with KV1.2; KCNQ2 with KCNQ3). Large-conductance, voltage- and Ca\(^{2+}\)-activated K\(^+\) (Maxi-K or BK) channels regulate the resting potential and repolarisation of the action potential and play a critical role in modulating contractile tone of smooth muscle and neuronal processes.

BKCa channels play an important role in controlling membrane potential and contractility of urinary bladder smooth muscle [473,474]; SKCa channels are
regulators of excitability in detrusor smooth muscle. Ca\(^{2+}\) entry through voltage-dependent Ca\(^{2+}\) channels activates both BKCa and SKCa channels, but Ca\(^{2+}\) release through ryanodine receptors (Ca\(^{2+}\) sparks) activates only BKCa channels. BKCa channels are able to counteract enhanced spontaneous mechanical activity with urinary bladder smooth muscle stretch [475, 476]. However, the ability of BKCa channels to regulate spontaneous contractility in tissue from neuropathic DO patients appears more limited [477, 478]. NS-8, a selective antagonist for BKCa channels, decreased afferent pelvic nerve firing rate during bladder filling. Thus NS-8 might have the potential for treating patients with urinary frequency and incontinence [479]. A further demonstration of the importance of the BKCa channel is that local injection of hSlo cDNA (i.e. the BKCa channel) ameliorated detrusor overactivity in a rat model of partial urinary outlet obstruction [480]. Consistent with increased bladder contractility caused by absence of BKCa currents, Slo(-/-) mice show a marked elevation in urination frequency [481]. Phasic contractions of human detrusor are dependent on Ca\(^{2+}\) entry through L-type Ca\(^{2+}\) channels and BKCa and SKCa channels play a key role in the modulation of this activity and supports the concept that increasing conductance through BKCa, SKCa and even KATP channels may represent attractive pharmacological targets to decrease phasic contractions in OAB [482, 483]. BKCa channel activity also reduces significantly both cholinergic- and purinergic-induced contractions and suggests that alterations to BKCa channel expression or function could contribute to pathologies such as OAB [484].

A novel BKCa channel blocker, A-272651, represents one of the first small molecules that could serve as a useful tool for their further characterization in physiological and pathological states [485]. No other K\(^+\) channel opener has passed the proof-of-concept stage, and there is at present no convincing evidence showing that K\(^+\) channel opening is a useful principle for treatment of detrusor overactivity [486]. The safety and tolerability of escalating doses of hMaxi-K, a gene transfer product of human Maxi-K\(^+\) channel, were confirmed by clinical evaluations and laboratory tests in 11 patients with moderate to severe erectile dysfunction. It was proposed that hMaxi-K gene transfer is a viable approach to treat erectile dysfunction and other smooth muscle diseases with targeted access [487].

d) Transient receptor potential (TRP) cation channels

The TRP superfamily of cation channels, whose founder member is the Drosophila Trp channel, can be divided, in mammals, into six families; TRPC, TRPM, TRPV, TRPA, TRPP and TRPML based on amino acid homologies. TRP subunits contain six putative transmembrane domains and assemble as homo- or hetero-tetramers to form cation selective channels with varied permeation properties. The TRPC ('Canonical') and TRPM ('Melastatin') subfamilies consist of seven and eight different channels, respectively (i.e. TRPC1-TRPC7 and TRPM1-TRPM8). The TRPV ('Vanilloid') subfamily comprises six members (TRPV1-TRPV6), whereas the TRPA (Ankyrin) subfamily has only one mammalian member (TRPA1). Established, or potential, physiological functions of the individual members of the TRP families are discussed in detail in the recommended reviews and are only briefly mentioned here (Figure 20). The established, or potential, involvement of TRP channels in disease has been reviewed [488, 489]. In the bladder, afferent nerves have been identified not

---

**Figure 20. Phylogenetic relationships between members of the human transient receptor potential (TRP) channel superfamily.** TRPC2 is a pseudogene in primates and TRPN channels have not been identified in mammals.
only in the detrusor, but also in the suburothelium, where they form a plexus immediately beneath the urothelium. The bladder epithelium plays important roles in mechanosensory transduction [490], bladder distention causes release of ATP which excites small-diameter sensory neurons via P2X3 receptors [491].

Mechanosensitive molecules in the epithelial cells are responsible for stretch-evoked ATP release [492] and include ENaC (above) and TRP (transient receptor potential) ion channels. TRP are subclassified into seven superfamilies, and many of them are mechano- and thermo-sensing [454]. Among several thermo sensing TRP channels, TRPA1, TRPM8, TRPV1, and TRPV4 are candidates of molecular targets of the novel treatments for OAB (Figure 21) [493-495]. An understanding of the physiological function of these different channels will provide insight into how they control bladder function and if they may be exploited to control dysfunction in the lower urinary tract.

1. DISTRIBUTION AND FUNCTION OF THE TRP CHANNEL FAMILY IN UROGENITAL ORGANS

The potential roles of TRP channels have been explored in the bladder. Thus far, expression of TRPV1, TRPV2, TRPV4, TRPA1 and TRPM8 has been reported in different regions of urogenital tracts [493] (Table 9). TRPs are not only mechanosensitive but also thermosensitive (Figure 21).

Figure 21. Thermo-sensing transient receptor potential (TRP) channels
Expression of other TRP channels, e.g. TRPM8 and TRPA1, has been found in sensory C-fibres in the bladder [493,496-499]. The diagnostic ice water test is utilized to determine whether disturbance of bladder function involves neurogenic components, one of which could be related to TRPM8 function, in patients with spinal cord lesion [500].

The neurochemical phenotypes of TRP melastatin-8 (TRPM8)-immunoreactive afferent neurons innervating the rat urinary bladder were examined by using a highly-sensitive tyramide signal amplification method, combined with wheat-germ agglutinin-horseradish peroxidase (WGA-HRP) retrograde tracing. It was suggested that the TRPM8-expressing bladder afferents should be classified as Aδ-fibres and C-fibres, whilst some of these afferents may be involved in nociceptive sensations [501]. TRPA1 in sensory afferents is activated by several known ligands (allyl isothiocyanate and cinnamaldehyde), thereby inducing bladder overactivity [502].

The TRPV (“vanilloid”) family, on the basis of structure and function, comprises four groups of mammalian TRPVs: TRPV1/2, TRPV3, TRPV4 and TRPV5/6; reviews [502,503]. TRPV1-4 are non-selective cation channels that are thermosensitive, although TRPV1 and TRPV4 can also be activated by numerous other stimuli [502,504,505]. TRPV3, and to a lesser extent also TRPV2 and TRPV1, but not TRPV4, can be activated by 2-aminoethoxydiphenyl borate (2-APB), which, in contrast, blocks some TRPC and TRPM channels [506,507]. All channels of the TRPV family contain 3-5 NH2-terminal ankyrin repeats.

2. **TRPV1**

TRPV1 is an ion channel activated by capsaicin, heat, H+ and endogenous ligands such as anandamide. It is largely expressed in the urinary tract of mammals, especially in sensory fibres and urothelial cells. As in other systems, pain perception was the first role attributed to TRPV1 in the urinary tract. However, it is now increasingly clear that TRPV1 also regulates the frequency of bladder reflex contractions, either through direct excitation of sensory fibres, or through urothelial-sensory fibre cross-talk involving the release of neuromediators from urothelial cells. Capsaicin and resiniferatoxin (RTX) are agonists for TRPV1, and their desensitization of the receptor has been investigated for therapeutic purposes for painful bladder syndrome of neurogenic and non-neurogenic OAB. However, desensitization may become obsolete when non-toxic, potent TRPV1 antagonists become available [508]. TRPV1 channel blockers are used to ameliorate chronic pain, whereas TRPV1 agonists that induce desensitization are used to treat diseases in which channel over-expression occurs [509]. A splice variant of TRPV1, TRPV1b, in which 60 amino acids are deleted in the intracellular N-terminal region, forms capsaicin-insensitive and stretch-inhibited cation channels [510]. This channel is activated by hyper-
dose is requested with a second injection, a 150 U dose will be used; no doses higher than 150 U will be used [518]. The effects of BoNT/A on the expression of nerve growth factor (NGF) and TRPV1 in the urothelium and detrusor muscle of rats with partial bladder outlet obstruction-induced detrusor overactivity is being investigated. Detrusor wall injection of BoNT/A modulates the expression of NGF, which is greater in BOO, in both urothelium and detrusor muscle. However, TRPV1 expression particularly in the urothelium was not changed [519]. In 2011, Botox has received FDA approval for use in neurogenic DO in the treatment of urinary incontinence that results from neurological impairments such as spinal cord injury or multiple sclerosis.

3. TRPV4

TRPV4 was originally postulated to serve as a mechano- or osmosensor [520]. Recent studies using mice lacking TRPV4 revealed its involvement in sensing mechanical pressure, osmolality and warmth in vivo [521,522]. TRPV4 is abundantly expressed in rodent bladder epithelium [523]. TRPV4 knockout mice manifest an incontinence phenotype in spontaneous voiding pattern with a lower frequency of voiding contractions and increased bladder volume in continuous filling cystometry [524]. In cultured rat bladder urothelial cells, TRPV4 agonists promote Ca\(^{2+}\) influx and enhances ATP release [523]. The role of TRPV4 channels in a stretch sensing mechanism in mouse primary urothelial cell cultures using both wild-type (WT) and TRPV4-deficient mice was investigated. The results showed that TRPV4 senses distension of the urothelium, which is converted to an ATP signal in the micturition reflex pathway during urine storage (Figure 22) [525]. Thus, TRPV4 may contribute to physiological bladder function, especially mediating bladder distension signals to primary afferent nerves during urine storage. These findings indicate that modulation (inhibition) of TRPV4 channels could represent a novel therapy for OAB and storage dysfunction. Only the effects of TRPV4 channel agonists on bladder function have been described to date. Compounds endowed with antagonistic activity are being developed and it is anticipated that their effects on different models of bladder overactivity will be evaluated [526]. The development of cystitis-induced bladder dysfunction is strongly impaired in TRPV4(-/-) mice, and that HC-067047, a previously uncharacterized, potent, and selective TRPV4 antagonist increases functional bladder capacity and reduces micturition frequency in normal mice and rats with cystitis. HC-067047 did not affect bladder function in TRPV4(-/-) mice. These results also indicate that TRPV4 antagonists may provide a promising means of treating bladder dysfunction [527-529].

4. TRPA1

TRPA1 is the only mammalian member of the Ankyrin TRP subfamily and is a potential candidate for mechanosensor and/or nociceptor responding to chemicals: allyl isothiocyanate (the pungent compound in mustard oil); allicin (garlic); cinnamaldehyde (in cinnamon) [530,531] and thermal stimuli [524]. TRPA1 is probably activated by noxious cold (<17°C) [532]. TRPA1 is expressed in rodent and human bladders [526,533] and sensory C-fibres beneath the bladder mucosa. TRPA1 activation induces bladder contractions, mediated by sensory afferent stimulation and release of neuropeptides and prostanoids.

Figure 22. Measurement of stretch-evoked ATP released from primary cultured urothelial cells. WT, Wild type mice; TRPV4 KO, knock-out mice of TRPV4 receptor; RR: ruthenium red, a non-specific TRP channel blocker, *p<0.05 vs WT
The expression levels of TRPA1 mRNA in the bladder mucosa and muscular layers as well as prostate were in the ratio of 639:1:16. TRPA1 mRNA in the bladder mucosa of obstructed bladders was significantly upregulated to more than twice control. The expression of TRPM8 mRNA (below) in the prostate was much higher than that in the bladder mucosa (3024:1), but was not found in the bladder muscle layer. BPH or bladder obstruction did not significantly affect the expression of TRPM8. TRPA1 in the bladder epithelium might be involved in bladder sensory transduction and the induction process of OAB by bladder obstruction [496].

The relevance of TRPA1 in OAB induced by spinal cord injury (SCI) was evaluated using a rat SCI model, HC-030031 (a TRPA1 antagonist), and the TRPA1 antisense oligodeoxynucleotide (AS-ODN). TRPA1 activation and upregulation exerted an important effect in OAB following SCI [534]. TRPA1 distribution and the effects of hydrogen sulphide, as a TRPA1 activator, on micturition in conscious rats were examined. The expression of TRPA1 on C-fibre bladder afferents and urothelial cells, together with the finding that intravesical hydrogen sulphide initiates detrusor overactivity indicates that TRPA1 may have a role in sensory transduction in the rat urinary bladder. Hydrogen sulphide as a TRPA1 activator potentially is involved in inflammatory bladder disease [535].

5. TRPM8

TRPM8 is not only mechanosensitive, but also cold-sensitive. The bladder-cooling reflex is observed in guinea pigs if animals were pretreated with menthol, as a TRPM8 agonist. This reflex was sensitive to ganglion blockade or capsaicin-sensitive C-fibre deafferentation and might be mediated by C-fibre activation through TRPM8 [499]. TRPM8 in nerve fibres of overactive and painful bladders, and its relationship with clinical symptoms have been demonstrated. TRPM8 may play a role in the symptomatology and pathophysiology of these disorders, and may provide an additional target for future overactive and painful bladder pharmacotherapy [500].

A TRPM8 channel blocker, N-(3-aminopropyl)-2-(159)-N-(2-thienylmethyl)benzamide hydrochloride salt (AMTB), can act on the bladder afferent pathway to attenuate the bladder micturition and nociceptive reflex responses. Targeting TRPM8 channel may provide a new therapeutic opportunity for OAB and painful bladder syndrome [536]. Intravesical infusion of menthol facilitated the micturition reflex and capsaicin pretreatment had no effect on this response. Menthol inhibited carbachol-induced contraction of the detrusor smooth muscle. This suggests that intravesically infused menthol cannot relax detrusor muscle, and acts on capsaicin-resistant afferents (probably through TRPM8 on urothelium or sensory nerve endings) to facilitate the micturition reflex [537]. The TRPM8-expressing bladder afferents in rat should be classified as Aδ-fibres and C-fibres, while some of these afferents may be involved in nociceptive sensations [538]. The function and expression pattern of TRPM8 in urinary bladder afferent neurons from control and bladder outlet obstruction rats has been investigated. The neuronal input through TRPM8-positive bladder afferent neurons are augmented after bladder outlet obstruction, however, the neurochemical phenotype of the up-regulated TRPM8-positive bladder afferent neurons is not changed [538]. There is no explanation for the mechanism of urinary urgency evoked by cold sensation. Cold and menthol stimuli to the skin generate bladder nerve responses conducted through dichotomizing axons, which significantly decreased in the presence of the TRPM8 blocker [N-(4-tert-butylphenyl)-4-(3-chloropyridin-2-yl)piperazine-1-carboxamide] (BCTC). Sensory neurons expressing TRPM8, with dichotomizing axons projecting to the skin and bladder, may be responsible for the urinary urgency evoked by cold sensation [539].

Overall, many lines of evidence suggest that TRP ion channels are candidates for mechano-sensors in the urinary bladder as summarized in Figure 23.

VII. BIOMARKERS FOR OAB AND DO

1. INTRODUCTION

A biomarker is “a biological molecule found in blood, other body fluids, or tissues that is a sign of a normal or abnormal process, or of a condition or disease.” It may be objectively measured and evaluated as an indication of normal biological and pathogenic processes, or pharmacological responses to a particular treatment or condition [540]. Biomarkers are widely used as analytical tools to assess biological parameters for a rapid and comprehensive therapeutic analysis. In addition, biomarker measures can further the development and evaluation of new therapies [541]. An ideal biomarker should be quick, consistent, economical, and quantifiable in an accessible biological fluid or clinical sample (e.g., plasma, urine, or prostatic fluid) that is readily interpretable by a clinician [542,543]. In the search for reliable, non-invasive biomarkers, interest has focused on urinary factors, imaging and genetic markers.

Along with other cytokines detectable in urine, prostaglandin E2 and nerve growth factor are indicators of low-grade inflammation. Although they correlate with OAB symptom severity, they have not been shown to have independent prognostic benefit.

Imaging biomarkers have been investigated since the earliest days of urodynamics. Despite extensive research on the ultrasonographic estimation of bladder wall thickness, further standardization of the technique is required before conclusions can be reached regarding diagnostic accuracy.

Genetic factors contribute about half of the total risk for urgency incontinence. Functional polymor-
Figure 23. Interactions between receptors, chemical mediators released from bladder urothelial cells and different nerve endings in the bladder. Different receptors (bradykinin, trkA, trkB, adrenergic, cholinergic, and TRP) are expressed on urothelial cells. ATP, NO, acetylcholine (ACh), nerve growth factor (NGF), and prostaglandins (PG) can be released from the urothelium via activation of urothelially expressed ligand receptors and/or mechanoceptive receptors such as the epithelial Na+ channel.

Phisms of the cytochrome P450 IID6 gene significantly alter the metabolism of some commonly used anticholinergic drugs, but no genetic loci that influence the risk of OAB have been definitively identified. The first genome-wide association studies for OAB are in progress, and should identify new susceptibility genes. Although current putative biomarkers correlate with OAB severity, much future work is required to assess their prognostic value, and establish their role in clinical practice [544].

Urodynamic assessment of DO may be associated with a diagnosis of overactive bladder (OAB), but there is not always a one-to-one correspondence and OAB is detected by a history of exclusion of obvious pathological causes. In addition, by the definition used above urodynamic measurements would not be considered as a biomarker. However, a short section on urodynamics will be included to place this method in context.

2. URODYNAMIC FINDINGS

A study of urodynamic results in OAB women with and without urodynamic DO found that patients with DO were more likely to have abnormal sensations, lower volume for strong desire and urgency and more urinary urge incontinence (UUI) episodes. In patients with persistent urinary frequency, urgency and/or UUI, involuntary detrusor contractions were observed in 100% of neurologically-impaired patients, compared with 76% of control patients [540]. Urgency associated with increased sensation is common and may presage DO [546]. Interestingly, the efficacy of a combination of anti-cholinergics and bladder training for OAB symptoms was not different in groups with or without DO [547]. Therefore, a less invasive method to diagnose OAB and assess therapeutic outcomes, especially for female patients, is still required.

The gender difference in the measurement of urodynamic DO of OAB patients could result from anatomical differences, causing increased urge sensation in women during their daily life and mimicking OAB symptoms [548]. Pelvic organ prolapse (POP) frequently presents with urinary incontinence, either urge (UUI), stress (SUI), or mixed (MUI).

OAB symptoms in men could result from bladder outflow obstruction (BOO) or idiopathic DO (IDO), as LUTS suggestive of DO are commonly associated with these conditions [549]. The incidence of DO after TURP for BPH, and the influence of lower urinary tract perfusion on postoperative outcomes were prospectively evaluated in 50 men. Before and
one year after TURP, IPSS and QoL scores were recorded and perfusion of the lower urinary tract was measured with transrectal colour Doppler ultrasonography. Persistent DO in men after TURP was associated with increased vascular resistance, with subsequent reduced perfusion and hypoxia [550].

3. URINARY BIOMARKERS

Recent studies in patients with lower urinary tract disorders, particularly OAB, indicate that changes to the concentration of several urinary molecules, such as neurotrophins, prostaglandins, cytokines and several smaller molecules, are altered. Therefore, such changes could be used as potential biomarkers of OAB.

a) Cytokines and chemokines

Chemokines constitute a large family of secretory proteins that are expressed by leucocytes as well as bladder tissue. The detection of bladder inflammation associated with OAB through altered urine levels of cytokines, chemokines, and growth factors has been attempted. Elevated urinary levels of markers involved in inflammation and tissue repair are raised in OAB patients. This suggests an association between inflammation and OAB, and could also provide suitable diagnostic tests for OAB [551].

Alternatively OAB could produce inflammatory cytokines due to afferent neural plasticity or urothelial dysfunction. An analysis of urinary proteins using an antibody-based array chip for 120 human cytokines found that the majority were expressed at similar levels in control and OAB patients. However, some cytokines were upregulated, such as monocyte chemo-attractant protein, MCP1; TARC; PARC and Fas/TNFRSF6. Others were also increased in urinary tract infections and included: MCP2; MCP3; tumour necrosis factor-β, GCSF and eotaxin3. In addition, some were down-regulated in OAB, including IL5, IL6, IL7, and GM-CSF [552]. Pre-clinical studies have shown that increased urine levels of MCP1 and CXCL1 are evidence of bladder inflammation [553].

b) Prostaglandins in OAB

In the urinary bladder, prostaglandin E2 (PGE2) is a cytoprotective eicosanoid that inhibits apoptosis of epithelial cells. Intravesical instillation of PGE2 induces detrusor contraction while topical application of PGE2 to the urethra causes relaxation [554].

Non-steroidal anti-inflammatory drugs (NSAIDs) are effective in animal models of disease, by suppressing prostaglandin synthesis. Aspirin, in contrast to ketoprofen or indomethacin, does not cause significant gastrointestinal lesions and has been proposed as an NSAID treatment of choice for overactive bladder [555]. The association between OAB symptoms in patients with suprapontine brain diseases and the urinary levels of prostaglandins (PGE2 and PGF2α), nerve growth factor (NGF) and substance P were measured. PGE2 levels were raised in this cohort, compared to control, and were positively associated with the OAB symptom score [556]. In young boys with lower urinary tract obstruction due to urethral stricture higher levels of PGE2 were also associated with the incidence of OAB. [557].

Several studies have demonstrated the in vivo efficacy of PGE2 receptor 1 (EP1) antagonists in pre-clinical models of inflammatory pain and overactive bladder [558,559]. Others studies have also showed the possible efficacy of EP4 receptor antagonists for treatment of patients with OAB [444,445].

c) Urine ATP and nitric oxide (NO)

ATP and NO are released from the bladder urothelium during several physical and chemical stresses, and the amount released is increased in tissue from NDO and IDO patients and analogous animal models (section 3.1). Thus, a quantifiable relationship between their levels and the presence of DO may be available.

The relationship between ATP and NO release in 1) early diabetic bladders - an overactive bladder model; and 2) in “diuretic” bladders - an underactive bladder model were measured. ATP release positively correlated, whilst NO release negatively correlated with bladder contraction frequency. The relation between the improvement of LUTS and urinary ATP level has also been measured. Improvement of LUTS with α1 receptor antagonists or anti-muscarinic agent was associated with a decrease of the urinary ATP/creatinine ratio in patients with BPH or OAB. The urinary ATP/NO ratio or urinary ATP concentration itself may be a clinically relevant biomarker to characterize the extent of bladder dysfunction [90,560].

d) Urinary nerve growth factor (NGF) in OAB

NGF is a small, secreted protein that induces the differentiation and survival of particular target neurones and is produced by urothelium and smooth muscle [561]. NGF levels in the urinary bladder can be affected by its pathology and this change can be measured in urine. Urinary levels of NGF, and PGE2, were significantly increased in male patients with OAB compared with control. Urodynamic measurements on patients in this study showed that more than half had DO and BOO. Also of interest, was that several patients demonstrated bladder underactivity where PGE2 were lowered compared to control [562]. Urinary NGF levels in patients with BOO, with or without OAB have been compared. NGF/creatinine ratios were low in the control group and in BOO patients without OAB. However, ratios were higher in the BOO/OAB and BOO/DO groups. Moreover, urinary NGF/Cr levels returned to normal after successful relief of OAB symptoms [563]. Together, data such as these provide the possibility that measurement of urinary NGF and prostaglandin levels may be useful in detecting OAB/DO in male patients.
The effect of botulinum toxin A (BoNT/A) treatment on NGF levels in DO patients has also been evaluated. Participants included patients with idiopathic and neurogenic DO (IDO, NDO) who were untreated, well-treated, and failed-treated with antimuscarinic agents. BoNT/A treatment significantly reduced urinary the NGF/Cr ratio in responders within the IDO and NDO groups. In patients who failed to respond to BoNT/A treatment NGF levels remained significantly higher after three months [564].

Urinary NGF levels in women with stress urinary incontinence (SUI) and OAB have also been measured and indicated that it could be a potential biomarker of DO in women with mixed UI [565]. The effect of bladder volume on urinary NGF production in normal controls and patients with OAB has been measured. Urinary NGF increases physiologically in normal subjects at urge to void, but is pathologically elevated in OAB patients at small bladder volumes and does not significantly increase at urgency sensation [566]. The effect of antimuscarinics (tolterodine, 4 mg once daily) on urinary NGF levels in patients with OAB has also been measured. Changes to urinary NGF levels correlated with alteration of the urgency severity score (USS) after antimuscarinic treatment and discontinued medication [567].

A comparison between urinary NGF and other biomarkers has been evaluated. Urinary NGF and PGE2 levels among patients with DO, increased bladder sensation (IBS), interstitial cystitis/bladder pain syndrome (IC/BPS) and controls have been compared. Urinary NGF/Cr levels were elevated in women with IC/BPS or DO, but not in those with IBS. The differential diagnosis of women with IC/BPS from those with frequency-urgency syndrome may possibly be based on the urinary NGF/Cr levels but not the urinary PGE2/ Cr level [568]. Differences in urinary NGF and detrusor wall thickness (DWT) measured by transabdominal ultrasound between OAB and control patients were also examined. Urinary NGF level in natural-filling urine samples was a better biomarker for assessment of OAB-wet compared to DWT. Patients with OAB-dry or hypersensitive bladder did not have an elevated urinary NGF level [569,570].

However, the relationship between urinary NGF levels and lower urinary tract pathology is not always evident. About 30% of patients with OAB symptoms do not have elevated urinary NGF levels [571]. Stress-related events may also result in increased plasma NGF levels that can involve the neuroendocrine system. Patients with OAB may have symptoms that wax-and-wane without definite treatment and this may contribute to fluctuations of NGF in the urine. Thus before other confounding factors that cause urinary NGF levels to alter, its use as a biomarker must be treated with caution.

4. SERUM BIOMARKERS
a) C-reactive protein (CRP)

Chronic inflammation has been implicated in the development of OAB and IC/BPS. An elevation of CRP has been associated with chronic inflammation and LUTS. In one study serum CRP levels were significantly higher in subjects with OAB than in controls. No significant difference in CRP level was noted between patients with OAB and IC/BPS. There was no significant correlation between serum CRP and urinary NGF levels in the controls or patients with OAB or IC/BPS, except in the OAB patients with CRP >3 mg/l. These data may confirm the association between chronic inflammation of the urinary bladder in patients with OAB or IC/BPS [572].

5. BLADDER WALL IMAGING BIOMARKERS
a) Ultrasonography

Because patients with OAB may have frequent detrusor contractions during the storage phase, sustained isometric detrusor contractions could result in increased muscle bulk and hence, increased detrusor wall thickness (DWT) or bladder wall thickness (BWT). It has therefore been hypothesized that DWT increases in patients with DO [573]. The thickened bladder wall might decrease in response to antimuscarinic treatment, and measurement of DWT might also be a potentially useful biomarker for evaluation of disease progression and effectiveness of treatment for OAB. Consequently, ultrasound measurement of BWT has been proposed as a diagnostic variable in patients with BOO and other voiding dysfunctions. BWT measurement was assessed as a non-invasive test in control and test patients with BOO, DO or increased bladder sensation [574]. However, values were similar in all test groups, including those in the control and bladder dysfunction groups, and it was therefore concluded that it was unreliable predictor of BOO or DO.

In more definitive groups some predictive value has been suggested. DWT is increased in men with BOO and children with bladder-induced enuresis [575-577]. In men with BOO measurement of DWT was proposed as a useful diagnostic parameter, although there was not a consensus that it could replace conventional urodynamics as a predictor of DO [577-579]. However, further confirmation of the extent of the difference in DWT between patient groups is needed.

The diagnostic value of DWT in predicting DO in women has also been investigated. There was a statistically significant association between DWT and DO, however further analysis demonstrated that DWT as measured by translabial ultrasound was of limited use as a diagnostic test for DO [580]. Women with OAB might also have a greater DWT, suggestive of detrusor DO. DWT was measured by transabdominal and transvaginal ultrasonography
in controls and women with OAB-dry and OAB-wet. A greater DWT at bladder capacity measured by transabdominal ultrasound was observed for women with OAB and DO [581,582].

The clinical usefulness of measuring DWT as a non-invasive test in women with OAB was evaluated in sub-groups with no OAB symptoms, OAB-dry and OAB-wet. Women with OAB-wet had significantly greater DWTs than controls at maximal bladder volume. The maximal bladder capacity was significantly greater in controls than in those with OAB. DWT measured by transabdominal ultrasound in women with OAB and without OAB was not different and did not differ with urodynamic status and was not recommended as a useful diagnostic test for DO in women with OAB [583].

The ultrasound measurement of BWT in women was compared with different urodynamic diagnoses and data were compared with different urodynamic findings of DO. Women with DO had a significantly greater BWT and a cut-off of 6.5 mm had a positive predictive value of 100% for all DO. The ultrasound BWT showed a highly significant association with DO. However, it was considered that the performance of this test could not replace urodynamic testing [584].

However, the relationship between ultrasound estimation of bladder weight (UEBW) and variation of age, height, body-mass index (BMI) and body surface area (BSA) of individuals in the general population might confound the use of the method to identify bladder pathologies. A significant correlation between UEBW and both height and BSA for healthy volunteers (30 men and 40 women) has been measured [585]. Therefore, caution should be taken when extrapolating ultrasound data to patients with pathological function until the dependence of normal demographic factors on ultrasound variables has been fully-accounted for.

Methodological factors can also impact on the interpretation of data obtained from ultrasound measurements of bladder structure. A low echogenic zone between two layers of bladder wall has been used in the assessment of DWT, with a reported very low inter-observer and intra-observer variability in its measurement [586]. Discrepant data in measurement of DWT in patients with DO might include inconsistent bladder filling conditions or differences in resolution of the ultrasound probe. Total measured bladder volume is greater than that determined by transabdominal ultrasound or infused volume, and DWT decreased rapidly during the first 250 ml volume of filling, followed by a slower decrease during the second 250 ml [581,583] and represents the relative geometrical change of bladder shape during progressive filling. In addition, DWT measurements obtained using a low frequency probe (2-5 MHz) were greater than those obtained using a high frequency probe (7.5-10 MHz) [574,577-579,581,583,586].

Transvaginal ultrasound assessment of mean BWT has been postulated as a sensitive screening tool to detect DO in women with equivocal laboratory urodynamics. Measurement of BWT using transvaginal ultrasound has been claimed to discriminate between women with confirmed DO and those with urodynamic stress incontinence. Bladder wall thickness showed a positive correlation with pdet/Gmax and to urodynamic diagnoses of stress incontinence, DO and obstruction [587].

How then should bladder wall thickness be measured? A comparison of vaginal, perineal and abdominal ultrasound has been made to determine if abdominal, perineal and vaginal ultrasound measurements of bladder wall thickness are comparable. Vaginal ultrasound of BWT showed the smallest values, abdominal ultrasound the largest. At the trigone, differences were significant between vaginal and perineal ultrasound but not between abdominal and the perineal approach [588].

Ultrasonographic measurement for diagnosis and characterisation of LUTS is relatively new, but shows a promising future. Measurements of BWT, DWT and UEBW are potentially non-invasive clinical tools for assessing the lower urinary tract. Quantification of bladder wall hypertrophy seems to be useful for the assessment of diseases, prediction of treatment outcomes, and longitudinal studies investigating disease development and progression. However, lack of data in healthy asymptomatic subjects currently may account for some of the disparity between studies and hampers the use of ultrasound in routine practice. If methodological discrepancies can be resolved, BWT, DWT and UEBW should be valuable in assessing LUTS.

b) Near-infrared spectroscopy (NIRS) and DO

NIRS is an optical technology and detects the haemodynamic changes in tissues via non-invasive measurement of changes to the concentration of tissue chromophores such as oxyhemoglobin and deoxyhemoglobin. Involuntary bladder contractions may cause changes detectable by NIRS. A prospective cohort study was carried out on 41 patients with OAB symptoms to address the accuracy and reproducibility of NIRS and to detect the haemodynamic effects of DO. Those patients underwent one or more filling cystometries with simultaneous NIRS of the bladder as a successful proof-of-principle [589].

6. CONCLUSION

OAB is not a single clinical entity. Hence, it is difficult to develop a satisfactory biomarker for all kinds of OAB, but recent research has identified several potential biomarkers. In the near future, with further trials of urine, serum and bladder tissue biomarkers from patients with OAB, potential molecules which give rise to the urgency sensation might be isolated and serve as ideal biomarkers for OAB assessment.
1. INTRODUCTION

The rectum and anus serve as a reservoir for faecal contents and regulator of continence respectively. A number of mechanisms are involved in the maintenance of faecal continence and include a resting internal anal sphincter (IAS) tone, which is the main contributor to the development of a resting anal intra-luminal pressure and the external anal sphincter that enhances sphincter tone during voluntary squeeze. In addition, the endovascular cushions and the anal mucosal folds aid continence by maintaining an effective seal. A number of recto-anal reflexes involving all three arms of the autonomic nervous system (parasympathetic, sympathetic, enteric) act to regulate faecal storage and provide efficient evacuation of contents during defecation.

Faecal incontinence is a common condition defined as the uncontrolled passing of material or gas. The condition affects more than 10% of the population and that number may approach 20% in the elderly [590]. The most common cause of faecal incontinence is obstetric trauma to the internal or external sphincters, or the pudendal nerves. Often the injuries to younger women do not result in faecal incontinence until middle age when increasing general muscle weakness related to ageing also impacts, thus reflecting the common multi-factorial nature of this condition [591]. Other causes include damage to the endovascular cushions or mucosa resulting in a poor anal seal, pudendal neuropathy which interfere with sensory mechanisms leading to stool accumula-

tion and then faecal overflow and systemic sclerosis where the main cause is usually impaired function of the internal anal sphincter [592].

2. BASIC PHYSIOLOGY OF THE RECTUM AND ANUS

For the maintenance of faecal continence and timely defecation, coordination of rectal and anal activities are essential; there are two main recto-anal reflex pathways regulating activity in these regions. The first involves an excitatory pathway that is triggered by low volume rectal distension and elicits a desire to defecate and produces contraction of the puborectalis muscle and the IAS [593]. The second reflex is the recto-anal inhibitory reflex (RAIR), which is triggered by higher volume rectal distension and produces the urge to defecate and a transient relaxation of the IAS [593-596]. Thus the IAS receives both excitatory and inhibitory pathways from the rectum and both are important for normal continence.

Defecation requires the reflex activation of peristalsis in the rectum and the simultaneous relaxation of the internal anal sphincter (IAS). Excitatory motor responses in the rectum involve acetylcholine and substance P, while noradrenaline and ATP are the predominant transmitters operating in the IAS. The inhibitory motor reflexes are mediated predominantly via nitric oxide (NO) and vasoactive intestinal peptide (VIP) in both regions.

a) The internal anal sphincter (IAS)

The IAS is a ring of involuntary muscle formed by the thickening of the circular smooth muscle of the intestine (Figure 24). The sphincter develops spontaneous tone and contributes 50-85% of normal resting anal pressure [597,598]. This tone is predominantly

Figure 24. Structure of the human anus
myogenic in nature, but neuronal (mainly sympa-
thetic) and hormonal (eg angiotensin II) influences
may also contribute to the maintenance of sphincter
tone and the relatively high resting luminal anal pres-
sure required to maintain continence. The resting
anal pressure in humans decreases with age and is
linked to the increased prevalence of faecal inconti-
nence (F1) with age [599]. Also, it has been reported
that sphincter relaxation is enhanced in patients with
incontinence [600], again highlighting the important
role played by this tissue.

3. INNERVATION OF THE RECTUM AND ANUS

Studies of muscle contraction suggest that the
sympathetic innervation mediates contraction in
the internal anal sphincter but not rectum, while
nitrergic nerves mediate relaxation responses in
both tissues (see [601]). Thus in the rat, the my-
enteric ganglia of the rectum and anus appear to
receive cholinergic and nitrergic innervations and
this would agree with studies showing that atropine
inhibits both ascending and descending contractile
pathways, while NO synthase inhibition increases
contractile responses in both pathways [602].

a) Parasympathetic innervation

The parasympathetic nervous system innervates the
IAS and will be involved in defecation reflexes, but
the parasympathetic nerves do not significantly con-
tribute to the resting anal sphincter tone in vivo [603].
Early studies of IAS function in vitro reported that the
IAS contracted in response to muscarinic receptor
stimulation [604]. However this could not be con-
ferred in later studies where acetylcholine appeared
to act on muscarinic receptors to induce a relaxation
of the IAS [605]. These confusing results were later
explained when it was shown that the relaxation re-
sponses were mediated indirectly via the release of
nitric oxide [606]. The muscarinic receptor subtypes
involved in these direct contractile and indirect inhibi-
tory responses are unknown, but would represent
novel drug targets for influencing IAS tone.

In the rectum the predominant innervation is para-
sympathetic and atropine depresses ascending and
descending excitatory reflex pathways in this region
[602]. The innervation however runs to the myen-
teric ganglion, and the influence on smooth muscle
activity is indirect and mediated via interstitial cells
with which the nerves are closely associated.

b) Sympathetic innervation

The sympathetic system also has a dual role in the
IAS and has the ability to cause both contraction
and relaxation. Contraction of the IAS in response
to noradrenaline is attributed to the stimulation of α
adrenoceptors and relaxation is attributed to stimu-
lation of β adrenoceptors. It has been shown in sev-
eral species that there is a high density of α1 and
α2-adrenoceptors in the IAS and synthetic mixed
agonists such as clonidine induce IAS contraction
via both receptors [607]. The α2-adrenoceptors of this
tissue have been classified as the α2D-adrenoceptor
subtype [607]. However the overwhelming response
to nerve stimulation (see Figure 25) and the pre-
dominant mechanism maintaining tone of the IAS
is noradrenaline acting on α1-adrenoceptors. It

Figure 25. Effects of guanethidine on IAS responses to electrical field stimulation. In the presence of
guanethidine (10µM) contractile responses to EFS (5 Hz stimulation) were abolished, while relaxation re-
sponses were enhanced. (from [619]).
has been reported that the IAS also possesses β3-adrenoceptors that cause relaxation. Non-selective β-adrenoceptor agonists such as isoprenaline induce relaxation by a direct action on the smooth muscle, but β3-adrenoceptor selective agonists exert a direct relaxation action on the smooth muscle and also activate smooth muscle eNOS to induce nitric oxide release; both actions being antagonised by selective β-antagonists [608,609]. These sphincter inhibitory responses are totally masked by the α1-adrenoceptor contractile responses and the role of β-adrenoceptors in normal continence mechanisms is unclear.

Beta3-adrenoceptors are also generally expressed in the human enteric nervous system where they may release somatostatin and reduce neuronal activity [610,611]. Whether these sympathetic influences are involved in ano-rectal function is currently unknown.

c) Non-adrenergic, non-cholinergic (NANC) innervation

Vasoactive intestinal peptide (VIP) and the gaseous transmitters nitric oxide (NO) and carbon monoxide (CO) have been implicated in the relaxation of the IAS during defaecation. The presence of VIP and the enzymes responsible for the synthesis of NO (NO synthase) and CO (haem oxygenase, HO-1 and HO-2) have been demonstrated in the myenteric plexus of the mouse IAS (Rattan et al., 2005), while Western blot studies have shown the presence of nNOS, HO-1 and HO-2 in the smooth muscle of the IAS [612]. Functional studies using electrical field stimulation suggest that NO is the major transmitter mediating 80% of relaxation response, while VIP mediates the remainder. Evidence linking CO to relaxant responses of the IAS is lacking. CO and CO-releasing agents such as CORM-2 induce relaxation of the IAS [612,613], but inhibitors of CO (e.g. tin protoporphyrin IX) do not affect responses to field stimulation. Furthermore, in HO-2 knockout mice IAS responses to field stimulation are normal. Thus NO, VIP and CO can all cause relaxation of the IAS, but only NO and VIP appear to be involved in mediating nerve induced effects. This conclusion is supported by studies with nNOS deficient mice where relaxation of the IAS to rectal distension was significantly diminished [614].

d) Sensory innervation

The sensory innervations to the rectum and anus are very different. The anal canal is densely supplied with sensory nerves that respond to many modalities including touch, pain, temperature and friction. The sensory mechanisms in the rectum in contrast are limited and mainly respond to distension [615], low levels of distension stimulating the desire to defaecate, greater distension stimulating the urge to defaecate and activate the RAIR [593,596]. At least in the mouse, this sensitivity to a wide range of distension appears to be mediated via individual sensory fibres and nearly all of the rectal fibres sensitive to stretch respond from low levels of stretch right up to noxious distension [616]. Furthermore, the sensitivity of rectal mechanoreceptors increases during chemically-induced inflammation and is also augmented by inflammatory mediators such as bradykinin [617].

4. SMOOTH MUSCLE AND INTERSTITIAL CELLS

a) Smooth muscle

Rectal and anal smooth muscle differ in their functions: rectal muscle producing transient phasic contractions resulting in peristalsis; anal muscle developing spontaneous myogenic tone to maintain continence. To enable different functions, the muscles have different morphology, innervation and cell biology. In the rectum the circular muscle layer is composed of large muscle bundles spanning the whole muscle layer, whereas the muscle bundles of the IAS are subdivided into many smaller bundles separated by connective tissue layers [601]. The innervations (see above) and ICC distribution and function (see below) also differ between the rectum and IAS. Unlike the rectum, the smooth muscle of the IAS receives direct sympathetic and nitrergic innervations and the tissue possesses receptors for a range of transmitters and hormones including noradrenaline, acetylcholine, VIP, 5-HT, ATP, angiotensin II [618].

Contractile responses of the IAS are dominated by the sympathetic rather than the parasympathetic system and IAS smooth muscle contraction is mediated predominantly via α1-adrenoceptors. Three subtypes of α1-adrenoceptor exist (α1A, α1B, α1D) and an isoform of the α1A-adrenoceptor (the α1A/L) with a low affinity for prazosin has been identified in functional experiments [386]. The receptors of the IAS have been pharmacologically characterised as belonging to the α1A/L subtype [619]. Thus selective agonists at this receptor are a potential treatment for faecal incontinence and a few small-scale clinical trials with topical phenylephrine have been undertaken. These studies reported increases in anal pressure with 10% phenylephrine gel [620,621] and greater improvements with 40% gel [622]. Patients also reported subjective benefit but further clinical studies with α1-adrenoceptor agonist are required (for review see [623]).

As previously discussed, β-adrenoceptors are also located on IAS smooth muscle where they mediate relaxation. Using Western blotting, all three β-adrenoceptor subtypes have been shown to be present at the protein level (β2≥β1≥β3) in the human IAS [609]. In some species (e.g. rat) the β3-adrenoceptors predominate, but in human tissues β3-agonists induce maximum responses only one third the magnitude of those to non-specific β-adrenoceptor stimulation. Activation of the recep-
Rectum and IAS, where they are involved in the regulation of contractile activity. The cells express a tyrosine kinase (c-Kit) that is not expressed in muscle or nerves, and antibodies against this protein can be used to examine ICC distribution. Using these immunohistological techniques ICC have been identified as dense networks within the IAS in all species so far examined including human [629]. The c-Kit receptor is essential for the development of the ICC phenotype and mice lacking c-Kit (W/Wv mice) or its ligand, stem cell factor (Sf(Sf[d]) mice) have drastically reduced numbers of ICC (see [630]).

Several types of ICC exist with different morphology (spindle vs stellar) and function (neurotransmission vs pacemaker). One population which has an intramuscular distribution running along muscle fibres has a spindle appearance and generate slow electrical waves which are thought to be involved in neurotransmission. These cells transduce excitatory signals from the effenter parasympathetic nerves, with which they make synaptic connections, to smooth muscle fibres with which they make close contact via gap junctions [631]. The other population of ICC are located in the myenteric plexus and submucosal plexus. These have a stellate appearance, and are thought to act as pacemakers of contractile activity. In these cells spontaneous phasic slow wave activity passes between ICC and muscle fibres via gap junction and these can summate and initiate phasic contractile activity [632,633].

Contractile functions of the rectum and anus differ, the rectum demonstrating phasic contractile activity and the IAS spontaneous tonic muscular tone. These differences in function are reflected in the characteristics of their respective ICC. Also the density of ICC is higher in the rectum than the IAS [629]. Rectal ICC more closely resemble the spindle-shaped intramuscular ICC found throughout the rest of the gastrointestinal tract [601]. These ICC are involved in neurotransmission, with vagal and nitrergic motor fibres innervating intramuscular ICC. Gastrointestinal ICC possess receptors for acetylcholine (M2 and M3 receptors), tachykinins (NK1 and NK3 receptors) and VIP (VIP-1) [630].

The function of the sphincter is to develop tone rather than phasic contractile activity and the IAS differs from the rectum in having a predominantly sympathetic excitatory input and also a different distribution of ICC. In this tissue, the sympathetic motor fibres do not innervate the ICC of the myenteric plexus as in the rectum and do not appear to be associated with intramuscular ICC. Thus sympathetic nerves are likely to innervate directly the smooth muscle of the IAS [601], while the ICC may contribute to myogenic tone as proposed for these cells in some tissues such as the urethra [634].

As in the rectum the IAS has a nitrergic innerva-
tions, but unlike the rectum, these do not seem to innervate the ICC. The role of ICC has been investigated in mice deficient in c-Kit positive cells (W/Wv mice). These studies have identified a dense network of c-Kit immunoreactive cells in the IAS of normal but not mutated mice, and unlike the sphincters in the upper gastrointestinal tract where these cells are involved in nitricergic neurotransmission, in the IAS they do not appear to be involved in relaxation responses to EFS, since responses were normal in c-Kit knockout animals [635] although inhibitory junction potentials were depressed. Whether c-Kit expressing cells are essential for the RAIR is not yet clear. The reflex has been reported to be intact in c-Kit deficient mice in one study, while another has reported IAS relaxation in response to rectal distension is reduced in c-Kit deficient mice [595,614]. Thus in the sphincter, ICC do not participate in neurotransmission but may be involved in regulating muscle tone, and basal myogenic tone is lower in ICC deficient mice compared with controls [614].

Thus ICC in the rectum and anus differ, reflecting the different functions of these two tissues. There is also growing evidence that ICC play a role in sensory mechanisms in the gastrointestinal tract. Vagal afferent nerve endings are found in close proximity to ICC and it has been suggested that they are involved in stretch perception. In the stomach, mutations resulting in the loss of c-Kit or its ligand result in loss of vagal intramuscular mechanosensitivity (see [636]), Furthermore, in the bladder, interstitial cells release ATP when stretched, a chemical known to sensitise afferent nerves [87].

5. FUTURE DIRECTIONS FOR RESEARCH

Our lack of understanding of the physiology of the IAS and rectum hinder the development of new treatments for faecal incontinence. The distribution, types and regulation of interstitial cells and their activity in the anorectal region requires further investigation and this may yield novel drug targets. Several receptor systems have been identified within the IAS that warrant further attention (α1-adrenoceptor, muscarinic) and regulators of ICC activity may also be potential drug targets.

Drug development should be easier for faecal incontinence than urinary incontinence, since the location of the internal sphincter allows drugs to be administered topically as a gel by the patient. This has the benefit of avoiding any undesirable adverse effects that may be observed with oral administration. Surprisingly few drugs with actions on the IAS are currently in use, but this may reflect the lack of research support anorectal problems attract. The lack of knowledge in this area will make the development of new drug therapies difficult. A few clinical trials have examined α1-adrenoceptor agonists in patients with faecal incontinence but the numbers of patients have been very small.

One problem when using receptor agonist as a treatment option is that tissues may become desensitised to the drug. This is a general phenomenon the importance of which varies depending on the receptor subtype and the tissue in which the receptor is found. Whether the IAS α1-adrenoceptor undergoes desensitisation is unknown and this will be critical information for the development of a clinically useful drug.

The emergence of the RhoA/ROK pathway as an important regulator of myogenic sphincter tone also offers new possibilities for the development of novel treatments. More selective inhibitors of the RhoA/ROK isoforms could be developed. Alternatively, it has been suggested that small interfering RNA (siRNA) may provide a more selective approach to inhibiting this pathway [625].

Two other cellular approaches to treatment include the use of stem cells to improve anal pressure [637] and the bioengineering of new sphincters using the patient’s own smooth muscle cells [638]. Both techniques are in the very early stages of development and problems associated with blood supply to developing tissue and the establishment of a functional innervation once transplanted into the patient, pose major obstacles to development.

IX. RECOMMENDATIONS FOR RESEARCH CONCERNING LOWER URINARY TRACT (LUT) AND LOWER GASTROINTESTINAL TRACT (LGIT)

1. Integrate research obtained from isolated cells, tissue and organs to inform data from whole-organism measurements.

2. Increase research activity in poorly-investigated areas; e.g.: LUT outflow tract; lower GIT; nervous regulation of LUT and LGIT function.

3. Use genome-wide bioinformatic surveys to generate testable hypotheses regarding the physiological and pathophysiological functions of the LUT and LGIT

4. Investigate the pathophysiology of the LUT and LGIT by: developing animal models to address specific pathophysiologies; using human tissues from patients with clinically-defined pathologies.

5. Integrate multidisciplinary approaches to investigate LUT and LGIT function through collaborations in areas of e.g.: physical/mathematical modelling of LUT and LGIT function and physiological measurements; bioinformatics, genomics and cellular signalling; protein structure modelling
and generation of novel receptor ligands; tissue engineering.

6. Develop centres of excellence in LUT and LGIT research and integrate expertise from university departments, academic medical units and industry.

7. Encourage translational research to develop alongside basic research units.

8. Develop inter-institutional research-training programmes to allow new researchers the opportunity to better interact and exchange ideas.

9. Allow researchers-in-training better access to international meetings through reduced registration charges and travel grants.

10. Lobby research-funding organisations about the medical and social importance of LUT and LGIT disorders.

LP lamina propria
LUT lower urinary tract
Notes on convention of units and symbols

1 SI (Systeme Internationale) units have been used in the report; based on units of length (metre, m); mass (kilogramme, kg); time (second, s); electric current (ampere, A); amount of substance (mol, M):

2 Prefixes are k (10³), m (10⁻³), μ (10⁻⁶), n (10⁻⁹), p (10⁻¹²).

3 Derived units are combinations of SI units and include: voltage (V, = kg.m².s⁻³.A⁻¹); resistance (Ω = V.A⁻¹); conductance (S = Ω⁻¹); force (Newton, N = kg.m.s⁻²); frequency (Hz, s⁻¹); pressure (Pascal, Pa = Nm⁻²).

4 Some non-SI units, derived from SI units, include gramme (g), minute (min).

5 Some non-SI units without a precise definition are sometimes used: these include litre (l, approximate to dm³); mmHg and cmH₂O as units of pressure (1 mmHg ≈ 0.133 kPa; 1 cmH₂O ≈ 0.0981 kPa).

6 The molar unit of concentration (moles per dm³ solvent) is used, denoted by the letter M. Thus, the non-standard form of concentration - mol/L - is avoided, as it is meaningless in the SI system of units.

7 Symbols for ions in solution, e.g. Ca²⁺, Na⁺, K⁺, Mg²⁺ etc, refer to the species that are presumed to take part in chemical reactions. No assumptions are made about the activity coefficient of the species in solution.

OVERVIEW

This chapter deals with individual components regulating the neural control of the urinary bladder. This chapter has been completely remodeled and updated with the focus on factors and processes involved in the two models of operation of the bladder: storage and elimination. There has been significant new information since the last consultation in a number of fields:

- The urothelium and impact of various stresses on barrier as well as cell-signaling ('sensory web') as well as possible therapeutic targets
- The location and properties of bladder afferents including factors involved in regulating afferent sensitization including cross-talk between bladder and the bowel
- The neural control of the pelvic floor muscle and pharmacology of urethral and anal sphincters highlighting integral role in coordinating somatic and visceral function
- Efferent pathways to the urinary bladder
- Abnormal lower urinary tract function including abnormalities in afferent signaling, urine storage, voiding as well as co-morbid disorders associated with bladder pain syndrome and incontinence

Also incorporated are sections dealing with the current understanding of brainstem neuronal networks, which regulate lower urinary tract function[1-4]. The importance is reflected in the current advances in functional brain imaging which have had a major impact on understanding CNS control of the human bladder. This section has been completely revised to include recent advances in understanding of the central pathways regulating the control of detrusor and sphincter, discussion of homeostatic function and evidence that structural damage to critical connecting neural pathways may contribute to urgency incontinence.

Levels of Evidence

This book attempts to use Levels of Evidence throughout. The Oxford Centre for Evidence Based Medicine has laid down guidelines that apply to Levels of Therapeutic Interventions and Grades of Recommendations to Patients; the existence of dispute regarding each major conclusion should be documented. However this advice does not really apply to the basic sciences, where randomized controlled trials are not a common format of investigation, and acute studies with internal controls are more common.

Within this chapter we intend to be selective and report scientific evidence that has appropriate controls and achieves statistical significance. Other categories of evidence, e.g. uncontrolled studies, anecdotal information, hypothesis or speculation will be referred to as such.

Of some importance in this field are species differences, and efforts have been made to make it very clear when each new topic is introduced in which species the observation was made with special emphasis as to the extent comparable data exists for humans.

In this report, we intend to indicate whether the conclusions are based on (A) peer-reviewed papers in reputable journals (B) evidence in book chapters or reviews, and (C) Abstracts: abstracts will only be mentioned if they refer to a systematic study with good statistical methodology.

I. UROTHELIUM

The urothelium can be thought of as a first responder to various types of stress that can include physiological, psychological and disease-related factors. Alterations of bladder urothelium at the molecular and structural levels have been reported in both patients and animals modeled for various bladder disorders. It is likely that many therapies currently used in the treatment of bladder disease may target urothelial receptors and/or their release mechanisms.
1. ANATOMY AND BARRIER FUNCTION

The urothelium is the epithelial lining of the lower urinary tract between the renal pelvis and the urinary bladder. Urothelium is composed of at least three layers (the exact number of layers is species dependent): a basal cell layer attached to a basement membrane, an intermediate layer, and a superficial or apical layer composed of large hexagonal cells (diameters of 25-250 μm) known as ‘umbrella cells’. [5-8] These umbrella cells exhibit a distinctive plasma membrane that contains both ‘hinge’ and ‘plaque’ regions (Figure 1). The umbrella cells (which are also termed facet or superficial cells) are interconnected by tight junctions (which are composed of multiple proteins such as the claudins) and are covered on their apical surface (nearly 70-80%) by crystalline proteins called uroplakins that assemble into hexagonal plaques.[9-11] Uroplakins and other urothelial cellular differentiation markers, such as cytokeratin 20, are not expressed in the stratified epithelium of the urethra. There have been suggestions in early studies in some species, that the umbrella cells and perhaps also the intermediate cells may have projections to the basement membrane.[6, 7] The ability of the bladder to maintain the barrier function, despite large alterations in urine volume and increases in pressure during bladder filling and emptying, is dependent on several features of the umbrella cell layer. These features include tight-junction complexes that reduce the movement of ions and solutes between cells and specialized lipid molecules and uroplakin proteins in the apical membrane, which reduce the permeability of the cells to small molecules (water, urea, protons).[7, 12] The lipid composition of the apical membrane is unusual in composition and is rich in cholesterol, phosphatidylcholine, phosphatidylethanolamine and cerebroside.[13] Recent studies suggest that liposomes, consisting of an aqueous core enclosed in one or more phospholipid bilayers, may help to restore urothelial-barrier function. Liposomes have typically been used to transport drug molecules in a variety of cells. Urothelial cells appear to take up liposomes via an endocytotic process, providing evidence for a possible mechanism by which liposomes act as a drug delivery system.[14] In addition, empty liposomes have shown promise to repair and enhance the barrier function of a dysfunctional urothelium.[15-19] (Figure 2)

The apical surface of the urothelium is also covered with a sulfated polysaccharide glycosaminoglycan (GAG) or mucin layer that is thought to act as a nonspecific anti-adherence factor and as a defense mechanism against infection.[20-22] In addition, during bladder filling the umbrella cells become flat and squamous and this shape change is accompanied by vesicular traffic (i.e. exocytosis/endocytosis), adding membrane to the apical surface thereby increasing overall urinary bladder surface area.[11, 23, 24] This process of ongoing replacement of apical membrane by newly fused discoid vesicles also serves to maintain the urothelial barrier. [25] There is evidence that this stretch-induced exocytosis is dependent on activation of epidermal growth factor receptor (EGFR). [26, 27] These processes allow the bladder to accommodate increasing volumes of urine during filling without compromising the barrier function. There is some evidence that superficial urothelial cells exhibit a lower level of endocytotic activity, which may be a protective mechanism against internalization of toxic substances excreted in the urine.[28] Exocytosis/endocytosis (vesicular recycling) may also play an important role in modulating the release of a number of neurotransmitters/mediators as well as regulation of the function of many receptors and ion channels in urothelial cells. [29, 30]

2. UROTHELIAL CELLS AND REPAIR

Epithelial integrity is maintained through a complex process of migration and proliferation (to restore cell numbers) and differentiation (to restore function). [31] Basal cells, which are thought to be precursors for other cell types, normally exhibit a low (3-6 month) turnover rate, in fact the slowest turnover of

Figure 1. Ultrastructural features of umbrella cell apical membrane. Left: Scanning electron micrograph (high magnification) of apical surface of rabbit umbrella cell layer (hinges «H» marked with arrows). Right, high power view of tight junctions. (from Apodaca, 2004; Truschel et al., 1999).

Figure 2. (A,B) Fluorescent images following application of liposomes. A, liposomes instilled in a rat bladder forming a coating (green) on urothelial surface and in B, liposomes (in green) attached to primary cultured urothelial cell membrane. In C, rats treated intravesically with protamine sulfate (PS) exhibit damaged urothelium; D, rats treated with PS followed by liposomes had intact urothelium demonstrating protective effect of liposomes (from Kaufman et al., 2009 and Nirmal et al., 2012)
any mammalian epithelial cells.[13, 32] It has been suggested that neither urine-derived factors nor cyclic mechanical changes contribute to urothelial proliferation and differentiation. However differentiation of urothelial cells in culture can be stimulated by prostaglandin (which is abundant in the urine) [9, 33] and accelerated proliferation can occur in various bladder pathologies. For example, using agents (protamine sulfate; cyclophosphamide) that damage the umbrella cell layer, it has been shown that the urothelium rapidly undergoes both functional and structural changes in order to restore the barrier in response to injury.[28, 34, 35] Following disruption of the barrier, in the early stages of regeneration the superficial cells may appear smaller in size and often covered with microvilli.[34] In some pathologies, a deficiency or defect in maturation or terminal differentiation of superficial umbrella cells have been reported, though the factors which may be involved are not yet known.[36]

The processes underlying urothelial repair is complex, involving several structural elements, signaling pathways, trophic factors and the cellular environment. Furthermore, the interaction between these biochemical signals and mechanical forces in the bladder during the course of urothelial repair is not well understood. For example, the initiation of urothelial proliferation or differentiation of intermediate cells is thought to involve up-regulation of growth factors such as fibroblast growth factor and nerve growth factor (NGF).[37, 38] In addition, members of the PPARγ and EGFR signaling pathways may contribute to urothelial ‘re-epithelialization’ in wound repair.[33] There is also evidence that Hedgehog/Wnt signaling acting across the basal urothelial cell-stromal cell boundary, contributes to increases in urothelial proliferation in response to injury.[39] Though the urothelium maintains a tight barrier to ion and solute flux, a number of local factors or stressors such as tissue pH, mechanical or chemical trauma, hormonal changes or bacterial infection can modulate the barrier function of the urothelium.[7, 29, 40] Stress-mediated activation of the hypothalamic-pituitary-adrenal axis can result in increased production of corticotrophin releasing factor, which can regulate neuroendocrine and autonomic responses to stress. The net effect can include disruption of the epithelial barrier and increased prevalence of infection. In addition, altered levels of circulating estrogens have been associated with changes to the urothelial structure including epithelial shedding or mucosal atrophy.[41, 42] Other conditions such as bladder pain syndrome/interstitial cystitis (BPS/IC), senescence or spinal cord injury are also associated with changes in the urothelial barrier.[43, 44] Studies utilizing aged animals have demonstrated significant alterations to the bladder mucosa including areas of mucosal denudation.[45, 46] In addition, there is evidence in many types of epithelium (including uro-epithelium) that adhesion molecules such as members of the cadherin family play important roles in establishing and maintaining epithelial-cell contacts.[47] Altered urothelial-cadherin expression has been reported in BPS/IC patient bladder urothelium. Disruption of urothelial barrier integrity has also been linked to the expression of substances such as antiproliferative factor (APF), which also slows urothelial cell growth. [48-50] APF, a frizzled 8 protein detected in the urine of patients with BPS/IC, is secreted by bladder epithelial cells obtained from these patients. Treatment of urothelial cells from normal patients with purified APF decreases the expression of adhesion and tight junction proteins.

Both physiological and psychological stress can result in a failure of urothelial and suburothelial defensive systems and thereby promote changes in both urothelial barrier and signaling function. For example, alterations in proteins including proteoglycans and bacterial defense molecules may lead to distinctive changes in urothelial structure and play a role in bacteria adherence.[51] In this regard, urinary tract infections produced by uropathogenic Escherichia coli (UPEC) are initiated by bacterial adherence to uroplakin proteins on the apical surface of umbrella cells.[40, 52] (Figure 3A) The UPEC express filamentous adhesive organelles

Figure 3A: Image depicts an intracellular bacterial “pod” on surface of a C3H/H3J mouse bladder infected with UT189. (from Anderson et al., 2003).

(type 1 pili) that mediate bacterial attachment, invasion and apoptosis of the urothelial cells. It has been suggested that urothelial differentiation (and increased uroplakin III expression) plays a pivotal role in sensitizing urothelial cells to UPEC-induced infection and possible cell death.[53] Even acute contact (within hours) of the mucosal surface by bacteria may result in altered urothelial barrier function.[54] UPEC can also internalize within umbrella cells forming intracellular colonies (biofilm-like pods) of UPEC that has been implicated in the mechanism of chronic urinary tract infections. UPEC are able to commandeर the endocytic/exocytic machinery of urothelial cells, residing inside fusiform vesicles. [55] This permits the bacteria to escape elimination during voiding and re-emerge into the urine during distension. When expelled into the urine during the storage phase, the urine may provide a nutrient-rich environment optimizing bacterial survival. Evidence supports a role for endotoxin (lipopolysaccharide, LPS) on the bacterial cell wall in mediating the pain associated with UPEC infection.[56] (Figure 3B).

Disruption of urothelial function can also be induced by more remote pathological conditions that influence neural or hormonal mechanisms. For example, spinal cord transection in rats leads to a rapid alteration in the urothelial barrier including ultrastructural changes and increased permeability.[44] The changes are blocked by pretreatment with a ganglionic blocking agent, suggesting an involvement of efferent autonomic pathways in the acute effects of spinal cord injury on bladder urothelium. Other types of urothelial-neural interactions are also likely, based on the recent reports that various stimuli induce urothelial cells to release chemical mediators that can in turn modulate the activity of afferent nerves.[7, 29] This has raised the possibility that the urothelium may have a role in sensory mechanisms in the urinary tract.

In summary, modification of the urothelium and/or loss of epithelial integrity in a number of pathological conditions can result in passage of toxic/irritating urinary constituents through the urothelium or release of neuroactive substances from the urothelium. This may lead to changes in the properties of sensory nerves and in turn sensory symptoms such as urinary frequency and urgency. Thus chemical communication between the nervous system and the urothelial cells may play an important role in the generation of urinary bladder dysfunction.

3. UROTHELIAL HETEROGENEITY

Studies (comparing a number of species) have shown that the major part of the urinary tract is lined with a fully differentiated urothelium.[9] Findings in cultured cells reveal a distinct difference in morphology of ureteral and bladder urothelial cells, supporting a difference in cell lineage. Present evidence suggests at least 3 urothelial lineages: 1) those of the ureter/renal pelvis, 2) detrusor/trigone and 3) bladder neck/proximal urethra.[57] There seems to be no apparent difference between the urothelium of the trigone compared to the detrusor, in contrast to cells from the proximal urethra.[9, 58] In this region, there is a transition from urothelium to a stratified or columnar epithelium accompanied by a lack of urothelial-specific differentiation markers. In addition, peptide/amine-producing endocrine cells termed ‘paraneurons’ are distributed within the urethral epithelia. These cells, which are often exposed to the lumen and may share similarities to GI enterochromaffin cells, are covered with microvilli (Figure 4), and may also serve a sensor role for chemical as well as mechanical signals. [59] The functional significance of these findings has yet to be determined.

4. ROLES FOR UROTHELIAL CELLS IN VISCERAL SENSATION

While urothelial cells are often viewed as bystanders in the process of visceral sensation, recent evidence has supported the view that these cells function as primary transducers of some physical and chemical stimuli and are able to communicate with underlying cells including bladder nerves, smooth muscle and inflammatory cells. (Figure 5)

The urothelium is able to respond to a wide variety of mechanical stresses during bladder filling and emptying by activating a number of possible transducer proteins. Possibilities of mechanical signals include bladder pressure, tension in the urothelium

Figure 4. Images depicts “open type” paraneurons in the dog urethra. A, paraneuron reaching the lumen; B-D, Scanning EM identifies (arrows) microvillous cells among the epithelial cells. A: x14,000; b: x4600, c: x12,000, d: x16,000. (from Hashimoto et al., 1999).
or bladder wall, torsion, geometrical tension, movement of visceral organs and even urine tonicity. Alterations in the composition of urine are a type of stress whose contents can vary in both their rate of delivery as well as the particular constituents.

Additional lines of evidence suggest that urothelial cells participate in the detection of both physical and chemical stimuli. Bladder nerves (afferent and efferent) are localized in close proximity, and some within, the urothelium.[60-63] In addition, urothelial cells express numerous receptors/ion channels similar to that found in both nociceptors and mechano-receptors. And finally, these cells secrete a number of transmitters or mediators capable of modulating, activating or inhibiting sensory neurons.

a) Urothelial-Neuronal Signaling

Recent studies have shown that both afferent and autonomic efferent nerves are located in close proximity to the urothelium. Peptidergic, P2X- and TRPV1-immunoreactive nerve fibers presumed to arise from afferent neurons in the lumbosacral dorsal root ganglia are distributed throughout the urinary bladder musculature as well as in a plexus beneath and extending into the urothelium.[29, 62] In humans with neurogenic detrusor overactivity intravesical administration of resiniferatoxin, a C-fiber afferent neurotoxin, reduces the density of TRPV1 and P2X3 immunoreactive suburothelial nerves, indicating that these are sensory nerves.[64, 65] In addition, immunohistochemical studies have also revealed both adrenergic (tyrosine hydroxylase) positive as well as cholinergic (choline acetyltransferase, ChAT) positive nerves in close proximity to the urothelium.[61]

A network of cells with morphologic characteristics similar to those of myofibroblasts or interstitial cells is also detected in the suburothelial space of the bladder in both humans and animals.[66-70] These cells, which are extensively linked by gap junctions and have close contacts with nerves, can respond to neurotransmitters, such as ATP released from nerves or urothelial cells, suggesting that they could act as intermediaries in urothelial-nerve interactions.[66, 69, 71] Thus the anatomic substrates for bidirectional urothelial-neural communication exist within the urinary bladder.

b) Involvement of the Urothelium in “Sensing” Chemical and Mechanical Stimuli

The involvement of urothelial function in sensory signaling is suggested by the finding that urothelial cells express various receptors that are linked to mechano- or nociceptive sensations. Examples of neuronal “sensor molecules” (receptors / ion channels) that have been identified in urothelium include receptors for purines (P2X [1-7] and P2Y [1,2,4]) adenosine (A1, A2a, A2b and A3), norepinephrine (α and β), acetylcholine (muscarinic and nicotinic), protease-activated receptors (PARs), amiloride- and mechanosensitive epithelial sodium channels (ENaC), bradykinin (B1 and B2), neurotrophins (p75, trkA, EGF family Erb1-3), corticotrophin releasing factor (CRF1 and CRF2), estrogens (ERα and ERβ), endothelins and various TRP channels (TRPV1, TRPV2, TRPV4, TRPM8 and TRPA1). [72-82] The expression of these various receptors enable the urothelium to respond to a number of “sensory inputs” from a variety of sources. These inputs include increased stretch

Figure 5. Hypothetical model depicting possible interactions between bladder nerves, urothelial cells, smooth muscle, interstitial cells and blood vessels. Urothelial cells can also be targets for transmitters released from nerves or other cell types. Urothelial cells can be activated by either autocrine (i.e. auto regulation) or paracrine (release from nearby nerves or other cells) mechanisms.
during bladder filling, soluble factors (many found in the urine) such as epidermal growth factor (EGF), or chemical mediators/peptides/transmitters such as substance P, calcitonin gene-related peptide (CGRP), corticotrophin releasing factor (CRF), acetylcholine, adenosine or norepinephrine released from nerves, inflammatory cells and even blood vessels.[29, 30, 83, 84]

Various stimuli can lead to secretion of numerous chemical substances such as neurotrophins, peptides, ATP, acetylcholine, prostaglandins, prostacyclin, nitric oxide (NO) and cytokines that are capable of modulating the activity of underlying smooth muscle [71, 85] as well as nearby sensory neurons. For example, urothelial-specific overexpression of NGF results in increased bladder nerve ‘sprouting’ and increased voiding frequency.[86, 87] It has been shown that urothelial-derived NO can be released in response to mechanical as well as chemical stimulation and may either facilitate or inhibit the activity of bladder afferent nerves conveying bladder sensation.[82, 88] In this regard, activation of urothelial-receptors and release of inhibitory mediators may explain in part, the mechanism of action for therapies (e.g. β3-adrenergic receptor agonists) in treatment of bladder disorders such as OAB.[89-91]

The mechanism underlying release of chemical mediators from the urothelium, including whether all sensory “inputs” stimulate membrane turnover (i.e. vesicular exocytosis) is not well understood. What little is known about the roles and dynamics of membrane-bound cytoplasmic vesicles in urothelial cellphysiology is derived from measurements of membrane capacitance and microscopy of fixed tissues and cells. For example, there is evidence that once released, ATP can act as an important autocrine mediator, which can induce membrane turnover as well as enhance both stretch induced exocytosis and endocytosis.[92] Alterations in membrane turnover can not only increase apical surface area (as described above) but also regulate the number and function of receptors and channels at the cell surface.

There is evidence that epithelial cells in different organ systems may express similar receptor subtypes. [93-95] Accordingly, epithelial cells could use multiple signaling pathways, whose intracellular mechanisms differ according to location and environmental stimuli. This would permit a greater flexibility for the cell to regulate function and respond to complex changes in their surrounding microenvironment. Whether urothelial-sensor molecules all feed into a diverse array of signaling pathways or share similarities with systems such as olfaction, whereby hundreds of receptors share identical transduction cascades[96], is yet to be uncovered.

1. **Purinergic Receptors**

Since the first report of distension-evoked ATP release from the urothelium there is now abundant evidence supporting a role for urothelially-derived release of ATP in autocrine and paracrine signaling within the lower urinary tract. ATP is abundant in the cell cytoplasm and can be released extracellularly by several mechanisms including vesicular exocytosis, transporters such as a member of the ATP-binding cassette (ABC) transporter superfamily, or anion-selective channels such as the maxi-anion channel.[75] ATP is released from both the apical and basolateral urothelial surfaces in response to bladder stretch and can act on P2X2 and P2X3 urothelial receptors to stimulate stretch-induced exocytosis.[92] (Figure 6) The expression of both P2X and P2Y receptors in nerve fibers and myofibroblasts in close proximity to the bladder lumen and the sensitivity of these cells to ATP suggests that basolateral ATP release from the urothelium may also influence function of myofibroblasts and bladder nerves.[97] The amiloride-sensitive apical sodium channel, ENaC, may be involved in mechanotransduction by controlling basolateral release of ATP.[98] In addition, intercellular communication mediated by gap junctions in myofibroblasts could provide a mechanism for long-distance spread of signals from the urothelium to the detrusor muscle. [71] Interestingly, this type of nucleotide-mediated wave of cell-cell communication may also play a role in the response to injury.[99] While evidence supports a role for ATP and purinergic receptors in modulating symptoms in several urologic diseases, the mechanisms underlying activation of the micturition pathway at lower bladder volumes (during urgency) and mediators (amount; type) involved are not understood. In addition, the directionality of transmitter release, the mixture of receptor subtypes in the apical and basolateral domains and interactions between multiple-transmitters is likely to affect the nature of the output in both health and disease.

2. **TRP Channels**

The ability of capsaicin to evoke NO release from rat urothelium, reported in 1998, provided the first, albeit indirect, demonstration that TRPV1 channels

![Figure 6. Image is a 3-dimensional reconstruction (taken with a confocal microscope) depicting localization of P2X3 (green; nuclei blue) in the urothelium (from wang et al.2005).](image-url)
are expressed in urothelial cells and that urothelial cells and afferent nerves, which also express these channels, share a number of common properties. [100] This ion-channel protein is activated by capsaicin, as well as to moderate heat, protons, nitro-fatty acids and lipid metabolites such as anandamide (an endogenous ligand of both cannabinoid and vanilloid receptors).[101, 102] Activation of urothelial cells with capsaicin or resiniferatoxin can increase intracellular calcium, evoke transmitter (nitric oxide, NO or ATP) release and elicit transient currents.[82, 103] Similar to that in sensory neurons, urothelial response to vanilloids are enhanced by low pH, blocked by TRPV1 antagonists and eliminated in TRPV1 null mice.[62] In afferent neurons, TRPV1 is thought to integrate/amplify the response to various stimuli and to play an essential role in the development of inflammation-induced hyperalgesia. It seems likely that urothelial-TRPV1 might participate in a similar manner, in the detection of irritant stimuli following bladder inflammation or infection.

Though TRPV1-null mice are anatomically normal, they exhibit a number of alterations in bladder function, including a reduction in stretch-evoked and hypotonic-evoked ATP release and stretch-evoked increases in membrane capacitance.[62] In addition, TRPV1 knockout mice have a higher frequency of low-amplitude, non-voiding bladder contractions suggesting the possibility of a small but ongoing role for TRPV1 in normal urine storage function. Altered responses to distension were also detected in TRPV1 null mice, demonstrating a role of TRPV1 in excitability of lower threshold bladder afferents.[104] These relatively benign changes may result from TRPV1 expression not only in afferent nerves that form close contacts with bladder epithelial (urothelial) cells but also in urothelial cells themselves. These findings demonstrate that the functional significance of TRPV1 in the bladder extends beyond pain sensation to include participation in normal voiding function, and is essential for mechanically evoked purinergic signaling by the urothelium.

3. ADDITIONAL TRP CHANNELS

Much less is known about the involvement of other TRPs in bladder function or disease. TRPV4 which is a nonselective cation channel activated by a number of stimuli including heat, shear stress, changes in osmolarity and lipid ligands is expressed mainly within the epithelium of the urinary bladder.[105] While a definitive role for TRPV4 in bladder function has not been established, there is evidence that null mice exhibit impaired voiding responses and, intra vesical instillation of a TRPV4 agonist in the rat triggers a novel voiding reflex which could regulate the late phase of micturition.[63, 106] Additional studies suggest activation of urothelial-TRPV4 facilitates bladder reflexes via activation of mechanosensitive, capsaicin- (insensitive) C fibers.[107] In addition, in the awake ewe, TRPV4 may also be involved in a urethra to bladder reflex, proposed to facilitate bladder emptying.[108] Another member of the TRP family, TRPA1 (characterized as a thermoreceptor activated by noxious cold), is expressed in C-fiber afferents as well as urothelium and agonists to this channel induce bladder hyperreflexia.[109] Of interest is the finding that hydrogen sulfide, which may be formed during infection/inflammation, is an activator of TRPA1.[110]

4. ACETYLCHOLINE AND THE UROTHELIUM

There is evidence that the urothelium expresses the full complement of muscarinic receptors as well as enzymes necessary for the synthesis and release of acetylcholine.[83, 111] Further, the urothelium is able to release acetylcholine following both chemical and mechanical stimulation. [83] The mechanism underlying acetylcholine release from urothelium may be through organic cationic transporters (OCTs) rather than vesicular exocytosis, differing from that of bladder nerves.[112] Once released, urothelial-derived acetylcholine is likely to exert effects via a number of sites including smooth muscle, nerves as well as urothelial associated-muscarinic or nicotinic receptors, the latter that could contribute to feedback mechanisms modifying urothelial function.[79, 113] In addition, stimulation of urothelial-cholinergic receptors elicits release of mediators such as nitric oxide, prostaglandin as well as ATP, which could alter bladder sensation by stimulating nearby sensory afferent nerves.[79, 114-116]

Thus, targeting muscarinic receptors and/or urothelial synthesis or release mechanisms may play an important role in the treatment for a number of bladder disorders. By inhibiting SNARE-dependent exocytotic processes, botulinum toxin A (BoNT/A) can prevent the release of transmitters from bladder nerves as well as translocation of various receptors and channels to the plasma membrane.[117] Urothelial-derived acetylcholine may not be sensitive to BoNT/A, however studies have shown that other transmitters (such as ATP) released by the urothelium can be blocked by this treatment in addition to normalizing the expression of urothelial-receptors (TRPV1; muscarinic) and trophic factors.[118, 119] [120, 121] Preliminary studies using immunoblotting indicate expression of the SNARE proteins SNAP23; SNAP25 (Birder unpublished observations) as well as the high affinity binding site SV2 in both rodent (Birder unpublished observations) and human mucosa.[122] These and other studies suggest that the urothelium may be a target for this treatment and that urothelial-released mediators may contribute to sensory urgency.

5. CLINICAL SIGNIFICANCE OF THE SENSORY WEB

Defects in urothelial sensor molecules and urothelial-cell signaling are likely to contribute to the pathophysiology of bladder diseases. For example, a number of bladder conditions (BPS/IC, spinal cord injury (SCI), chemically-induced cystitis) are associated with
augmented release of urothelial-derived ATP, which is likely to result in altered sensations or changes in bladder reflexes induced by excitation of purinergic receptors on nearby sensory fibers.[76, 123] ATP can also act in an autocrine manner to facilitate its own release from urothelial cells. Augmented expression/release of urothelial-derived chemical mediators is likely to reduce the threshold for activation of nearby bladder afferents. Thus, the urothelium has the potential for amplifying signals, both within the urothelium and the bladder wall and contributing to a gain of function in sensory processing. Stressors that can impact on this ‘gain of function’ include alterations in levels of trophic factors as well as stress and steroid hormones. For example, altered levels of circulating estrogens may play a role in urinary bladder dysfunction, including urgency and frequency.[124] The resulting structural and functional abnormalities may lead to enhanced signaling between the urothelium and underlying cells.

Changes in epithelial signaling/barrier function would not be unique to the urinary bladder. For example, airway epithelia in asthmatic patients as well as keratinocytes in certain types of skin diseases also exhibit a number of similar abnormalities and compromised repair processes.[125, 126] This is particularly relevant given the high incidence of associated diseases that can include both visceral and somatic conditions, many of which exhibit a shared loss of epithelial barrier function. Taken together, epithelial cells can respond to a number of challenges (including environmental pollutants and mediators released from nerves or nearby inflammatory cells) resulting in altered expression and/or sensitivity of various receptor/channels as well as changes in release of mediators, all of which could impact function.

II. AFFERENT NEURONES

1. OVERVIEW: PROPERTIES OF AFFERENT NEURONES

The bladder and lower urinary tract serves to store and evacuate urine and is controlled by a complex hierarchy of neural mechanisms organized by local, spinal and brain circuits. Most of the time is spent in storage mode during which the bladder accommodates urine and maintains continence via reflexes that prevent contraction of bladder smooth muscle and contract the urethral sphincter. This switches during micturition when the bladder contracts and the sphincter opens to facilitate voiding. This switch relies on sensory signals, which provide the input to the reflex circuits that control bladder filling and emptying and are also the source of both non-painful sensations of fullness and pain. Dysfunction leads to a number of distressing disorders such as overactive bladder syndrome (OAB) and Bladder Pain Syndrome/Interstitial Cystitis (BPS/IC) with symptoms including urgency, pain and urinary incontinence. Currently available therapeutic approaches are aimed primarily at reducing bladder contraction in order to relieve intravesical pressure and maintain continence. Interest in bladder afferent signalling has been fuelled by the recent realization that symptoms are a feature of dysregulated storage rather than exaggerated contractile responses and therefore targeting afferent mechanisms may be a rational approach to treatment.

Our understanding of bladder afferent signalling has been advanced by studies that are designed to reveal firstly, the morphological features of the afferent terminations in both the periphery and spinal cord; secondly, identify the receptors and ion channels present on these terminations that determine afferent excitability and, thirdly, by recording electrophysiologically the action potentials in afferent fibres it has been possible to characterize the stimulus-response functions of the various populations of afferents conveying sensory information towards the CNS. Such afferent recordings have been performed in vivo in anaesthetized animals and in vitro using isolated tissue preparations. In vivo studies have the advantage that reflex function remains intact although they may be influenced by the use of anaesthetics. Also, by maintaining vascular perfusion, tissue oxygenation will be better maintained, and blood borne factors, including leukocytes, important for neuro-immune functions, can be recruited to the bladder milieu. Similarly, any biochemical factors released into the tissue will be rapidly eliminated into the blood stream. However, an intact vascular supply may also offer a number of disadvantages. Reflex changes in blood flow may lead to secondary alterations in afferent firing, while in the absence of blood flow there is the potential for surgical and pharmacological interventions to probe stimulus-response function. For example, flat-sheet preparations with the urothelium uppermost in a tissue bath allow the pinpoint mapping of receptive fields and the localized application of stimuli directly to the surface of the urothelium. In contrast, surgical removal of the urothelium and sub-urothelial tissue has been used to determine the source of afferent signals from different layers of the bladder wall and the role of urothelial factors in afferent activation. The perfusion medium can incorporate drugs to target specific ion channels and receptors that would be lethal to the whole animal or can be manipulated (calcium-free conditions) to attenuate processes that require calcium entry for downstream signalling. The combination of these different approaches has been essential in understanding the nature of sensory signalling from the lower urinary tract.

2. PATHWAYS TO THE SPINAL CORD

Afferent fibres reach the lower urinary tract via pelvic, hypogastric (lumber splanchnic) and pudendal nerves. These nerves are mixed nerves that also contain the efferent parasympathetic, sympathetic and motor fibres supplying the bladder, urethra and sphincters. Axonally transported dyes applied to these nerves are taken up and transported to the
cell bodies in the lumbosacral dorsal root ganglia and the terminations in the spinal cord. Mapping the distribution of these dorsal root ganglia (DRG) allows the pattern of innervation to be determined in detail and when used in combination with immunocytochemistry provide information on the neuronal phenotype. Moreover, these neurones can be isolated and maintained in cell culture and the labelling using to identify specific functional properties of bladder projecting sensory neurones.

Only a small proportion of DRG neurones supply the viscera with majority supplying somatic targets in the skin and skeletal muscles. Those supplying the bladder are pseudounipolar with a central projection into the dorsal horn of the spinal cord and a peripheral axon that terminates at different levels in the bladder wall. DRGs supplying pelvic and pudendal afferents originate in the thoracic, lumbar and sacral regions while hypogastric afferents arise mainly from the rostral lumbar dorsal root ganglia. The central projections of these DRG neurones carry the sensory information from the lower urinary tract to second order neurons in the spinal cord. These second order neurons provide the basis for spinal reflexes and ascending pathways to higher brain regions involved in micturition and in mediating sensation (described elsewhere in this volume).

The cell size of bladder DRGs is consistent with there being 2 populations of afferent with one connecting to small unmyelinated C-fibre afferents and the other to finely myelinated A-delta fibres. These cell bodies can be further classified according to the presence or absence of certain biochemical markers, namely peptidergic and non-peptidergic. Many unmyelinated afferents are peptidergic, containing calcitonin-gene related peptide (CGRP) and many of these also contain substance P as well as various other peptides. However, some small myelinated fibres also express CGRP. Non-peptidergic neurones can be identified by labelling for isolectin IB4, which recognizes terminal sugar residues on the cell membrane. Both small and medium sized DRGs are labelled with IB4. This non-peptidergic subgroup also expresses P2X3 receptors, which is predominantly found in small unmyelinated fibres. TRPV1 and other sensory markers described below are expressed on both peptidergic and non-peptidergic populations.

Staining for these sensory markers have also been used to identify the terminations of sensory afferents in the bladder wall. CGRP-containing afferent fibres are abundant in the bladder wall and distributed within 4 different layers distinct layers: within the urothelium, around the base of the urothelium within the lamina propria, in the muscle and associated with blood vessels in the serosa. These fibres have conspicuous varicosity, which are release sites for stored transmitter indicating a role for these afferents in so called “axon reflexes”. Upon activation the afferents convey information towards the CNS but also release mediators onto cells in their vicinity to mediate localized responses. Targets for these mediators include vascular smooth muscle, detrusor muscle, urothelium, fibroblast-like cells, mast cells and other neurones. In the human bladder, CGRP containing fibres occur only infrequently in nerves in the muscle but are moderately frequent in the suburothelial layer. Some of these fibres synapse on intramural ganglia within the bladder forming the basis for local neural reflexes.[127-130] Ultrastructural studies of human bladder have found only unmyelinated nerves in the urothelium and immediate suburothelial layer, small myelinated nerves being closely associated with the smooth muscle layers.[131] The plexus of afferent nerves in the lamina propria is thickest in the neck of the bladder and in the initial portion of the urethra, and becomes progressively less dense in the adjacent regions such that cranial region of the bladder have no afferent axons. In contrast, the afferent innervation of the musculature is more uniform throughout the bladder.

3. FUNCTIONAL PROPERTIES OF BLADDER AFFERENTS

Recording from bladder afferents has confirmed the diversity of afferent populations described above based on morphology.[132] Conduction velocity measurements confirm the predominance of fibres conducting action potentials in the A-delta and C-fibre range. The majority of these are mechanosensitive, responding to bladder filling with a range of thresholds from volumes that would be encountered under normal bladder filling to extreme levels of distension that would be considered noxious and give rise to pain. Those with lower thresholds have small myelinated axons while unmyelinated fibres have generally higher thresholds for activation. Other afferents do not respond to bladder filling. Some can be activated by intraluminal chemicals such as hypertonic saline, capsaicin or ATP, suggesting they may function as chemoreceptors. Others may be so called “silent afferents” that have been described elsewhere including the gastrointestinal tract. These afferents can be sensitized during inflammation suggesting a role in signaling pain.

A series of studies have used open-sheet preparations of guinea-pig bladder to examine the diversity of bladder afferents and to attempt to correlate structure with function. Low threshold afferents have terminals in the muscle where they have been described as having “antenna-like endings” and are referred to as stretch sensitive muscular mechano-receptors. [133-135] Since these afferents also respond to contraction of the detrusor muscle there are also called tension receptors since they respond to tension generated by both elongation during stretch and shortening during contraction. High threshold afferents are also likely to terminate in the deeper muscle layers or in the serosa. These mechano-sensitive endings have receptive fields (located by mechanical probing) associated with blood vessels. These likely respond to high levels of stretch that distort the bladder wall but may also become sensitized in response to inflammation.
Another class of mechanoreceptor can be activated by stretch and by light stroking of the urothelium. These endings are referred to as muscular-mucosal by analogy to similar endings in the bowel wall but muscular-urothelial mechanoreceptor may be a more correct term. Their sensitivity could arise because the afferent terminal branches to supply the muscle and urothelium or a single ending in the lamina propria might detect changes in muscle tension and stimulation of the urothelium. Zagorodynuk et al suggest that non-peptidergic “grape like” endings in the lamina propria may be the substrate for these endings. Other urothelial endings respond to stroking but not stretch and some of these are stimulated by luminal chemicals such as capsaicin, acid and are temperature-sensitive. Peptidergic afferents identified by dye filling from the pelvic nerve may be the basis for these epithelial responses.

Mechanosensitivity can arise either directly as a consequence of mechanosensitive ion channels on the sensory nerve ending or secondary to chemicals released in response to stimulation, which in turn activate the ending secondary to stimulation of ligand-gated ion channels. As outlined below there is considerable debate as to the role of the urothelium in sensory signaling. One attempt to resolve this has been to dissect off the urothelium and lamina propria and determine the impact on mechanosensitivity. In the case of muscular and serosal mechanoreceptors removal of the urothelium has little impact on distension response, suggesting these endings may be directly responsive, although the nature of the mechanosensitive ion channels has yet to be elucidated. In contrast the response of muscular-urothelial endings to distension is markedly attenuated following removal of the surface layers of urothelium. The same is true for the mucosal endings. This could imply that the urothelium is involved in transducing stimuli. However, an alternative view might be that dissection causes damage to the underlying nerves that are no longer able to respond to any stimulus. An alternative approach to determining the role of the urothelium may rely on pharmacological manipulations that interfere with urothelial signaling. In this respect the response of low threshold mechanoreceptors was unchanged in calcium-free buffer, which would be expected to prevent urothelial mediator release through exocytosis.

More recent studies in the mouse identified similar populations of afferents and used a systematic classification system to establish the relative proportion of these different types of afferents in the pelvic and lumbar splanchnic nerve supply. The basis for classification and the relative distribution of the terminals and projecting pathway is shown in Figure 7. Another important observation in this study was the finding that both low threshold and high threshold mechlosensitivity became heightened following exposure to inflammatory mediators which has implications for our understanding of how sensory signaling is altered in disease and a basis for altered miciliation and sensations such as pain. There are also recent studies that identified and characterized sacral afferents responding to ‘low’ through the urethra. These are important observations whereby properties of these flow-responsive afferents seem

Figure 7. LUT afferent nerve classes and distribution. A, fiber classes in bladder wall and urethra. B, in pelvic nerve 4 types of mechanosensitive fibers were identified by stretch, stroke and probe. C, proportion of afferent fiber types recorded in pelvic nerve. D, low and high threshold receptive fields of pelvic nerve muscle fibers based on response to stretch. E, receptive fields of 4 pelvic nerve fiber classes (Kanai and Andersson, 2010).
to parallel that of cutaneous afferents. This could be important in terms of restoration of bladder emptying following spinal cord injury.

4. MODULATING AFFERENT SENSITIVITY

The discussion above has emphasized how stimulus-response function can be used to define the features of the various sub-populations of afferents that supply the lower urinary tract. The relationship between stimulus and response is not fixed but can be changed according to the mechanical and chemical environment of the sensory ending. Contractions can distort the afferent ending while connective tissue elements will transmit or dissipate stimulus energy within the tissue determining for example whether a response is rapidly or slowly adapting to maintained stretch. Similarly, chemicals released from a variety of cells within the bladder wall and particular the urothelium and lamina propria will influence afferent firing.

Many mediators are released during inflammation, injury and ischemia, from platelets, leukocytes, lymphocytes, macrophages, mast cells, glia, fibroblasts, blood vessels, muscle and neurons. Each cell type may release several of these modulating agents. Some mediators act directly on sensory nerve terminals, while others act indirectly, causing release of yet other agents from nearby cells. This “inflammatory soup” acts on sensory nerve terminals to modify signalling (this is often referred to as “plasticity”). The increased sensitivity to both mechanical and chemical stimuli may contribute to chronic pain states – a feature of clinical relevance. Moreover, since these afferents also trigger reflexes that coordinate bladder function, sensitization can also cause detrusor overactivity or dysreflexia. Various experimental models have been employed to examine changes in the bladder innervation in disease. These include spinal cord injury, bladder outlet obstruction, and various models of hyperactivity based upon chemical injury and autoimmune reactions to name just a few. While these models have generated a wealth of information there is some concern about their translational value and as a consequence their predictive value when testing novel therapeutics.[139]

Local mediators may include neurotrophins, amines, purines, prostanooids, proteases, and cytokines. They produce their effects on visceral afferent nerves by three distinct processes. First, they can act directly, by opening ion channels on the nerve terminals. Secondly, they can sensitize endings, without causing direct stimulation, but causing hyperexcitability to other chemical and mechanical stimuli. This can occur when G-protein coupled receptors (GPCRs) are activated by mediators, which act via second messenger systems, to phosphorylate membrane receptors and ion channels that control excitability. Thirdly, as is the case for neurotrophins, they can change the phenotype of the afferent nerve over long periods. For example, they may alter expression of channels, receptors or mediators in the sensory neuron.[140] They may also modulate ligand-binding characteristics or coupling efficiency of receptors. The result of sensitization is a leftward shift in the stimulus-response function. This means that for any given level of stimulation a greater afferent barrage is generated. Peripheral sensitization normally develops rapidly and is relatively short-lived. However, in the presence of maintained injury or inflammation, the sensitization can be prolonged by changes in gene expression. Genes influenced in this way include those that determine the amount and pattern of neurotransmitters release by central nerve terminals in the brain and spinal cord. This alters the way that sensory signals are processed within the CNS and contributes to “central sensitization”. [141]

Role of the urothelium in sensory signal transduction

The urothelium can no longer be considered a passive barrier protecting against diffusion of urine constituents. Recent evidence suggests instead that the urothelium possesses sensory functions and may transduce mechanical and chemical stimuli to underlying structures including smooth muscle, fibroblast-like cells, immune cells and bladder nerves including the terminals of afferents which are located in close proximity, or even within, the urothelium. The recent evidence supporting involvement of a number of these urothelially-derived factors in sensory signalling and the therapeutic potential of targeting these signalling pathways is considered below.

a) Nitric oxide

Enzymes responsible for the generation of nitric oxide (NO) are expressed in both the urothelium and in the adjacent nerve fibres. Knockout mice in which neuronal NOS has been deleted do not have an obvious bladder phenotype. The same is true when inducible NOS is knocked out. However, NO may be involved in bladder dysfunction since expression of NOS is elevated in neurogenic bladder and release of NO may be reduced in experimental interstitial cystitis. Munoz et al [142] recently found that while electrical stimulation-evoked release of some urothelial mediators (ATP) was attenuated by disruption of the urothelium, release of NO was maintained which may suggest that under these conditions NO is derived from suburothelial structures. Interestingly, NO release triggered by cholinoreceptor stimulation was lost after urothelial disruption, consistent with NO derived from multiple sources including the urothelium. A recent study by Aizawa et al (2010) examined the effect of NO on sensory signalling by directly recording afferent activity arising from the bladder in vivo. [107] Release of NO can be inhibited using non-metabolizable analogues that compete with L-arginine as substrate for NOS. On such inhibitor, L-NAME, increased the afferent response to bladder filling by about 50%, which was reversed by activation of NO pathways with L-arginine. This data suggests that NO is able to inhibit afferent activity, an observation consistent with earlier cystometric analysis of
the effect of activating the NO pathway.[143, 144] In addition to studying NO mechanisms in the normal bladder, Aizawa and colleagues also showed that application of L-arginine significantly inhibited hypersensitivity induced by the cyclophosphamide metabolite acrolein that is used experimentally as a model for BPS/IC. The actions of NO are mediated through elevation of the intracellular second messenger cGMP. In contrast, phosphodiesterase (PDE) type 5 terminates the action of NO, and PDE inhibitors can be used therapeutically to prolong the action of NO. Behr-Roussel et al found that inhibition of PDE5 attenuated bladder afferent activity in a rat model of spinal cord injury,[145] an indication that this might represent a target for treatment of hypersensitivity disorders of the bladder such as BPS and OAB.

b) Purinergic Signalling

ATP acting via purinergic receptors modulates bladder function mediated by both afferent and efferent pathways involved in urine storage and emptying. It is well established that the urothelium releases ATP in response to stretch and that this acts in a paracrine fashion to influence the function of myofibroblasts and bladder afferent nerves. P2X2 and P2X3 receptors are expressed on unmyelinated afferent fibres innervating the bladder, and thus the hypothesis has been put forward that mechanosensitivity, at least in those afferents in proximity to the urothelium, involved ATP release by stretch and activation of P2X2 and P2X2/3 receptors on the afferents.[146, 147] The sensitivity of bladder afferents to ATP and mechanical stimuli has been directly examined. In the rat, 90% of bladder afferent neurons responded to the P2X agonist α,β-methylene ATP and were inhibited by the P2X antagonist 2', 3'-O-trinitrophenyl-ATP (TNP-ATP) which suggests that pelvic nerve afferents from the rat bladder express predominantly P2X(2/3) heteromeric receptors. In the mouse the majority of both low and high threshold receptors were sensitized by α,β-methylene ATP, i.e. the mechanical threshold was reduced and peak activity was increased during distensions.[148] In addition some ‘silent’ afferents became mechanosensitive after treatment with ATP. The absence of sensitization in P2X3 knockout mice indicated that the responses were mediated by the P2X3 receptor. These knockout mice exhibit a marked urinary bladder hyporeflexia, characterized by decreased voiding frequency and increased bladder capacity, but normal bladder pressures.[149, 150] In addition, they have reduced pain-related behaviour in response to injection of ATP. Recently, Sadananda et al [151] investigated whether other stimuli, besides bladder distension, could stimulate urothelial ATP release. They compared ATP release levels in rat bladder when subjected to stretch, capsaicin and acid. Interestingly, the amiloride-sensitive apical sodium channel, ENaC, may be involved in mechanotransduction by controlling basolateral release of ATP.[98] Adenosine is also produced and released by the urothelium, and may play important roles in modulating sensory afferent function and smooth muscle contraction.[152]

In the normal bladder, it is believed that a balance between the excitatory effects of ATP and inhibitory effects of NO release may determine micturition thresholds and frequency and that this balance may be disturbed in bladder disorders. Elevated ATP levels have been demonstrated in patients with detrusor overactivity and BPS [153], Munoz et al, using a rat model of detrusor overactivity (diabetic bladder), found increased levels of ATP but normal levels of NO.[142] Conversely in an underactive bladder model, induced by chronic sugar intake, NO levels were increased while ATP remained normal. This suggests that the balance between ATP and NO is altered in bladder dysfunction.

c) Cholinergic Mechanisms

The discovery that ACh can be released from the human bladder urothelium has led to the concept that cholinergic mechanisms could contribute to sensory signalling.[154] This concept has been reinforced by clinical findings showing that anticholinergic drugs, the current mainstay for the treatment of bladder overactivity, appear to exhibit efficacy during the bladder storage phase when parasympathetic cholinergic activity is minimal.

A number of studies have examined the effect of cholinoreceptors on bladder afferent firing. However, the data are conflicting and a consensus has yet to emerge. In vivo studies using clinical anticholinergic agents such as oxybutynin and darifenacin suggest that inhibiting muscarinic receptors, attenuates the afferent response to bladder filling.[155, 156] However, due to the nature of in vivo studies it is unclear if these effects are direct, at the level of the sensory terminal, or secondary to altered muscle tone following either peripheral or central effects on parasympathetic transmission. Similarly, Matsumoto et al found that stimulating muscarinic receptors induced bladder hyperactivity, and that this was blocked by inhibiting the M2 receptor, suggesting that M2 receptors play a role in cholinergic modulation of bladder afferent excitability. However, it is important to note that in this study, excitability was inferred from cystometry and afferent activity was not measured directly.[157] In contrast, Masuda et al (2009) found that pharmacological activation of muscarinic receptors attenuated micturition reflexes in the rat suggesting that muscarinic receptor activation leads to attenuated afferent signalling.[158] Such inhibition has been observed in afferent recording studies using isolated bladder preparations in which any secondary effects on muscle tone could be controlled [104]. In these studies blocking cholinesterase activity to augment endogenous cholinergic activity lead to attenuated afferent signalling that could be reversed by antimuscarinics. Surprisingly, antimuscarinics alone had no effect on bladder afferent re-
sponses to distension suggesting that acetylcholine release during stretch was not part of the sensory transduction pathway but cholinergic influences become manifested only under circumstances in which acetylcholine release is increased.

How ACh and muscarinic receptor pathways could modulate transmission is unclear. It is possible that there is a direct action and in this respect DRG neurones retrogradely labelled from the bladder have been shown to express M2, M3 and M4 receptors. [159] However, stimulation of muscarinic receptors on the urothelium causes the release of other excitatory and inhibitory mediators including ATP and NO.[83, 160] It is possible therefore that muscarinic receptors modulation of afferent activity is indirect via the release of a secondary mediator. Such a view is supported by the observation that bladder hypersensitivity, triggered by cholinergic stimulation was abolished by inhibition of P2X receptors, suggesting that muscarinic receptors and purinergic receptors may work in tandem to modulate afferent transmission. [161] These studies highlight the complex nature of cholinergic signalling in the bladder, and indicate that more research is necessary to fully understand whether muscarinic receptors on the afferent limb could become a therapeutic target for OAB.

d) Botulinum Toxin

Botulinum toxin A (BoNT/A) inhibits the vesicular release of acetylcholine following uptake into presynaptic nerve terminals (see Figure 8) and proteolytic cleavage of the SNARE protein SNAP-25 which prevents docking and fusion of synaptic vesicles at the neuro-muscular junction. BoNT/A was first clinically used in the bladder to treat neurogenic bladder overactivity caused by spinal cord injury.[162] Since then, intravesical injections of BoNT/A has proved a highly effective treatment for patients with detrusor overactivity, with numerous studies reporting improvements in the sensory symptoms of urgency and urinary frequency.[163] Since acetylcholine can be released from the urothelium it is possible that BoNT/A is acting at this level to modulate sensory signalling. In addition, there is recent evidence that SNAP-25, the intracellular target for proteolysis by BoNT/A, is expressed in the urothelium (Birder unpublished). This is consistent with experimental data showing that BoNT/A inhibits the release of ATP and augments NO release from the urothelium in animal models of spinal cord injury.[164] Others have shown that application of BoNT/A directly attenuated afferent firing in ex vivo mouse models [165-167]. Other potential targets for BoNT/A include the suburothelial sensory nerve endings, and in this respect a decrease in suburothelium immunoreactivity for P2X3 and TRPV1 has been reported in human bladders following treatment with BoNT/A.[168]. BoNT/A has been shown to inhibit the release of CGRP and substance P from afferent nerve terminals.[169]

e) Transient Receptor Potential (TRP) Cation Channels

A number of different members of the transient receptor potential (TRP) channel family are expressed in the bladder mostly in association with sensory nerve fibres involved in mechanotransduction and nociception. TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, have all been shown to be expressed in the bladder. TRPV1 has been shown to play an integral role in modulating the excitability of bladder afferents and the generation of hypersensitivity, induced by bladder inflammation.[62, 65] It is through desensitization of this receptor that agents like resiniferatoxin act to treat symptoms in OAB.[170] TRPV1 is predominantly expressed on sensory nerves and has been identified within nerve plexuses running in both the muscle layer and suburothelium. In addition some investigators have also demonstrated that TRPV1 is expressed within the urothelium, however the specificity of commercially available TRPV1 receptor antibodies has been questioned.[106]

Interest in TRPV4 has been fuelled by the observation of impaired voiding behaviour in knockout mice. [106] This channel shows mechanosensitivity and is proposed to play a role in the micturition reflex by activating C-fibre afferents.[171] However, the site of action of TRPV4 agonists may in fact be the urothelium which expresses the TRPV4 channel,[63] particularly in association with adherence junctions where they may be preferentially activated by stretch and lead to the release of ATP.[172] Inhibition of TRPV4 has recently been shown to improve symptoms in a model of experimental cystitis.[173]

TRPA1 is also expressed in the bladder and is particularly associated with C-fibre endings in the suburothelium that co-localize CGRP. Agonists acting at the receptor cause bladder hyper-reflexia and is suggested to play a role in mechanotransduction and in signalling pain. TRPA1 has also been demonstrated in the urothelium at both transcriptional and protein
levels. Expression is increased in a spinal cord injury model and both pharmacological blockade and RNA knockdown of TRPA1 were effective in normalizing bladder reflex function. [174]

TRPM8 was first described as a cold receptor and interest in its role in the bladder stems from the observation that instillation of cold saline into the bladder elicits a contractile response (at pressures or volumes below the threshold for normal voiding). This response to a cooling stimulus (which has been referred to as the bladder cooling reflex) was originally thought to indicate a supraspinal neurological lesion and the test (termed the ‘ice water test’) [175] has been used in the diagnosis of bladder disorders such as detrusor overactivity. Expression of TRPM8 has been identified on bladder afferent fibers and on the cell bodies in the DRG where it co-localizes with nociceptive markers such as CGRP and IB4. [176] Previously Lashinger et al (2008) showed that application of a TRPM8 channel blocker, decreased voiding frequency and abdominal motor responses in the rat [177] suggesting that in addition to cold sensing TRPM8 may also be involved in the afferent control of micturition and nociception.

f) Cannabinoids

The multi-centre CAMS study (Cannabinoids in Multiple Sclerosis) reported that the use of cannabis based extracts significantly improved symptoms of urge incontinence and detrusor overactivity in patients with multiple sclerosis. This observation has provoked interest in the study of expression and function of cannabinoid receptors in the bladder. Endogenous cannabinoids can potentially interact with TRPV1 but in addition can act on G-protein coupled cannabinoid receptors 1 and 2 (CB1, CB2). In the human bladder, both receptors could be identified in the urothelium and detrusor where CB1 receptors were more abundant than CB2. [178] In patients with bladder pain syndrome and idiopathic detrusor overactivity (IDO), a significant increase in nerve fibres expressing CB1 in the urothelium was observed, strongly suggesting a role for CB1 in overactive bladder. [179] In contrast, Gratzie and colleagues [180] found CB2 receptors predominated in the urothelium, suburothelium and on sensory nerve fibres and found that CB2 agonists inhibited nerve induced contractions of the bladder providing evidence that CB2 receptors are important in micturition.

Expression of CB1 receptors were also identified in the urothelium and on nerve fibres in the detrusor of mouse bladder.[181] These receptors co-localized with P2X3 receptors, suggesting an interaction between cannabinoid and purinergic systems. In addition, a synthetic cannabinoid active at both CB1 and CB2 receptor was shown to inhibit the evoked release of CGRP from afferent nerve terminals. [182] Functional experiments also found a reduction in distension evoked afferent firing in response to application of a CB1 agonist. In particular, high threshold afferents typically associated with noxious stimuli were directly affected. Taken together these studies suggest that CB receptors in the bladder may have a modulatory role in sensory afferent signalling and a greater understanding of which could lead to new therapeutic strategies for treatment of bladder disorders. Understanding the differential roles of CB1 and CB2 receptors may add a new dimension to our ability to target these pathways.

g) Adrenoreceptors

Alpha-1-adrenoreceptor (α1-AR) antagonists are the current first line for treatment of lower urinary tract symptoms (LUTS) due to benign prostatic hyperplasia (BPH). By inhibiting prostatic smooth muscle contraction, these agents relieve bladder outlet obstruction (BOO). In addition, recent data report an improvement in other symptoms, such as frequency, nocturia and urgency, suggesting that they may also act via the afferent system to influence storage function. Adrenoreceptors have been detected throughout the urothelium and on the sensory neurones innervating the bladder. [183, 184] Bladder afferent responses to distension in vivo are inhibited following intravesical application of the clinical α1-AR antagonist Tamulosin. Moreover, chronic systemic treatment with two different α1-AR antagonists inhibited reflex voiding in a rat model of BOO. [185] A recent experimental study by Nagabukuro et al investigated changes in afferent firing following treatment with a number of commonly used clinical drugs. The study found that Tamulosin treatment significantly attenuated activation of the early gene c-fos in the spinal cord, used as a marker for sensory neuronal activation. [186]

Figure 9: Dichotomizing afferents. Panels depict retrogradely labeled cell bodies in rat DRG following urinary bladder and colon injections of Alexa Fluor 388 and 647-conjugated cholera toxin B (CTB). A, CTB-positive bladder afferents, B, CTB-positive distal colon afferents and C-dual labeled cells. (from Christianson et al., 2007).
In contrast to the α-adrenoreceptors, the beta adrenoreceptors (βARs) mediate relaxation of the bladder smooth muscle in response to sympathetically released noradrenaline. The β3-AR subtype is the predominant isoform responsible for relaxation of the human detrusor and β3-AR agonists are currently in clinical trials for the treatment of OAB. A recent study by Kullmann et al demonstrated the presence of the β3-AR in the urothelium and observed inhibition of voiding contractions in response to the β3-AR agonists TAK-677 and BRL37344. This effect was independent of any changes in smooth muscle tone suggesting that β3-AR could also participate in bladder afferent function.[187]

5. CROSS TALK BETWEEN THE BLADDER AND BOWEL

Patients with IBS often report bladder symptoms including nocturia, frequent and urgent micturition, and incomplete emptying.[188] The counterpart is also true with patients with BPS complaining of bowel symptoms.[189] These observations are consistent with the concept of cross-organ sensitization which extends to different abdominal and pelvic structures and contributes to a more generalized chronic pelvic pain syndrome reviewed recently by Brumovsky et al.[190] In experimental models inflammation of the colon has been shown to lead to increased frequency of bladder contractions and altered micturition reflexes.[191] In contrast, experimental bladder inflammation has been reported to sensitize the bowel to distension.[192] Such cross-organ sensitization has also been demonstrated between the uterus, pelvic urethra and vagina. In men there is the potential for cross-organ sensitization between the prostate and other pelvic organs.

The mechanisms underlying cross-organ sensitization have not been fully elucidated but there are potentially several levels at which the sensory innervation to the different pelvic structures can interact. In terms of periphery mechanisms there is evidence that afferent fibres branch extensively to innervate multiple target structures. Different retrograde tracer injected into the bladder and bowel results in a number of DRG neurones carrying both labels although the numbers are low (Figure 9).[193] Similarly, dichotomizing afferents have been shown to innervate the colon and uterus with DRGs expressing TRPV1 and P2X3 receptors implying a role in nociception. Sensitization of the endings in one organ by local inflammation would likely impact on overall sensitivity following upregulation in excitability in all terminal receptive fields. Central sensitization may also contribute to cross-organ sensitization (Figure 10). Excitability of spinal neurons receiving afferent input from the bladder has been shown to respond to afferent input from other pelvic structures such as the colon.[194, 195] Second order neurones in the spinal cord therefore receive convergent input from various visceral structures as well as somatic inputs. The later explains the phenomenon of referred pain where sensations from the viscera are experienced in the associated somatic sensory field, the classic example being angina. Such viscero-somatic convergence has been extensively investigated and only recently has viscero-visceral referral received attention. Nevertheless convergent inputs would explain the poor localization of pelvic pain and the difficulty in diagnosis and treatment.

III. NEURAL CONTROL OF FEMALE PELVIC FLOOR MUSCLES AND RHABDOSPINCTERS

The urethral rhabdospincter and pelvic floor muscles are important in maintenance of urinary continence and in preventing descent of pelvic organs (i.e. pelvic organ prolapse, POP). It is estimated that 11 % of US women will undergo a surgical procedure for POP or urinary incontinence during their lifetime.[196] Because of the importance of understanding pelvic floor function, recent clinical and preclinical studies have focused on this topic. Reviews of functional anatomy[197] and neural control[198] of the pelvic floor muscles and the urethral and anal rhabdospincter have been published.

1. STRUCTURAL ELEMENTS OF THE PELVIC FLOOR (FIG. 11)

The pelvic floor[197] in women is a bowl-shaped structure comprised of bone, muscle, and connective
tissue. The rim of the bowl is formed by the bones of the pelvic girdle (sacrum, ilium, ischium, and pubis). The “bottom” of the bowl is lined with striated muscle: the iliococcygeus and pubococcygeus (which together comprise the levator ani - LA - muscle), the coccygeus, and puborectalis [197, 199, 200] muscles. The muscles are attached to the bone and to each other with various connective tissue supports. These three components, bone, muscle, and connective tissue provide support of the pelvic viscera (i.e. rectum, vagina, and bladder) but also allow for excretory and sexual function.

The viscera, as well as striated muscles that serve as true sphincters - urethral and anal rhabdosphincters, attach to pelvic floor muscles and each other by connective tissue but do not attach directly to bone. The urethrovaginal sphincter, the compressor urethrae muscle, the ischiocavernosus, and bulbospongiosus muscles are additional striated perineal muscles that are intimately associated with the viscera.[197, 199, 200] During embryogenesis, the rhabdosphincter and perineal muscles develop from the cloaca with a two-week delay in striated muscular differentiation compared to the LA and other skeletal muscles.[201, 202] Furthermore, rhabdosphincters are completely separated from the LA muscles by connective tissue.[199] Thus, the striated muscles associated with the viscera (i.e. rhabdosphincters) are quite distinct from the striated skeletal muscle of the pelvic floor (e.g. LA). The urethral rhabdosphincter has been referred to by many names, including the external urethral sphincter, the striated urethral sphincter, the striated urethralis muscle and other names. The term “external urethral sphincter” is downplayed because the urethral rhabdosphincter is not really external to the lower urinary tract; it surrounds the middle of the urethra. Therefore the term urethral rhabdosphincter is recommended.

2. PERIPHERAL INNERVATION OF THE FEMALE LEVATOR ANI (LA) MUSCLES

The LA muscle of the pelvic floor is innervated by the LA nerve in human, (Fig. 11A)[203, 204] squirrel monkey [205-207], dog[208], cat (Karicheti and Thor, unpublished observations) and rat.[209, 210] The LA nerve primarily arises from sacral spinal roots (e.g. S3-S5 in humans) and travels along the intrapelvic face of the LA muscle with a high degree of variability in branching patterns.[203] In humans, there is some controversy whether or not the pudendal nerve also innervates the LA muscle.[211-213] In human female fetus samples, a contribution to LA innervation by the pudendal nerve was only seen in about half the samples. A recent detailed study of women 45-55 years of age, using an elaborate Sihler’s stain to trace branches down to single fibers, did not describe any contribution of the LA muscle from the pudendal nerve.[204] In animal studies, a number of findings refute

---

**Figure 11.** A) Sagittal drawing of medial surface of a woman’s pelvic floor showing the course of the LA nerve (LAN) from the sacral roots (S3-S5) across the internal surface of coccygeus (Cm), iliococcygeus (ICm) puborectalis (PRm) and Pubococcygeus (PCm) muscles. B) Drawing of a posterior view of the hip muscles showing the course of the pudendal nerve (PN) from the S2-S4 roots across the lateral surface of the superior gemellus (SG) and obturator internus (Olm) muscles, through the pudendal canal (PC), and its branching into the inferior rectal nerve (IRN) and perineal nerve (PeN). P=periformis muscle; STL=sacrospinous ligament; C=coccyx; IS=ischial spine; SSL=sacrotuberous ligament; S=sciatic nerve; EAS=external anal sphincter; IG=inferior gemellus muscle. Adapted from Barber et al., 2002.
an innervation of the LA muscles by the pudendal nerve:

1. a marked decrease in LA muscle mass and myocyte diameter, as well as vacuolization of the muscle following transection of the LA nerve (Fig. 12) but not after pudendal neurectomy. [205, 210]

2. transection of the LA nerve abolished LA muscle EMG activity in rats,[209] while transection of the pudendal nerve had no effect on LA EMG activity but abolished rhabdosphincter activity.

3. an absence of contractions of LA muscles upon electrical stimulation of pudendal nerve efferent fibers (Thor and Karicheti, unpublished observations in cats and rats).

4. only a single motor endplate zone is found in the LA muscle, located at the point of LA nerve insertion into the muscle.[205, 210]

5. large α motor neuron axons (i.e. 10 μm diameter), which are a hallmark of skeletal muscle innervation, are not found in the pudendal nerve. [214][210]

6. distinct populations of motor neurons, extremely unique in phenotype, are labeled following application of tracers to the pudendal nerve versus the LA nerve[208, 215-220].

Thus, divergent techniques support the conclusion that only the LA nerve innervates the LA muscles with no significant contribution from the pudendal nerve in non-human species. These direct observations, coupled with the distinct embryological origins of LA muscles versus rhabdosphincter and perineal muscles [201, 202], as well as a respective “compartmentalization” of the rhabdosphincter and perineal muscles by connective tissue[199], are in line with distinct “special somatic” motor innervation of the rhabdosphincter by the pudendal nerve versus typical skeletal motor innervation of the LA muscle by the LA nerve. The work in human female fetal samples[212, 213] suggests that an innervation of the LA muscle by the pudendal nerve should be considered, especially during the perinatal period. Whether these pudendal branches to the LA muscle recede during maturation or aging should also be considered in light of the difficulty identifying them in older women[204].

The complexity of the perineal region, which consists of various small muscles [puborectalis, compressor urethrae, urethrovaginal sphincter, urethral and anal rhabdosphincter, ischiocavernosus, and bulbocavernosus], blood vessels, connective tissues, and nerves, makes dissection, identification, and nomenclature of specific nerve branches and muscles difficult in cadavers. Indeed, even the nomenclature of the muscles themselves is uncertain[199, 200]. A recent study has suggested more attention to detail and more rigorous adherence to “origin – insertion” nomenclature standards are being adopted[204].

Detailed anatomical, histological, and physiological studies of the small, intricate muscles of the perineum coupled with studies of their afferent and efferent neurons in humans and larger laboratory species (where they can be readily visualized) is an important area for future research. As a first step, agreements regarding muscle classification should be established in regard to which muscles actually comprise the LA or pelvic floor versus those that are more intimately associated with the viscera. In other words, should “pelvic floor muscles” include only the skeletal striated muscles such as pubococcygeus, iliococcygeus, coccygeus, and puborectalis muscles, while non-skeletal striated muscle such as urethralis, urethrovaginal sphincter, and compressor urethrae be distinguished from the pelvic floor? Are these latter muscles similar to the urethral and anal rhabdosphincter? Presumably, characteristics of their muscular function, their innervation, their pharmacological responses, or physiological integration with visceral function may allow better understanding of their roles in excretion or sexual function.

Clarity regarding pudendal versus LA nerve innervation is also important because attributes ascribed to pudendal nerve involvement may be more correctly
ascribed to LA nerve involvement. For example, the intrapelvic positioning of the LA nerve on the surface of the muscles may expose it to damage as the fetal head passes through the birth canal[203] and may contribute to the correlation between parity and POP[197]. This positioning also allows exposure to electrical current applied with a St. Mark’s electrode situated in the rectum with subsequent EMG activation of the LA muscle. The LA nerve positioning, close to the ischial spine, also risks entrapment by sutures used for various POP suspension surgeries or may account for dyspareunia, pelvic pain, and/or recurrent prolapse[221] associated with such surgery. Finally, since the ischial spine is a landmark for transvaginal “pudendal nerve” block[212], the possibility that this procedure also anesthetizes the LA nerve should be considered.

a) LA Motor Neurons

Retrograde tracing studies in cats[222], dogs[208], and squirrel monkeys[216] identify LA motor neurons in a longitudinal column in the sacral ventral horn of the spinal cord, while in rats[223-225] they are in the L6-S1 ventral horn. In contrast to dense packing of sphincter motor neurons in Onuf’s nucleus[215, 217-220], the LA motor neurons are distributed more diffusely. Furthermore, LA motor neurons show a bimodal distribution of large neurons (presumably α motor neurons) and small neurons (presumably γ motor neurons) in contrast to the uniform intermediate size of pudendal motor neurons. The two sizes of LA motor neurons are in keeping with the presence of muscle spindles (whose intrafusal muscle fibers are innervated by γ motor neurons) in LA muscle (Fig. 12A)[226-228], while muscle spindles are absent from the rhabdosphincter muscles[226, 229-233]; consequently LA may exhibit Ia (muscle spindle) evoked monosynaptic stretch reflexes, whereas the urethral rhabdosphincter does not[218, 234-236].

LA motor neuron processes (dendrites or axon collaterals) project into two important areas in the sacral spinal cord [206]. One area, medial lamina VI, is where primary afferent fibers from muscle spindles and Golgi tendon organs terminate[237, 238], again suggesting an important role for stretch-activated reflex contractions of LA muscles. The second area is to Onuf’s nucleus that contains rhabdosphincter motor neurons. These LA motor neuron processes form close appositions with sphincter motor neurons in both monkey[216] and rat[223, 225]. Presumably, these appositions reflect a neuroanatomical substrate for coordination of the rhabdosphincter and the pelvic floor muscles during micturition and defecation. These projections could be dendrites receiving common afferent input with rhabdosphincter motor neurons or axon collaterals transmitting information to rhabdosphincter motor neurons, which might provide insight into functional coordination.

Ovariectomy in rats reduced LA neuron dendritic arbors, while estradiol and progesterone expanded them, indicating hormonal regulation[239]

b) LA Afferent Innervation

Afferent LA fibers innervate muscle spindles (Fig. 12A)[205, 226] and Golgi tendon organs[227] which are common in skeletal muscles but absent in the rhabdosphincters[226, 229-233]. Cholera toxin B (CTB) injection into the LA muscle[206] of squirrel monkeys labels approximately 4 times as many afferent neurons versus motor neurons. About 25% of these primary afferent neurons are large, myelinated (i.e. RT-97 neurofilament positive) neurons and are negative for the peptide transmitter calcitonin-gene-related peptide (CGRP), binding sites for isolectin-B4 (IB-4), and the growth factor receptor, TrkA. Of the remaining small, RT97 negative neurons, approximately 50% contain CGRP, IB-4 binding sites, and TrkA. It is tempting to speculate that large, myelinated afferent neurons signal proprioceptive information from muscle spindles [205] and Golgi tendon organs and in turn control reflex activity of the LA muscles, while the small peptidergic, IB-4, TrkA positive neurons transmit nociceptive information. In addition, large sensory neurons may regulate bladder reflex pathways during LA motor activity; while the small peptidergic fibers might play a role in bladder hyperreflexia associated with pelvic floor trauma or nerve entrapment.

CTB labeled afferent terminals were only seen in medial lamina VI of the lumbosacral spinal cord[206], an area for termination of large, myelinated proprioceptive terminals[237, 238]. The absence of CTB labeling in the superficial dorsal horn, which should contain the central terminals of small peptidergic, IB-4, and TrkA positive afferent neurons, is likely due to an inability of small afferent neurons to transganglionically transport CTB rather than a true absence of LA nociceptive terminals in the region. Experiments with a tracer (e.g. horseradish peroxidase, HRP) that is transported to nociceptive spinal terminals should be done to confirm this.

3. REFLEX ACTIVATION OF PELVIC FLOOR MUSCLES

There is little preclinical information regarding reflex control of pelvic floor muscles associated with visceral function (e.g. micturition). A recent study in female rabbits[240] showed that during bladder filling (i.e. the storage phase), the pubococcygeus muscle was active, while during micturition it was quiet. The same study showed the opposite relationship for the ischiocavernous and bulbospongious muscles, which were silent during bladder filling but active during micturition. One study in the male rat[241] indicated that the pubocaudalis muscle is active during bladder contractions and shows high frequency bursting like the urethral rhabdosphincter EMG.

Preliminary studies (Fig. 13, Mori and Thor, unpublished) in female rats also indicated that the pelvic floor muscles could be activated during a micturition contraction under certain circumstances. Pubocaudalis EMG activity increased during a micturition contraction in 50% of the rats under control
conditions. The remaining rats showed micturition-associated pubocaudalis EMG activity after administration of various drugs (e.g. α2 adrenoceptor antagonists) known to enhance motor neuron reflexes[242]. The pubocaudalis muscle EMG was always smaller (about 80% smaller) than the urethral rhabdosphincter EMG and was only elicited by a fast bladder-filling rate, suggesting that the pubocaudalis reflexes require a stronger afferent drive from the bladder than rhabdosphincter reflexes (Fig. 13). The micturition-related pubocaudalis EMG activity exhibited phasic, high frequency bursting (like the rhabdosphincter EMG) but was much less prominent (dashed lines in Fig. 13B). Furthermore, the pubocaudalis muscle exhibited very little activity preceding or following a bladder contraction in contrast to rhabdosphincter EM. Thus although there are some similarities in pubocaudalis and rhabdosphincter EMG activity, there are also distinctions that suggest separate but possibly overlapping control mechanisms.

The iliocaudalis muscle also exhibited an increase in EMG activity during bladder contractions (Fig. 13C) in 60% of the rats. However, the iliocaudalis activity never showed phasic bursting during micturition and instead showed only an asynchronous tonic discharge (Fig. 13D). Even after facilitatory drug treatments, when the iliocaudalis activity was strongest, no bursting was observed. To evoke iliocaudalis EMG activity, the bladder infusion rate was rapid, and the signal was again smaller than the rhabdosphincter EMG signal. Thus, both the iliocaudalis and pubocaudalis appear to have a weaker activation from bladder pathways than the rhabdosphincter. The pubocaudalis muscle exhibits a weak phasic bursting pattern during micturition
(similar but weaker than that of the urethral rhabdosphincter), while the iliocaudalis shows only asynchronous, tonic firing during micturition.

A recent detailed study of pelvic floor muscle activity in female rats during bladder filling and voiding also found that “pelvic floor muscle” activity was highly variable during bladder filling and voiding, while the rhabdosphincter EMG activity was reliable[209]. This study also reported that LA EMG activity did not increase in response to bladder pressure elevation by manual compression of the bladder with a cotton swab but did increase in response to a pinch of the perineal skin. Transecting the pudendal or LA nerves eliminated only rhabdosphincter or pelvic floor muscle activity, respectively. Thus it appears that segmental activation of LA muscle by bladder pathways is very weak.

4. PERIPHERAL INNERVATION OF URETHRAL AND ANAL Rhabdosphincters

The urethra and anal canal are surrounded by bands of striated muscle fibers; the urethral and anal rhabdosphincters, respectively as they pass through the pelvic diaphragm. The muscles do not attach to skeletal structures and thus act as true sphincters (i.e. contraction produces virtually no movement except constriction of the lumen). In addition, there are small, thin bands of striated muscle (compresor urethra, urethrovaginal sphincter, bulbocavernosus, and ischiocavernosus) that surround the urethra, vagina, and/or rectum and have connective tissue attachments to the perineal body[197].

The urethral rhabdosphincter, anal rhabdosphincter, bulbocavernosus, and ischiocavernosus muscles are innervated by the pudendal nerve[203, 215, 217-220, 241, 243], which originates from the S2-4 sacral roots and passes along the lateral surface of the internal obturator and coccygeus muscles and through Alcock’s canal (Fig. 11B). As the nerve passes through the canal, it branches into the inferior rectal nerve (which innervates the anal rhabdosphincter), the perineal nerve (which innervates the urethral rhabdosphincter, the bulbospongious muscle, the ischiocavernosus muscle, superficial transverse perineal muscle, and the labial skin), and the dorsal nerve of the clitoris. The branches of the perineal nerve are more superficial than the dorsal nerve of the clitoris and, in most cases, travel on the superior surface of the perineal musculature. The terminal branch of the perineal nerve to the striated urethral sphincter travels on the surface of the bulbocavernosus muscle then penetrates the urethra to innervate the sphincter from the lateral aspects (Fig. 11B). The specific innervation of the smaller bands of muscles attached to the perineal body has not been characterized.

Nerve fascicles[244], as well as the motor nerve terminals and end plates[228] of the urethral rhabdosphincter, are preferentially located along the lateral aspects of the urethra in rat. Overlap, or crossing of the midline, between the left and right pudendal nerve terminal fields has been described in monkey anal rhabdosphincter[245]. The rhabdosphincter of both men and women contain neuronal nitric oxide synthase (nNOS), which is contained in a subpopulation (43%) of the muscle fibers, as well as nerve fibers, with concentration at the neuromuscular junction in humans and sheep[246-248]. Additionally, nNOS has been localized to pudendal motor neurons, which innervate the rhabdosphincter in rats, cats, monkeys, and humans[249, 250]. nNOS is responsible for producing the transmitter nitric oxide (NO). While NO is known to increase cGMP levels in many types of smooth muscle, its role in control of striated muscle and in neuromuscular transmission is not well established[251]. An NO donor has been shown to reduce urethral pressures at the level of the rhabdosphincter[252], but it is difficult to determine if the effect is on smooth or striated muscle.

The possibility that the urethral rhabdosphincter receives a “triple innervation” from somatic, parasym pathetic, and sympathetic nerves[253] was raised in early histological studies. However, this has been disputed by subsequent studies[254] that showed no physiological effects of autonomic nerve stimulation on striated sphincter function and showed that the autonomic fibers are only “passing through” the outer layer of striated muscle to reach the inner layers of smooth muscle.

a) Urethral and Anal Rhabdosphincter Motor Neurons

Pudendal motor neurons that innervate the urethral and anal rhabdosphincters (and bulbocavernosus and ischiocavernosus) muscles are situated along the lateral border of the sacral ventral horn in Onuf’s nucleus in human[255] monkey[217, 256], dog, cat[219, 220, 257], hamster[258] and guinea pig[259]. Studies in cat[218], monkey[217], and human[255] show that urethral rhabdosphincter motor neurons occupy a ventrolateral position and anal rhabdosphincter motor neurons occupy a dorsomedial position within the confines of Onuf’s nucleus (Fig. 14A). However in other species, urethral and anal rhabdosphincter motor neurons are located in separate nuclei (Fig. 14E). In rat[215], anal sphincter (and bulbospongious) motor neurons are located medially in the ventral horn, just ventrolateral to the central canal; while the urethral sphincter (and ischiocavernosus) motor neurons are located in the same region as others species, i.e. along the lateral edge of the ventral horn. In the domestic pig[260] and Mongolian gerbil[261], anal sphincter (and bulbospongious) motor neurons are located just dorsolateral to the central canal.

Sphincter motor neurons are different from motor neurons that innervate skeletal muscles. They are densely packed within the confines of Onuf’s nucleus and exhibit tightly bundled dendrites that run rostrocaudally within the confines of the nucleus.
Transverse dendrites are particularly unique in bundling and projecting laterally into the lateral funiculus, dorsally towards the sacral parasympathetic nucleus, and dorsomedially towards the central canal (Fig. 14)[218, 257, 262]. This is similar to bladder preganglionic neurons[263], suggesting that rhabdosphincter motor neurons and preganglionic neurons receive inputs from similar spinal regions. The dense packing and dendritic bundling of sphincter motor neurons may be related to their special sphincteric function and facilitate simultaneous activation of sphincter motor units. Recurrent axon collaterals (Fig. 14D)[257] in the absence of recurrent inhibition[234, 264] suggests a recurrent facilitation that may also reinforce simultaneous activation. Finally, the arrangement of peripheral motor nerve terminals bilaterally at dorsolateral and ventrolateral positions in the urethra may also provide symmetrical force generation[228].

Rhabdosphincter motor neurons are also physiologically different from skeletal muscle motor neurons in that they do not exhibit significant monosynaptic inputs[234], Renshaw cell inhibition[234], nor crossed disynaptic inhibition[264]. Patch clamp recordings from urethral rhabdosphincter motor neurons in spinal slices[265] demonstrate higher resting membrane potentials, higher membrane resistance, and a lower rheobase compared to other motor neurons in the slice (Fig. 15A-C). These in vitro results are similar to in vivo results that also showed unique passive membrane properties (e.g. high input resistance, low rheobase, short after-hyperpolarization,

Figure 14. A-C. Composite drawings (A1-C1) and photomicrographs (A2-C2) of pudendal motor neurons in cat labeled by application of horseradish peroxidase (HRP) to the pudendal nerve as seen in transverse (A), horizontal (B), and sagittal (C) sections. The photographs provide raw data from 1 of the single sections used to make the corresponding composite drawing. Note that the dendrites of pudendal motor neurons project into the lateral funiculus (LF). D=dorsal, V=ventral, M=medial, L=lateral, R=rostral, C=caudal, DDB=dorsal dendritic bundle, LDB=lateral dendritic bundle. Primary afferent terminal labeling can also be seen in Lissauer’s tract (LT), the lateral pathway (LP), medial pathway (MP), and dorsal gray commissure (DGC) in panel A1. (Primary afferents were not drawn in panel A1, only motor neurons). Adapted from Thor et al., 1989. D. Composite drawing of a single pudendal motor neuron labeled by intracellular injection of HRP showing the transverse (D1) and sagittal (D2) distribution of dendrites (Designations, such as 1d/l, 2l, 3l, 6 etc., indicate individual dendrites that are shown in both panels D1 and D2). The arrow head in the insert of D1 indicates the cell’s axon. The dashed line in D2 represents the border between the ventral horn and ventral funiculus. Inset in D1 is a 3D rendition of the neuron. Adapted from Sasaki et al 1994. E. Diagrams comparing locations of urethral rhabdosphincter and ischiocavernosus (IC) versus anal rhabdosphincter and bulbospongiousus (BS) motor neurons in various species.
membrane bistability, and non-linear responses to depolarizing current injection, which was recently reviewed[266]. This combination of biophysical properties is uniquely conducive to simultaneous, prolonged, tonic activity, in keeping with the anatomical and functional properties described above.

b) Afferent Innervation of the Urethral and Anal Rhabdosphincters

Various studies have characterized primary afferent neurons sending axons into the pudendal nerve[215, 218, 267]. However this nerve carries the innervation to many visceral structures (e.g. urethra, genitalia, rectum, vagina) in addition to skin and rhabdosphincters, thus it is difficult to specifically characterize the sensory innervation of the sphincters per se. Nevertheless, the paucity of large sensory neurons in sacral dorsal root ganglia following application of tracers to the pudendal nerve suggests that the sensory innervation of the rhabdosphincters does not contain large myelinated fibers (i.e. Type Ia and Ib) that innervate these sensory organs[226, 229-233] that typically innervate muscle spindles, Golgi tendon organs, or Pacinian corpuscles. Indeed, multiple investigators using various techniques have not found muscle spindles or Golgi tendon organs in the rhabdosphincters. This is consistent with the finding that the pudendal nerves lack small g motor neuron axons (which innervate muscle spindles) [231] and the absence of rhabdosphincter connections to bone by tendons. On the other hand, Pacinian corpuscle-like structures have been found in the urethra of cat[233] and may play a role in sensing urine flow during micturition to inhibit sphincter activity and/or reinforce detrusor contractions.

The spinal terminals of pudendal primary afferent fibers are distributed throughout laminae I, V, VII, and the dorsal gray commissure (Fig. 14A2), while labeling in laminae III and IV is well-defined and restricted to the medial third of the dorsal horn[218]. This restricted pattern in laminae III and IV is consistent with the somatotopic organization expected for cutaneous mechanoreceptors originating in the perineal skin[268]. Local injection of tracers targeted to the urethral and anal rhabdosphincters [218, 269] only produced labeling of the spinal terminals of primary afferent neurons in lateral and medial lamina I, the intermediate gray matter, and the dorsal commissure gray matter, not in laminae III or IV. Since the HRP likely spread into the urethra and rectum, it is possible that this labeling occurred in visceral as well as rhabdosphincter afferent pathways. However, since no labeling was seen in large diameter primary afferent neurons nor in terminals in medial laminae III and IV (cutaneous fields) nor medial lamina VI, an area where large diameter myelinated fibers of muscle spindle and Golgi tendon organs nerves terminate [237, 238] it is reasonable to conclude that the rhabdosphincters are not significantly innervated by large myelinated nerve fibers typically associated with other striated muscle.

5. REFLEX ACTIVATION OF URETHRAL AND ANAL RHABDOSPINCTERS

Rhabdosphincter motor neurons can be activated via segmental[214, 234-236] and descending pathways (Fig. 16)[234, 270, 271]. The segmental inputs can be activated by stretch receptors and nociceptors in the bladder or urethra or genitalia[272-274]. Electrophysiological studies in cats[214, 218, 235, 236, 275, 276] show that stimulation of either pelvic nerve or pudendal nerve afferent fibers can activate polysynaptic spinal segmental reflexes that can be recorded at central delays of 1.5 msec with intracellular electrodes in sphincter motor neurons[277, 278] and at a latency of about 10 msec from electrodes placed on pudendal nerve efferent fibers or inserted directly into the urethral or anal rhabdosphincter muscles[275, 279-281]. The segmental reflex is considered polysynaptic based on the latency[234, 277, 278] and retrograde transynaptic labeling of interneurons in laminae I and V of the dorsal horn and in the dorsal gray commissure by pseudorabies virus (PRV) injected into the urethral rhabdosphincter[269]. The dorsal horn interneurons are likely those that participate in the segmental reflex activation of sphincter motor neurons while the dorsal gray commissure interneurons are likely inhibitory (see below). Studies in rats also show that electrical stimulation of afferent axons in the pelvic nerve elicits reflexes in pudendal nerve efferent fibers or the urethral rhabdosphincter[282, 283] similar to the cat. Also similar to the cat, PRV injected into the urethral rhabdosphincter[284] labels interneurons in laminae I and V of the dorsal horn and in the dorsal gray commissure.

Previously, the afferent inputs from the urinary bladder have been emphasized as being of primary importance for activation of the segmental reflex by pelvic nerve stimulation because bladder distension will activate the urethral rhabdosphincter[285]. This reflex activation is often referred to as the “guarding reflex” or “continence reflex”. However, recent studies are placing greater emphasis on urethral afferent fibers[273, 286, 287]. It is tempting to speculate that the guarding reflex is actually activated more vigorously by urethral afferent fibers if urine inadvertently begins to pass through the bladder neck and into the proximal urethra, with a requirement for a rapid closure of the more distal urethral sphincter (i.e. guarding against urine loss) compared to simple bladder distension or increases in intravesical pressure.

The greater importance of urethral afferent fibers is also suggested by experiments where bladder afferent fibers are electrically stimulated. For example, in studies by McMahon et al[235], electrical stimulation of pelvic nerve fibers close to the bladder was not able to evoke pudendal nerve firing in a large proportion of cats but placement of electrodes more centrally on the pelvic nerve was able to evoke firing. Karicheti and Thor (unpublished observations) also found that stimulating nerve bundles close to the
Figure 15. Membrane properties, responses to noradrenaline, and involvement of TASK and SKCa channels in retrogradely-labeled rhabdosphincter motor neurons recorded using patch clamp electrophysiology in L5/6 spinal cord slices from 6-14 day old female rats. Comparison of resting membrane potential (RMP, A), input resistance (B), and rheobase (C) in urethral rhabdosphincter motor neurons (dorsolateral nucleus, DLN), axial motor neurons (Ventral nucleus, VN), and hindlimb motor neurons (retrodorsolateral nucleus, RDLN). D) Noradrenaline (NA, 20 μM) depolarizes rhabdosphincter motor neurons and induces robust firing. E) NA and phenylephrine (PE), and alpha1 adrenoceptor agonist, increase input resistance, rheobase, and firing rate-current injection (F-I slope) relationship in a prazosin-sensitive (alpha1 adrenoceptor antagonist) manner in rhabdosphincter motor neurons. Significant and reversible, mean increases in RMP (F) and firing frequency (G) in rhabdosphincter motor neurons produced by NA (20 μM). Doxapram (H), a TASK channel blocker, at 10 μM (D10) and 100 μM (D100), mimics NA’s ability to depolarize rhabdosphincter motor neurons. Decreasing extracellular pH to 6.5 (I), which closes TASK channels, mimics NA’s ability to depolarize these neurons. NA significantly reduces the afterhyperpolarization (AHP) in rhabdosphincter motor neurons (J) in a prazosin-resistant manner. Apamin (A), an SKCa channel blocker, reduces AHP (K), increases the F-I slope (L) and occludes NA’s ability to reduce the AP and increase the F-I slope. Apamin does not influence the input resistance (M) or holding current (N), nor occludes NA’s ability to do so. From Yashiro et al., 2010.
bladder is often ineffective in producing a spinal reflex to the urethral rhabdosphincter, but in the same animals it evokes reflex activity on the hypogastric nerve (indicating that the electrical stimulation is activating bladder afferent fibers). Furthermore, it was possible to consistently evoke a reflex when the stimulus was applied more centrally on the pelvic nerve, which would include fibers from the urethra. Since the more central electrode placement would also activate colonic and genital afferent fibers, additional experiments are needed to specifically compare urethral versus bladder versus colonic afferent fibers in evoking the "guarding reflex".

Electrical stimulation of pudendal afferent fibers also evokes a spinal reflex to activate the rhabdosphincter in cat[235, 279, 288] and rat[282, 283]. Since some urethral afferent fibers (as well as rectal, genital, and cutaneous afferent fibers) travel in the pudendal nerve, it is possible that the spinal urethral rhabdosphincter activation by pudendal afferent stimulation is also a manifestation of the "guarding reflex".

Sphincter reflexes in the cat also exhibit prolonged changes in excitability following short trains (5-10 second) of electrical stimulation of afferent axons in the pudendal nerves[288]. Recordings from sphincter motor neurons in the sacral spinal cord and from rhabdosphincter peripheral motor axons revealed that stimulation of pudendal afferent axons elicited not only short latency transient responses but also sustained activity persisting for 3-30 seconds after the end of the stimulus train [288]. The persistent activity was associated with a small membrane depolarization and was terminated by small hyperpolarizing currents. Similar persistent activity has been observed in hindlimb motor neurons with slow axonal conduction velocities similar to those of sphincter motor neurons[289].

6. INHIBITION OF URETHRAL RHABDOSPINCETER (URS) REFLEXES DURING VOIDING

Voiding is induced voluntarily or reflexively by neural circuitry in the brain.[3] For voiding to occur, there must be contraction of the bladder and simultaneous relaxation of the urethral rhabdosphincter. These responses are mediated by descending projections from neurons in the pontine micturition center (PMC) that excite the sacral autonomic outflow to the bladder and inhibit the motor outflow to the sphincter (Fig. 16). This coordination is lost following spinal cord injury,[3] Electrical or chemical stimulation in the PMC in cats excites the bladder and inhibits sphincter EMG activity[269, 270, 290-292] and hyperpolarizes sphincter motor neurons[288]. The descending inhibitory pathway from the PMC to sphincter motor neurons is thought to involve spinal GABAergic inhibitory neurons in the dorsal commissure of the sacral spinal cord (Fig. 16) [293, 294]. A role for glycinergic and enkephalinergic interneurons in the dorsal commissure has also been proposed[269, 294-298] in mediating inhibition of the sphincter during voiding (Fig. 16).

In addition to supraspinal inhibitory mechanisms, a "spinal, urine storage reflex, inhibitory center" (SUSRIC) was found that inhibited both the somatic and the sympathetic urine storage reflexes controlling the urethral rhabdosphincter and smooth muscle, respectively, in the cat[280, 299]. Activation of this inhibitory center by electrical stimulation of the pelvic nerve afferent fibers occurs simultaneously with the activation of the URS reflex itself. The latency of the inhibition was < 50 msec and had a duration of 500-1,000 msec. Activation of this inhibitory center explains the diminished capacity of the URS evoked reflex to follow frequencies of pelvic afferent stimulation greater than 5 Hz[280, 299]. Physiological stimulation of the pelvic nerve afferent fibers, which occurs with distension of the bladder, has also been reported to inhibit rhabdosphincter EMG activity in both spinal intact [276] and spinalized cats [236] in the absence of a bladder contraction and its associated inhibitory mechanisms. Possibly the inhibition of rhabdosphincter activity by distension of the bladder represents a physiological corollary for the inhibition of rhabdosphincter activity by high frequency electrical stimulation of pelvic nerve afferent fibers. Although the inhibitory effects are localized to the spinal cord caudal to the T12 level, they are regulated by supraspinal systems that respond to 5-HT1A receptor activation and enhance sphincter activity through disinhibition[300-302]. A possible clinical correlation of SUSRIC activation may be the elegant demonstration in men that conditioning stimuli applied to the dorsal nerve of the penis (i.e. pudendal nerve afferent fibers) inhibited urethral rhabdosphincter contractions reflexively evoked by magnetic stimulation of the spinal cord applied at intervals of 20 - 100 msec after the conditioning stimuli[303].

The situation is different in rats, where the urethral rhabdosphincter activity shifts from a tonic, asynchronous firing pattern during urine storage to a phasic bursting pattern during voiding, resulting in well-documented "high frequency oscillations" (HFOs) of pressure recorded from the urethra or bladder[269]. These HFOs contribute to efficient voiding in the rat, and their suppression due to drug treatment[300], pudendal nerve damage[269, 304, 305], spinal cord transection[269, 282, 306], or STZ-induced diabetes[307-312] (Kullmann and Thor, unpublished observation) results in a significant drop in voiding efficiency and an increase in postvoid residual urine volumes.

7. SUPRASPINAL ACTIVATION OF RHABDOSPINCETERS AND PELVIC FLOOR MUSCLES

Supraspinal activation of urethral and anal rhabdosphincter motor neurons can be mediated in response to voluntary (i.e. corticospinal[256]), as well as involuntary reflexic inputs (e.g. during coughing, sneezing, vomiting) presumably from nucleus retroambigus in
Figure 16. Drawing of proposed model for spinal and Supraspinal excitation and inhibition of rhabdosphincter pudendal motor neurons with an example of the evoked potential recorded by an electrode on the pudendal nerve in response to electrical stimulation of the pelvic nerve at 0.5 Hz and a table showing the predominant effects of various receptor subtypes on evoked potentials recorded from the pudendal nerve or urethral rhabdosphincter. Red stellate shapes and lines represent excitatory neurons and their axonal pathways, respectively; while the black oval shape and line represent an inhibitory interneuron and its axonal pathway. Simulation of the pelvic nerve activates a polysynaptic spinal reflex arc that produces an evoked potential recorded from axons of sphincter motor neurons in Onuf’s nucleus at a latency of about 10 msec. In addition, this stimulation also activates inhibitory interneurons that, after 50 msec delay, produce inhibition of sphincter motor neurons for about 1,000 msec (see text for details). Presumably this arrangement allows low frequency pelvic afferent activity (1 Hz) to increase sphincter activity during urine storage and to inhibit sphincter activity when the pelvic afferent activity markedly increases (> 5 Hz) as might occur with very large bladder volumes or during a micturition contraction. The model includes GABAergic, glycinergic, or enkephalinergic inhibitory neurons located in the dorsal gray commissure.

In addition to spinal excitatory sphincter reflexes, Supraspinal pathways originating in the medullary nucleus retroambiguis (NRA) and the pontine “L region” can activate sphincter motor neurons during Valsalva maneuvers and during urine storage, respectively. When micturition occurs, neurons in the pontine micturition center (PMC) provide descending activation of the GABAergic, glycinergic, or enkephalinergic neurons in the dorsal gray commissure to inhibit sphincter motor neurons and allow voiding to begin. In addition to these predominant pathways, various other areas of the brain (e.g. medullary raphe serotonergic pathways, pontine locus coeruleus noradrenergic pathways, etc) provide “modulation” of the reflexes. Those excitatory and inhibitory modulatory pathways that have been explored pharmacologically are also listed in the table. For simplicity, the inhibition associated with PMC activation and the inhibition associated with pelvic nerve stimulation are shown passing through the same inhibitory interneuron. However, no evidence yet exists that this is the case.

the caudal medulla (Fig. 16)[271, 285, 313-316]. Nucleus retroambiguus also innervates the pelvic floor muscles[222, 317], as well as abdominal muscles, consistent with a role in raising intra-abdominal pressure during Valsalva maneuvers. Generally, the pelvic floor and rhabdosphincter muscles are activated as a functional unit when voluntarily contracted. However, differential activation of the rhabdosphincter and the pelvic floor muscles has been demonstrated[244], indicating distinct CNS control systems and innervation.

Rhabdosphincter motor neurons are unique among somatic motor neurons in receiving input from the paraventricular hypothalamus[270], although the function of this input has not been determined. In addition, their input from brainstem serotonergic and noradrenergic neurons is among the densest in the spinal cord [318-321].

8. NEUROCHEMICAL ANATOMY OF RABDSPHINCTER MOTOR NEURONS

In addition to their unique morphology, neurophysiology, and supraspinal inputs, rhabdosphincter motor neurons in Onuf’s nucleus also exhibit a plethora of amino acid transmitters, ion channels, and growth factors (Figs. 16, 17 and Table 1) and indicate a role in continence and/or sexual function.

a) Pharmacology of Urethral and Anal Rhabdosphincter (Fig. 16)

The excitatory amino acid neurotransmitter, glutamate, mediates initiation of action potentials in rhabdosphincter motor neurons (and subsequent rapid contraction of the muscle) by binding to NMDA and AMPA receptors [242, 282, 322-329]. Thus it is useful to think of these transmitters as part of the “hardwired” reflex circuitry that is involved in all or none activation of consistent and reliable storage reflexes, as compared to monoamines and peptide transmitters (see below).

The inhibitory amino acids glycine, acting through strychnine-sensitive ionotropic receptors[297, 298], and GABA, acting through both GABA-A (ionotropic) and GABA-B (metabotropic) receptors[260, 295, 330, 331] are thought to be major inhibitory transmitters regulating rhabdosphincter activity. Clinical studies indicate that systemic[332] or intrathecal[331, 333] administration of the GABA-B agonist, baclofen, may reduce bladder-sphincter dyssynergia in some patients with neurogenic bladder.

In addition to amino acid transmitters, the monoamine transmitters (norepinephrine and serotonin) are also important in modulating rhabdosphincter motor neuron activity [334]. It was the preferential distribution of norepinephrine and serotonin terminals in Onuf’s nucleus[318-321] that led to extensive animal studies of noradrenergic and serotonergic control of rhabdosphincter function and eventual clinical studies of duloxetine, a norepinephrine and serotonin reuptake inhibitor, as a treatment for stress urinary incontinence [274, 315, 316, 335-338]. Elegant studies in humans using magnetic stimulation of brain and sacral nerve roots[339] have indicated that duloxetine increases the excitability of rhabdosphincter motor neurons to both supraspinal and segmental inputs to increase urethral pressures. Importantly, duloxetine’s ability to increase urethral rhabdosphincter activity did not interfere with the inhibition of sphincter activity during voiding (i.e. bladder-sphincter synergy was well-maintained)[274]. Similar clinical results occurred after administration of S,S-reboxetine, a selective norepinephrine reuptake inhibitor[340, 341]. This approach of increasing synaptic levels of serotonin and/or norepinephrine is logical, since it has been shown that noradrenergic and serotonergic terminals associated with rhabdosphincter motor neurons show an age-dependent decrease in density in rats[342] that might explain the increased incidence of stress incontinence with aging.

Multiple adrenergic receptor subtypes play a role in control of rhabdosphincter motor neurons, and the results with norepinephrine reuptake inhibitors indicate that these receptors can be activated by endogenous norepinephrine[275]. Strong evidence exists that a1 adrenoceptors excite rhabdosphincter motor neurons[275, 343]. Patch clamp studies[265] have shown that norepinephrine produces a direct depolarizing effect, accompanied by an increase in input resistance and decreased rheobase (Fig. 15D-G). These excitatory effects are largely mimicked by the a1 adrenergic agonist, phenylephrine, blocked by the a1 adrenoceptor antagonist, prazosin, but were resistant to apamin (Fig. 15M-N), a small conductance Ca+2 activated K+ (SKCa) channel blocker. The depolarization, increase in input resistance, and decrease in rheobase produced by norepinephrine was mimicked by a doxapram, a TASK (TWIK-related acid-sensitive K1) channel blocker, or reducing extracellular pH to 6.5 (Fig. 5H-I, manuscript in preparation, Yashiro, Thor, Burgard, et al., 2012). Doxapram and pH 6.5 effects also occluded the responses to norepinephrine (manuscript in preparation, Yashiro, Thor, Burgard, et al., 2012). These findings indicate that norepinephrine is working through a second messenger system to close TASK K+ channels and increase rhabdosphincter motor neuron excitability (manuscript in preparation, Yashiro, Thor, Burgard, et al., 2012). In addition to the depolarization, increase in membrane resistance, and decrease in rheobase, norepinephrine also increased excitability of rhabdosphincter motor neurons by reducing the afterhyperpolarization (Fig. 15J) and increasing the firing frequency of the neurons (Fig. 15D)[265]. Both of these effects are blocked by apamin (Fig. 15K-L), indicating closure of SKCa channels is responsible for the reduction in afterhyperpolarization. Surprisingly, afterhyperpolarization reduction by norepinephrine was resistant to prazosin, indicating that this effect is not mediated by a1 adrenoceptors.

Excitatory effects of a1 adrenoceptor stimulation on rhabdosphincter neurons are supported by clinical studies[343] where decreases in rhabdosphincter...
activity were seen after administration of prazosin to human subjects. On the other hand, strong evidence exists that α2 adrenoceptor stimulation has the opposite effect, i.e. inhibition, of rhabdosphincter activity[275, 344, 345]. Importantly, reflex activity in the sympathetic pathway to the urethral and anal smooth muscle (i.e. the hypogastric nerve) shows similar adrenergic pharmacology - an enhancement of activity by α1 adrenoceptors[275, 346] and inhibition of activity by α2 adrenoceptors[275, 347]. Our lab (Yashiro, Thor, and Burgard) has been unable to demonstrate direct inhibitory effects of α2 adrenoceptor agonists in extensive patch clamp studies of rhabdosphincter neurons in neonatal rat spinal cord slices, indicating that the inhibitory effects seen in vivo are mediated via presynaptic or interneuronal actions.

Multiple subtypes of serotonin (5-hydroxytryptamine, 5-HT) receptors are also involved in modulating rhabdosphincter motor neuron excitability. Strong evidence exists that 5-HT2 receptors can excite sphincter motor neurons[279]. Indeed duloxetine’s facilitatory effects on rhabdosphincter activity in anesthetized cats are mediated in part through activation of 5-HT2 receptors[274]. Both 5-HT2A and 5-HT2C receptor agonists increase rhabdosphincter EMG activity in dogs, guinea pigs, and rats[348, 349]. Recent in vitro rat spinal cord slice patch clamp studies show that part of this effect may be directly on rhabdosphincter motor neurons, as opposed to interneurons[350], since 5-HT induces a direct depolarization of rhabdosphincter motor neurons. The effect of 5-HT to enhance the bistable behavior, plateau potentials and persistent firing of motor neurons[351] very likely contributes to its facilitatory effect on sphincter reflexes and sphincter motor neuron firing[288]. Interestingly, substance P, a peptide transmitter that is co-localized with 5-HT in raphespinal nerve terminals, also produces direct depolarization of rhabdosphincter motor neurons in rat spinal cord slices[352], and thyrotropin releasing hormone (TRH), another peptide transmitter co-localized with 5-HT in nerve terminals, induces excitation of rat sphincter activity[353, 354] in vivo.

Immunohistochemical and molecular studies in humans and dogs[348] have shown that 5-HT2A, 5-HT2B, and 5-HT2C receptor subtypes are associated with Onuf’s nucleus motor neurons. In addition, 5-HT2C receptor mRNA has been localized to anal sphincter motor neurons in the rat[355]. On the other hand, another immunohistochemistry study with retrograde labeling of urethral rhabdosphincter motor neurons and ischiocavernosus motor neurons in male rats indicates that the 5-HT5A receptor is associated with the rhab-
dosphincter motor neurons, while the 5-HT2A receptor is preferentially associated with the ischiocavernosus motor neurons[137] and thus may be preferentially involved in sexual function.

As described above, supraspinal 5-HT1A receptor stimulation also enhances rhabdosphincter activity in cats[280, 299-302]. Importantly, the excitatory effects of 5-HT1A receptor agonists on the rhabdosphincter can still be “over ridden” by inhibitory mechanisms during voiding, i.e. bladder-sphincter synergy remains despite 8-OH-DPAT induced enhancement of rhabdosphincter activity[280, 299, 301, 302, 356]. The enhancement of sphincter activity by 8-OH-DPAT in cats is not seen following acute[280, 299] or chronic[300, 301] spinal cord transection, indicating the 5-HT1A receptors mediating these effects are located supraspinally. 5-HT1A receptor activation may inhibit supraspinal neurons that facilitate SUSRIC-mediated inhibition of sphincter reflexes and thereby facilitate URS activity through disinhibition.

In spinal cord injured rats that have lost micturition-associated HFO bursting of the urethral rhabdosphincter, 5-HT1A receptors have been shown to restore the bursting. Chang et al[306] further showed that the center responsible for bursting activity in spinal rats was located between the T11 and L4 spinal segments. In the studies of Gu et al[301], 5-HT1A receptor stimulation had no effect on sphincter activity in control rats or on the asynchronous rhabdosphincter activity that precedes, and follows, micturition-associated bursting, in the spinal rats. 8-OH-DPAT only restored the bursting pattern during micturition in spinal rats.

In addition to amino acid and monoamine control of the rhabdosphincter motor neurons, peptides have also been shown to influence their activity. Onuf’s nucleus is densely innervated by the opioid peptides encephalin (Fig. 17E) and dynorphin[296, 357-359]. In cats, the k opioid receptor agonist, ethylketocyclazocine, selectively inhibits spinal rhabdosphincter reflexes[281]. However, attempts to block sphincter inhibition during voiding with high doses of the opioid receptor antagonist, naloxone, were unsuccessful, indicating the enkephalins are not mediating physiological inhibition. In spinal intact rats, it was found that a k2 opioid receptor agonist inhibits the rhabdosphincter bursting pattern associated with micturition, leading to decreased voiding efficiency[300]. In these studies, k opioid receptor stimulation had no influence on the asynchronous rhabdosphincter activity that precedes and follows micturition-associated bursting, only on the bursting itself. Onuf’s nucleus is abundantly invested with other peptidergic terminals. Excitatory effects of peptides; vasopressin, thyrotropin-releasing hormone (TRH) and substance P (SP), on rhabdosphincter motor neurons have been demonstrated[352-354].

9. LA AND RHABDOSPHINCTER NEUROPATHY

Childbirth is a risk factor for development of pelvic organ prolapse (POP)[360]. Furthermore, various studies have indicated damage to the innervation of the pelvic floor muscles, which might be expected to initiate pelvic descent and prolapse[361-366]. Early studies using pudendal nerve terminal latency as a measure of nerve damage[367] were met with skepticism for many reasons, however with more sophisticated analyses using EMG interference patterns a more recent series of elegant studies[365, 366, 368, 369] have provided evidence that LA nerve damage accompanies parturition in about 25% of women with approximately 1/3 of those continuing to show evidence of nerve damage at 6 months after parturition[365, 369]. Importantly, women undergoing elective Caesarian section (i.e. without preceding labor) showed no signs of LA nerve damage[366]. Furthermore, changes in function of the urethral rhabdosphincter were also associated with pregnancy (i.e. before labor), and these remained evident at 6 months postpartum[365, 366]. In rabbits[370], it has also been shown that multiparous females have thinner, longer, and weaker pubococcygeus muscles than nulliparous females, which may indicate nerve damage also occurs in this species. A recent study comparing continent and incontinent women[371] also demonstrated that incontinent women showed evidence of poor neuromuscular function of the rhabdosphincter, and the authors indicated that there was a correlation with age.

Because the pelvic floor supports the viscera, damage to the LA innervation and subsequent muscle flaccidity was thought to promote POP. To test this expectation experimentally, the LA muscles were bilaterally denervated in 7 squirrel monkeys[207], which is a species that shows age- and parity- correlated POP similar to humans[372]. Surprisingly, these monkeys showed no POP following this procedure for 2-3 years after surgery, despite showing statistically significant decreases in LA muscle mass and myocyte diameter (Fig. 12A), as well as vacuolization of the muscle. Thus, these experiments suggest that, in the absence of childbirth, the pelvic floor muscle innervation plays a minor role in providing visceral support and suggests that the connective tissue plays the major role.

In women, the appearance of levator ani muscle abnormalities in magnetic resonance images after vaginal delivery concluded that frank damage of the LA muscle (and presumably the associated connective tissue) is correlated with sphincter damage, prolapse and incontinence [373, 374]. Thus, future research might focus on the changes in pelvic ligaments or extracellular matrix that occur with pregnancy, childbirth, and aging. Possibly after childbirth and stretching of the pelvic connective
tissue, the muscle plays a compensatory role. In support of this possibility, it was shown that LA muscle mass and myocyte diameter in monkeys with naturally occurring POP was equal to or greater than age-, parity-, and weight-matched monkeys without POP[207, 375], suggesting that LA muscle stretching might induce reflexes and subsequent muscle activity and hypertrophy.

Relative contribution of LA and pudendal nerves to continence mechanisms during sneezing in rats and cats.

Analysis of the urethral closure mechanisms during sneeze-induced stress conditions in anesthetized female rats and cats has revealed that pressure increases in the middle portion of the urethra are mediated by reflex contractions of the rhabdosphincter as well as the pelvic floor muscles[285, 376]. Transection of the pudendal nerves reduced sneeze-induced urethral reflex responses by 67% and transecting the nerves to the ilioinguinal and pubococygeus muscles reduced urethral reflex responses by an additional 25%. Transecting the hypo gastric nerves and visceral branches of the pelvic nerves did not affect the urethral reflexes indicating that sneeze-evoked urethral reflexes in normal rats were not mediated by these autonomic pathways. However, hypogastric nerve transection in conscious, chronic spinal cord injured, female rats reduced urethral baseline pressure, reduced post-void residual urine volumes, reduced maximal voiding pressure, and increased voiding efficiency. This indicates that sympathetic pathways to the bladder neck and proximal urethra contribute to urethral pressure and functional outlet obstruction and voiding dysfunction after spinal cord injury in unanesthetized animals, but not during sneezing[377].

**Summary**

Neural control of the pelvic floor (LA and coccygeus) is provided by the LA nerve, while the urethral and anal rhabdosphincters are controlled by the pudendal nerve. LA motor neurons are similar in morphology to other skeletal motor neurons, showing large α and small γ neuronal populations diffusely distributed in the sacral ventral horn. One distinguishing feature, however, is projections from LA motor neurons into Onuf’s nucleus, the location of rhabdosphincter motor neurons. Presumably these projections coordinate pelvic floor and rhabdosphincter function. This proposed coordination of visceral and rhabdosphincter activity with pelvic floor muscle activity is one important area for future research. Rhabdosphincter muscles and their innervation are remarkably different from skeletal muscles. The rhabdosphincter striated muscles do not have Golgi tendon organs and muscle spindles, which are common in skeletal muscles. In addition, the rhabdosphincters are intimately associated with the urethra and anal canal and participate extensively in voiding and sexual function. Thus it should not be surprising that rhabdosphincter motor neurons are quite distinctive from skeletal muscle motor neurons. In contrast to the diffuse distribution of LA motor neurons in the sacral ventral horn, the rhabdosphincter motor neurons are densely packed within Onuf’s nucleus (and homologous nuclei in other species). Finally, rhabdosphincter neurons exhibit a number of unique membrane properties that may contribute to simultaneous activation and which are distinctive from skeletal muscle motor neurons. Important species differences exist in the spinal localization of anal sphincter neurons. Other distinguishing characteristics of rhabdosphincter motor neurons are their unique morphology, their association with abundant neurotransmitters and receptors, a diverse physiology, and a rich pharmacology. These differences presumably reflect their integral role in coordinating somatic and visceral function during micturition, defecation, and copulation. Denervation of both the pelvic floor and the rhabdosphincters has been associated with childbirth and aging.

Table 1. Neuronal markers preferentially associated with rhabdosphincter motor neurons in Onuf’s nucleus. nNOS = neuronal nitric oxide synthase; CRF = corticotrophin releasing factor; CPON = C-flanking peptide of neuropeptide Y; 5-HT = 5-hydroxytryptamine; D = dopamine; NPY = neuropeptide Y; NK = neurokinin; TRP = transient receptor potential; CaV = voltage sensitive Ca²⁺; CNTF = ciliary neurotrophic factor; GAP = growth associated peptide; trk = receptor tyrosine kinase
Three main neural pathways regulate lower urinary tract efferent activity: 1) sacral parasympathetic (pelvic) nerves provide excitatory input to the bladder; 2) thoracolumbar sympathetic nerves provide inhibitory input to the bladder and excitatory input to the bladder neck and urethra; and 3) sacral somatic (pudendal) nerves innervate the striated muscles of the sphincters and pelvic floor.[397] This section will describe the spinal and then peripheral pathways controlling efferent drive to the bladder. Efferent innervation to the rhabdosphincter is discussed in Section III.

Parasympathetic and sympathetic pre-ganglionic neurons release acetylcholine, which acts on nicotinic receptors to activate post-ganglionic fibres. In some species they also release opioid peptide transmitters and express nitric oxide synthase[398]; there is also evidence of involvement of putitary adenylate cyclase activating peptide (PACAP), a peptide present in visceral afferent neurones, and of prostaglandins within the spinal cord.[399]

Parasympathetic post-ganglionic fibres terminate predominately at the detrusor muscle and release acetylcholine, resulting in detrusor contraction during voiding. Studies in animals have shown that sympathetic post-ganglionic fibres predominately terminate at the mucosal and urothelial level, releasing noradrenaline (NA), contributing to bladder relaxation during storage (via stimulation of beta-adrenergic receptors expressed in detrusor).

2. PREGANGLIONIC NEURONS

Parasympathetic preganglionic neurons are located in the lateral part of the sacral intermediolateral gray matter in a region termed the sacral parasympathetic nucleus. The neurons are small, fusiform-shaped cells which send dendrites into lateral lamina I of the dorsal horn, the lateral funiculus and medially into the dorsal grey commissure (DGC). The bladder preganglionic motor neurons are located in the S1-S3 segments in the cat,[400] guinea-pig[401], dog[401] and monkey[402]. In cat and guinea pig, these motor neurons are bilaterally located ventrolaterally in the intermediolateral column. The rat is different, as preganglionic motor neurons are located at L6-S1.[403, 404] unilateral ventral root rhizotomy at the L5 level in the rat decreases peak cystometrical pressures. [405] The parasympathetic preganglionic neurones project through the ventral spinal roots to the major pelvic ganglion.[406-408]

At spinal levels L1–L2, both the intermediolateral horn and the DGC contain sympathetic preganglionic neurones whose axons also project to the major pelvic ganglion. Electrical stimulation of the lumbar sympathetic chain evokes firing in the pelvic nerve and in postganglionic nerves on the surface of the bladder and colon, at latencies of 60-150 ms.[409] With ageing, there is selective attrition of preganglionic sympathetic neurones in L1–L2, which project to the pelvic ganglion, with reductions in the extent of the dendritic arbors of remaining cells. [406, 407, 410]

In spinal cord injured patients, where disruption to pathways at pre-ganglionic levels is observed, several groups have used neural stimulation techniques to restore normal bladder function. Stimulating parasympathetic pre-ganglionic roots at S3 with implanted electrodes elicits two principal responses[411]: at low levels of stimulation, the external urethral sphincter, external anal sphincter and pelvic floor muscles are contracted. At high levels of stimulation, parasympathetic activation contracts the detrusor muscle, leading to efficient emptying of the bladder when the sphincter muscle relaxes.[412]

The recent increase in the use of sacral neuromodulation for the treatment of detrusor overactivity has resulted in numerous potential theories of its actions, including stimulation of efferents, direct effect on the muscle, stimulation of the afferents, induction of spinal plasticity, and modifications of cortical activation.[413]

The DGC also contains a group of interneurones, which have recently received more attention as main players in the guarding reflex (these are further discussed below in Bladder and Outlet).[414]

2. GANGLIA

The peripheral ganglia are the link in the relay of autonomic innervation to the lower urinary tract and reproductive organs, along with a substantial part of the extrinsic motor innervation of the lower bowel. There are species differences in organization and neurochemistry of pelvic ganglion cells and their spinal inputs. Large mammals have a plexus of pelvic and intramural ganglia, containing both sympathetic and parasympathetic neurons. The guinea pig is intermediate in complexity, with separate posterior and anterior plexuses innervating different pelvic organs. In the rat and mouse, the pelvic plexus consists of the major pelvic ganglia (MPG) and a number of small accessory ganglia.

Within the pelvic plexus there is topographical representation of the pelvic organs. In the female dog, neurons supplying different pelvic organs are located in separate ganglia, which possess a distinctive composition of neurone types and different preganglionic supply.[415] Neurons retrogradely labelled from the urinary bladder mainly occur in ganglia located at the vesico-ureteric junction. They comprise catecholaminergic calbindin neurons and noncatecholaminergic neurons containing calbindin or NOS, with relatively sparse pericellular varicose fibre fibres. In male mice[416], the major pelvic ganglia are close to the dorsal surface of the prostate gland. Their main inputs are the pelvic nerves, and the hypogastric nerve from the inferior mesenteric ganglion. The
major outputs are the penile (cavernous) nerve and the supply to the urogenital organs.

Functionally, the preganglionic sympathetic and parasympathetic neurons synapse on post-ganglionic fibres within the specific ganglia, releasing acetylcholine, which acts on nicotinic receptors. Patients with megacystis-microcolon-intestinal-hypoperistalsis syndrome (MMHIS)[417] have reduced or no alpha-3 nicotinic receptor subunit.[418] Selective gene knockout mice lacking the alpha-3 nicotinic receptor subunit alone or the beta-2 and beta-4 subunits in combination[419], develop severe bladder distension soon after birth, and later overflow incontinence. The detrusor muscle in these animals contracts in response to field stimulation or muscarinic agonists, but not nicotinic agonists[420], indicating the potential importance of alpha-3, beta-2, and beta-4 nicotinic receptor components in functional control of voiding, but not their location.

About half of the cholinergic ganglion cells contain VIP, distributed throughout most of the ganglion, with a cluster near the origin of the penile nerve.[416] Neurones with NPY are numerous and apparently randomly distributed throughout the ganglion, with marked variation between mouse strains. All noradrenergic neurones contain NPY, but many NPY neurones are not noradrenergic. Many of the cholinergic NPY neurones also contain VIP. Neurons immunostained for choline acetyl transferase (ChAT) have a complementary distribution to noradrenergic neurones. ChAT is seen in varicose axon terminals closely associated with ganglion neurones. Neither NPY nor VIP is present in preganglionic terminals, except for a small number of individual neurones. The latter may arise from visceral fugal neurones in the myenteric plexus of the lower bowel.[421] Tyrosine hydroxylase (TH) is expressed by one-third of neurones, almost all co-expressing dopamine beta hydroxylase (DBH). Numerous TH axons are present in the hypogastric nerve, but very few in the pelvic nerve, supporting a primarily sympathetic origin. Non-neuronal cells containing TH are also present, resembling small, intensely fluorescent cells observed in many other autonomic ganglia.

The bladder wall itself contains intramural ganglia, and small clusters of autonomic ganglion cells are present in the adventitial connective tissue and among the detrusor muscle bundles. There is species variation in the extent of intramural innervation of the bladder; ganglia are present in many species such as the guinea pig, while the rat bladder contains the postsynaptic innervation alone.[422] The ganglia are found throughout the bladder wall and vary considerably in size.[130, 423] They show immunoreactivity to vasoactive intestinal polypeptide (VIP), nitric oxide synthase (NOS), neuropeptide Y (NPY) and galanin (Gal) in varying amounts. However, they do not contain enkephalin (ENK), substance P (SP), calcitonin gene related peptide (CGRP) or somatostatin (Som)[129], suggesting that cell bodies of sensory neurones are not located in the intramural ganglia. Postganglionic sympathetic nerves, identified with antibodies to TH and NPY, also synapse on these neurones. Nicotinic receptors have been identified on intramural nerve cell bodies within the bladder.[420]

3. TERMINAL NERVE FIBERS

Smooth muscle cells in the bladder are grouped into fascicles, several of which make up a muscle bundle. They receive a dense innervation, which runs in line with the axis of the fascicle and is derived from coarse nerve trunks in the connective tissue around the fascicles and bundles. This innervation mediates the widespread co-ordinated detrusor contraction accompanying voiding. The anatomical relationship between the preterminal innervation and the muscle fascicles has been described in a serial sectioning study in the human bladder.[424] The nerve supply is distributed by a series of dichotomous branchings, illustrated schematically in Figure 18. Adjacent to the muscle bundles, 1 or 2 primary nerve trunks run parallel to the long axis of the bundle. These give rise to circumferential peribundle branches. Both the longitudinal and circumferential trunks give off transverse interfascicular branches, entering the bundle perpendicular to its long axis, approximately at the midpoint of the bundle. Within the bundle they give axial interfascicular branches running along the long axis within and closely adjacent to individual fascicles, ending in the preterminal and terminal varicose intrafascicular axial innervation.

The majority of nerves running in the detrusor stains positively for acetylcholinesterase and for vesicular acetylcholine transferase (VACHT)[423, 425, 426] and are thought to be parasympathetic. Electrical field stimulation studies have been used to elucidate the neurotransmitter content from muscle strips (with or without mucosa). Acetylcholine and ATP appear to provide the bulk of the excitatory input, since electrical field stimulation responses are blocked by muscarinic receptor antagonists combined with purinergic antagonists. Both transmitters are released in the innervated muscle layer and persist after removal of urethra. By using high-frequency field stimulation, it is possible to delineate the cholinergic and purinergic component.[427] Apart from acetylcholine and ATP, there are additional substances present in parasympathetic efferents (VIP, NOS, Gal), which allow immunohistochemical subclassification of nerve fibres, and raise the question as to whether additional transmitters (other than ACH/ATP) have a role in normal micturition function or disease pathophysiology.

Cholinergic nerves are also present in the suburothelium; most of them in addition contain NPY and TH and some contain NOS. In the muscle of the trigone, the most common axons contain both VIP and NPY, with noradrenergic axons forming only a sparse supply. Indeed, noradrenergic neurones are rare in the detrusor and absent in the mucosa.[416]
4. TRANSMITTERS

a) Glutamate

Glutamate is present in the terminals of primary afferent neurons in the spinal cord along with interneurons and fibres originating in the medulla oblongata. In general, glutamatergic neurons tend to be excitatory, contrasting with generally inhibitory effects of glycineergic neurons; however, excitatory/inhibitory effects of transmitters can be reversed by the nature of the post-synaptic neuron. Thus, glutamatergic neurons can indirectly have an inhibitory effect if an inhibitory neuron is interposed before the ultimate target.[428] Glutamate acts on spinal neurons through a variety of receptor subtypes. These include NMDA receptors, which are important in controlling polysynaptic reflex pathways at the lumbosacral levels. The NMDAR1 glutamatergic receptor subunit is present in the spinal cord of male rats, and is expressed in the SPN. Glutamate is present in the dorsal root ganglion cells supplying the bladder,[429], and the NMDAR1 sub-unit is also present in L6 dorsal root ganglion cells of the rat.[430] In female rats intrathecal injection of an NMDA receptor antagonist decreases bladder contraction pressure.[431] With ageing, there is a decrease in the density of glutamatergic synaptic inputs, which may influence urinary tract function.[408]

b) Glycine/ gamma amine butyric acid

Glycinereric and GABAergic interneurones have a major role in neural control processes mediating bladder function. [432]Glycinergic/ GABAergic projections to the lumbosacral cord inhibit the micturition reflex and also inhibit glutamatergic neurons. [433] Clinically, detrusor overactivity can be inhibited by GABA receptor activation.[330] Rectal distention prolongs the interval, decreases the amplitude and shortens the duration of bladder contractions in rats; this effect is not seen after simultaneous intrathecal injection of low dose strychnine (a selective glycine-receptor antagonist) and bicuculline (GABA-A receptor antagonist), suggesting that the inhibitory rectovesical reflex involves glycineergic and GABAergic mechanisms in the lumbosacral spinal cord, which may be synergistic.[434]

Indeed, in the spinal cord, several transmitters synergistically mediate the effects of modulatory pathways that influence the onward progression of efferent activity. In a rat model of neurogenic bladder dysfunction (autoimmune encephalomyelitis), an exaggerated descending excitatory control arises at the spinal segmental level, which gives rise to detrusor overactivity. Some animals with autoimmune encephalomyelitis develop detrusor areflexia rather than overactivity;[413] in these animals, the excitatory control is probably dominated by segmental inhibition, mediated primarily by glycine receptor activation. Spinal shock in rats induces an alteration of glycine/glutamate concentration ratio. [433] A change in the ratio of excitation and inhibition was also observed in humans suffering from spasticity and pain [435]. This balance of inputs, and the potential plasticity of neuronal circuits, is crucial in understanding pathophysiological processes.

c) Serotonin

Spinal reflex circuits involved in voiding function have a dense serotonergic innervation.[436] Immunocytochemical studies in rats, cats and primates show that lumbo-sacral sympathetic and parasympathetic autonomic nuclei receive serotonergic inputs from the raphe nuclei.[320, 321, 437, 438] Activation of the central serotonergic system can suppress voiding by inhibiting the parasympathetic excitatory input to the urinary bladder, and 5-HT elicits a prolonged activation of thoracic sympathetic preganglionic neurons. Stimulation of the raphe nuclei in the cat inhibits reflex bladder activity,[439-441] 5-HT1A and 5-HT2 receptors are present in the SPN. However, in different species serotonin (5-hydroxy tryptamine, 5-HT) may have varying functions in the central nervous control of bladder activity. For example, activation of 5-HT1A receptors facilitates reflex bladder activity in rats,[436, 442] and has been used to reverse the effects of diabetes mellitus [443].

Inhibitory effects on bladder activity are most likely mediated primarily by 5-HT1A receptors. The transmitter released by inhibitory interneurons has not been identified. Activation of 5-HT1A and 5-HT3 receptors also inhibits afferent input passing from the bladder to the brain. Blockade of 5-HT1A receptors in raphe neurons would increase raphe neuron firing and enhance serotonergic control of spinal reflex mechanisms. This effect would promote urine storage by enhancing sphincter activity and depressing bladder activity.[302, 444] Indeed, 5-HT1A receptor activation is associated with increased rhabdosphincter activity in spinal intact but not spinalised animals [280].

d) Adrenergic

Descending catecholaminergic neurones are primarily located in the upper medulla or pons[342] (Figure 18). In clinical use, non-selective α1-adrenergic antagonists influence urine flow and storage phase lower urinary tract symptoms; the two effects probably occur by different mechanisms, and central or peripheral locations may be responsible.[445] Reflex bladder activity is modulated by at least two spinal α1-adrenergic mechanisms. Firstly, there is inhibitory control of reflex bladder contractions, probably by modulation of afferent processing. Secondly, there is excitatory modulation of the amplitude of bladder contractions due to regulation of the descending glutamatergic limb of the spinobulbospinal bladder reflex pathway.[446, 447] α1-A adrenoceptors comprise 70% and α1B-adrenoceptor 30% of the α-adrenergic receptors in the rat lumbar spinal cord,[448] while α1D adrenoceptors do not appear to have a significant role.

Blood pressure, vascular resistance and tissue blood flow are also regulated by α-adrenergic receptors.
Aging is thought to impact pelvic blood flow and thus, bladder function. Pharmacological blockade of the vascular α1B-adrenoceptor may increase pelvic blood flow and contribute to an improvement in bladder dysfunctions associated with aging and/or hypertension.[449] β3-adrenoceptors, although well documented peripherally, are also present in the rat sacral spinal cord. They are upregulated in rat models of partial urethral obstruction.

e) Substance P

Substance P-containing terminals are closely apposed to both sympathetic and parasympathetic preganglionic neurons projecting to the major pelvic ganglion.[450] Substance P-containing afferents in the pelvic nerve terminate in the outer laminae of the dorsal horn and in the region of the SPN and DGC.[451] Substance P is also located in intraspinal neurons located in the dorsal horn[452] or DGC[453]. In young adult rats, substance P in the ventral horn is almost exclusively co-localized with serotonin and derived from descending axons of medullary neurons[454, 455] and is also often co-localized with serotonin in axon terminals in the lumbosacral spinal cord.[456] Functionally, substance P affects micturition reflex activity;[457] intrathecal administration of Substance P at spinal levels L5–S1 induces bladder contraction. [458] Substance P also increases the firing rate of sympathetic preganglionic neurons.[459] Studies in the rat show that substance P levels decline with ageing in both the dorsal and ventral regions of the lumbosacral cord.[460, 461] Substance P-immunoreactive innervation of the dorsolateral nucleus (supplying the EUS) is not obviously altered with ageing. [462]

f) Purinergic

ATP is released together with noradrenaline and neuropeptide Y from sympathetic nerves. It is also released as a cotransmitter with acetylcholine from parasympathetic nerves supplying the bladder. Cotransmission likely offers subtle, local variations in neurotransmission and neuromodulation mechanisms.[463]

5. PELVIC ORGAN INTERACTIONS AT THE EFFERENT NEURAL LEVEL

a) Bladder and Outlet

Neural coordination of physiological and behavioral functions depends on convergence within the nervous system of information from relevant areas. There is extensive convergence of pelvic organ input[464, 465] at the levels of the spinal cord, dorsal column nuclei, solitary nucleus, medullary reticular formation, and thalamus.[466] The fundamental role
of spinal and supraspinal mechanisms in maintaining normal lower urinary tract synergy, between the bladder and sphincter, is well recognized.

In this context, the role of spinal interneurons must be considered. Involuntary bladder emptying during urine storage is considered to involve somatic nerve activity originating from cells in the lateral ventral horn, in a region called Onuf’s nucleus. Normally, cholinergic spinohypogastric moto-neurons project to the urethral striated muscle/rhabdosphincter via the pudendal nerve, resulting in its contraction.[3] This contraction can be activated by bladder afferent activity conveyed through pelvic nerves, and is considered to be organized by interneuronal circuitry in the spinal cord. It is thought to come into play in response to sudden increases in bladder pressure – for example, during a cough, sneeze, laugh. With aging, there is a loss of innervation at the terminal muscle level, which is displayed as a loss of striated muscle fibres in the sphincter and thus, a loss of urethral closing pressure. [467]

Synergic lower urinary tract function may also be a feature of the peripheral innervation, independent of CNS co-ordination. In the female minipig, pre-ganglionic pelvic nerve stimulation evokes a pressure increase in the bladder and a pressure decrease in the urethra.[468] It remains to be determined whether this observation suggests pre-determined, separate inputs to the bladder (excitatory to the bladder, inhibitory to the outlet), or whether the divergence occurs at postganglionic motorneuron level, which send branches supplying both bladder and urethra. In the latter arrangement, release of different neuromuscular transmitters from branches of the same motoneuron, or interposition of an additional intermediary cell would be required. The former is circumstantially supported by the observed co-localization of acetylcholine- and nitric oxide-related enzymes.[469]

b) Bladder and Bowel

Clinicians are familiar with the detrimental effect of bowel disorders on lower urinary tract activity. Physiologically, the effenter limb of the micturition reflex is inhibited by afferent input from the rectum;[470] thus, rectal distention inhibits bladder activity via glycinergic and GABAergic mechanisms in rats. Dual labeling studies show that many neurones in Barrington’s nucleus supply both colon and bladder, with smaller populations supplying the two organs separately (Figure 19) – with dorsal neurons being bladder-related and ventral neurons being colon-related.[471] At the level of the major pelvic ganglion, double-labeled cells are relatively infrequent, but processes of colonic-retrograde-labeled cells often surround cell bodies of equivalent cells for the bladder. Dual-labeled cells in the spinal cord are rare.

c) Bladder and Prostate/Uterus

Voiding dysfunction is commonly associated with symptoms of chronic prostatitis/chronic pelvic pain syndrome, suggesting a prostate-bladder neural reflex. Electrical stimulation of the prostate following transection of the prostate nerves or lidocaine injections into the prostate, evokes changes in bladder cystometry parameters.[472] Anatomically, voiding cannot be initiated unless the prostate first rotates around the symphysis.[473] This preceding action of the prostate is suggestive of a higher centre efferent coordination.

Neurons labeled from the prostate are found mainly in L1-L2 whereas neurons labeled from the bladder are found mainly in L6-S1. Double-labeled neurons are located in L1-L2 mainly in the dorsal gray commissure. However, the number of bladder neurons are much greater than that of prostate, and both neurons increase significantly at longer incubation times. [474] At the brainstem level, double-labeled neurons are more common (Figure 20).

Inflammation of the uterine horn or colon gives rise to inflammation in the bladder, an effect that can be eliminated by sectioning the hypogastric nerve.[475] Similarly, inflammation of the bladder causes heightened sensitivity of uterine cannabinoid receptors, likely inhibiting its adrenergic input.[476] Bladder overactivity induced by inflammation is influenced by estradiol, probably mediated through effects on the sympathetic nervous control of the bladder.[477] There are several potential mechanisms by which neural input could contribute to emergence of inflammation in neighboring organs (Figure 21):

1. A dorsal root reflex; hypogastric afferents from the inflamed organ could, via a spinal interneuron, sensitize and antidromically activate other hypogastric afferents from a non-inflamed organ.[478]

2. Axon reflexes occurring in hypogastric sensory nerves that branch to supply more than one pelvic organ. Though such branching has not yet been specifically identified, a small proportion of single afferent fibres may branch to supply the colon and bladder.[478]

3. Input from the inflamed organ (via the hypogastric nerve) activates neurons in the dorsal horn that activate postganglionic neurons in the pelvic ganglion via thoracolumbar preganglionic neurons.

4. A spinal mechanism could be mediated by intraspinal connections to lumbosacral preganglionic neurons (as seen for gynaecological organs). [479]

5. A suprasacral mechanism could be mediated through the brain stem.[471, 480, 481]

6. EFFERENT INHIBITION

The sympathetic pathway contributes to inhibition of parasympathetic efferent input to the detrusor smooth muscle. In isolated whole bladders, there is a high level of spontaneous contractile activity,[482-487] suggesting active neural inhibition of
the bladder during urine storage. In a novel perfused decerebrate preparation of the whole rat, ganglion blockade using hexamethonium also leads to an increase in spontaneous activity.[488] Rat brainstem/spinal cord/bladder preparations or neonatal spinal cord/bladder preparations show tonic inhibition, arising at L6-S1 and involving a peripheral ganglionic synapse.[489, 490] Clearly, efferent inhibition of the bladder facilitates urine storage.

In the neonatal rat, considerable activity arises in the bladder wall when inputs from the lumbosacral spinal cord are disrupted.[485] Selective spinal cord and root lesions indicate that intrinsic bladder activity of the neonatal rat is tonically inhibited by parasympathetic efferent outflow. This path is additional to the predominant cholinergic preganglionic efferents mediating the main voiding reflexes. The functional difference in the two sets of cholinergic ventral root efferents may result from differing synaptic targets, since both are blocked by the nicotinic antagonist hexamethonium. Thus, inhibitory efferents must synapse with noncholinergic inhibitory neurons in the major pelvic ganglia, in contrast to excitatory efferents synapsing with the cholinergic detrusor innervation.

In addition to efferent input, local reflexes may contribute to the inhibition of detrusor activity, probably driven by interstitial cells[491], so that peripheral autonomous activity increases as a result of bladder distension.[486] This has been proposed to signify the presence of a regional regulatory influence[492] and a peripheral “pacemaker”[493] and various mechanisms for the propagation of activity within the bladder wall.

7. PERIPHERAL EXCITATORY MECHANISMS

Agonist exposure appears to elicit contraction by two different mechanisms, comprising a component derived from direct stimulation of the muscle cell (‘classical’ efferent), and a separate component that is more phasic, responsible for the obvious pressure fluctuations. The latter ‘intrinsic’ mechanism may involve an intermediary cell type.[494] Optical imaging and calcium-/ voltage-sensitive dyes in whole rat bladder preparations have detected electrical activity moving in a coordinated manner from localized regions over the entire bladder.[99, 495] The isolated whole bladder shows regionalized responses when exposed to cholinergic/muscarinic agonists.[485, 494, 496, 497] Dynamic migrating localities of contraction and elongation, give rise to a complex mix of micro motion phenomena, including micro contractions, micro stretches and propagating waves.
Several species show differences in contractile activity according to the region of the bladder from which a muscle strip is taken. Different effects are seen according to stage of development - spontaneous activity is high in bladder strips from neonatal rats, but small or almost non-existent in adults and reemerges in older bladders.\[498\] The likely functional significance of peripheral excitatory mechanisms is exemplified by the rodent neonate voiding reflex, which is induced by parental stimulation of the perineum, prior to establishment of mature control by the higher micturition centres. \[499\] The physiological role of such activity in the older adult is not known, but could include; 1. Optimization of the bladder wall configuration for volume contained, to ensure efficient voiding regardless of volume.\[500\] 2. Stimulation of ‘in series’ receptors for signaling bladder volume.\[501\] 3. A mechanistic component of accommodation during filling, a counterintuitive suggestion supported by the observation that accommodation in the colon involves synchronous contraction and relaxation.\[502\] 4. Maintaining the voiding contraction until complete evacuation is achieved.\[503\]

The integral role of the brainstem in bladder function was initially realized by the demonstration in cats that micturition was abolished by lesions at the level of the inferior colliculus whereas lesions anterior to the colliculus facilitated micturition, presumably by removing inhibitory influences.\[1, 504\] Anatomical and physiological studies in both rat and cat have delineated midbrain-pontine-spinal cord circuits in reflexes controlling filling, storing and emptying of the bladder. The roles of pontine nuclei revealed by animal models translates well to humans as indicated by brain imaging during micturition\[505-507\] and clinical cases showing that specific pontine lesions can result in either bladder continence or incontinence problems.\[506, 508, 509\] This section will review the anatomical and physiological evidence for the pontine-midbrain circuitry that regulates the parasym pathetic and sympathetic motor innervation of the detrusor and smooth muscle of the urethral

**Figure 20. Neurons in selected brain nuclei, arranged in caudal to rostral order labeled by virus from the bladder or from the prostate.**

- **A:** Raphe and gigantocellular reticular nuclei. Double-labeled neurons are common.
- **B:** The A5 adrenergic nucleus. Note that there are numerous double-labeled neurons.
- **C:** The locus coeruleus. Several neurons are double-labeled.
- **D:** Barrington’s nucleus (the pontine micturition center). Bladder virus labels the overwhelming number of neurons. Only a few neurons contain prostate virus.
- **E:** The paraventricular nucleus. Approximately equal numbers of bladder and prostate neurons. Some are double-labeled.
- **F:** The medial preoptic nucleus. Only bladder neurons are found. From Nadelhaft et al., 2002.
Sensations of bladder fullness are conveyed to the spinal cord by the pelvic and hypogastric nerves, while input from the bladder neck and urethra is carried in the pudendal and hypogastric nerves. Afferents arising from the bladder and urethra are mechanoreceptive (Aδ fibres) and nociceptive (C fibres). The most important afferents for initiating micturition are those passing in the pelvic nerves, whose fibers terminate in discrete regions of the lateral aspect of the dorsal horn of the lumbar and sacral spinal cord (see [3, 510, 511] for reviews). Many of these dorsal horn neurons make spinal connections that mediate segmentally organized reflex responses. However, a proportion of the spinal interneurons send ascending projections to specific nuclei in the pons and midbrain that can regulate bladder activity through a descending loop (Figure 22). The interpretations of the circuitry through which the bladder initially communicates with the brain vary somewhat depending on the species in which the anatomy was characterized. Initial characterizations using the cat as a model point to the periaqueductal gray (PAG) region of the midbrain as the initial site of termination of spinal afferents. [512] In this species anterogradely labeled fibers from the lumbosacral spinal cord form a dense terminal field particularly in the lateral PAG. As the PAG is a prominent afferent to Barrington’s nucleus (the pontine micturition center), which in turn projects to the preganglionic parasympathetic neurons that innervate the detrusor, the anatomical findings in the cat suggested a loop comprised of spinal neurons carrying bladder information to the PAG and the PAG in turn relaying this information to back to the bladder through descending projections from Barrington’s nucleus to the preganglionic parasympathetic neurons that innervate the detrusor. Later studies in the rat using retrograde tracing from Barrington’s nucleus and anterograde tracing from the spinal cord provided evidence for direct projections from spinal neurons to Barrington’s nucleus, taking the PAG out of the primary loop in this species.[513] This would be consistent with the finding that lesions anterior to the inferior colliculus (i.e., between the Barrington’s nucleus and the PAG) do not abolish the micturition reflex. Given the role of the PAG in nociception and defensive behavior it is likely that in rats the PAG exerts an influence on micturition through Barrington’s nucleus under specific conditions but that it is not necessary for micturition to occur with
bladder filling. The PAG may also play an important role in relaying bladder information to limbic and cortical brain regions as well as in integrating descending information from these regions, which provide contextual information concerning the appropriateness for micturition. [511]. Although these putative circuits are based on animal models, a pivotal role for both the PAG and PMC has been confirmed in man using positron emission tomography and functional magnetic imaging with and without a full bladder (see Figure 23). [2, 514, 515] [516]

2. DEFINING THE CENTRAL CIRCUITRY REGULATING BLADDER FUNCTION BY TRANSNEURONAL TRACING

Transneuronal retrograde tracing from end organs with pseudorabies virus (PRV) has been an invaluable tool in delineating the central circuitry that regulates visceral function. [517] The population of rat brain neurons labeled from PRV injections in either the bladder wall or urethra of the rat exhibit an overlap and similar time course of labeling, supporting a close coordination of detrusor and urethral muscle function by brain circuits as previously suggested. [284, 518-520] The first neurons to be labeled in brain from bladder or urethra and therefore the most direct links to the spinal efferents are the ventral medullary raphe, parapyramidal reticular formation, A5 and Barrington’s nucleus. The PAG, hypothalamus and medial preoptic nucleus, which are prominent afferents to Barrington’s nucleus, are labeled at a slightly later time when the LC, cortex and red nucleus are also labeled. Interestingly, PRV labeling from other pelvic viscera including the distal colon yield a similar pattern and time course suggesting a certain degree of central coordination of these functions. [471, 521]

The PRV studies provide information regarding some hierarchy of neurons that is anatomically linked to the bladder and/or urethra. However, the PRV technique does not imply precise information about connectivity or functionality. This must be delineated by additional tract tracing between putatively connected brain nuclei and physiological studies. Of the brain regions that are initially labeled with PRV from the bladder or urethra, most anatomical, electrophysiological and imaging studies to date implicate Barrington’s nucleus as pivotal in regulating bladder function in both animals and man.

3. BARRINGTON’S NUCLEUS: THE PONTINE MICTURITION CENTER (PMC)

In 1925 Barrington was the first to describe a pontine control centre for micturition in the cat through lesion studies. [1, 504] This region was better localized to a nucleus in the dorsal pons (now termed Barrington’s nucleus) using more discrete lesions that abolished micturition and caused urinary retention in cats and rats. [522, 523] Lesions in humans as a result of stroke or multiple sclerosis in an analogous region similarly result in urinary retention in man. [524]

In both cat and rat, Barrington’s nucleus is in the dorsal pons lying ventromedial to the rostral pole of the locus coeruleus (LC) in the rat and within the
The regulation of micturition reveals that the thalamus, the insula, the prefrontal cortex, the anterior cingulate, the periaqueductal grey (PAG), the pons, the medulla and the supplementary motor area (SMA) are activated during the urinary storage. From DasGupta et al., 2007.

Figure 23. Brain areas involved in the regulation of urine storage. Ameta-analysis of positron-emission tomography and functional MRI studies that investigated which brain areas are involved in the regulation of micturition revealed that the thalamus, the insula, the prefrontal cortex, the anterior cingulate, the periaqueductal grey (PAG), the pons, the medulla and the supplementary motor area (SMA) are activated during the urinary storage.

Neuronal recordings in cats that were localized to the rostral medial medulla (reticularis gigantocellularis and magnocellularis) revealed many neurons that were activated antidromically from the spinal cord (L1) and discharged in or out of phase with bladder contractions. More recently, bladder distention was found to excite nearly 80% of juxtacellularly labeled Barrington’s nucleus neurons.

Micturition also requires an inhibition of the urethral sphincter to be coordinated with detrusor contraction. This is controlled by somatic motoneurons of Onuf’s nucleus. Barrington’s nucleus neurons do not project to Onuf’s nucleus. Rather, in the cat a diffuse region ventrolateral to Barrington’s nucleus, termed the L-region, is thought to provide pontine control of sphincter function through its projections to Onuf’s nucleus. For coordination between the detrusor and sphincter, there should be some form of reciprocal communication between these regions. However, a lack of connections between Barrington’s nucleus and the L-region are argued against sphincter regulation by Barrington’s nucleus through this route. Rather it has been proposed that Barrington’s nucleus indirectly inhibits Onuf’s nucleus neurons through excitatory projections to GABA premotor interneurons in the dorsal gray commissure. Additionally, Barrington’s nucleus projections onto inhibitory interneurons located in the intermediolateral cell column at the sacral segmental level have been described that may provide an inhibitory influence over Onuf’s nucleus and both glycine and GABA are thought to play a role here.

Together, the anatomical and physiological findings described above point to Barrington’s nucleus as being the command center for initiating and orchestrating the act of bladder emptying. More recent evidence discussed below suggests a more complex role for Barrington’s nucleus neurons in coordinating a central response to bladder filling with the visceral response of bladder emptying through Barrington’s nucleus projections to the norepinephrine nucleus, locus coeruleus (LC).
Micturition requires a central component so that bladder emptying is coordinated with a set of behaviors. If animals are asleep they must be aroused. If engaged in some ongoing behavior that is not compatible with urination, this must be interrupted and behavior should be redirected to be compatible with the visceral response. Recent evidence suggests that neurons of Barrington’s nucleus neurons serve the role of coordinating visceral and behavioral limbs of micturition through collateral projections to the preganglionic parasympathetic spinal neurons and the major norepinephrine nucleus, locus coeruleus (LC).[537]

**a) Normal Function**

The LC, a cluster of neurons lying along the wall of the fourth ventricle just dorsolateral to Barrington’s nucleus, is the major source of norepinephrine in the brain.[538, 539] A characteristic anatomical feature of LC neurons is their massive projection system that innervates the entire neuraxis, serving as the sole source of norepinephrine in cortex and hippocampus.[538, 540] The LC-norepinephrine system initiates arousal in response to diverse stimuli. A representative example of this is the increase in LC neuronal activity elicited by elevations in bladder intravesicular or colonic intraluminal pressure.[541-543] LC activation elicited by these visceral stimuli is temporally correlated with cortical electroencephalographic (EEG) indices of arousal (e.g., desynchronization and a shift from high amplitude, low frequency activity to high frequency activity).[540, 542] In rats Barrington’s nucleus is involved in this response as lesions prevent LC activation by pelvic visceral stimuli.[544] Notably, simultaneous recordings of cortical EEG and bladder pressure during cystometry in unanesthetized rats indicate an offset between EEG correlates of arousal and micturition threshold such that cortical arousal precedes bladder emptying (Figure 25).[545] This is consistent with the idea that the behavioral program for voiding should be initiated before bladder emptying.

Recordings of LC neurons in non-human primates performing operant tasks suggest a role for the LC-norepinephrine system in facilitating decisions related to task-directed behavior, i.e., whether to maintain behavior in an ongoing task or to disengage and seek alternative strategies in a dynamic environment. [546] Tonic LC activation favors disengagement from ongoing behavior and tasks involving focused attention and promotes scanning of the environment for alternative strategies.[546-548] As bladder pressure rises towards micturition threshold the tonic excitation of LC neurons is speculated to increase arousal and facilitate disengagement from ongoing behavior and a shift towards the initiation of elimination-related behaviors. Thus, Barrington’s nucleus neurons are central to coordinating the descending limb of the micturition reflex with a central limb that facilitates a switch from on-going non-voiding related behavior to voiding behaviors (Figure 26A).[549] Importantly, the LC projects to cortical regions that are proposed to exert conscious control over micturition.

**b) Pathological Consequences**

Barrington’s nucleus projections to the LC can also relay signals from pathologic events in bladder to the forebrain, thereby providing a mechanism by which bladder disorders can have neurobehavioral consequences (Figure 26B). This was demonstrated in a rat model of partial bladder outlet obstruction.
Baseline LC neuronal activity was tonically elevated in PBOO rats compared to rats with sham surgery and was not further increased by elevations in bladder pressure. This was reflected at the level of the cortical EEG as a persistent desynchronization and a shift from high amplitude, low frequency activity to low amplitude, high frequency activity, effects indicative of hyperarousal (Figure 27). Additionally, a prominent theta frequency oscillation was apparent in PBOO rats, especially those with a urodynamic profile characterized by numerous non-voiding contractions. Theta oscillations are hypothesized to coordinate activity in different brain regions in preparation for motor responses to sensory input. Tonic LC activation is necessary for PBOO effects on cortical EEG activity because selective chemical lesion of forebrain LC projections prevents these effects without altering urodynamics.

The persistence of an activated cortical EEG and theta rhythm in PBOO rats suggests a state of hyperarousal and a decreased ability to grade or discriminate between different magnitudes of bladder pressure changes. This could explain the finding that some individuals can have chronic retention and enlarged bladder, yet no sensation or urge to urinate. Importantly, an effect on sensorimotor processing could also affect cortical processing of non-bladder related stimuli and adversely impact on functions requiring focused attention.

The PBOO model exemplifies how pathology that originates in the bladder can have pronounced adverse central consequences through the Barrington’s nucleus projections to the LC and spinal cord coordinate visceral and central limbs of micturition and also can relay pathology between the brain and bladder. A) Barrington’s nucleus neurons in the rat get afferent information from the bladder (blue arrow). Increasing intravesicular pressure activates these neurons. Through projections to the preganglionic parasympathetic neurons in the lumbosacral spinal cord, Barrington’s nucleus initiates bladder contraction. The same neurons are positioned to activate the LC-norepinephrine system which projects to the cortex and can initiate arousal and facilitate a shift toward voiding behaviors. B) The same circuit provides a means by which bladder pathology can have neurobehavioral consequences. Particularly by activating LC neurons, this can produce hyperarousal, anxiety and sleep disturbances. Psychological stressors can impact on this circuit, perhaps through the PAG to affect bladder function. Barrington’s nucleus (BN), locus coeruleus (LC), periaque ductal gray (PAG). From Valentino et al., 2011.
nucleus projections to the LC. It is not clear whether this occurs in humans. However, evidence for anxiety and sleep disorders in men with benign prostatic hypertrophy and in males and females exhibiting other bladder disorders is consistent with this process. [552, 553] Evidence for a causal role of the LC-noradrenaline system suggests that pharmacological manipulation of the activity of this system may be a useful therapeutic approach for central sequelae of overactive bladder.

Interestingly, a consequence of PBOO on Barrington’s nucleus circuit is the loss of responses of Barrington’s nucleus to acute increases in bladder pressure to micturition threshold. [550] This may be relevant to the visceral pathology because it represents a loss of central regulation of bladder function. Like spinal cord injury, the loss of central control could lead to local spinal regulation of the micturition reflex that is thought to underlie the detrusor overactivity often seen in patients with overactive bladder. [554] Thus, consequences of PBOO on Barrington’s nucleus neuronal activity may feed-forward to further contribute to the bladder dysfunction in addition to having central consequences.

5. SUPRASPINAL INPUTS TO BARRINGTON’S NUCLEUS

Afferents to Barrington’s nucleus would be positioned to initiate or regulate bladder activity and could be targets for modulating urinary function. The most prominent afferents in the rat are the PAG, lateral hypothalamus and medial preoptic area. [555] Particularly, the lateral and ventrolateral PAG densely innervate Barrington’s nucleus. As described above, the PAG receives bladder afferent information from spinal interneurons and this may be an indirect route through which the bladder communicates with Barrington’s nucleus that is in addition to a more direct route. The PAG afferents can trigger micturition as evidenced by the finding that chemical stimulation of ventrolateral PAG can cause voiding.[556] PAG stimulation can also elicit sphincter activation without bladder contraction suggesting an involvement in both voiding and storage functions.[556]

The lateral hypothalamus, particularly, the perifornical region is a major source of afferents to Barrington’s nucleus.[555] Like the PAG, the lateral hypothalamus is involved in defensive responses and modulation of Barrington’s nucleus by these two afferents likely plays a role in urination as a component of the defense response.[557, 558] A third major afferent arises from the medial preoptic area and these have been demonstrated to directly contact spinal-projecting Barrington’s nucleus neurons.[559] Many of these neurons express estrogen receptor alpha, suggesting that this is an estrogen sensitive pathway.[560] The medial preoptic region has been suggested to provide an inhibitory influence during sleep and/or sexual activity to suppress micturition.[511, 526, 561] Neurons in other brain regions are retrogradely labeled from Barrington’s nucleus although these are not as prominent as the PAG, lateral hypothalamus and medial preoptic area. Most notably, some neurons in motor cortex, insular cortex and infralimbic cortex are retrogradely labeled from Barrington’s nucleus and may serve to provide cortical control over bladder function.[555] The primary afferents to Barrington’s nucleus in the cat are similar to those reported in rat.[562] In addition, inputs are described from the ventromedial pontomedullary tegmental field and this has been hypothesized to play a role in establishing a neuronal set-point or threshold beyond which micturition occurs.[563]
6. DEFENSIVE STRATEGIES AND MICTURITION.

It is fitting that two of the most prominent afferents to Barrington’s nucleus (the periaqueductal gray and lateral hypothalamus) are critical components of the circuitry that underlies acute defensive behaviors because urination is a component of the acute defensive response. Stimulation of the PAG can trigger micturition together with defensive behaviours.[564, 565] Certain laboratory stressors, such as water avoidance, can produce an enduring increase in micturition frequency.[566] On the other hand, inhibition of micturition can also be evoked by stimulation of rostral dorsal and caudal ventral PAG regions.[567] This may be related to the finding that social stress in rodents, such as being a subordinate in a social hierarchy can induce prolonged urinary retention with prominent changes in urological function and structural changes in the bladder. [568],[569-572] In the resident-intruder rodent model of social stress, subordinate rats develop a urodynamic profile that resembles that produced by PBOO, with increased intermicturition interval, bladder capacity and micturition volume and numerous non-micturition contractions (Figure 28).[571] Interestingly, the urodynamic profile associated with social stress can be distinguished from that produced by PBOO by its lack of elevated micturition pressure, implying that it results from a loss of central drive to the detrusor as opposed to increased sphincter tone. This suggests that control of the two muscles is not necessarily interdependent. Like PBOO, social stress increases bladder mass and in mice some of the same transcription factors that are thought to be involved in PBOO-related bladder remodeling are upregulated by social stress, including NFAT and MEF2.[572] Urinary retention may be a visceral component of a defensive response to subordination that is mediated in part by certain aspects of the periaqueductal gray.

Social stress-induced urinary retention may involve the stress-related neuropeptide, corticotropin-releasing factor, CRF, which is highly expressed in Barrington’s nucleus neurons and has an inhibitory influence within Barrington’s nucleus projections to the preganglionic parasympathetic neurons that drive the bladder (Figure 30B)(see below). CRF mRNA and protein are overexpressed in Barrington’s nucleus neurons in rats exposed to repeated social stress but not to repeated restraint stress, which does not alter urodynamic function.[571]

The social stress-induced voiding dysfunction in the rodent may model dysfunctional voiding characterized by urinary retention in humans. In children dysfunctional voiding associated with detrusor hypoactivity has been hypothesized to arise from adverse events that are temporally proximal to toilet training[573, 574]. Consistent with this, children with voiding postponement have a less balanced family environment and more psychiatric co-morbidity compared to children with other types of voiding dysfunction.[575] In adults urinary retention has been associated with a history of sexual abuse, depression and social anxiety.[576, 577] As in the rat model, the persistence of retention can have severe structural consequences and proceed to chronic renal insufficiency.[578] Even in the absence of such severe consequences, the importance of the impact of social stress on urological health is underscored by a recent study of over 1000 women demonstrating statistically significant associations between urinary incontinence and psychosocial problems with feelings of vulnerability.[579]

7. COORDINATION OF BLADDER WITH OTHER PELVIC VISCERA BY BARRINGTON’S NUCLEUS

Transneuronal tracing studies with pseudorabies virus injection into different pelvic viscera suggests that Barrington’s nucleus neurons are also positioned to regulate activity of multiple pelvic viscera, including bladder, distal colon and sex organs, and perhaps coordinate activity between viscera. Dual PRV labeling from colon and bladder results in a large population of Barrington’s nucleus neurons that are double labeled from both viscera, suggesting that their axons diverge to innervate both bladder and colonic parasympathetic efferents[481]. PRV labeling from the penis, prostate and perineal muscles also suggests an overlap of central neurons and time course of labeling with bladder.[521] Chemical stimulation of Barrington’s nucleus neurons increases distal colonic intraluminal pressure and this is abolished by muscarinic antagonists.[580] Notably, most Barrington’s
nucleus neurons are activated by increases in bladder pressure and many of these are also activated by increases in colonic intraluminal pressure indicating that these neurons receive convergent information from both viscera.[471] Although these findings suggest a role for Barrington’s nucleus in coordinating bladder and colonic activity, currently there is no evidence that Barrington’s nucleus impacts on ongoing distal colon activity. Furthermore, the activity of the distal colon is highly dependent on other factors such as pressure gradients and the enteric nervous system. Nonetheless, the link between Barrington’s nucleus neurons and other pelvic viscera implies that pathology arising from pelvic viscera other than the bladder could have similar central consequences as those reported for bladder. For example, this circuit may underlie the well-documented co-morbidity of psychiatric and colonic symptoms that characterize irritable bowel disorder.[581, 582]

8. THE PONTINE CONTINENCE CENTRE (PCC)

The bladder’s function of urine storage requires detrusor relaxation accompanied by urethral sphincter contraction. Studies in the cat identified a pontine continence center also termed the L-region that is distinct from and lying ventrolateral to the micturition center.[535]. Neurons in this region project selectively to Onuf’s nucleus in the sacral cord, which contains the urethral sphincter motoneurons, and do not project to spinal regions influencing detrusor. The majority of neurons in this continence center, fire during the relaxation phase of bladder contractions and the onset of their firing can be prior to the initiation of bladder relaxation.[583] Indeed, this would make sense if their prime function were to close the urethral sphincter. Another potential role for these neurons is in off-switching micturition. Supporting this, stimulation of this region stops micturition, excites the pelvic floor musculature and contracts the urethral sphincter.[531] Conversely, bilateral lesions of the PCC cause incontinence, excessive detrusor activity, an inability to store urine and relaxation of the urethral sphincter.[531] However, there is no anatomical evidence for connections between Barrington’s nucleus and the L-region and it has been suggested that Barrington’s nucleus and the “continence center” function independently.[536] Notably, the L-region has been characterized primarily in cat and there is little evidence to date for a similar region in rat or human.

9. NEUROTRANSMITTERS & MODULATORS WITHIN BRAINSTEM NETWORKS CONTROLLING BLADDER

Knowledge of the neurochemical signals within the central circuits controlling micturition is important for understanding how these circuits function and how they can be manipulated for the treatment of bladder dysfunctions. These are reviewed in detail in [3, 510] Much of the current knowledge is based on studies using cat and less is known of rat or primate.

Glutamate is thought to be the primary neurotransmitter within Barrington’s nucleus neurons that innervate the preganglionic parasympathetic neurons responsible for detrusor contraction. Both NMDA and non-NMDA receptors have been implicated in this response.[322, 584-586]

Barrington’s nucleus neurons express CRF mRNA and protein and a dense CRF terminal field is present in the region of preganglionic parasympathetic neurons of the rat lumbosacral spinal cord.[587, 588] Recent findings suggest that CRF has an inhibitory influence in this same pathway.[533] Thus, discrete chemical activation of Barrington’s nucleus neurons elicits bladder contraction that is enhanced by blocking the CRF influence in the lumbosacral spinal cord with a CRF antagonist. Interestingly, CRF excites LC neurons and this is temporally correlated with cortical EEG correlates of arousal.[589] It is tempting to speculate that CRF release in the divergent spinal and LC projections of Barrington’s nucleus neurons serves to increase arousal while inhibiting bladder contraction. In this way it may be important in creating the offset between central and visceral components of micturition so that the appropriate behaviors can be initiated prior to bladder emptying. CRF is upregulated in Barrington’s nucleus neurons by the same social stress that causes urinary retention (see above), suggesting that this may be causal to the social stress-induced urinary retention that results in bladder dysfunction.[571]

Serotonin appears to affect nervous control of bladder function at multiple levels including sensory processing of bladder wall afferents within the dorsal horn of the spinal cord and at the level of the spinal motoneurons. In all cases this appeared to be an inhibitory influence on detrusor muscle activity but excitatory on urethral sphincter.[350] It was proposed that 5-HT1A receptors were located on the terminals of sensory afferent fibers to depress neurotransmitter release. Similarly, a predominance of an inhibitory effect evoked from the midline raphe system extending from thepons to medulla on micturition in cats has been described.[590] However, the site of this inhibitory action (i.e. supra-brainstem, pons or spinal cord) is unknown. A study of raphe neuronal recordings demonstrated that their firing was related to bladder pressure with 66% related to storage.[590] These data support a role of the raphe system in suppressing micturition and facilitating external urethral sphincter activity in cats, which is consistent with earlier studies identifying a central inhibitory role for 5-HT1A receptors.[302] In stark contrast, this does not seem to be the case in the rat where 5-HT1A system facilitates micturition as indicated by the effects of 5-HT1A antagonists, underscoring the importance of species differences in interpreting effects.[591, 592]

Future challenges

Although advances have been made in our understanding of central control of bladder function during
the last few years, many challenges remain. If we are to study the human condition in the laboratory, it is important to find species that best models human physiology and pathology. Much of our knowledge has been based on physiological and anatomical studies in the cat although more recent studies have focused on rat. Some of the species differences that would lead to different interpretations have been discussed above. The last decade has seen a major shift towards the use of genetically altered mice in neuroscience as these provide invaluable tools for creating unique animal models of disease and elucidating the roles of specific genes and proteins in specific functions. Although there is many examples of studies using genetically altered mice to understand bladder tissue, the use of mouse models for understanding neural regulation of the bladder is rare. In vivo mouse studies present challenges of size. Nonetheless, these can be overcome as new technology for recording and stimulating brain regions advances.

Although our knowledge in how the brain regulates the detrusor has advanced, less is known of the central regulation of the urethral sphincter. Particularly, the coordination between detrusor and sphincter activity at the level of the spinal cord or its regulation by supraspinal circuits is not well understood. This is critical for understanding the pathophysiology and treatment of urinary incontinence.

Very little has been done in the realm of sex differences in regulation of bladder function. Clearly, there are sex differences in certain types of bladder disorders. Notably, Barrington’s nucleus is regulated by afferents from a sexually dimorphic nucleus, the medial preoptic nucleus that are also sensitive to estrogen. Basic research studies are often performed in either male or female animals with little consideration as to the role of sex and there are no studies of systematic comparisons between male and female subjects. By contrast, brain imaging in humans have been addressing this issue. [505, 593-595] Nonetheless, the human studies are limited by the degree of anatomical resolution and do not allow for precise manipulation of specific circuit components that can be done in animals.

Whereas neuroscience research has come a long way in understanding how the brain processes visual, olfactory and auditory signals, the analogous processing of visceral information by the brain is has received comparatively little attention. This may stem in part because of a tendency for specialize rather than integration. Electrophysiological recording technology, optogenetic methods of neuronal stimulation, computational analysis and network modeling has greatly advanced in the last decade. This technology is currently available for understanding how the brain processes information from the bladder in normal and diseased states, how neural circuits in turn respond to control bladder function and how this is organized with respect to processing other information and regulation of other behaviors. The next few years should make use of this state-of-the-art technology to advance into this frontier.

VI. FOREBRAIN CONTROL OF BLADDER FUNCTION

1. BACKGROUND

This chapter is based on the material presented at the previous International Consultation on Incontinence, which was largely written by Professor Clare Fowler, and I am grateful to her for this and for allowing me to use material from other recent reviews. The aim of the chapter is to update the clinical and experimental evidence for the role of the forebrain in bladder control, and to summarize in a simple working model our understanding of the brain regions mediating specific aspects of human bladder behaviour.

The importance of the frontal cortex and pons in the control of voiding was clearly recognized prior to functional brain imaging, which, however, has tended to obscure the older clinical evidence summarized in Table 2. Most functional imaging studies have been carried out using either positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). A few used single-photon emission computed tomography (SPECT) or near-infrared spectroscopy (NIRS). All these methods provide indirect measures of regional blood flow, assumed to be related to local neuronal activity, but PET is good for measuring long-lasting states of a system, while fMRI is better for following relatively fast events. SPECT has rather poor temporal and spatial resolution. Functional NIRS is a relative newcomer that measures absorption of near-infrared light so as to quantify cortical activity from the changing concentrations of deoxy- and oxy-haemoglobin just beneath the skull. Despite limited penetration depth (≈ 10 mm) and modest spatial resolution, it has great advantages: it requires no scanner, is relatively inexpensive, can be used in an ordinary urodynamics laboratory, and has good temporal resolution that can present results in real time, simultaneously with urodynamic pressure and flow signals. Preliminary results suggest that similar regions to those seen with fMRI are activated with bladder filling or detrusor overactivity.

2. ROLE AND IMPORTANCE OF CEREBRAL CONTROL OF VOIDING

In order to understand the cerebral control of voiding it is helpful first to examine what would happen if there were no such control. Provided brainstem and midbrain are intact, micturition is organized in 2 phases, storage and voiding, governed by reflexes involving the brainstem and spinal cord. During storage (99.8% of the time in health) the urethral sphincter mechanism contracts tonically, preventing urine leakage, while the detrusor remains relaxed, so as to avoid developing a pressure that would expel urine. Urethral contraction is maintained by sacral reflexes.
### Table 2. Clinical evidence for the involvement of specific brain regions in bladder control.

known collectively as the ‘guarding reflex’; detrusor relaxation is ensured by absence of excitatory parasympathetic input as well as active sympathetic inhibition provided by spinal reflexes.[3]

During human voiding the urethral sphincter relaxes, facilitating urine flow, and the detrusor contracts so as to expel urine. This coordinated relaxation and contraction of urethra and bladder respectively is driven by a long-loop spinobulbospinal reflex[3], shown schematically in Figure 22 of the companion chapter on pontine-midbrain control. As the bladder fills, increasingly strong bladder afferents travel via synapses in the sacral cord to the brainstem and midbrain, where they synapse in the central periaqueductal gray (PAG) and possibly Barrington’s nucleus or pontine micturition center (PMC) (green lines in Figure 22).

There are differing views about how the brainstem circuitry is organized. One is that, if the afferent signals exceed a trigger level in the PAG, efferent fibres in the PAG are excited and they in turn excite the pontine micturition center (PMC).[596, 597] Another is that there is continuous communication between PAG and PMC and the trigger level is set in the PMC (DeGroat 2012, in press), which may also receive direct afferent input. In cats, the voiding reflex is intact after brain transection between PAG and PMC[598], consistent with the second view. Regardless, if the trigger level is exceeded, efferent signals from the PMC descend to the sacral cord (blue lines in Figure 22), where they excite an indirect inhibitory pathway via the nucleus of Onuf that leads to sphincter relaxation[599] and an excitatory pathway to the bladder that leads to detrusor contraction; thus voiding occurs. Therefore the
spino-bulbospinal voiding-reflex pathway functions as a switch, either "off" (storage) or "on" (voiding).

In the absence of higher control, this switching behaviour would lead to involuntary bladder emptying (i.e. incontinence) whenever the bladder volume reached a critical level sufficient to trigger the brainstem switch. However underlying this apparently simple mode of behaviour are complex networks of cerebral neurons. During storage of urine the ascending afferent signals received by the PAG are relayed to higher regions of the brain, generating unconscious changes as well as conscious bladder sensations which are factored into the assessment of whether voiding is appropriate. Crucially, motor output from these higher centres is able to suppress or promote voiding by manipulating the brainstem switch.

This arrangement forms the substrate for the bladder behaviour characteristic of our species. Embarrassment caused by inappropriate voiding and feelings of shame about incontinence are deeply embedded in human behaviour. Voiding at a socially acceptable time and place is achieved by maintaining strict voluntary control of the voiding reflex. Knowledge of the extent to which one’s bladder content is ‘safe’ is central in this process. Thus, voluntary control of the bladder and urethra has 2 important aspects: registration of bladder filling sensations and manipulation of the voiding reflex switch. The PAG seems to have a pivotal role in both. On the one hand it receives bladder afferents[599] and transmits them to higher brain centres and into the realm of conscious sensation. On the other hand it receives projections from many higher centres and provides critical input to the PMC. [511] This input, together with some direct input from the hypothalamus (Figure 22), normally suppresses excitation of the PMC during bladder filling, so preventing voiding or incontinence. Thus the net effect of higher control is tonic suppression of the voiding reflex. If voiding is necessary (bladder volume is adequate), and is judged (perhaps unconsciously) to be safe, and is consciously assessed to be socially acceptable, suppression can be voluntarily interrupted to allow the brainstem switch to be turned on.

3. CORTICAL AND SUBCORTICAL CENTRES INVOLVED IN BLADDER CONTROL. EVIDENCE FROM OBSERVATIONS OF LESIONS AND FROM FUNCTIONAL BRAIN IMAGING IN HUMANS

a) Frontal Lobes

Although Andrew and Nathan [4] were not the first to describe disturbances of micturition resulting from a variety of causes of frontal lobe pathology, their celebrated paper reporting the syndrome of frequency, urgency (and in some patients faecal) incontinence, is regarded as seminal in the field. Their description of these patients cannot be improved upon:

“[They] were not demented, indifferent or lacking in social awareness; they were much upset and embarrassed … The acts of micturition and defaecation occur in a normal manner; what is disturbed … is the higher control of these acts. The lesion causes frequency and extreme urgency of micturition when the patient is awake, incontinence when asleep. The sensation of gradual awareness of increasing fullness of the bladder and the sensation that micturition is imminent, are impaired. When the syndrome is less pronounced, the sensation underlying the desire to micturate is absent, whereas the sensation that micturition is imminent still occurs. Then the patient is waylaid by a sudden awareness that he is about to pass urine; when neither sensation is experienced, the patient is amazed to find that he has passed urine. The threshold of the micturition reflex is much lowered. In the most complete form of the syndrome, the patient cannot inhibit the detrusor contraction of the micturition reflex; he is thus forced to empty his bladder as soon as the reflex occurs. When the syndrome is less pronounced, the patient can make a conscious effort to stop the act of micturition, and he may or he may not succeed …”

The cases of leucotomy in Andrew and Nathan’s series were regarded as most useful for localizing the lesion causing the syndrome. The significant plane of the lesion lay immediately anterior to the tips of the ventricles and the genu of the corpus callosum. Such lesions involved grey matter, in particular the superomedial part of the frontal lobe (Figure 29D); but they caused a permanent disorder of the control of micturition and of defaecation only when they involved some of the white matter lateral to the anterior horns of the lateral ventricle (Figure 29 A-C).
Subsequently the same features were observed in 7 patients out of a series of 50 consecutive frontal tumours[600]. In an analysis of patients with acute hemispheric strokes the occurrence of disturbance of micturition was found to be more common in frontal than occipital lobe lesions and there was an association with hemiparesis.[601]

In 3 cases, Andrew and Nathan observed that lesions in similar areas to those discussed above led to urinary retention rather than incontinence (Table 2). Three further cases of frontal lesions with urinary retention have been reported. Successful treatment brought recovery of bladder function. [602, 603]

White-matter damage that causes permanent incontinence (Figure 29 A-C) appears to do so by disrupting a pathway (from medial frontal cortex to brainstem, either direct or via the thalamus) carrying the signal that maintains continence by tonically inhibiting the voiding reflex during storage (see discussion below and Figure 32). In confirmation, recent studies have identified white-matter disease (white-matter hyperintensities [WMH] or leukoaraiosis) as the pathology underlying a trial of symptoms commonly seen in the elderly – incontinence, impairment of gait and cognitive disability.[604-606] The Kuchel group used structural MRI (FLAIR) to demonstrate that the burden of white-matter disease in right inferior frontal regions and selected white-matter tracts predicted incontinence, incontinence severity, and degree of bother. The Pittsburgh group[606] used fMRI to show that, in elderly incontinent women, regional brain activations and deactivations became more prominent with increased global WMH burden, suggesting that activity aimed at suppressing urgency was augmented. Damage affecting the anterior thalamic radiation seemed to be particularly associated with urinary incontinence and indeed this tract includes the pathway from medial prefrontal cortex to brainstem that appears to be critical for continence (see Figure 32). It would appear from this account that bilateral lesions would be required to cause incontinence, yet in practice a lesion on one side seems to be sufficient. Andrew and Nathan’s suggestion – that this is because a unilateral lesion is likely to involve the fibres connecting one side with the other – is difficult to follow.

Imaging studies (see Table 2), using PET[514, 593, 607-609] or fMRI[60, 515, 610, 611], are in agreement that, during bladder filling, storage and withholding of urine, there is activity in the right inferior frontal or dorsolateral prefrontal cortex, perhaps extending into the lateral part of the superior frontal cortex (Figure 30A,B). There is some right-sided predominance. In contrast there is little evidence for activation of the medial parts of the frontal cortex during storage (Figure 30C). One PET study showed medial frontal activity during sacral nerve stimulation[611], but this is difficult to interpret; another study that showed medial frontal activity during filling[612] employed SPECT imaging, which has poor spatial resolution. An fMRI study showed abnormally weak activation in medial prefrontal cortex in subjects with urge incontinence[515], and further analysis suggested that bladder filling tends to provoke deactivation in this region.[594] Regardless, there is little overlap with the superomedial frontal region described by Andrew and Nathan [4], except possibly in part of the anterior cingulate gyrus (see Figure 30D). These observations are consistent with the concept that functional imaging reveals grey-matter activation or deactivation, while lesions may damage critical links in white-matter connecting pathways also.

There have been many studies showing connections between the medial and orbital prefrontal cortex and PAG; see [511, 613] for summary. Presumably this pathway is the one discussed above that is responsible for tonic suppression of the voiding reflex and maintenance of continence, and is susceptible to disruption by white-matter lesions. Prefrontal involvement in voiding is considered in section 3.

b) Anterior Cingulate Gyrus (ACG), Supplementary Motor Cortex (SMA) and Insula

The anterior cingulate is an extensive area with parts serving varied functions. The cases of aneurysm in Andrew and Nathan’s series of frontal lobe pathologies were thought to have involved the anterior end of the cingulate gyrus.[4] Incontinence was observed as part of a complex behavioural disorder following bilateral infarction of the anterior cingulate gyrus.[614] A recent report of a patient in whom a glioma in the right posterior ACG and supplementary motor area was resected described how she experienced urgency incontinence and loss of bladder sensation following surgery.[615]

Many functional imaging studies have observed responses (mostly activations) in ACG to bladder filling, storage or withholding[514, 515, 593, 607, 609, 612, 616]. The reported locations form a trail extending from dorsal to ventral ACG, suggesting that different parts of the ACG respond to the very varied experimental paradigms that were used (Figure 30D). Response to bladder filling in the dorsal ACG and adjacent supplementary motor area (SMA) is abnormally pronounced in patients with urge incontinence[515, 594] when, with full bladder but without any actual bladder contraction, they experience the abnormal sensation of urgency (a compelling desire to void that is difficult to inhibit [617], also associated with fear of leakage, i.e. embarrassment).[618] Thus urgency is a powerful homeostatic and social emotion that provides strong motivation to void together with motor output aimed at suppressing incontinence until a
socially acceptable location can be reached. fMRI observations in rats confirm activation in the cingulate cortex during bladder filling[619] although whether this region is homologous with the human dACC, and whether rats ever experience urgency, is not known.

The dACC or midcingulate is the cortical region associated with motivation and can be considered as the limbic motor cortex.[620] It is an essential integrator of afferent bodily function that drives sympathetic output[621], playing a similar role for several organ systems. For example it contributes to heart rate regulation via the sympathetic nervous system.[621, 622] By analogy, the dACC may be involved in sympathetic regulation of bladder and urethra, acting on alpha- and beta-adrenoceptors that can respectively tighten the urethral smooth muscle and relax the bladder, thus helping to control incontinence.

dACC and adjacent sensorimotor areas, especially the supplementary motor area (SMA) (see Table 3), seem to form a functional complex that is often co-activated. The SMA is also activated during purely voluntary contraction of the pelvic floor muscles and striated urethral sphincter.[607, 623-626] Thus SMA activation during urgency may reflect tightening of the striated urethral sphincter, via somatic pathways that might include the brainstem nucleus called the pontine continence center or L-region[531] (see Figure 32 and Figure 22).

Co-activation of the insula and ACC is frequently seen in functional brain imaging studies[627] and has been seen in almost all functional imaging bladder experiments. The insula, an island of cortex deep beneath the operculum of the temporal and fronto-parietal lobes, is regarded as the seat of “interoception”, the sense of the physiological condition of the entire body.[628] including visceral sensation.[629, 630] A key feature of such sensations is an association with an affective, motivational aspect: hence their value in homeostasis. Consistent with this role, the Pittsburgh group has shown a correlation between the degree of bladder filling and insula activation in healthy controls with an exaggerated increase in activation at high volumes in women with poor bladder control.[515] The homolog of the insula in the rat responds to bladder filling, although it is also activated during voiding[619].

Given these observations it is remarkable that there has not been more reported cases of bladder dysfunction from insular lesions. One patient in whom a glioma affecting the inferior frontal gyrus and the insula was excised experienced experienced incontinence without loss of bladder sensation.[615]

Imaging studies during storage or withholding of urine show that regions reported as insula form a cluster near the expected location (Figure 30A).
Table 3. Selected regional activations and deactivations during the storage phase (bladder filling, withholding of urine, or full bladder with urgency but without bladder contraction). BA = Brodmann Area; [x y z] = Montreal Neurological Institute (MNI) coordinates.

</table>
[505, 515, 593, 608, 612, 631] There is slight right-sided predominance, not visible in Figure 30 where right and left sides are projected on the same brain surface. In healthy subjects, insular activation becomes stronger with increasing filling of the bladder, consistent with its postulated role in bladder sensation.[594] In normal elderly, this insular response to bladder filling decreases with age, consistent with age-associated loss of sensation. However, insula activity cannot by itself be responsible for conscious desire to void or urgency, because these sensations are lost following extensive frontal lesions,[632] suggesting that integrity of connecting pathways between insula and frontal cortex is essential for conscious sensation. Cingulate and insula involvement in voiding is considered in section 3.

c) Periaqueductal Grey (PAG)

A single case history describes a young man presenting with urinary retention in whom the only abnormality found was a small, presumed inflammatory lesion in the PAG.[633] Presumably in other cases the clinical picture was dominated by other symptoms and deficits that were more striking to a neurologist.

The brainstem/midbrain activations reported during the storage and voiding phases seem to cluster in 3 distinct regions (Figure 30E), one of them being the PAG. PAG response to bladder filling is reported in 3 studies.[514, 515, 609] This response may reflect increased afferent signals arriving at the PAG (Figure 22) or increased inhibitory activity from the medial PFC, needed to prevent triggering of the voiding reflex (see Figure 32). The PAG responded to imagined voiding in one fMRI study[624], but not to real voiding.

d) Hypothalamus

Lesions at this site as a cause of bladder symptoms are rare but 3 cases of pituitary tumours, extending upwards into the hypothalamus have been described with urgency incontinence or retention, weight loss, psychiatric disturbance and bitemporal field restriction.[603] Other instances include gliomas involving the hypothalamus or vascular disturbances of the anterior hypothalamus. Andrew and Nathan also reported five patients with bladder symptoms appearing after a ruptured cerebral aneurysm and speculated that the site of lesion responsible was the anterior hypothalamus.[634]

Animal observations suggest that the anterior and caudal hypothalamus have monosynaptic projections to the PAG and PMC.[511] Correspondingly, two human brain imaging reports suggest response to bladder filling in a region near the caudal hypothalamus,[514, 594] and one near the preoptic area.[515] It has been suggested that these connections allow the hypothalamus to inhibit voiding unless the situation is judged to be safe.

e) Pons

The demonstration by Barrington[504] in the cat that a centre existed at the level of the pons necessary for activation of micturition, provided the background for recognizing a comparable centre in humans and the early report of the association of difficulty with micturition with posterior fossa tumours. Later histories of individual cases of discrete pontine lesions[524, 635-637] and reports of difficulties with micturition or retention as a feature of brainstem gliomas in children[638, 639] or vascular lesions [509], confirmed the likely existence of a comparable centre in humans. Studies using MRI to visualize the precise location of the responsible lesions, sited this in the dorsolateral pons, including the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and locus coeruleus[509]. Lesions in this location are frequently associated with disturbances of consciousness and respiration and bladder symptoms may therefore be overlooked. The commonest clinical association of urinary retention arising from a pontine lesion is an internuclear opthalmoplegia or disorder of eye movements.

Functional imaging experiments have shown a cluster of activations near the postulated location of this pontine micturition centre (PMC), Figure 29E. There are 3 reports of PMC activation during voiding[505, 593, 608], consistent with the “switch” concept. One report of response to bladder filling seems to support the view (see section 2) that the PMC receives continuous input from PAG and/or afferents from the bladder. However, excitation during bladder filling[594] might be either excitatory or inhibitory, a distinction that cannot be made by functional imaging. The PMC homolog is activated during voiding in the rat.[619]

A few studies suggest activation of the postulated pontine L-region or continence centre, somewhat ventral, lateral and/or caudal to the PMC (Figure 22): during storage[514], during failed attempt to void[593], during imagined voiding[505], and during imaginary inhibition of voiding[624]. However, not all these studies recognized the L-region as such.

f) Other Regions

The regions discussed in sections 3.1 to 3.5 are observed in lesion, imaging and (in some cases) animal studies of bladder function. The triad insula/ACG/prefrontal cortex is well known from studies of other organ systems[621]. Other regions relevant to bladder control however have been revealed only by functional imaging (see Table 3). They include parts of parietal and frontoparietal
cortices, posterior cortex (precuneus, posterior cingulate cortex), parts of the limbic system (hippocampal complex, amygdala), and various parts of the cerebellum.

Functional imaging has occasionally shown activity in the basal ganglia, particularly the striatum (e.g. caudate - see Table 3) and putamen [640]. Correspondingly, dopamine pathways are thought to have a profound inhibitory effect on the PMC in health which is lost in Parkinson’s Disease (PD) [641]. The subthalamic nucleus (STN), also part of the basal ganglia, is the site of deep brain stimulation (STN-DBS) used to treat PD. Patients whose motor symptoms are effectively treated experience an increased bladder volume at first sensation and at capacity with the stimulator on.[642-644] A detailed PET imaging study showed a significant interaction between bladder state and STN-DBS in ACC and lateral frontal cortex. [644]

4. VOIDING

Forebrain changes have been much less studied during voiding than during storage, mainly because of technical limitations of fMRI. The insula was activated in only one [608] of four imaging studies of real [593, 607] or imagined [624] voiding, suggesting that it is not strongly involved in this phase of micturition. All 4 studies revealed AGC involvement, particularly of the perigenual part of the ACC adjacent to the ventromedial prefrontal complex.

Further reports are as follows.

PET studies of voiding. One fMRI study of voiding in the anesthetized rat[619] showed several regional activations, but human homologs are difficult to establish. Blok and Holstege used PET to show that a pontine region probably homologous with the PMC was activated during voluntary voiding in humans, suggesting that the voiding reflex had indeed been triggered.[505, 593] They showed also that the right inferior frontal gyrus (or lateral prefrontal cortex) was activated during voiding. The perigenual cingulate, close to the ventromedial prefrontal cortex which, during storage, is typically deactivated (see Table 3), was activated during voiding. This change may indicate that the tonic inhibition of the voiding reflex, which the medial frontal cortex exerts to maintain continence (Figure 32), has been switched off, allowing voiding to take place. During voiding the PAG was activated, as were a number of other regions, including the hypothalamus and right inferior frontal gyrus.

Some subjects who were unable to void in the scanner failed to show activation either in the perigenual region or in the PMC. They did however show activation of a different region in the pons, believed to be the L-region[531] or pontine storage center (see Figure 32 and Figure 22). This suggests involuntary tightening of the urethral sphincter.

Nour et al [608] using PET, demonstrated many regional activations during voiding, including the PAG and a pontine region close to the PMC. However, the perigenual region was not activated, while the supplementary motor area, dACC, and left insula were unexpectedly active.

Imagined voiding. In a group of 11 healthy women, relaxation of the pelvic floor, as if intending to void but without actually voiding, evoked activations in many of the same regions as contraction of the pelvic floor muscles.[624] Thus this does not seem to be a good model of real voiding. In fact, a pontine region apparently homologous with the pontine continence center or L-region (but not recognized as such by the authors), was activated, just as in Blok’s subjects who tried but were unable to void in the scanner. [505]

Involuntary voiding. A preliminary fMRI study of involuntary voiding (detrusor overactivity, DO)[645] showed marked deactivation of the frontal cortex during DO, a finding that awaits confirmation.

5. WORKING MODEL OF BRAIN / BLADDER CONTROL

We have seen that many forebrain regions respond with altered neuronal activity to bladder filling or voiding, and thus presumably form part of the brain-bladder control network (Table 2). Some are part of a general ‘homeostatic afferent brain network’ that processes sensation and generates appropriate output for many different organ systems.[594, 629, 630] This is not surprising because the ultimate purpose of bladder control is to maintain homeostasis by ensuring that the bladder is emptied regularly, yet only when safe and appropriate. Sensations such as desire to void and urgency are homeostatic emotions[621, 622, 630] that both motivate behaviour and provide corresponding motor output. [596]

The brain regions involved in bladder control are believed to be organized in neural circuits that perform different tasks related to homeostasis, answering questions regarding the adequacy of bladder filling, and the safety and social appropriateness of voiding, as well as the reflex or mechanical aspects dealt with by the brainstem switch. We should therefore expect forebrain control of the switch to involve both limbic circuits (concerned with basic emotion and safety) and cortical circuits (concerned with social propriety [646] and conscious decision-making). In the working model shown in Figure 32, the PAG and PMC form the brainstem switch. The PMC is the final efferent brain nucleus involved in bladder control. The PAG receives numerous projections from forebrain regions,[647, 648] including the medial and orbital
Figure 31. An early conceptual framework that suggests a scheme for the connections between various forebrain and brainstem structures that are involved in the control of the bladder and the sphincter in humans. Arrows show probable directions of connectivity but do not preclude connections in the opposite direction. Reproduced, with permission Fowler et al., 2008 and based on the work of Kavia et al. 2005.

Figure 32. Working model of forebrain control of micturition, showing the brainstem switch and neural circuits that mediate 2 possible continence mechanisms. The normal mechanism (red) operates when there is a normal sensation of bladder filling. It depends on tonic inhibition of the brainstem switch via a long return pathway from the medial prefrontal cortex to the brainstem switch (probably via the anterior thalamic radiation, but shown for simplicity as a direct connection to the PAG). The inhibition is switched off for voiding. A backup mechanism (yellow) corresponds to the abnormal sensation or urgency. It may operate via brainstem nuclei such as the L-region (pontine storage center) or by modulating the sympathetic input to bladder and urethra. The dashed blue arrows show a possible circuit concerned with monitoring safety and/or maintaining continence without conscious sensation. PMC = pontine micturition center; PAG = periaqueductal grey; L-reg = L-region; THAL = thalamus; INS = insula; lat PFC = lateral prefrontal cortex; med PFC = medial prefrontal cortex; dACC = dorsal anterior cingulate cortex; SMA = supplementary motor area; HYP = hypothalamus; HIP = (para)hippocampal complex (may include amygdala, inferior parts of temporal lobe and parts of posterior cortex).
prefrontal cortex. Possible pathways that connect these regions to form the neural circuits that govern bladder and urethral behaviour are shown schematically in Figure 31 and sketched provisionally in the working model (Figure 32), which incorporates as far as possible the lesion and functional imaging observations described above.

a) The Normal Continence Mechanism

During urine storage, as the bladder fills it generates afferent signals (purple ascending pathway in Figure 32) that are transmitted to the brainstem switch but do not trigger it. They are relayed from the PAG via the thalamus to the insula (red circuit) and, if activation is strong enough, generate a desire to void. Propagation of this insular activity to the lateral and medial prefrontal cortex enables both a conscious decision about voiding and an assessment of social propriety and possible embarrassment. If no voiding is planned, a return pathway from the medial frontal cortex to the brainstem tonically suppresses the voiding reflex. The pathway may run directly or via the thalamus in the anterior thalamic radiation (not shown in Figure 32). The resulting red circuit is postulated to be the normal continence mechanism. When there is a normal sensation of bladder filling it exerts negative feedback on the brainstem switch, preventing incontinence. Interruption of the negative feedback, for example by white-matter damage in the mPFC-PAG pathway, leads to incontinence. During normal daily life however there is usually no conscious awareness of the bladder at all. The mechanism that monitors bladder behaviour in this situation requires further research. One possibility is a circuit involving the parahippocampal complex and hypothalamus (Figure 32 and section 5.3).

b) A Back-up Continence Mechanism

Activation of dACC and SMA, associated with urgency, suggests the possibility of another neural circuit — in yellow in Figure 32 — in which an ascending signal from the PAG travels via the thalamus to the dACC and SMA, generates urgency and sends a descending efferent signal that suppresses bladder contraction and tightens the urethral sphincter, using sympathetic (via dACC) and somatic (via SMA) pathways that may involve the pontine L-region. Because urgency is evoked in extreme circumstances this probably should be regarded as a back-up continence mechanism.

What ascending signal activates the dACC and the SMA and generates urgency? The conventional view is that the bladder or the urethra generates abnormal — or merely greater — afferents if leakage threatens, but an alternative is that the PAG should use its knowledge of the brainstem switch to generate a signal indicating how close the switch is to being triggered. This signal, relayed via the thalamus to the dACC, would presumably evoke urgency if triggering were imminent.

c) Limbic or Paralimbic Circuits

Both of the continence mechanisms just described use cortical circuits that involve conscious bladder sensation. However bladder filling, especially in women with OAB experiencing urgency, sometimes provokes subcortical or limbic changes, particularly parahippocampal deactivations (Table 2 and Figure 32). These subcortical changes may have a number of functions:

1) They presumably evoke no conscious sensation, and therefore may reflect an automatic evaluation of bladder events that occurs at small bladder volumes, maintaining continence without conscious awareness.

2) They may reflect evaluation of the safety of voiding. The resulting “safe/unsafe” signal would be relayed to the brainstem switch (PAG and/or PMC), perhaps via the hypothalamus (Figures 31, 32 and 22).

3) They may represent the substrate concerned with basic emotions such as fear, on which the ventromedial prefrontal cortex builds the secondary, social emotion called urgency.

d) Voiding

Referring to Figure 32, if voiding is voluntarily decided upon in the prefrontal cortex a series of stereotypical actions follows (finding a toilet, adjusting clothing, adopting the correct posture) and ultimately the red return pathway from mPFC to brainstem PAG is silenced, removing inhibition of the voiding reflex and allowing activation of the PMC — provided that other PAG inputs, notably from the hypothalamus (reflecting safety), permit it.

6. CONCLUSION: CORTICAL CONTROL OF BLADDER FUNCTION

The fact that voiding and continence are under forebrain control is now well established by multiple lines of evidence. Some of the brain regions involved are known with reasonable certainty, although further investigations, particularly of normal behaviour, voiding, and different age groups of both genders, will be helpful. The specific functions of these regions and the pathways connecting them are less well known but they can be speculatively organized in a working model comprising a few neural circuits that perform various tasks related to homeostasis and maintenance of continence. There is evidence that structural damage to certain critical connecting pathways causes or contributes to urgency incontinence. The working model is highly simplified, but will help understanding of functional disorders such as overactive bladder and guide new research aimed at ameliorating the scourge of urgency incontinence.
VII. ABNORMAL LOWER URINARY TRACT FUNCTION

Lower urinary tract (bladder and urethra) function, while dependent on autonomic neural control, does not mean that control of urinary continence and micturition is involuntary. On the contrary, unlike other autonomically innervated organs (i.e. heart), control of lower urinary tract function is highly volitional and dependent on neural connections to the brain. This control in humans is established during the unique period of toilet training occurring between ages of 2 and 3. The exact mechanisms and pathways that are involved in this important and ubiquitous event are unknown. It is likely that cortical inhibition of the micturition center are emphasized and strengthened during this time.

Later on in life, continence and/or micturition disturbances (interpreted by the patients as lower urinary tract symptoms) are likely associated with alterations/dysregulation of these neural pathways. However, the current diagnostic tools to detect these alterations are not available. Neurogenic alterations can be differentiated into pathologies that affect afferent versus efferent pathways. Afferent dysfunction would involve abnormalities in sensation (both increased and decreased) including emergence of pain instead of usual bladder filling sensations. Efferent abnormalities can be increased, reduced or uncoordinated. The following is not a comprehensive description of the entire scope of this complex arena, but focuses on key issues relevant in the clinical context.

Basic investigations into abnormalities in lower urinary tract function require a multi-modal approach using both animal models and human subjects. While all animal models have issues related to relevance to human condition, animal models will continue to play a critical role in testing mechanistic hypotheses related to lower urinary tract physiology and pathophysiology. Using human subjects for translational studies, such as exploring for biomarkers related to lower urinary tract physiology and pathophysiology. Using human subjects for translational studies, such as exploring for biomarkers related to lower urinary tract function, will provide additional mechanistic hypotheses that can be taken to the laboratory for testing.

1. ABNORMALITIES INVOLVING AFFERENT SIGNALING

a) Bladder Pain Syndrome / Interstitial Cystitis (BPS/IC)

Although no consensus has been reached on the fundamental causes of BPS/IC, existing data suggest three pathophysiological mechanisms: mast cell activation, neurogenic inflammation and epithelial dysfunction.[651]

Mast Cell Activation – Mast cells may be activated by a number of mechanisms within the bladder wall. Increased permeability with influx of potassium ions may lead to sensory nerve upregulation/activation resulting in mast cell activation. Vasoactive, nociceptive and pro-inflammatory molecules released from mast cells can produce neuronal sensitization and secretion of neurotransmitters that further stimulate mast cells. Mast cell could interact with nerves and provoke a vicious cycle in BPS/IC, contributing to the painful symptoms of the disease.[652]

Neurogenic Inflammation – The close physical relationship between the C fibres and mast cells is of particular importance, as substance P (SP) released from the nerve fibres degranulates mast cells. During degranulation, the mast cells release a multitude of proinflammatory agents including nerve growth factor (NGF), tumour necrosis factor-α (TNFα), histamine, heparin, proteases, interleukins, serotonin and others. This induces an inflammatory response in the form of vasodilatation (redness) and plasma protein extravasation (oedema). Additionally, newly released nerve growth factor (NGF) stimulates a further increase in the number of afferent fibres, thus increasing the potential for further releases of SP and the transmission of nociceptive impulses. Inflammatory models of cystitis result in increased levels of TNF-alpha, SP and NGF production in the bladder, paralleling the hypothesized neuro-inflammatory etiology of IC. [653] During mammalian development, NGF is required for the survival and growth of several populations of neurons. There is evidence to suggest that it also plays a role in the ongoing regulation of neural function, as well as inflammation and pain.[654] In the urinary tract, NGF could be produced by the bladder, smooth muscle and urothelium. In one study, patients with BPS/IC were found to have elevated levels of neurotrophic factors in their urine, including neurotrophin-3, nerve growth factor and glial cell line-derived neurotrophic factor.[655] In another study, urine from BPS/IC patients have increased NGF[656], but interestingly did not have increased prostaglandin E2 (PGE2). Another study showed increased NGF mRNA and protein in bladder biopsies from patients with BPS/IC compared with controls[119]. However, the source of the NGF has not been always traceable, although a likely source of the NGF is the bladder urothelium.

A transgenic mouse with overexpression of NGF restricted to the urothelium [86] was shown to exhibit similar phenotype to BPS/IC patients – that is urinary frequency and pelvic pain. This animal model suggests that alterations in the bladder urothelium can drive overall changes in bladder function and increase pelvic pain sensation. Therefore, this animal model is consistent with the data derived from human studies. The importance of the bladder urothelium in pathophysiology of BPS/IC has been also been demonstrated by the discovery a novel glycononapeptide, antiproliferative factor (APF)[49] secreted by the BPS/IC bladder urothelial cells. APF inhibits in vitro proliferation of normal bladder urothelial cells grown in culture[657] and affects

236
the β-catenin signaling pathway.[658] However, whether APF affects neural signaling within the bladder is unknown.

Intravesical NGF is known to sensitize bladder afferent fibres, and sequestration of NGF can reduce inflammation associated with chemical cystitis in a rat model.[659] Blockade of NGF using either endogenous antibody or antibody against the NGF receptor, or a fusion protein that prevents interaction between NGF and its receptor, prevents neural plasticity and bladder overactivity in experimental models of these conditions.[660] Other substances including neurotrophins, prostaglandins, and tachykinins may also contribute to altered afferent excitability.[661] The potential relevance of these changes has been demonstrated in cats diagnosed with feline interstitial cystitis (FIC) (which demonstrates nearly all the characteristics and symptoms of human BPS/IC), in which capsaicin sensitive neurons are larger, with dorsal root ganglia that exhibit increased excitability and slower desensitization to capsaicin.[662] These findings suggest changes in the properties of the primary afferent neurons, a finding that may be associated with tendency of NGF to stimulate TRPV1 expression.

From the translational perspective, a monoclonal antibody to NGF, tanezumab, has been tested in a proof-of-concept trial in treating symptoms associated with BPS/IC. This study showed that tanezumab had significant benefits at alleviating BPS/IC symptoms[663] compared to placebo suggesting promise for this agent that blocks NGF’s actions. Further peer-reviewed publications are needed to determine whether this agent will be useful in a larger clinical population of BPS/IC patients.

b) Pelvic Organ Cross-talk

Another neurogenic phenomenon that might be related to BPS/IC is that of pelvic organ crosstalk. Investigators have theorized that because pelvic organs share the same innervation pathways that when one pelvic organ dysfunctions (i.e. colon) this can lead to bladder dysfunction similar to BPS/IC.[664, 665] A term coined cross-sensitization. This theory is based on the notion that afferent input from one pelvic organ can lead to the dysfunction of another pelvic organ. Researchers are focusing on the mechanism of underlying cross-sensitization and how those mechanisms could be targeted for therapeutic intervention.

Clemens recently coined a term “afferent neurourology” to describe the study of sensory signaling related to the genitourinary tract, which encompasses other organs besides the bladder including the prostate, urethra, vagina, testicles and scrotum.[666] Therefore, disorders in afferent neurology would include other urologic symptoms perceived by the patients outside of the bladder including disorders, for example, such as chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS), pelvic pain syndrome, vaginal pain syndrome, and urethral pain syndrome. These other conditions, because they are not perceived to be related to the bladder, are not the topic of this review. However, Clemens’ review suggests that many of these afferent neurologic symptoms, including BPS/IC, may be due to systemic pathophysiology rather than localized to the organ of suspicion.

2. INVOLVING ABNORMAL URINE STORAGE

a) Overactive Bladder / Detrusor Overactivity

Detrusor overactivity can be due to neuropathic conditions, bladder outlet obstruction or unknown causes. Several observations on structural and functional properties of the bladder have been made in individuals with detrusor overactivity:

- Patchy denervation is present within the bladder wall, while sensory neurones and parasympathetic ganglion cells are enlarged.
- Exaggerated spontaneous myogenic activity can be seen in isolated detrusor muscle strips, with increased incidence of fused tetanic contractions.
- Muscle strips also show altered responsiveness to nervous and pharmacological stimuli.
- Characteristic changes in smooth muscle ultrastructure have been described.

Smooth muscle strips dissected from the bladder in detrusor overactivity often show altered responses to nerve stimulation and to various agonists. For example, in obstructed overactive bladders there is reduced contractile response to intrinsic nerve stimulation, along with supersensitivity to muscarinic agonists and potassium solutions.[667-670] Among neuropathic conditions, spinia bifida is associated with supersensitivity to cholinergic agonists and potassium solutions, but there is no change in the sensitivity to intrinsic nerve stimulation.[671] In spinal cord injury, there is no reduction in sensitivity to electrical field stimulation, but the maximum force generated by each milligram of bladder tissue is significantly reduced. In idiopathic detrusor overactivity, bladder strips show supersensitivity to potassium, but not to muscarinic agonists, and there is a reduced contractile response to intrinsic nerve stimulation.[672] Where functional denervation is present, there appears to be an increase in spontaneous contractile activity and presence of fused tetanic contractions, a feature more typical of well-coupled smooth muscles.[673, 674] A common ultra-structural feature of the overactive detrusor is the emergence of protrusion junctions and ultra-close abutments between the smooth muscle cells.[675] Overall, the cells may be better coupled electrically in detrusor overactivity, perhaps allowing spontaneous activity to propagate over a wider area. Bladder biopsies from overactive detrusor show a patchy denervation; some muscle bundles may be completely denervated, whilst neighbouring ones appear normal and in other areas sparser innervation is also seen.[672, 676] A similar pattern is seen in animal models.[668, 677] Overall,
these observations suggest that response to loss of local innervation by the smooth muscle cell may explain the altered behaviour of the bladder in detrusor overactivity.[667, 678]

Recent studies using function MRI or positron emission tomography (PET) of the brain in patients with urge incontinence and comparing to normal control subjects suggest that urge incontinence is associated with measureable changes in brain activities.[594, 650] Bladder control depends on neural networks within the brain regions including the pontine micturition center, periaqueductal gray (PAG), anterior cingulate gyrus (ACG), insula, amygdala and prefrontal cortex. Neural targets, in addition to detrusor smooth muscle, may be target for future urge incontinence treatments.

Preclinical studies in animal models of OAB / detrusor overactivity contribute further to our understanding of the importance of neural control in this condition. The main models relevant to OAB include (i) instillation of irritative agents into the bladder during cystometry, (ii) partial bladder outflow obstruction, (iii) the spontaneously hypertensive rat, (iv) spinal cord injury, and other CNS lesions similar to those responsible for bladder dysfunction in humans [679]. Irritative agents are employed in animals to evoke a painful or irritant response, in particular through C-fibres. Both acetic acid and citric acid have been used, although the latter probably represents a better model since it is less irritant and therefore less likely to invoke an acute inflammatory response. Both agents have been shown to increase bladder contractile activity, decrease bladder capacity and reduce bladder compliance, while micturition pressure remains normal or is increased, suggesting that this model may contribute to understanding of increased bladder sensory activity, as may occur during the symptom of urgency. These effects are due to stimulation of nociceptive afferent fibres, confirmed through demonstration of increased c-fos expression in rat spinal cord and in regions of the periaqueductal grey. [680] This effect can be eradicated by desensitization of TRPV1 receptors on the sensory neurones following pretreatment with resiniferatoxin.[681]

Partial bladder outflow obstruction has been achieved through application of urethral ligatures or a constricting ring that results in partial urethral occlusion, mimicking the obstruction seen in men with BPH who often develop secondary OAB.[669] The animals develop cystometric features such as increased bladder capacity and non-voiding bladder contractions, with associated histological features (muscle hypertrophy, patchy denervation and enlarged sensory neurones and parasympathetic ganglia) and detrusor functional features (spontaneous myogenic activity and altered response to stimuli) reminiscent of the human condition.[678] Afferent plasticity in animals with bladder outflow obstruction involves NGF, the content of which is increased in obstructed bladders prior to the enlargement of bladder neurons and the development of urinary frequency.[682] The relevance of NGF in the response to obstruction in animals is suggested by the finding that rats immunized with mouse NGF in order to develop autoantibodies do not develop neural plasticity and urinary frequency in response to obstruction.[683] While neuronal changes are evident in the obstructed model, further observations appear to indicate that the overactive phenotype in obstructed rats derives from a combination of increased propensity to localized muscle contraction, together with a tendency towards wider propagation of this activity in an organ that may have developed greater autonomy from central control as a result of the neuronal changes.[424] In this context, the relevance of peripheral contractile modules appears to emerge as the functional units of detrusor activity.

The spontaneously hypertensive rat (SHR) is a genetic model of hypertension, which is also known to exhibit abnormal bladder function; in particular, SHRs have been shown to have reduced bladder capacity and voided volume, increased urinary frequency and increased occurrence of non-voiding contractions, associated with altered detrusor innervation and physiological response. Again, increased bladder smooth muscle NGF levels appear to be associated with these changes.[684] The bladders of SHRs also show increased levels of calcitonin gene-related peptide immunoreactive fibres (presumably afferent) with increased size of neuronal cross-sectional area profiles for bladder afferents in the L6–S1 dorsal root ganglia as well as the major pelvic ganglia.[685] The potential importance of the afferent innervation in this model can be highlighted by the finding that intrathecal application of antisense oligonucleotide against the tetrodotoxin-resistant sodium channel (Nav1.8) reduces bladder hyperactivity.[684, 686]

Spinal cord injury (SCI) in animals has been shown to result in changes in lower urinary tract function similar to those seen in humans.[687] Recovery of bladder function from the initial areflexia after SCI in animal models is dependent in part on plasticity of bladder afferent pathways and the unmasking of reflexes triggered by the normally silent capsaicin-sensitive C-fibre bladder afferent neurones, resulting in cystometric changes akin to those seen in neuregic detrusor overactivity. Studies in rats indicate that the increased excitability in the C-fibres is associated with an increase in the expression of sodium channels from a high-threshold TTX resistant type to a low-threshold TTX-sensitive type.[688]

Recent clinical studies has been performed to determine whether neurosurgical somatic-to-autonomic nerve re-routing can reverse detrusor areflexia secondary to autonomic neural injury secondary to spinal dysraphism[689]. The intended goal of this procedure is to trigger somatic afferent signal that will be reflected in a autonomic motor reflex. Whether this procedure will have potential for widespread clinical application to other neuro-
logic conditions causing detrusor areflexia remains to be seen. Furthermore, this surgical nerve re-routing procedure has been highly controversial arising from ethical concerns.[690]

Other animal models of CNS lesions associated with bladder dysfunction have also been developed. For example, a model of Parkinsonism secondary to 6-hydroxydopamine injections into the substantia nigra pars compacta in rats has been developed, confirming the relevance of D1/D5 dopaminergic stimulation in improving bladder capacity. Furthermore, a model of bladder overactivity associated with cerebral infarction due to occlusion of the middle cerebral artery in rats has been shown to lead to significant ischaemia within the putamen and cerebral cortex, confirming the importance of these areas in the control of micturition.[691] In this latter model, a role for glutamatergic and dopaminergic stimulation in the development of bladder dysfunction has been demonstrated.[691, 692] These findings are consistent with the observation that anterior brain lesions in humans are more likely to be associated with incontinence than posterior, occipital lesions.[601]

Additional evidence for the importance of emergent C-fibre contribution to afferent signalling in OAB and detrusor overactivity can be found in experimental clinical studies. For example, patients with various idiopathic and neurogenic bladder dysfunctions have reduced current perception threshold to direct bladder stimulation[693] and urethral stimulation[694] frequencies that selectively stimulate C-fibres, indicating increased excitability in the C-fibre afferents in these patients. Similarly, ice water instillation (which excites C-fibres) into the bladder can trigger involuntary detrusor contraction in patients with neurogenic detrusor overactivity.[695] In addition, the efficacy of capsaicin and resiniferatoxin in the treatment of patients with both idiopathic and neurogenic detrusor overactivity confirms the role of C-fibres and the afferent limb of the micturition reflex in bladder storage conditions.[696] While the hyper-excitable C-fibres appear to be the conduit for the abnormal sensory signals from the overactive bladder, the origin of the sensations probably lies in the bladder wall itself, either in uncoordinated asynchronous localized detrusor contractile activity[697] which may lead to urgency with negligible associated pressure rise within the bladder, or in a more co-ordinated propagation of autonomous contractile activity via emergent gap junctions providing more syncytial characteristics to the overactive detrusor.[675]

b) Stress Urinary Incontinence

Stress urinary incontinence (SUI) is characterized by reduced outflow resistance during urinary storage due to weakness in the urethral sphincter mechanism. It is often associated with weakness of the pelvic floor and urethral musculature, but peripheral nerve dysfunction is also implicated, in particular pudendal nerve damage following childbirth in women.[698] Animal models have contributed to understanding of the importance of the peripheral innervation of the urethra in SUI, with development of disease models association with pudendal nerve crush and vaginal distension initiating neuropraxic nerve injury in rats[304] and mice[699]. The role of pharmacological neuromodulation in the treatment of SUI has shown that urethral function and therefore incontinence can be improved by augmenting somatic neuronal discharge using the serotonergic (5HT) and noradrenergic (NE) reuptake inhibitor duloxetine, which is thought to act in the sacral spinal cord at Onuf’s nucleus, the pudendal somatic motor nucleus of the spinal cord which is densely innervated by 5HT and NE terminals.[700]. Duloxetine has shown beneficial effect in a placebo-controlled, randomized clinical trial for treating stress urinary incontinence.[335]. The selective noradrenergic reuptake inhibitor, [S,S]-reboxetine in the treatment of SUI, indicate that the serotonergic activity of duloxetine may be redundant and that effects are dependent solely on noradrenergic reuptake inhibition.[340, 701]

3. INVOLVING ABNORMAL VOIDING

a) Bladder Outflow Obstruction

Bladder outflow obstruction (BOO) is typically associated with prostatic enlargement in men, although it is also seen in women following surgery for stress urinary incontinence and in children secondary to proximal urethral valves. Bladder overactivity is seen in many patients with BOO, and this storage dysfunction together with the associated neuronal changes has been described above. The voiding dysfunction per se seen in patients with BOO is caused by a combination of both passive and dynamic obstruction of the proximal urethra and, in some patients, by detrusor decompensation resulting in a deterioration in the contractile function of the bladder during voiding.

During obstructed voiding, the bladder is subject to high pressures required to expel urine through a region of high resistance. These pressures compromise detrusor blood flow during voiding leading to periods of ischaemia and hypoxia, followed by reperfusion.[702] Recurrent cycles of ischaemia and reperfusion result in progressive neuronal damage in the bladder wall, an effect that has been seen in animal models of obstruction and bladder distension, as well as in an in vitro model in which detrusor muscle is intermittently exposed to hypoxic glycopenic perfusate followed by oxygenated glucose-containing perfusate.[703] This neuronal damage initially has a patchy appearance, when it seems to be related to the development of an overactive phenotype in pigs.[678] With time, however, bladder decompensation with incomplete voiding and chronic retention can develop, and this is associated with a more generalized detrusor denervation and reduced contractile response to neuronal stimulation in organ bath studies.[704]
4. CO-MORBID DISORDERS

The significance of neural control mechanism in lower urinary tract dysfunction is further implied by a number of comorbid conditions that have been associated with BPS/IC and incontinence. Patients with BPS/IC and SUI are more likely to report depressive symptoms. Findings on two validated depression measures indicate that patients with interstitial cystitis report significantly greater depressive symptomatology than healthy controls, although less than 20% notice moderate or severe depressive symptoms. This finding is consistent with the observation that patients with chronic pain experience a higher level of depressive symptoms than healthy controls and other chronically ill populations. Patients report low mood (56%), fatigue (63%), difficulty concentrating (49%), insomnia or excessive daytime sleepiness (49%) and are 3 to 4 times more likely to report suicidal thoughts than the general population.[705] The association of BPS/IC [194]and incontinence [706] with depression has been corroborated in other studies, although a more recent study suggests that, after multivariate adjustment for the influence of other urogenital symptoms, only the symptom of nocturia remains significantly associated with depression.[707]

BPS/IC has also been associated with other chronic pain conditions, especially fibromyalgia. An association has also been shown for child abuse.[194, 708] Based on recent improvements in understanding of pain processing pathways in the central nervous system, and in particular the role of limbic structures, especially the anterior cingulated cortex, hippocampus and amygdala, in chronic and affective pain perception, a condition termed limbic associated pelvic pain has been proposed to explain the concurrence of these various chronic pain conditions. This limbic dysfunction is manifest both as an increased sensitivity to nociceptive afferents from pelvic organs, and as an abnormal efferent innervation of pelvic musculature, which undergoes tonic contraction as a result of limbic efferent stimulation, generating a further sensation of pain. The nociceptive afferents from these pelvic organs then follow the medial pain pathway back to the sensitized, hypervigilant limbic system. Chronic stimulation of the limbic system by pelvic pain afferents again produces an efferent contraction of the pelvic muscles, thus perpetuating the cycle.[708]

Investigators have shown in an animal model that social stress in a virgin young male rat can lead to voiding dysfunction not dissimilar to bladder outlet obstruction (smooth muscle hypertrophy, enlarged bladder).[572] The social stress model (also called the social defeat, resident-intruder paradigm[709] is created by placing the virgin young male rat in the same cage as a retired male breeder. These two animals can see and smell each other, but are physically separated by a screen. The molecular mechanism underlying the bladder dysfunction could be secondary to corticotrophin-releasing factor (CRF).[571] The link between CRF and bladder innervations was first reported by de Groat in 1994.[382] Specifically, this early paper showed that CRF-like immunoreactivity was associated with bladder afferent projections in the sacral spinal cord suggesting that CRF may be a neurotransmitter in the afferent pathway. Valentino’s work [571] showed that CRF is upregulated in Barrington’s nucleus neurons during stress. These studies highlight the importance of higher neural centers integrating bladder function, thus linking bladder disorders to psychological variables such as emotion, behavior, and motivation. Holstege has penned an editorial that highlights these connections with the provocative title “Micturition and the Soul”. [511]

Pathophysiology of Urinary Incontinence, Faecal Incontinence and Pelvic Organ Prolapse

H. Koelbl

PREFACE

For this 5th International Consultation on Incontinence, the Committee on Pathophysiology has considered the causes of pelvic organ prolapse and urinary and faecal incontinence. Knowledge has increased in the recent years about childbirth and pregnancy, leading to urinary and faecal incontinence. Special problems of the elderly have also been included for this ICI. We have also been asked to consider pathophysiological mechanisms underlying pelvic organ prolapse. These three areas (urinary incontinence, pelvic organ prolapse and faecal incontinence) are closely interconnected by virtue of similar location within the body. In the case of women, childbirth and pregnancy may contribute to one or all of these conditions. Yet there are also neurological factors, and gender specific factors which must be considered in the evaluation of any given patient. Thus, we have tried to provide a balanced overview of the subject, keeping in mind both the common and the distinct qualities of the various conditions, while organising them in a logical, narrative manner that make any one section of the chapter easy to read.

In the area of women’s stress incontinence, intrinsic urethral function continues to receive increased attention. As newer pharmacological agents to provide neural stimulation of the striated sphincter appear, and the limits of vaginal suspensory operations for correction of urethral dysfunction are reported, considerations of pathophysiology have shifted from the 50 year old paradigm regarding urethral mobility associated with vaginal prolapse in the genesis of incontinence. However, these newer directions should be considered against the background of half a century of observation and practical clinical experience. We therefore continue to recommend a balanced approach.

In the area of men’s incontinence, the greatest concern remains the problem of sphincter injury following radical pelvic surgery and brachytherapy. While many thousands of procedures are performed annually, our knowledge about sphincter anatomy and function has progressed little. Instead, empirical methods of treatment and hopefully prevention have been advanced to treat affected individuals, and insofar as prosthetic implants remain an effective method of treatment, enthusiasm for further basic research into male sphincter function remains limited. In contrast to this kind of sphincter injury, the causes of incontinence associated with bladder outlet obstruction and prostatic enlargement have been well characterised, and little new knowledge has appeared in recent years.

A. THE OVERACTIVE BLADDER

I. INTRODUCTION

The International Continence Society defines urgency as “the complaint of a sudden compelling desire to pass urine, which is difficult to defer” [1]. The “overactive bladder” (OAB) is a symptom syndrome which is defined by the presence of urgency, with or without urgency incontinence, but usually with frequency and nocturia in the absence of infection or other obvious pathology [1]. Therefore, urgency is the pivotal symptom of the OAB syndrome. A better understanding of the genesis of urgency and its relationship to other aspects of bladder function is required to unravel the pathophysiology of OAB and to develop more effective treatments [2].

OAB symptoms are suggestive of urodynamically demonstrable detrusor overactivity (DO; involuntary detrusor contractions) during the filling phase which may be spontaneous or provoked [1]. However, OAB is not interchangeable with DO regardless of whether they are associated with reported urgency. Only about half of all patients with DO experience
urgency [3], whereas among patients with urgency 44–69% exhibit DO during cystometric studies [4-7].

The definition of urgency as a complaint implies that it can only be measured in cognitively intact patients [2, 8]. Quantifiable and objective demonstration of urgency is difficult, and thus surrogate measures are often used as outcome measures in OAB, leading to inconsistency between clinical trials. Urgency is a pathological sensation and does not necessarily involve the same mechanisms as those underlying the physiologic desire to void upon bladder filling. Therefore, comparisons between urge in healthy people and urgency in patients may help our understanding of the mechanisms involved in the latter but, in fact, may be misleading [8].

The emphasis on urgency, rather than DO, as the defining element of OAB gives the condition a subjective foundation which renders derivation of basic science insights challenging. The subjective nature of urgency makes development of animal models impossible. Despite these limitations, most studies on mechanisms related to urgency/OAB have employed the use of isolated tissues and experimental animals. Non-voiding contraction remains the most frequently used surrogate parameter in such experimental animal studies [8]. The pathophysiology of the OAB syndrome and DO is still incompletely known, but most probably multifactorial. Against the background mentioned above, this section focuses on pathophysiology of OAB and reviews studies that have provided insight into the mechanisms underlying OAB symptoms and DO.

DO may be further characterised as neurogenic when there is a relevant neurological condition. The dependence of lower urinary tract (LUT) functions on complex central neural networks makes these functions susceptible to a variety of neurological disorders. Non-neurogenic aetiologies may be related to outflow obstruction, aging and female anatomical incontinence, but most cases are idiopathic. There may be two possible origins of OAB symptoms; 1) decreased capacity to handle the afferent signals in the brain, and 2) abnormally increased afferent signals from the bladder and/or urethra (Figure 1).

Figure 1. Two possible origins of OAB symptoms; 1) decreased capacity to handle the afferent signals in the brain, and 2) abnormally increased afferent signals from the bladder and/or urethra.
Two theories probably contribute in varying proportion to the complex mechanisms underlying the genesis of DO and the associated storage symptoms comprising OAB, have been put forward (Figure 2):

- The urothelium-based hypothesis: changes in urothelial receptor function and neurotransmitter release as well as in the sensitivity and coupling of the suburothelial interstitial cell network lead to enhancement of involuntary contractions [9, 10].
- The myogenic hypothesis: changes to the excitability and coupling of smooth muscle cells with other myocytes or interstitial cells lead to the generation of uninhibited contractions [11, 12].

1. THE UROTHELIUM-BASED HYPOTHESIS

There is increasing evidence that urothelial cells play an important role in modulation of bladder activity by responding to local chemical and mechanical stimuli and then sending chemical signals to bladder afferent nerves. It has been shown that urothelial cells express various "sensor molecules" such as receptors of bradykinin, neurotrophins, purines (P2X and P2Y), norepinephrine (NE) (α and β), ACh (nicotinic and muscarinic), epithelial Na+ channels (ENaC), and a number of transient receptor potential (TRP) channels. These sensor molecules respond to mechanical as well as chemical stimuli and in turn release chemicals such as ATP, prostaglandins (PG), nerve growth factor (NGF), ACh, and NO. These agents are known to have excitatory or inhibitory actions on afferent nerves, which are located close to or in the urothelium (Figure 3) [10].

The urothelium interacts closely with the underlying suburothelial layer, in particular the interstitial cell network contained within it, so that the whole structure can be regarded as a functional unit [9]. The suburothelium is an area composed of nerves, blood vessels, and connective tissue in intimate contact with the urothelium. Recently, the roles of the urothelium and suburothelial myofibroblasts in afferent activation have become the focus of intense interest. The C-fibre afferents generally have endings in the suburothelial layer of the bladder wall, but in some cases, they also penetrate the urothelium [13].

ATP was the first neurotransmitter demonstrated to be released directly from the urothelium [14]. Non-vesicular ATP release is evoked by chemical stimuli or by stretch proportional to the extent of bladder distension [15-19]. Both P2X and P2Y purinergic receptor subtypes have been identified in the bladder urothelium. It is now thought that these may respond to urothelial-derived adenosine triphosphate (ATP) release in autocrine and paracrine signalling [15, 16, 20-23]. By acting on structures such as nerves [24] and interstitial cells in the suburothelial space, it is thought to trigger the underlying afferent signalling bladder fullness and pain and possibly even to activate the micturition reflex [25].

**Figure 2. Mechanisms involved in increased afferent input from the bladder: the urothelium-based and myogenic theories**
increased significantly in human obstructed bladders OAB. Expression of the mechanosensitive ENaC treatment was significantly correlated with a decrease in urinary ATP level in female patients with OAB.

The presence and localisation of muscarinic receptor protein and mRNA in the human [29-34] and mouse [35] urothelium have been studied. All five muscarinic subtypes are expressed throughout the urothelial layers with a specific localisation of the M2 subtype to the umbrella cells and M1 to the basal layer, with M3 receptors more generally distributed. Release of ACh from human urothelial and suburothelial sites increases with age, as well as during bladder stretch, and represents a functional, non-neuronal, alternative cholinergic system [31]. At therapeutic doses, antimuscarinics act mainly during the filling phase and exert little effect on detrusor contraction [36-38]. This lends support to the suggestion that urothelial muscarinic receptors might be involved in the generation of afferent impulses.

Urothelial cells express both α and β adrenoceptor subtypes, stimulation of which has been shown to trigger the release of ATP and nitric oxide (NO), respectively [39, 40]. Stimulation of urothelial β adrenoceptors also triggers an urothelially-derived inhibitory factor [41]. Catecholamines could be released from nerves adjacent to the urothelium; however, neither a role for catecholamines nor an altered adrenoceptor profile has yet been shown in pathological conditions.

In addition to the changes in ACh-release mentioned above, several specific alterations in urothelial function and ultrastructure have been demonstrated in OAB. Expression of the mechanosensitive ENaC is increased significantly in human obstructed bladders in comparison to unobstructed controls and correlates significantly with storage symptom scores [42]. It is possible that increased expression of mechanosensitive channels such as ENaC in the urothelium enhances substance release upon bladder stretch. Levels of PG, which is locally synthesised in bladder muscle and mucosa, and levels of NGF are increased in subjects with OAB in comparison to controls; and in symptomatic patients, levels of PGE 2 are positively correlated with voiding behaviour and maximum cystometric capacity [43, 44]. Bladder biopsies from patients with both idiopathic detrusor overactivity (IDO) [45] and neurogenic detrusor overactivity (NDO) [46] have shown increased urothelial TRPV1 expression. This may be in accordance with the fact that intravesical vanilloids (resineferatoxin) have been shown to improve OAB symptoms in patients with idiopathic detrusor overactivity as well as with hypersensitivity disorders [47, 48].

This sensory process is more complex than originally thought. A suburothelial layer of myofibroblasts (interstitial cells) that or a functional syncitium through connexin 43 gap junction can be identified in the bladder wall [49, 50]. These myofibroblasts make close apposition to unmyelinated nerves (afferent C-fibre nerves) [51]. The studies investigating human myofibroblasts show that the cells can respond to ATP by generating an intracellular Ca2+ transient, which is mediated by a P2Y receptor, most likely including a P2Y6 [52]. On the basis of these observations, it has been hypothesised that the close relation between nerves and myofibroblasts allows for an amplification of the afferent system in its response to stimulatory mediators such as ATP. Overall, up-regulation of urothelial function and increased release of various chemical mediators and known neurotransmitters may influence afferent nerve activity to generate OAB symptoms, although the precise mechanism by which these processes interact with neural tissue to achieve signal transmission remains to be clarified.

2. MYOGENIC HYPOTHESIS

Brading and Turner [11, 12] have emphasised that myogenic changes (regardless of aetiology) may contribute to the pathophysiology of idiopathic detrusor overactivity. On the basis of observation that denervation is consistently found in detrusor biopsy specimens from patients with various forms of non-neurogenic detrusor overactivity, it has been proposed that partial denervation of the detrusor may alter the properties of smooth muscle, leading to increased excitability and increased coupling between cells [53]. Thus, local contraction (activity) that occurs somewhere in the detrusor will spread throughout the bladder wall, resulting in coordinated myogenic contraction of the whole bladder. In addition, this local contraction in the bladder wall has been shown to generate afferent discharge [54, 55]. Recently,
localised bladder activity was assessed by the micromanometry detection method, demonstrating that women with increased bladder sensation on filling cystometry had a significantly higher prevalence of localised activity than the control group [56]. This observation suggests that localized distortion of the bladder wall simulates afferent activity, which would precipitate a feeling of urgency and detrusor overactivity [57, 58] (Figure 4).

Although the relationships between intercellular communication and spontaneous mechanical activity and the degree of involvement of different types of connexins (Cxs) need further study, Cx43 and Cx45 appear to be the most prominent Cxs expressed in human detrusor smooth muscle tissue and cultured cells. Observations in tissue biopsies from patients with neurogenic DO and urgency symptoms clearly demonstrated an increase in the presence of Cx43-derived gap junction channels in detrusor muscle [59].

In addition, another population of cells in the bladder known as interstitial cells has been proposed for a pacemaking role in spontaneous activity of the bladder [60, 61]. Because it has been reported that the number of interstitial cells is increased in a guinea-pig model of BOO [62] and that c-kit tyrosine kinase inhibitors, which inhibit interstitial cell activity, decreased the amplitude of spontaneous contractions in the guinea-pig and human bladder [63, 64], interstitial cells may also be involved in the emergence of detrusor overactivity because of enhanced autonomous detrusor muscle activity.

3. OTHER LOCAL FACTORS

a) Ischaemia

Ischaemia/reperfusion has been proposed as a pathophysiological factor of OAB/DO. Recent studies suggest that arterial obstructive disease, such as atherosclerosis, may cause OAB in both men and women via ischaemia, hypoxia and oxidative stress in the bladder [65-68]. DO associated mitochondrial stress may have a central role in epithelial damage, smooth muscle cell injury and neurodegeneration. Superoxide dismutase and aldose reductase up-regulation in the overactive bladder imply intrinsic defensive reaction against free radicals that apparently fails to prevent oxidative damage and neurodegeneration [67]. HIF, TGF-β, VEGF and NGF up-regulation in the ischaemic bladder was accompanied by the loss of mitochondrial structural integrity, fibrosis, and the degeneration of microvasculature and nerve fibres [69]. These observations may suggest the role of ischaemia in the overactive bladder with impaired contraction, as reported in elderly patients without obstruction. Ischaemia may be a key factor in aging associated LUTS.

b) Inflammation

Recent studies have noted signs of inflammation in bladder biopsy specimens from OAB patients [69, 70]. Increases in cytokines, chemokines, and growth factors have been reported in the urine of OAB patients [71]. Consistent association of increasing serum CRP levels and OAB has been also demonstrated [72, 73]. All together, these results support the hypothesis for the role of inflammation in the development of OAB.

Figure 4. The myogenic hypothesis of the mechanisms involved in increased afferent input from the bladder
III. MECHANISMS INVOLVED IN ABNORMAL HANDLING OF THE AFFERENT SIGNALS IN THE BRAIN

The ‘neurogenic hypothesis’ suggests that damage to the central inhibitory pathways, or sensitisation of afferent nerves, leads to the unmasking of primitive voiding reflexes which trigger overactive detrusor contraction [74, 75]. Plasticity both in the peripheral innervation and within the CNS may have a pathophysiological role in DO [76], and increased release of nerve growth factor has been reported, which may alter the neural regulation of detrusor muscle [77-79]. Peripherally, neurological diseases might cause a sensitisation of C fibres that are silent under normal circumstances, thereby leading to the emergence of a C-fibre-mediated reflex.

1. NEUROGENIC DETRUSOR OVERACTIVITY

Recent advances in functional brain imaging have made it possible to directly study the supraspinal control system operating during bladder filling. Comparisons between brain response in subjects with normal bladder function and those with OAB may give us a neural correlate of urgency and possible origins of OAB symptoms [80-82].

While many neurological diseases predispose patients to neurogenic detrusor overactivity (NDO), the only populations that have been systematically studied are adults with multiple sclerosis, adults with spinal cord injury (SCI) and children and young adults with myelodysplasia [73]. As a sensation it can be affected by neurological disorders and may, therefore, be perceived differently in patients with neurological lesions.

a) Suprapontine lesions

It is generally accepted that suprapontine lesions such as cerebrovascular disease and Parkinson’s disease produce DO. The patient with a suprapontine lesion loses voluntary inhibition of micturition, which corresponds to uninhibited overactive bladder according to a classification by Fall et al. [83, 84].

Higher brain centres provide an additional level of urinary control, which is responsible for conscious sensation, volition and emotional response. Key higher centres include the prefrontal cortex, insular cortex and anterior cingulate gyrus, and functional brain imaging has shown changes in higher CNS activity in OAB [75, 80, 81]. Although such observations have been made infrequently, they do point to some key areas for consideration. For example, the participation of several brain areas in urinary control may explain why brain diseases and senile cerebral atrophy are risk factors for lower urinary tract dysfunction [75]. Variation in observations between individuals implicates a diversity of processes in the mechanisms that underlie OAB, although these are expressed clinically in the common manifestation of OAB. The increased activity observed in certain regions of the brain in patients with OAB may actually be compensatory, to counteract urgency, rather than being responsible for the symptom [75]. This confounds interpretation of function, and there are many questions that still need to be answered.

Brain transection studies in animals with an intact neuroaxis showed that suprapontine areas generally exert a tonic inhibitory influence on the pontine micturition centre (PMC) [85, 86]. In humans, the cerebral cortex (medial frontal lobes) and the basal ganglia are thought to suppress the micturition reflex. Thus, damage to the brain induces DO by reducing suprapontine inhibition.

1. STROKE (CEREBRAL INFARCTION)

The mechanism of DO induced by cerebral infarction or Parkinson’s disease has been further studied using animal models [87, 88]. In the central nervous system, a glutamatergic pathway is known to play a role in both excitatory and inhibitory regulation of micturition [88-90]. It has been demonstrated that in the rat cerebral infarction model, bladder overactivity is mediated by NMDA glutamatergic and D2 dopaminergic excitatory mechanisms [88], suggesting that cerebral infarction may alter a balance between the facilitatory and inhibitory mechanism that results in up-regulation of an excitatory pathway and down-regulation of a tonic inhibitory pathway.

2. PARKINSON’S DISEASE

Parkinson’s disease (PD) is characterised by the degeneration of dopamine-producing cells in the substantia nigra of the midbrain and Lowy body formation. PD is the most common cause of parkinsonism which is the neurological syndrome bearing the hallmark, hypokinaesia and postural instability. Urgency occurs in 33-54% of patients with PD. Neurogenic DO was seen in 45-93% of PD patients [91]. The most widely accepted theory of pathophysiology of DO in PD is that basal ganglia inhibits the micturition reflex in the normal situation via D1 receptors, and that cell depretion in the substantia nigra in PD results in loss of D1-mediated inhibition and consequently DO [91, 92]. The absence of dopaminergic tone via D1 receptors may cause a dysfunction in GABA regulation in the periaqueductal gray (PAG) and DO [93]. Kitta et al [94] demonstrated an increased activation in the PAG, supplementary motor area, cerebellar vermis, insula, putamen and thalamus during DO in male patients with PD. Compared with previous results in healthy volunteers the periaqueductal gray, insula, putamen and thalamus were common activation sites responding to bladder filling, while the pons was not activated during DO, suggesting alteration in brain activation sites in response to bladder filling may be related to the pathophysiology of DO in patients with PD.

b) Spinal cord lesions

A spinal cord lesion above the lumbosacral level eliminates voluntary and supraspinal control of micturition,
leading to DO mediated by spinal reflex pathways [85]. Disruption below the level of the pons leads to unsustained and uncoordinated detrusor contractions often associated with uncoordinated sphincter overactivity (detrusor-sphincter dyssynergia, DSD). Impairment or loss of bladder sensation is a typical feature.

Electrophysiological studies of the effect of capsaicin on voiding reflexes have shown that the afferent limb of the micturition reflex in chronic spinal cats, consists of unmyelinated C-fibre afferents, whereas in normal cats it consists of myelinated A-delta afferents [85, 95, 96]. Since C-fibre bladder afferents in the cat do not usually respond to bladder distension [97], a considerable reorganisation of reflex connections takes place in the spinal cord following the interruption of descending pathways from the brain. In humans with spinal cord lesions, NDO is likely to be mediated by capsaicin-sensitive C-fibre afferents. Clinical experience with capsaicin supports the role of these C-fibre afferents in the pathophysiology of NDO. Capsaicin has been used for the treatment of NDO in patients with spinal cord injury or multiple sclerosis. When administered intravesically, capsaicin increases bladder capacity, reduces micturition contraction pressure, decreases autonomic dysreflexia and reduces the frequency of incontinence [98-100]. More recently, resiniferatoxin, an ultra-potent analogue of capsaicin, has also been used [101-103].

Increased TRPV1, P2X3 and pan-neuronal marker (PGP9.5) staining in suburothelial nerves and increased TRPV1 staining in the basal layer of the urothelium have been observed in patients with neurogenic bladder due to SCI and multiple sclerosis [26]. Treatment of NDO patients with intravesical capsaicin or resiniferatoxin reduces the density of TRPV1, P2X3 and PGP9.5 immunoreactive nerve fibres and urothelial TRPV1 immunoreactivity in those patients exhibiting symptomatic improvement [104]. Injections into the bladder wall of botulinum neurotoxin type A (BoNT/A), an agent that blocks the release of neurotransmitters from afferent and efferent nerves, and from urothelial cells, also reduces NDO and the density of TRPV1- and P2X3-immunoreactive nerves [105]. These results indicate that an abnormality of the C-fibre afferent innervation contributes to NDO.

Upregulation of TRPA1 protein and mRNA levels, in bladder and in dorsal root ganglion (DRG; L6-S1) has been reported in rats with SCI. Moreover, HC-030031 (TRPA1 antagonist) treatment decreased the number and the amplitude of DO, suggesting that the TRPA1 activation and upregulation seem to exert an important role in DO following SCI [106].

Following SCI changes in the electrophysiological properties of bladder afferent neurons have also been observed consisting in multiple action potentials (tonic firing) in response to long depolarizing current pulses [107]. In addition, A-type K+ channels are suppressed in parallel with an increased expression of TTX-sensitive Na+ currents, thereby increasing excitability of C-fibre bladder afferent neurons[108]. These electrophysiological changes contribute to the emergence of the C-fibre-mediated spinal micturition reflex following SCI.

**B. PREGNANCY, CHILDBIRTH AND THE PELVIC FLOOR**

Despite the great achievements made in modern obstetric practice in developed countries during the last 100 years, delivery remains the most stressful and dangerous event the female pelvic diaphragm is submitted to during a woman’s lifespan.

Reduction in both perinatal and maternal mortality rates in recent decades has allowed us to focus increasingly on maternal morbidity and the long-term sequelae of childbirth. Due to improved investigative techniques available over the past decade, the incidence and mechanisms of obstetric injury to the pelvic floor have come under scrutiny.

However, the controversial debate on whether and how pregnancy and vaginal delivery are responsible for pelvic floor damage is still wide open.

During pregnancy, muscular, connective and nervous pelvic structures are already subjected to anatomical, morphological, functional and hormonal changes. During vaginal delivery, the pelvic floor undergoes an enormous amount of stretching to allow the passage of the newborn through it.

During the pregnancy and just after delivery, the functions sustained by the pelvic floor (urinary and faecal continence, pelvic organ containment and sexual function) often begin to fail. Evident or hidden injuries of the pelvic floor may manifest themselves through symptoms of urinary and faecal incontinence, prolapse or sexual dysfunction, with a considerable impact on quality of life.

If several mechanisms of birth trauma have already been investigated, a lot needs to be understood regarding the role of pregnancy on the pelvic floor.

The growing knowledge of the consequences of childbirth and pregnancy on the pelvic floor, offers the chance to develop prevention and treatment strategies. It is important that contributing obstetric factors are identified and their occurrence minimised, in order to focus efforts on preventable risk factors.

### I. DAMAGE TO FUNCTIONS SUSTAINED BY THE PELVIC FLOOR

#### 1. POSTPARTUM URINARY INCONTINENCE

A recent systematic review of 33 studies reported a 33% prevalence of any type postpartum urinary incontinence (UI) in the first 3 months postpartum, with a prevalence of weekly and daily incontinence of 12% and 3% respectively. The prevalence in the
vaginal delivery group (31%) was double that of the caesarean section group (15%). Long-term studies in the first year postpartum showed small changes in prevalence over time [109]. Cesarean section seems to decrease the risk of postpartum UI [110, 111], but its protective effect seems to diminish over time and disappears after multiple deliveries [111, 112].

In a recent cohort study extracted by the national Swedish Medical Birth Registry between 1973 and 1982, two groups were identified: 30,880 women who had their first and all subsequent deliveries by cesarean vs. an age-matched sample of 60,122 women who delivered vaginally only. Stress urinary incontinence (SUI) surgery was observed in 0.4% of the cesarean group and 1.2% of the vaginal group (follow-up time 26.9 years), and the risk of SUI is estimated to be 2.9 times higher after vaginal delivery compared with women after cesarean section. Among women with vaginal deliveries, rates of SUI surgery increased with the number of births, whereas in the cesarean delivery cohort it slightly decreased with a higher number of births. Compared with cesarean delivery, the risk of SUI was more than doubled for vaginal delivery with vacuum extraction and tripled for a vaginal non-instrumental delivery, but this lower risk for a vacuum extraction delivery has been in part explained by an overall lower birth rate in this subset of patients. After vaginal delivery, the incidence rates for SUI surgery steadily increased, reaching a peak close to 3 decades after the first delivery. For cesarean delivery, the incidence of SUI increased more slowly and started to diverge from the curve for vaginal delivery very early during follow-up (Figure 5 A) [113].

After the first delivery, women who delivered vaginally seem to have at least a two-fold greater risk of urinary incontinence than those who delivered by cesarean. However, data for the rates of incontinence after elective and emergency cesarean section are mixed; therefore meaning that the information as to whether cesarean done before labour confers greater protection than cesarean done after labour is lacking.

To understand the true impact of cesarean delivery on urinary incontinence, future studies must compare incontinence by planned (not actual) delivery modes, consider a woman’s entire reproductive career, focus on leakage severe enough to be problematic, consider other bladder symptoms as well as incontinence, and take into account other risk factors, particularly antepartum urinary incontinence [114].

2. ANAL INCONTINENCE

De-novo anal incontinence symptoms after childbirth are reported as up to 26-38% between 6 weeks-6 months postpartum [115-120].

In a population-based survey estimating the postpartum incidence of faecal incontinence, Guise et al. [116] reported that 29% of 8,774 women reported faecal incontinence (defined as recurring episodes of involuntary loss of stool or flatus since delivery) within 3-6 months postpartum: almost half (46%) of them reported incontinence of stool, and 38% reported incontinence of flatus only. Approximately 46% reported the onset of incontinence after the delivery of their first child. Higher body mass index, longer pushing, forceps-assisted delivery, third or fourth-degree tears and smoking were associated with severe faecal incontinence. The authors conclude that in this population-based study, more than one in four women reported faecal incontinence within 6 months of childbirth, with almost half reporting the onset of symptoms after delivery of their first child. Four in ten women reported loss of flatus or stool during intercourse. Given the burden of this condition, both in number and social impact, coupled with the hesitancy of women in initiating this conversation, providers should ask women about symptoms of faecal incontinence during postpartum examinations. Additionally, these data suggest that there may be a benefit to extending postpartum follow-up visits beyond the typical 6-8 weeks to provide surveillance for potential incontinence. LEVEL OF EVIDENCE: II.

Figure 5 [113] Incidence rates in relation to mode of delivery and time since first childbirth
In comparison to cesarean section, vaginal delivery seems to be associated with an increased risk of anal incontinence. In a population-based study, Guise et al. [115], reported that vaginal delivery has a greater risk of FI compared to cesarean (OR 1.45; 95%CI: 1.29-1.64) 3-6 months postpartum. However, a vaginal delivery without a tear or instrument assistance did not create a higher risk of FI than the risk with cesarean delivery. Being overweight (body mass index >/\=30 kg/m(2)), pushing for greater than 2 h, and constipation were independently associated with postpartum FI (p < 0.05) regardless of route of delivery.

A self-administered survey of faecal incontinence symptoms and delivery events administered to 50 women at 6 weeks postpartum, showed that vaginal delivery was associated with an increased risk of any faecal incontinence symptom in comparison with cesarean section (43% vs. 20%) [117].

3. PELVIC ORGAN PROLAPSE

The occurrence rate of pelvic organ prolapse stage \( \geq 2 \) in the first 3-6 months postpartum has been described in literature between 18.1-56% [121-123].

In a cross-sectional study of 382 primigravid women, pelvic organ support was explored 6 months postpartum: POP-Q stage \( \geq II \) was present in 7.7, 18.1 and 29.0% of women who delivered by cesarean section, spontaneous and instrumental vaginal delivery, respectively. Spontaneous vaginal delivery increased the risk by more than three times (OR 3.19) while instrumental vaginal delivery increased it more than five-fold (OR 5.52) in comparison with cesarean section. Instrument-assisted delivery did not increase the risk of prolapse in women who delivered vaginally. The authors concluded that cesarean section is associated with a lower prevalence of pelvic organ prolapse after delivery and instrument assisted delivery is not associated with an increased risk of postpartum prolapse among women who delivered vaginally [121].

In the cohort study extracted by the nationwide Swedish Medical Birth Registry [113], POP surgery was recorded in 2.2% of vaginal deliveries and 0.2% of cesarean sections (follow-up time 25.9 years). Among women who had only had vaginal deliveries, rates of POP surgery increased with number of deliveries. In the cesarean delivery cohort, rates of POP surgery slightly decreased with increasing parity. Compared with a cesarean delivery, the risk of POP surgery was increased nine-fold both after non-instrumental vaginal delivery and after vacuum extraction, whereas among women with forceps delivery a twenty-fold increase in risk was observed. The incidence rate of POP in women with cesarean deliveries showed very little variation over time, but started to diverge more notably from the vaginal delivery cohort 10 years after the first birth (Figure 5B).

The association between cesarean section and POP was investigated by Larsson et al. [124]: the Swedish Hospital Discharge Registry was used to identify women with an inpatient diagnosis of pelvic organ prolapse, and the data were linked to the Swedish Medical Birth Registry. A total of 1.4 million women were investigated. A strong and statistically significant association between cesarean section and pelvic organ prolapse was found (Adjusted OR 0.18 [95% CI: 0.16-0.20] and overall hazard ratio=0.20 [95% CI: 0.18-0.22]). The authors concluded that cesarean section is associated with a lower risk of pelvic organ prolapse than vaginal delivery.

The incidence rate of urinary incontinence (UI) and anal incontinence during pregnancy in previously continent women has been reported as 39.1% and 10.3% respectively. Age, baseline body mass index, and family history of UI were significantly associated with the occurrence of UI during pregnancy, while age and excess weight gain during pregnancy were associated with the occurrence of anal incontinence during pregnancy. The identified risk factors for both incontinences postpartum were incontinence during pregnancy and vaginal delivery. LEVEL OF EVIDENCE II [125].

About half of all women develop transient urinary incontinence during pregnancy [114]; SUI in pregnancy was a significant predictor for postpartum incontinence. The weight of the women and duration of their labour were also significantly associated with the development of SUI postpartum [126].

Women with incontinence before pregnancy were nearly three times more likely to have postpartum incontinence [127].

Among 272 eligible women attending follow-up at 2 years postpartum, 26 (9.5%) women reported persistent SUI since pregnancy. A higher BMI in pregnant women at term was recognised as an independent risk factor for the persistence of SUI from pregnancy to 2 years post partum [128].

Fear of birth is a frequent cause of cesareans demanded by the patient [129, 130]. A recent cross-sectional study based on the Norwegian Mother and Child Cohort Study (n=58,881), reported that 6% of the sample preferred cesarean over vaginal delivery in week 30 of pregnancy; 16% reported “fear of giving birth” as the reason for cesarean preference [131]. A general fear of pelvic floor trauma was cited as the most common reason for this choice [132]. Despite being based on incomplete prognostic data, this feeling may be echoed increasingly among obstetric patients and may lead to an unselected, and even misguided, increase in cesarean delivery rates.

However, so far, there is no evidence from randomised controlled trials, upon which to base any practice recommendations regarding planned cesarean section for non-medical reasons at term. This has been demonstrated by Lavender et al. [133]: their aim was to find out, from randomised trials, the effects on perinatal and maternal morbidity and
mortality, and on maternal psychological morbidity, of planned cesarean delivery versus planned vaginal birth in women with no clear clinical indication for cesarean section. A search of the Cochrane Pregnancy and Childbirth Group’s Trials Register (December 2005), MEDLINE (1974 to April 2005), EMBASE (1974 to April 2005), CINAHL (1982 to April 2005) and PsycINFO (1887 to April 2005) was carried out.

The selection criteria were the following: comparisons of intention to perform cesarean section and intention for women to give birth vaginally; random allocation to treatment and control groups; adequate allocation concealment; women at term with a single fetus with cephalic presentation and no clear medical indication for cesarean section. No studies were identified that met the inclusion criteria [133].

To our knowledge, scientific data are insufficient to justify an elective cesarean section in order to avoid pelvic floor symptoms in a woman without previous disorders [134], considering that pregnancy itself may be involved in the development of such problems.

A recent systematic review of Cochrane assessed the ability of cesarean delivery (CD), in comparison to vaginal delivery (VD), to preserve anal continence: 21 reports have been found eligible for inclusion, encompassing 31,698 women having had 6,028 CDs and 25,170 VDs, as the index event prior to anal continence assessment. Only one report randomised women (with breech presentation) to CD or VD, but because of extensive cross-over, 52.1% after randomisation, it was analysed along with the other 20 studies as treated, i.e. as a non-randomized trial. Only one of these reports demonstrated a significant benefit of CD in the preservation of anal continence, a report in which the incidence of incontinence was extremely high, 39% in CD and 48% in VD, questioning, relative to other reports, the timing and nature of continence assessment. The authors did not find any difference in continence preservation in women who had an emergency versus elective CD. They concluded that without demonstrable benefit, preservation of anal continence should not be used as a criterion for choosing elective primary CD [135].

Despite the great advances that have been made in many areas of obstetric care, the effect of pregnancy on the morphology and function of the pelvic floor is still mostly unknown. Prospective data assessing the severity of urinary and anal incontinence during pregnancy are scarce.

II. EFFECT OF PREGNANCY ON PELVIC FLOOR FUNCTION

1. EFFECT ON THE COLLAGEN

During pregnancy, hormones affect the biochemical composition of the solid matrix and hydration phases constituting all pelvic floor tissue. Remodelling mechanisms lead to changes in the organisation, orientation, and diameter of the collagen fibres as well as the crimp structure of the collagen fibrils reinforcing each tissue. Such effects can significantly affect the short and long-term viscoelastic properties of the vaginal wall, the pubovisceral muscles, and the perineal body, for example. They will largely determine (a) the extent and rate at which these structures can be stretched by an expulsive force acting cyclically on the fetal head, and (b) the resistance to stretch provided by those structures. The more a tissue exhibits creep behaviour, the further it will stretch under a constant load. And the more it exhibits relaxation behaviour, the more the stress in a tissue will decrease over time when held at a constant length, thereby helping to lower the risk of rupture in the next loading cycle. Were a tissue to exhibit viscoplasticity, it would behave as a solid below a critical level of stress, but above that level, it would flow like a viscous liquid. There is evidence that tensile failure in some soft tissues can be predicted by the product of the stress times the strain extent in the tissue, so mechanisms that lower one or both these variables will reduce the risk of rupture. Pregnancy is known to significantly affect the instantaneous stiffness and relaxation behaviour of vaginal tissues in rats. However, accurate data are lacking for pregnant human pelvic floor tissues, and the effects of pregnancy on injury at any tissue level, and on structural failure, are as yet largely unknown [136].

Changes in collagen may result in greater mobility of the bladder neck resulting in stress incontinence. In a study of 116 primigravidae, perineal ultrasound was used to assess bladder neck mobility. Women with antenatal bladder neck mobility of more than 5mm on linear movement (equivalent to >108° rotation) were found to be at higher risk of developing postpartum stress incontinence. Approximately 50% of this group reported stress incontinence at 3 months postpartum [137].

There may be a group of women at an inherent increased risk of developing incontinence due to abnormalities in collagen [138], as the collagenous component of the connective tissue contributes to structural support of the bladder neck. In pregnancy, the tensile properties of the connective tissue are reduced, with a reduction in total collagen content and increase in glycosaminoglycans [139].

2. NATURAL HISTORY

Distinguishing the time of onset, severity, and persistence of urinary and anal incontinences during and after pregnancy may provide an insight into the natural history of incontinence, and hence in the differences between transient incontinence due to the hormonal and mechanical effects of pregnancy and the damage that may occur as a result of delivery [125].

Solans-Domenech et al. [125] have brought to light the high incidence of urinary incontinence and anal incontinence over the three trimesters of pregnancy, and particularly in the second trimester. In this cohort study, an incidence rate of urinary incontinence
during pregnancy of 39.1% and 10.3% of anal incontinence was found.

**Figure 6** shows the evolution of severity of UI by data collection time, as well as the changes in trends between slight and moderate UI, with a tendency for slight to become moderate UI. The correlation between the severity of UI and level of interference in daily living was moderate but statistically significant in all periods of data collection with correlation coefficients of 0.35, 0.13, 0.46, and 0.47 for the first, second, and third trimesters and postpartum, respectively.

Ten percent of women presented anal incontinence at some point during pregnancy: the evolution of the prevalence of anal incontinence in this study cohort is 2.3%, 6.8% and 7.4% in the first, second and third trimesters. The presence of anal incontinence was characterised by loss of flatus in more than 90% of cases and common to all periods LEVEL OF EVIDENCE: II [125].

The prevalence of urinary and anal incontinence in a subgroup African American of pregnant adolescents (age: 14-19 years) in the third trimester, resulted even higher: 44% of patients complained of urinary urgency incontinence and 43% of stress incontinence; 12% complained of faecal and 41% of flatus incontinence [140].

Incontinence during pregnancy has been linked to age [141], body mass index [142], strenuous physical exercise [143] and smoking history [142].

The risk of UI increases in pregnant women aged more than 35 years, in women who are overweight or obese at baseline, and in those with a family history of UI, while the risk of anal incontinence rises with age and excessive weight gain during pregnancy [125]. Weight gain greater than the 50th percentile during weeks 0–15 of pregnancy was weakly associated with a higher incidence of UI at week 30 compared with weight gain less than or equal to the 50th percentile [144].

The recent data regarding the relationship between urinary incontinence during pregnancy and its persistence or worsening condition postpartum are controversial: the results of Solans-Domenech et al. [125] showed that the occurrence of UI and anal incontinence during pregnancy is related to the presence of incontinence in the postpartum period, and vaginal delivery increases the risk of persistent incontinence. On the other hand Wesnes et al [145] conclude that the association between incontinence postpartum and mode of delivery is not substantially influenced by incontinence status in pregnancy and the prediction of a group with high risk of incontinence according to mode of delivery cannot be based on continence status in pregnancy.

### 3. Familial Predisposition

A familial predisposition in the evaluation of the aetiology of urinary incontinence has also been considered, but the results are still controversial. Buchsbaum et al. [146] investigated the role of vaginal delivery and familial factors in the development of urinary incontinence by comparing the prevalence of this condition in nulliparous women and their parous sisters. Among this sample of biological sisters, urinary incontinence was reported by 47.6% of nulliparous women and by 49.7% of parous women (P =0.782). Considering the high concordance in continence status between sister pairs, and considering that the majority of parous women are continent, an underlying familial predisposition toward the development of urinary incontinence may be present. LEVEL OF EVIDENCE II-2.

---

**Figure 6.** Evolution of the severity of urinary incontinence symptoms by time of data collection. *From: Solans-Domenech. Incontinence During Pregnancy and Postpartum. Obstet Gynecol 2010 [125].*
A recent article of Nguyen et al. [147], analysed a large population comprising 1530 identical and 234 non-identical female twins (mean age 41.3 years), who answered a specific questionnaire focusing on symptoms of SUI. The two groups were comparable in terms of age, race, parity, BMI, menopausal status, tobacco use, mode of delivery and prior pelvic surgery. The authors demonstrated that environmental factors contributed significantly to the occurrence of SUI (shared environmental factors contribute 77.6% of the variance, unique environmental factors contribute to 20.9% of the variance; p<0.001). The heritability of SUI was not statistically significant for the contribution of the phenotypic variance (1.49%; p=0.46). Additional analyses were performed on the subgroup of women without prior incontinence or prolapse surgery (638 twin pairs) and in the subgroup of twins with “pure stress urinary incontinence” (458 twin pairs); the results in this cohort of patients showed no genetic influence. The authors underscore that environmental factors (in particular obstetric events) play a dominant role in middle-aged women; genetics contributed more toward the development of stress urinary incontinence in elderly women, as reported by Rohr et al. [148]: “nurture” before menopause and “nature” during aging. LEVEL OF EVIDENCE II.

Strong epidemiological evidence links vaginal childbirth and the development of postpartum incontinence and prolapse.

There would seem to exist three major mechanisms by which vaginal delivery might contribute to the pelvic floor trauma: a) muscle trauma, b) connective tissue damage, c) nerve injury, d) vascular damage.

1. MUSCLE TRAUMA

The effect of delivery on muscular structure has been widely investigated, either with computer models, MRI and ultrasound. In a three-dimensional computer model Lien et al. [149] predicted levator ani muscle stretch during vaginal birth. Serial magnetic resonance images from a healthy nulliparous 34-year-old woman, and engineering graphics software, were used to construct a structural model of the levator ani muscles along with related passive tissues. The model was used to quantify pelvic floor muscle stretch induced during the second stage of labour as a model in which the fetal head progressively engaged and then stretched the iliococcygeus, pubococcygeus and puborectalis muscles. The largest tissue strain reached a stretch ratio (tissue length under stretch/ original tissue length) of 3.26 in the medial pubococcygeus muscle, the shortest, most medial and ventral levator ani muscle. Regions of the iliococcygeus, pubococcygeus, and puborectalis muscles reached a maximal stretch ratio of 2.73, 2.50, and 2.28, respectively. Tissue stretch ratios were proportional to fetal head size: for example, increasing fetal head diameter by 9% increased medial pubococcygeus stretch by the same amount. The authors demonstrated that the medial pubococcygeus muscles undergo the largest stretch of any levator ani muscles during vaginal birth and it is therefore at the greatest risk of stretch-related injury [149] (Figure 7).

Svabik et al. [150] showed that the area of the levator hiatus needs a distension of between 25% and 245% to allow the passage of the fetal head, considering as average a cross-sectional fetal head area of 68 cm2, based on Caucasian biometric data.

The occurrence rate of postpartum levator avulsion in primiparae, diagnosed with 3D-4D ultrasound between 24 hours and 9 months after vaginal delivery, is reported between 15-39.5% [151-157]. The incidence of levator trauma evaluated with MRI is reported between 17.7%-19.1% 6-12 months postpartum [158-161].

III. PATHOPHYSIOLOGICAL MECHANISM OF BIRTH INJURY TO THE PELVIC FLOOR

Figure 7. Simulated effect of fetal head descent on the levator ani muscles in the second stage of labour. From Lien et al, Obstet Gynecol 2004 [149].
A study published by Novellas et al. [158], reported an occurrence of 19.1% levator abnormalities diagnosed with MRI in primiparae who underwent a cesarean section and they found that patients who underwent emergency cesarean sections had 2.7 times more abnormalities than patients who underwent elective cesarean. Only a study reported 4 cases of levator defect diagnosed with 3D ultrasound following emergency cesarean section [156].

Avulsion of the pubovisceral muscle seems to occur more frequently after forceps delivery than after spontaneous vaginal delivery: 1-12 months postpartum the occurrence rate of levator avulsion after forceps reaches the incidence rate of 59-72% [151, 162].

Kearney et al. [163] compared levator ani muscle injury rates in primiparous women who had a forceps delivery owing to fetal distress, with women delivered by forceps for second stage arrest; they compared these injury rates with a historical control group of women who delivered spontaneously. The major defect rates were 42% for women who delivered by forceps with a short second stage; 63% for women who delivered by forceps and had a prolonged second stage; and 6% for spontaneous delivery. The odds ratios for major injury were: 11.0 for forceps and short second stage compared with spontaneous delivery; 25.9 for forceps and second stage arrest compared to spontaneous delivery; and 2.3 for forceps and second stage arrest compared with short second stage (P=0.07). These authors also confirmed that women delivered by forceps have a higher rate of levator ani injury compared with spontaneous delivery controls, but the length of the second stage of labour does not influence the effect of the forceps on the levator ani muscle.

Several obstetrical factors associated with the occurrence of levator avulsion have been investigated: Valsky et al. [153] reported that a fetal head circumference ≥35.5 cm and a second stage of labour ≥110 min, increased odds of LAM trauma by a factor of 5.32. DeLancey’s group [161] demonstrated that injuries to the levator ani muscles in women after their first vaginal delivery are associated with forceps use (OR 14.7 [95% CI: 4.9-44.3]), anal sphincter rupture (OR 8.1 [95% CI: 3.3-19.5]) and episiotomy (OR 3.1 [95% CI: 1.4-7.2]); vacuum delivery (OR 0.9 [95% CI: 0.19-4.3]), epidural use (OR 0.9 [95% CI: 0.4-2.0]) and oxytocin use (OR 0.8 [95% CI: 0.3-1.8]) seem instead to have a protective effect against the occurrence of pubovisceral avulsion after delivery. LEVEL OF EVIDENCE II-3.

The levator ani muscle plays an independent role in pelvic organ support. The levator hiatus is the “hernial portal” through which female pelvic organ prolapse develops and damage to the levator ‘plate’ leads to a weakening of muscular supports to the pelvic organs and an increase in load carried by connective tissue and fascia. It has been demonstrated that increasing pelvic organ prolapse is associated with increasing urogenital hiatus size [164].

The results published by Dietz and Simpson [165] in a retrospective study of the urogynecological population, showed that prolapse was seen in 150/181 (83%) women with avulsion and in 265/600 (44%) women without avulsion, giving a RR of 1.9 (95% CI: 1.7-2.1). The association was strongest for cystocele (RR 2.3, 95% CI: 2.0-2.7) and uterine prolapse (RR 4.0, 95% CI: 2.5-6.5). The authors conclude that women with levator avulsion defects were about twice as likely to have pelvic organ prolapse of stage II or higher than those without.

Chen et al. [166] used a biomechanical model to explore how the impairment of the pubovisceral portion of the levator ani muscle, of the apical vaginal suspension complex, or both might interact to affect anterior vaginal wall prolapse severity. The authors stated that once a certain degree of pubovisceral impairment was reached, the genital hiatus opened and a prolapse developed; the larger the pubovisceral impairment, the larger the anterior wall prolapse became. A 90% impairment of apical support led to an increase in anterior wall prolapse from 0.3 cm to 1.9 cm (a 530% increase) at 60% pubovisceral muscle impairment, and from 0.7 cm to 2.4 cm (a 240% increase) at 80% pubovisceral muscle impairment.

The aetiological role of LAM integrity in bladder dysfunction is still not completely clear. A weakly significant association between levator avulsion and worsening or de novo urinary incontinence has been reported 3 months postpartum, through the use of ultrasound [155]. Recent evidence questions this link, reporting that women with major levator defect diagnosed by MRI are less likely to experience SUI [167], and that puborectalis trauma evaluated by ultrasound is not associated with an increased risk of SUI or urodynamic stress incontinence [168].

The involvement of the urethral function in the presence of levator avulsion has been approached recently, considering that it is often assumed that SUI may be due to abnormal pelvic floor muscle function or anatomy. Brincat et al [169], found no significant association between maximal urethral closure pressure (MUCP) and urethral closure pressure with a pelvic floor contraction or Kegel (KUCP) in women with or without LA defects (p = 0.94, p = 0.95). Additionally, there was no correlation between MUCP and vaginal closure force (r = 0.06, p = 0.41), and there was a weak correlation between KUCP and vaginal closure force (r = 0.20, p = 0.01). They conclude that urethral pressure profiles are unrelated to LA defect status after vaginal birth, indicating that the mechanism responsible for LA damage spares the urethra. Shek et al. [157], demonstrated that except at the bladder neck, there was no significant association between urethral mobility and avulsion.
With regard to anorectal function, Heilbrun et al. [159] showed a weak trend towards more faecal incontinence in women with LAM avulsion and anal sphincter tears, but the interpretation of these results must take into account that this is a rather select group, with a special set of risk factors.

One might speculate as to how 85–90% of first time mothers can undergo vaginal birth without the fetal head overstretching and rupturing the U-shaped loop of pubovisceral muscle tissue. One possibility is that the structure that lies in series with this muscle could protect it by stretching more than the muscle itself, just as a fusible link protects the wiring harness of an automobile against an electrical short. That structure, the perineal body, located between the vagina and rectum and comprised of relatively soft connective tissue, has material properties that do appear to change in late pregnancy, but these remain to be quantified [136].

2. NERVE INJURY

A geometric model has been used to predict the stretch ratios in the nerves innervating the levator ani, urethra, and anal sphincter during the second stage of vaginal labour [170]. The results showed that the inferior rectal branch exhibited the maximum strain, 35%, and this strain varied by 15% from the scenario with the least perineal descent to that with the most perineal descent. The strain in the perineal nerve branch innervating the anal sphincter reached 33%, whereas the branches innervating the posterior labia and urethral sphincter reached values of 15% and 13%, respectively. It was concluded that during the second stage (a) nerves innervating the anal sphincter are stretched beyond the 15% strain threshold known to cause permanent damage in the nonpregnant appendicular nerve, and (b) the degree of perineal descent is shown to influence pudendal nerve strain.

Pudendal nerve lesions usually result in demyelination of the fibres; axonal breaks may occur in severe cases where there is no recovery of the tissues [171]. c-Fos expression (an early reactive nerve injury marker) in the L6 to S1 spinal cord segments was observed in rats after simulated birth trauma, indicating acute nerve injury or irritation in spinal neurons. Also, histological studies have revealed a marked decrease of ganglion cells in the neural plexuses posterolateral to the vagina in rats after simulated birth [172].

Neuromuscular abnormal pelvic floor activation patterns may also contribute to the development of postpartum pelvic floor disorders [173-175]. Electroneuromyography studies have shown that 80% of primigravidae developed evidence of partial denervation with signs of reinnervation and increase in the density of nerve fibres in the postpartum period after vaginal delivery [176, 177]. The latency time of pudendal nerve motor fibres increased after 2 to 3 days following vaginal delivery, but values normalised after 6 months in 66% [177]. Most nerve lesions spontaneously recover within a year by regenerative processes [171]. However, pudendal nerve damage, even with partial reinnervation of the external anal sphincter muscle, may persist and become more marked in the long term [178]. Neurophysiological tests revealed nerve damage in 36% of women with persistent SUI at 3 months postpartum. Compared with nulliparous control subjects, patients with SUI and POP had changes in the levator ani and external anal sphincter consistent with either motor unit loss or failure of central activation, or both [179].

IV. PERINEAL TRAUMA

1. EPIDURAL ANALGESIA DURING LABOUR

Regional anesthesia for the relief of labour pain has become more popular during the past 20 years. Despite interest in its possible obstetric consequences, little attention has been paid to its potential effects on the pelvic floor and perineal injury.

The available published data describe controversial results. Some studies suggest that epidural analgesia, by enabling relaxation of the pelvic floor, leads to greater control of crowning of the fetal head and consequently fewer perineal tears [180], but prolongation of the second stage may also increase the incidence of pudendal nerve damage [181, 182].

Robinson et al. [183] examined whether epidural analgesia is associated with differences in rates of severe perineal trauma during vaginal deliveries. Among women who had epidurals, 16.1% (221/1376) had severe perineal tears compared with 9.7% (55/566) women who did not have epidurals (P < .001; OR 1.8, 95% CI: 1.3-2.4). When controlling for birth weight, use of oxytocin, and maternal age in logistic regression analysis, epidural remained a significant predictor of severe perineal injury (OR 1.4, 95% CI: 1.0-2.0). Epidural use is consistently associated with increased operative vaginal deliveries and consequent episiotomies, so the authors constructed a logistic regression model to evaluate whether the higher rates of those procedures were responsible for the effect of epidurals on severe perineal trauma. With operative vaginal delivery and episiotomy in the model, epidural was no longer an independent predictor of perineal injury (OR 0.9, 95% CI: 0.6-1.3). They concluded that epidural analgesia is associated with an increase in the rate of severe perineal trauma because of the more frequent use of operative vaginal delivery and episiotomy.

Carroll et al. [184], evaluated whether epidural analgesia was an independent risk factor for severe perineal tears. Among women who had epidural analgesia, 10.25% (65 of 634) had severe perineal tears compared with 5.22% (111 of 2,125) of the women who did not have epidural analgesia. After controlling for major variables in a logistic regression
analysis, epidural analgesia remained a significant predictor of severe perineal injury (OR 1.5, 95% CI = 1.0-2.1). A logistic regression model examining predictors of instrument use found that epidural analgesia does significantly increase instrument use (OR 3.01, 95% CI: 2.2-4.0). The author concluded that epidural analgesia is associated with an increase in severe perineal trauma as a result of an associated three-fold increased risk of instrument use. Instrument use in vaginal delivery more than triples the risk of severe perineal tears.

No significant association between anal sphincter injury and the use of epidural anesthesia was observed in 91 women in the retrospective study published by Christianson et al. [185]. On the other hand, Fitzgerald et al. [186] demonstrated that epidural analgesia was significantly associated with anal sphincter tear when the analysis was adjusted for maternal age, race, and gestational age.

In a study of 82 women, Meyer et al. [187] assessed the effects of epidural analgesia on pelvic floor function. Eighty-two primiparous women (consisting of 41 given an epidural and 41 not given an epidural) were investigated during pregnancy and at 2 and 10 months after delivery by a questionnaire, clinical examination, and assessment of bladder neck behaviour, urethral sphincter function and intravaginal/intra-anal pressures. Ten months after spontaneous delivery, there were no significant differences in the prevalence of SUI and decreased sexual vaginal response, or in bladder neck behaviour, urethral sphincter function and pelvic floor muscle strength between women who had or had not had epidural analgesia.

Sartore et al. [188] concluded that the use of epidural analgesia is not associated with symptoms related to perineal trauma and pelvic floor muscle weakness 3 months after vaginal delivery.

In a prospective observational study of 488 primiparae, Shek et al. [189], demonstrated with 3D ultrasound that intrapartum epidural appeared to have a protective effect (P=0.03; OR 0.42; 95% CI: 0.19-0.93) against levator trauma at the time of first delivery. Also Kearney et al. [161], using MRI, confirmed that epidural reduce the risk of developing a levator defect during vaginal delivery.

2. ROLE OF EPISIOTOMY

The episiotomy, a surgical incision in the perineum made to enlarge the vaginal opening and facilitate delivery, was originally introduced on the assumption that it would improve maternal and neonatal outcomes and rapidly became a part of standard obstetric care. However, since the 1980s, routine use of episiotomy has been challenged, based on the lack of evidence of benefits of the procedure [190] and the publication of multiple studies reporting increased blood loss at delivery, perineal scar breakdown and infection, postpartum pelvic pain, and dyspareunia [191-194]. Nowadays routine episiotomy is not recommended any more. Various types of episiotomy have been described in the past (median, modified median, J-shaped episiotomy, mediolateral, lateral, radical lateral and anterior) in papers and textbooks (Figure 8). The description of mediolateral episiotomy (the most frequently used in Europe) in standard obstetrics textbooks differs widely: some publications provide only descriptive terms, the angle of incision varies between 31° and 63°, suggesting the wide potential variation in the practice of episiotomy worldwide.

Some studies deal with the different use of various episiotomies in different countries (e.g. UK, Finland and Greece) [196-199]. However randomised trials comparing alternative methods or position of episiotomy are lacking, resulting in Level 2b or Level 3 of evidence, only. To ensure Level 1 evidence from randomised trials, there needs to be standardisation of the practice and reporting of the episiotomy incision. However, a standardised classification system has not been introduced yet, making it difficult to compare the various techniques. Even in the recent Cochrane review of episiotomy, an exact classification or definition of episiotomies is lacking [200].

Some studies have demonstrated increased incidence of third and fourth-degree lacerations associated with the use of midline episiotomy [201, 202]. The resulting damage to the internal and external anal sphincters can lead to devastating long-term sequelae, including faecal incontinence and rectovaginal fistulae [203].

Figure 8. Types of episiotomy. 1: median episiotomy, 2: modified median episiotomy, 3. ‘J’-shaped episiotomy, 4: mediolateral episiotomy, 5. lateral episiotomy, 6: radical lateral (Schchardt incision), 7: anterior episiotomy (white arrow). From Kalis et al. Classification of episiotomy: towards a standardization of terminology. BJOG 2012 [195].
To support the benefits of episiotomy, some clinicians have claimed that meticulous repair of a surgical episiotomy yields improved wound healing when compared with an unpredictable spontaneous tear [191]. This assertion, however, has not been substantiated by empirical evidence [204].

Kalis et al. [205] evaluated the results of mediolateral episiotomy with an incision angle of 60°; the study group comprised 60 consecutively recruited primiparous women who required an episiotomy during delivery. The results showed that the angles differed significantly among the incision (60°), repair (45°), and 6-month (48°) measurements (P < 0.001). There was a poor correlation between the suture angle and the angle measured at 6 months postpartum. No severe perineal tear was diagnosed in the cohort. At 6 months postpartum, only one woman reported mild symptoms of de novo anal incontinence, whereas 7 women reported perineal pain related to episiotomy.

Many institutions and individual obstetric practitioners have decreased their performance of episiotomy over the past 20 years, most likely as a result of practicing evidence-based medicine.

An electronic audit of the medical procedures database at Thomas Jefferson University Hospital from 1983 to 2000 was completed to determine if practice patterns have been altered by the large body of literature strongly advocating the selective use of episiotomy. Overall episiotomy rates in 34,048 vaginal births showed a significant reduction from 69.6% in 1983 to 19.4% in 2000. Significantly decreased risk of episiotomy was seen based upon year of childbirth (OR 0.87, 95% CI: 0.86-0.87), black race (OR 0.29, 95% CI: 0.28-0.31), and spontaneous vaginal delivery (OR 0.40, 95% CI: 0.36-0.45). Increased association with episiotomy was seen in forceps deliveries (OR 4.04, 95% CI: 3.46-4.72), and with third or fourth-degree lacerations (OR 4.87, 95% CI: 4.38-5.41). This study demonstrates a statistically significant reduction in the overall episiotomy rate between 1983 and 2000. White women consistently underwent episiotomy more frequently than black women, even when controlling for age, parity, insurance status, and operative vaginal delivery [194].

A population-based register of 514,741 women with singleton vaginal deliveries recorded in the Finnish Medical Birth Register was reviewed. Primiparous and multiparous women who had undergone episiotomy were compared to women who had not undergone episiotomy, for possible risk factors. The rate of episiotomy decreased from 71.5% in 1997-1999 to 54.9% in 2006-2007 among primiparous women, and from 21.5% in 1997-2001 to 9.2% in 2006-2007 among multiparous women. The use of episiotomy decreased in not only low-risk but also high-risk women who had operative vaginal or breech deliveries, macrosomic newborns, and oxytocin augmentation. The ratio of episiotomy use remained relatively unchanged in different subgroups even though episiotomy policy became increasingly restrictive over time. The authors concluded that the spectrum of indications for episiotomy has not changed over time, and use of episiotomy has declined arbitrarily to a similar extent among high and low-risk women [206].

To identify the risk factors for obstetric anal sphincter rupture (OASR), a retrospective population-based register study was carried out. A total of 514,741 women with singleton pregnancy and vaginal delivery between 1997 and 2007 in Finland were recruited. Episiotomy decreased the likelihood of OASR for the primiparous [OR 0.83, 95% CI: 0.75-0.92], but not the multiparous women (OR 2.01, 95% CI: 1.67-2.44). Episiotomy was associated with decreased risks for obstetric anal sphincter rupture in vacuum assisted deliveries (OR 0.70, 95% CI: 0.57-0.85). These results support the restrictive use of episiotomy, since 909 episiotomies appear to be needed to prevent one OASR among primiparous women. The equivalent estimate in vacuum assisted deliveries among primiparous women was 66, favouring routine use of episiotomy in such cases [198].

Robinson et al. [207], carried out a study to identify factors associated with the use of episiotomy at spontaneous vaginal delivery. They studied 1576 consecutive term, singleton, spontaneous vaginal deliveries; the association of demographic variables and obstetric factors with the rate of episiotomy use were examined. The overall rate of episiotomy was 40.6% (640 of 1576). Midwives performed episiotomies at a lower rate (21.4%) than faculty (33.3%) and private providers (55.6%) (P =0.001). After controlling for confounding factors with logistic regression, private practice provider was the strongest predictor of episiotomy use (OR 4.1, 95% CI: 3.1-5.4) followed by faculty provider (OR 1.7; 95% CI: 1.1-2.5), prolonged second stage of labour (OR 1.8; 95% CI: 1.2-2.7), fetal macrosomia (OR 1.6; 95% CI: 1.1-2.5), and epidural analgesia (OR 1.4 95% CI: 1.1-1.8). The authors conclude that the strongest factor associated with episiotomy at delivery was the category of obstetric provider. Obstetric and demographic factors evaluated did not readily explain this association.

A study was carried out to lower the episiotomy rate through physician education and to document the indication when episiotomy was performed. The intervention consisted of an evidence-based lecture recommending limited usage of episiotomy and requesting documentation of any indication for episiotomy. Data 3 months prior to the intervention were compared to those of the following year. For all vaginal deliveries, there was a 17% decrease in the rate of episiotomy, from 46.9% to 38.8%. For spontaneous vaginal deliveries, there was a 25% decrease in the episiotomy rate, from 40.8% to 30.8%. The most common indications for episiotomy reported were routine/elective, 41.0%; vacuum, 18.6%; forceps, 16.4%; and nonreassuring fetal heart tracing, 10.9% [208].

A review was conducted of women with consecutive vaginal deliveries at Magee-Women’s Hospital
between 1995 and 2005 to evaluate the episiotomy exposure at first vaginal delivery. A total of 6,052 patients were included, of whom 47.8% had episiotomy at first delivery. Spontaneous second-degree tears at the time of second delivery occurred in 51.3% of women with history of episiotomy at first delivery, compared to 26.7% without history of episiotomy (P<0.001). Severe tears (third or fourth-degree) occurred in 4.8% of women with history of episiotomy at first delivery compared with 1.7% without history of episiotomy (P<0.001). Previous episiotomy remained a significant risk factor for second-degree (OR 4.47, 95% CI: 3.78-5.30) and severe obstetric lacerations (OR 5.25, 95% CI: 2.96-9.32) in the second vaginal delivery after controlling for confounders. Based on these findings, for every four episiotomies not performed, one second-degree tear would be prevented. To prevent one severe tear, performing 32 fewer episiotomies is required. Episiotomy at first vaginal delivery increases the risk of spontaneous obstetric trauma in the subsequent delivery. This finding should encourage obstetric providers to further restrict the use of episiotomy. LEVEL OF EVIDENCE II [209].

V. CONCLUSION AND RECOMMENDATION

1. Prevalence of UI after vaginal delivery is double that after caesarean section [109]. Cesarean section seems to decrease the risk of postpartum UI [110, 111], but its protective effect seems to diminish over time and disappears after multiple deliveries [111, 112]. Risk of SUI is estimated to be 2.9 times higher after vaginal delivery compared with women after cesarean section [113]. Information regarding whether cesarean done before labour confers greater protection than cesarean done after labour is lacking. To understand the true impact of cesarean delivery on urinary incontinence, future studies must compare incontinence by planned delivery modes.

2. De-novo anal incontinence symptoms after childbirth are described as up to 26-38% between 6 weeks-6 months postpartum [115-120]. Vaginal delivery has a greater risk of FI compared to cesarean 3-6 months postpartum [115] [117]. It is recommended extending postpartum follow-up visits beyond the typical 6-8 weeks to provide surveillance for potential incontinence. LEVEL OF EVIDENCE: II.

3. Pelvic organ prolapse rate in the first 3-6 months postpartum is reported between 18.1-56% [121-123]. Spontaneous vaginal delivery increased the risk by more than three times while instrumental vaginal delivery increased it more than five-fold in comparison with cesarean section [121]. Cesarean section has a protective effect on the occurrence of pelvic organ prolapse [124].

4. The occurrence of UI and anal incontinence during the postpartum period is related to the presence of incontinence in pregnancy, and vaginal delivery increases the risk of persistent incontinence. LEVEL OF EVIDENCE II [125].

5. So far, there is no evidence from randomised controlled trials, upon which to base any practice recommendations regarding planned cesarean section for non-medical reasons at term or to avoid pelvic floor symptoms in a woman without previous disorder, considering that pregnancy itself may be involved in the development of such dysfunction [133] [134] [135].

6. Obstetrics factors associated with the occurrence of LAM trauma postpartum: forceps use, fetal head circumference ≥ 35.5 cm, second stage of labour ≥110 min, anal sphincter rupture, episiotomy. LEVEL OF EVIDENCE II-3. Levator ani avulsion is associated with the occurrence of pelvic organ prolapse later in life, but the role of LAM integrity in bladder and anorectal dysfunction are still not completely clear.

7. Epidural analgesia during labour: controversial results regarding its potential effect on the pelvic floor and perineal injury. There is a lack of prospective, randomized trials, requiring further research and development in order to draw recommendations.

8. Randomised trials comparing alternative methods or position of episiotomy are lacking, resulting in Level IIIb or Level III of evidence, only. To ensure Level 1 evidence from randomized trials, it needs a standardisation of the practice and reporting of the episiotomy incision. The actual evidence shows that episiotomy is associated with 3rd-4th degree of perineal tears and with an increased risk of spontaneous obstetrics trauma in the subsequent delivery. These findings encourage restriction of routine use of episiotomy. LEVEL OF EVIDENCE II.

C. PATHOPHYSIOLOGY OF STRESS INCONTINENCE IN WOMEN: URETHRAL STRUCTURE, SUPPORT AND FUNCTION

The factors necessary for the urethra to remain closed at rest and during increased abdominal pressure have been well characterised, but their functional inter-relationships are still not fully understood. These factors include: 1) healthy, functioning striated sphincter controlled by pudendal innervation, 2) well vascularised urethral mucosa and sub-mucosa, 3) properly aligned and functioning intrinsic urethral smooth muscle, and 4) intact vaginal wall support.
**I. THE FEMALE UROGENITAL DIAPHRAGM: URETHRAL SPHINCTER LOCATION**

Detailed descriptions of the urogenital diaphragm have been made by Max Brodel working with Howard Kelly [210], Oelrich [211] and further expanded by DeLancey [212]. These reports have provided clear descriptions of the urethral rhabdosphincter. The proximal one-third of the urethra is shown surrounded by a sleeve of striated muscle continuous with a longer ascending cone which extends to the vaginal introitus. Manometric and electrophysiological recordings from this proximal one-third of the urethra have shown that it generates the highest level of resting pressure and electromyographic activity.

This portion of the urethra is an intra-pelvic structure located immediately posterior to the pubic bone. In the past, much has been made of the loss of this intra-pelvic position in stress incontinence. It had been suggested that when the urethra descended away from its intra-abdominal position, intra-abdominal forces no longer constricted it during straining. This concept has survived and been modified into the “hammock hypothesis” [213] which suggests that the posterior position of the vagina provides a backboard against which increasing intra-abdominal forces compress the urethra. Data supporting this hypothesis are drawn from urethral pressure transmission studies showing that continent patients experience an increase in intra-urethral pressures during coughing. This pressure increase is lost in stress incontinence and may be restored following successful operations designed to stabilize or elevate the sub-urethral vaginal wall [214-223].

The urethra is supported posteriorly and inferiorly by the anterior vaginal wall. The superior vaginal sulcus, most clearly found in nullipara, exists at this junction of the lower and middle third of the vaginal wall. This point represents the two lateral insertion points of the vaginal “hammock”. Portions of the pubococcygeus muscle attach to these sulci within the pelvis and can produce elevation during voluntary contraction.

Immediately anterior to the proximal urethra are found the reflections of the endopelvic fascia are found. The most prominent of these, the pubourethral ligaments, are sufficiently condensed to form distinct and recognisable ligaments on either side of the pubis. Although these structures form one continuous complex, they are distinguished by their names, as posterior and anterior pubo-urethral ligaments. The posterior pubo-urethral ligaments, which can be seen at the time of retropubic surgery, are the more familiar of these. These are strong fascial condensations which most likely maintain their characteristics throughout life. Previous investigators, however, have suggested that elongation of these structures may be responsible for the loss of urethral support seen in stress incontinence.

Different authors have described the striated external urethral sphincter (EUS), both in foetuses [224, 225] and adults [226] as a superior horseshoe structure covering the urethra and an inferior one surrounding the anterolateral aspect of the urethra and the lateral part of the vagina (Figure 9).

The LAM is an important element in maintaining urinary continence. Wallner et al. [227] investigated the topographical relationship between the EUS and the LAM (Figure 10), showing that in female foetuses, but not in male, the inferior part of the EUS is firmly attached to the LAM by a tendinous connection. This determines an anterior bending of the midurethral zone when a simultaneous contraction of the LAM and EUS occurs, closing the urethral lumen and maintaining continence. The functional integrity of this connection between the EUS and the LAM is therefore crucial to avoid urinary incontinence.

---

**Figure 9. EUS in 18 weeks female foetus: A anterior view, B lateral view, C oblique view, D superior view, E inferior view - From Wallner et al., Eur Urol 2009 [227].**
The striated external urethral sphincter (EUS), both in foetuses and adults, has a superior horseshoe structure covering the urethra and an inferior one surrounding the anterolateral aspect of the urethra and the lateral part of the vagina.

Moreover, while the lower one-third of the vagina is oriented more vertically in the nullipara, the upper two-thirds of the vagina deviate horizontally. This orientation is due: 1) to the posterior attachments of the cervix by the cardinal and utero-sacral ligaments and 2) to the anterior position of the levator hiatus. Barium vaginograms have demonstrated this horizontal angulation of the upper two-thirds of the vagina, and show that during coughing and stressful manoeuvres, the levator hiatus is shortened in an anterior direction by the contraction of the pubococcygeus muscles. Thus, the pelvic organs receive support from the shape and active contraction of the levator muscles.

Modifications of the genital hiatus determining an increase in the genitohiatal distance can be associated with urodynamic stress incontinence. In a retrospective study of 396 women with urodynamic stress incontinence [228], pelvic floor ultrasound revealed a negative association of the genitohiatal distance to urodynamic functional urethral parameters such as the functional profile length, the maximum urethral closure pressure and a low Valsalva leak-point pressure ($r = -0.148, P = 0.018$ and $r = -0.227, P = 0.009$, $r = -0.199, P = 0.02$ respectively).

![Diagram](image)

**Figure 10:** The anatomical relationship of the EUS to the LAM in adults. Panels (A) through (D) show transverse sections through the EUS and the LAM of an adult female (54 yr): (A) superior part of the EUS (arrowheads), section stained immunohistochemically for striated muscle; (B) sequential section stained with sirius red for connective tissue; (C) inferior part of the EUS (arrowheads), section stained immunohistochemically for striated muscle; (D) sequential section stained with sirius red for connective tissue. Note in (C) that in the adult, the anatomical relationship between the inferior part of the EUS and the LAM is still maintained. The contrast of images (A) and (C) was increased digitally. $L =$ levator ani muscle; $U =$ urethra; $V =$ vagina. From Wallner et al Eur Urol 2009 [227].
II. EFFECT OF CHILDBIRTH, VAGINAL PROLAPSE AND URETHRAL POSITION ON URINARY CONTINENCE

Labour and delivery alter vaginal and pelvic anatomy and innervation in several ways as has been discussed in other sections of this chapter. Each of these may contribute to the eventual development of urinary incontinence:

1. PUDENDAL NERVE

Direct crushing or traction on the pudendal nerve has been discussed above and has previously been suggested as a primary cause of sphincter incompetence in stress incontinence. The pudendal nerve, which projects from Onuf’s nucleus and traverses Alcock’s canal before entering the ischiorectal fossa and innervating the EUS, can be injured during vaginal delivery, particularly in the area between the sacrospinous and sacrotuberous ligaments. Two different mechanisms of pudendal nerve damage during delivery have been described: 1) nerve compression and stretching which may cause an elongation of the 13% of its motor branch innervating the EUS [229]; 2) a reduced at 8% stretch and complete ischemia at 15% stretch of the nerve as shown in a tibial nerve rat model [230]. Thus, pudendal nerve ischemia likely occurs during vaginal delivery as a result of both stretch and compression [231].

2. CARDINAL AND UTERO-SACRAL LIGAMENTS

Cardinal and utero-sacral ligaments may be stretched or torn, resulting in anterior displacement of the uterus during straining or under the influence of gravity.

3. THE VAGINA

The vagina itself may be torn away from its intrapelvic attachments with subsequent loss of the superior vaginal sulcus. There may be direct attenuation of the vaginal wall itself, manifested by loss of vaginal rugae and a thin appearance. Cullen Richardson has suggested four distinct kinds of vaginal injuries: paravaginal, central, distal, and cervical, the first two being the most commonly seen in women with stress incontinence. These defects have been identified by sonographic examination [232].

4. LEVATOR MUSCLES

Finally, stretching, tearing and avulsion of the levator muscles result in a longer and wider levator hiatus. Consequently, the perineum is displaced anteriorly and posteriorly under stress and temporarily fails to support the pelvic organs. These changes in the levator hiatus with or without associated relaxation of cervical support result in chronic anterior displacement of pelvic organs with a loss of both active and passive organ support during rest and especially during straining.

In the patient with SUI these changes typically give rise to a rotational descent of the proximal urethra away from its retropubic position.

Radiographic images of stress urinary incontinence in women have noted this and generated our earliest concepts of this condition. Jeffcoate and Roberts [233], using lateral cystourography, concluded: “…the most common characteristic anatomical change, present in four out of five cases of incontinence, is loss of the posterior urethro-vesical angle so that the urethra and trigone tend to come into line.”

In 2002, fifty years later, perineal sonographic studies of urethrovesical angle differences in incontinent and normal patients have found excellent correlation identified between angle and degree of incontinence, supporting these original observations [234].

Hodgkinson, using a suspension of barium paste placed in the bladder and a small bead chain in the urethra, produced images of the urethra at rest and during maximum straining in women with stress urinary incontinence [235, 236]. He concluded: “…it is clear that the distinguishing topographic pathological feature is depression of the urethrovaginal junction to the lowest level of the bladder during the peak of the straining effort. It is also clear that the spatial relationships of the bladder and urethra to the symphysis make no difference in either the incidence or severity of stress incontinence.”

These kinds of radiographic studies, however, cannot distinguish between lateral or central defects in vaginal wall support. Therefore, while urethral movement can be identified as an important finding in stress incontinence, one cannot determine the exact location of the vaginal defect. Because the proximal urethra rotates out of the focal plane of ultrasonographic probes or MRI, coronal images of vaginal relaxation have not yet shown anatomical detail at the moment of incontinence. They cannot distinguish central from paravaginal defects. For this, an examination of the patient is required.

Although we have considerable knowledge about anatomical defects in the majority of patients with urodynamic stress incontinence (USI), less is understood about the exact effect of these defects, and indeed, vaginal position itself, on urethral closure. Early experience with operations for stress incontinence showed that not all women with stress urinary incontinence had vaginal prolapse, that correction of vaginal relaxation did not always correct stress incontinence, and that women who redeveloped stress incontinence symptoms after apparently successful surgery did not necessarily show a recurrence of their prolapse [237].

The effect on the urethral mechanism of anatomical defects induced by vaginal delivery has been recently investigated. In a rat model birth trauma has been simulated by inducing vaginal distension by balloon catheter inflation [238]. Sneeze
induced stress urinary incontinence was caused by decreased active closure mechanisms at the mid urethra without affecting the passive transmission of abdominal pressure in the proximal urethra.

The greater involvement of the urethral mechanism in the occurrence of post-partum stress incontinence was confirmed in a case control study evaluating urethral closure pressure and bladder neck movement assessed with ultrasound [239]. Eighty primiparous women complaining of de-novo stress incontinence 9-12 months after delivery were compared with 80 primiparous continent and 80 nulliparous continent women. Lower maximal urethral closure pressure was the closest association with de novo stress incontinence after first vaginal birth followed by vesical neck mobility.

### III. EMERGING CONCEPTS OF URETHRA WEAKNESS AND ISD

The idea that primary urethral weakness could cause urinary incontinence independent of vaginal weakness appeared in a proposed classification by Blaivas et al [240]. In their classification, they named this Type III incontinence to distinguish it from Types I and II, each of which showed movement, while Type III did not. This term still remains in the contemporary literature, although it has now been largely replaced by the term intrinsic sphincter deficiency (ISD), focusing attention on urethral elements which appear to be independent of vaginal position and mobility. These elements include pudendal innervation, striated sphincter mass and function, and urethral smooth muscle, mucosa and submucosal cushions.

When ISD was first introduced as a concept to explain surgical failures and the presence of stress incontinence in the absence of vaginal mobility, the diagnostic tendency was to consider the cause of stress incontinence as a dichotomy, due either to hypermobility (displacement, or prolapse of the vaginal wall) or ISD. The typical patient with ISD was described as having low urethral closure pressures, a “stovepipe” appearance on cystoscopy, and opening or funneling of the urethra under resting or minimal increases in intra-abdominal pressures on radiographic images. The common causes were thought to be surgical injury, ischemia following previous pelvic or vaginal surgery or radiation damage.

It appears now, that these examples of ISD may represent the most advanced or extreme forms.

### IV. HYPERMOBILITY VS. ISD: FROM DICHOTOMY TO CONTINUUM

Currently, these appear to be a shift away from this simple categorisation of stress incontinence as being due either to hypermobility or ISD. This has arisen in part because of the development of the concept of Valsalva Leak Point Pressure (VLPP) [241, 242] and more recent analyses of long term results of stress incontinence surgery [243].

VLPP emerged as an alternative method to study urethral closure during stress for studies of urethral bulking with collagen. Investigators recognised that improvements in continence following urethral bulking did not correlate with urethral closure pressures, but did correlate with the amount of pressure required to produce leakage in the absence of intrinsic detrusor contraction. Although VLPP still lacks specific anatomic or theoretical grounding and many uncertainties related to standardisation of recording methods and associated prolapse remain, low VLPP (without specified or established values) has been widely embraced as an indicator of ISD.

Just as the concept of VLPP blurred the previous distinction between simple ISD and simple hypermobility, long term outcome studies of correction of hypermobility have suggested that there may be more urethral weakness among patients with hypermobility than had been previously considered.

Long term outcome studies of stress incontinence surgery have shown that there is a much greater failure rate of many of the commonly performed stress incontinence operations than had been generally appreciated, and that slings providing direct sub-urethral support seemed to give the greatest long term protection against recurrence of incontinence [243]. Since slings had traditionally been the procedure of choice for recurrent incontinence or “Type III” (now ISD) incontinence, the possibility that ISD was more common than previously thought was more widely considered. Recently, Horbach and Ostergaard have found that age is a significant, independent predictor of ISD in the setting of urodynamic stress incontinence [244], suggesting that age-related reduction in muscle mass, slowed reflexes or repeated episodes of prolapse may all contribute to the condition.

In two interesting studies Perucchini et al [245, 246] showed that aging can cause a decrease in the number and density of urethral striated muscle fibres at the bladder neck and along the ventral wall of the urethra [246].

These two developments have led to a growing clinical impression that some degree of ISD may exist in many patients who, until recently, were thought to have only hypermobility as the cause of their incontinence. Atypical expression of this approach can be found in the conclusion of Kayigil et al. [247] following examination of 50 patients; “The high rate of intrinsic sphincter deficiency in patients with urethral hypermobility indicates that the incidence of stress incontinence may be greater than previously believed, and may influence the apparently higher failure rates after bladder neck suspension.” In contemporary clinical practice, this impression has given rise to a growing tendency to recommend suburethral sling surgery as a form of primary surgical treatment for all women with stress incontinence, where as formerly
this approach was reserved almost exclusively for patients with recurrent stress incontinence or significant ISD [248, 249].

1. DIRECT STUDIES OF URETHRAL FUNCTION

As recognition of the importance of urethral function has increased, so too have the number of investigations of urethral position, urethral closure and transmission pressure profiles, Valsalva leak point pressure measurements and electromyographic examinations of the pudendal nerve and the striated sphincter.

a) Studies of urethral position

Stress incontinence is frequently associated with loss of urethral position. This has been the primary pathophysiological paradigm since the observations of Hodgkinson and Jeffcoate and Roberts. Similar observations are still reported today [250, 251]. Even when some displacement is seen in continent nulliparous females, incontinent women show a greater degree of mobility [252].

This pathophysiological mechanism has been supported by different authors [172, 253, 254] using a rat model. Both (word missing) and induced trauma on structures supporting the urethra (such as the pubourethral ligaments) and uretherolysis resulted in SUI in short and long term because of increased urethral mobility.

Successful suspensory operations, whether by sling or paraurethral suspension stabilise urethral position [237] and, when studied, increase pressure transmission during stress. It is not clear if the active contraction of urethral support seen in the female is restored after surgery, nor is it known if it is necessary for continence. It has been suggested that passive support alone is what restores continence after suspension.

b) Studies of urethral pressure and resistance

Stress incontinence is generally thought to be characterised by a decrease in urethral transmission profiles and resting closure pressure. The correlation between low resting pressures and low leak point pressures is still controversial. With a bladder filled up to 200ml Almeida et al. [255] reported a significant correlation between MUCP and LPP. Patients with a LPP of 60 cm H2O or less also had shorter urethral functional length and lower sphincter activity. Moreover Sinha et al [256] showed that women with urodynamic stress incontinence were more likely to leak at cough leak point pressure than the Valsalva manoeuvre, with the opposite happening for women with detrusor overactivity. On the contrary Martan et al. [257] could not find any significant correlation between MUCP and VLPP.

Different urodynamic parameters have also been considered to assess urethral function and to correlate with women with stress incontinence. Digièsu et al. [258] showed that urethral resistance pressure (URP) and pressure flow parameters were reduced in women with stress incontinence. Salvatore et al. [259] found that the opening vesical pressure is significantly correlated with ISD.

Sonographic studies have recently shown a relationship between low urethral resistance and decreased urethral smooth and skeletal muscle layers [260].

Improvement in transmission pressures is associated with successful outcomes after suspensory operations for SUI [214, 218, 221, 222, 261, 262]. The exact mechanism for this increase in transmission is not clear. Increased exposure to intra-abdominal forces has been suggested [223, 263, 264]. Compression against the pubis by the pelvic viscera has also been suggested [265]. The final position of the urethra, however, may not be the key variable [214].

c) Electrophysiological studies of urethral function

Snooks and Swash [266, 267] first brought attention to the importance of urethral denervation after its possible contribution to urinary and faecal incontinence. Stress incontinence is frequently associated with a decline in the electrophysiological function of the pudendal nerve [268], the striated urethral sphincter [269], and the pelvic floor muscles [174, 179]. Most recent studies continue to support the finding of prolonged pudendal nerve terminal motor latency in SUI [270].

With the use of animal models simulating intrinsic urethra deficit through periurethral catherisation, urethral sphincterectomy or pudendal nerve transaction, different authors reported a decrease of LPP lasting for weeks [271-273]. Injury of the pudendal nerve determined a dramatic decrease of urethral resistance causing urinary loss during an intrabdominal pressure increase.

Electromyographic studies of normal sphincter function show that in continent women, pressures begin to rise in the urethra before rising in the bladder, suggesting an active muscular component [274].

Women with stress incontinence have an altered pattern of pelvic floor muscle response during successive coughing efforts [275] with a sharp decrease in MUCP after repeated coughs [276]. EMG studies have also shown that women with persistent stress incontinence after previous surgery have poorer urethral neuromuscular function than naïve stress incontinent women [277]. Experimental studies of urethral function and the role of Onuf’s nucleus in the sacral spinal cord have led to recent practical innovations in the development of serotonin uptake inhibitor agents in the treatment of stress incontinence [278]. Most electrophysiological studies have concentrated on motor rather than sensory innervation, however, and the role of urethral sensation in urodynamic stress incontinence is unknown.

d) Genetic factors

Recent research is now focusing on the identification of factors related to stress incontinence which
might be genetically determined. Chen et al. [279] reported that genes involved in elastin metabolism were differentially expressed in vaginal tissue from women with stress incontinence, suggesting that elastin remodelling may be important in the molecular aetiology of stress incontinence. Wen et al. [280] recently reported a decreased expression of alpha2-M mRNA and protein and protease inhibitor activity in the vaginal wall tissues of women with stress incontinence.

There is a need for a hypothesis which would integrate these various observations regarding hypermobility, ISD and pudendal nerve function, place them within the context of an abnormal pelvic floor and provide a model to guide research and studies of the natural history of the condition.

2. ROLE OF ADVANCED IMAGING IN UNDERSTANDING PATHOPHYSIOLOGY

Many imaging modalities have been used to improve our knowledge on pelvic floor dysfunction, such as: radiographic imaging, ultrasound, computed tomography and magnetic resonance imaging (MRI).

Radiographic imaging has provided considerable insight into the pathophysiology of stress incontinence, ever since the advent of bead chain cystograms and simple static and straining lateral cystograms.

MRI and real time ultrasonography, in addition to showing the events of stress incontinence on both a global pelvic and local urethral scale, have suggested a relationship between the proximal urethra to vaginal wall movement.

a) Magnetic resonance imaging

Dynamic fastscan MRI can visualise all compartments of the female pelvis during increased intraabdominal straining [281]. MRI is comparable to standard cystography in demonstrating cystocele defects [282].

Using the pubococcygeal line as a reference marker, the normal displacement of bladder base, cervix or vaginal cuff, and the rectum can be identified and compared to women with prolapse. The urethra is shown in the context of global pelvic relaxation [283]. Although most MRI studies have been descriptive rather than quantitative, they still show far more soft tissue detail than earlier radiographic studies and continue to offer promising research opportunities. Recent studies have utilised an endovaginal coil to obtain higher resolution images of the urethra [284].

Dynamic MRI with cine-loop reconstruction produces vivid, intuitively appealing images which can show movement of all compartments of the relaxed pelvis during straining [283]. Static MRI shows details of urethral and peri-urethral anatomy and the striated sphincter can be clearly seen [285]. Pending further improvements in resolution, MRI remains a most promising tool for studying details of urethral movement [286].

Ultrasonography, however, is simpler and less expensive, and, for now, provides better visualisation of moving structures.

Functional MRI has recently been evaluated to assess the efficacy of pelvic floor muscle training with EMG- biofeedback in women with stress incontinence. After a 12-week training period a more focused activation in the primary motor and somatosensory cortical representation sites of the lower urogenital tract was found [287].

b) Real time ultrasonography

Several sonographic approaches have been used for the study of stress incontinence: suprapubic, translabial, transvaginal and transperineal.

As resolution of sonographic probes has improved, the detail previously best seen with the transrectal approach may now be seen by a transperineal approach. Earlier studies with a transrectal approach have shown that funneling of the proximal urethra was the sonographic sign most-frequently associated with loss of urine [288].

In about half the patients with stress incontinence in the study of Schaer et al. [289], funneling was seen only with straining. In the other half, some degree of funneling was already present at rest, increasing with straining and present with actual leakage. Enhanced views of the urethra are possible with sonographic contrast material.

Most recently, 3-D reconstruction from translabial views of the urethra has been used to compare findings in normal volunteers and those with ISD [290].

The most recent sonographic study of women with stress urinary incontinence found funneling at rest in 109 of 330 patients, and found that the degree of vaginal relaxation as well as the parameters of intrinsic urethral function, including VLPP and urethral closure pressures, were worse in patients with funneling than without. The authors of this study concluded that: “In primary genuine stress incontinence, bladder neck funneling on ultrasound cystourethrography implies the potential coexistence of poor anatomic support and an intrinsic sphincter defect [291].” Ghoniem et al. [292] also found that urethral funneling was more likely to be associated with low closure pressures, low VLPPs, and a higher incidence of ISD in patients with stress urinary incontinence. However, recently, Tunn et al. [293] could not find an association between the ultrasound findings of urethral funneling with stress incontinence using an introital approach, demonstrating it only in 59% of the patients with stress urinary incontinence.

Ultrasound has been used to identify paravaginal defects prior to Burch colposuspension to guide surgical modification, and then repeated after surgery to show correction of the defects [294].
Urethral movement and funnelling seen by ultrasound resemble the rotational descent previously described by Nichols and Randall [295]. It is also consistent with the previously cited descriptions of Jeffcoate and Roberts, and that of Hodgkinson. Improved soft tissue detail seen with ultrasound has permitted an extension of these original observations. The anterior and posterior walls of the proximal urethra appear to move differently during increases in intra-abdominal pressure. At first, they appear to move together: the urethra begins its descent as a single unit. At some point, however, the anterior urethra becomes arrested in its rotational movement and appears to move more slowly. The posterior portion of the urethra continues to descend along with the vaginal wall [288, 296].

This difference in movement suggests a shearing apart of the two walls, leading to the appearance of funnelling, which can be seen as urine leaks out of the urethra.

On Valsalva, the proximal urethra rotates in a postero-inferior direction approximating to the symphysis pubis. This movement can be measured by comparing the angle of inclination between the proximal urethra and any other fixed axis. No normal values of bladder neck descent have been defined but cutoffs of 20, 25 and 30 mm have been reported to classify urethral hypermobility [297, 298]. The anatomical and functional integrity of PFM have an important role in the urethral support system and, therefore, in the continence mechanism. It has been shown that women with UI, compared to continent subjects, have less effective PFM in terms of: strength, reduced endurance, reduced thickness, coordination of PFM and lower abdominal muscles, and altered electromyographic activity [299-301]. With transperineal ultrasound it is possible to evaluate the urethral displacement towards the pubic bone caused by pelvic floor muscle contractions [302]. This mechanism is involved in maintaining urinary continence by determining good efficacy in intraurethral pressure transmission [303].

Anatomic correlation suggests that the pubourethral ligaments may restrict the movement of the anterior urethral wall, facilitating downward traction by the prolapsing vagina during stress, contributing to the shear. At the level of the pubis, the posterior portion of the pubourethral ligament travels beneath the pubis to form an anterior portion, which supports the clitoris in women, and the corpora cavernosa in men. Milley and Nichols [304], Zacharin [305, 306] and Mostwin [307] have previously suggested that the posterior pubourethral ligaments might support the urethra, and their laxity could contribute to the descent of the urethra in stress incontinence. These studies, however, suggest a different interpretation. Longitudinal and cross-sectional views of the proximal urethra show that the ligaments travel along only the anterior portion of the urethra as they pass beneath the pubis to emerge as the anterior pubourethral ligaments.

The vagina and its bilateral attachments forming the lateral sulcus support the posterior part of the urethra. It is more likely that the vaginal wall and its attachments become weaker than the strong condensations of endopelvic fascia forming these ligaments. Therefore, the pubourethral complex, even if attenuated, probably remains stronger than the underlying vaginal wall. Sonographic examination of the prolapsing urethra therefore suggests arrest of anterior urethral wall movement by the pubourethral complex, while the vaginal wall continues to rotate, pulling the posterior wall of the urethra along with it.

These anatomical considerations, combined with current knowledge about pudendal nerve activity in normal, prolapse or stress incontinence, suggest an inter-relationship regarding urethral closure and vaginal movement. As intra-abdominal pressure increases, the proximal urethra experiences two kinds of forces, which may lead to opening. The first of these is a shearing force produced by the unequal separation of the anterior and posterior urethral walls from the pubis during straining. This is the effect of vaginal mobility on urethral closure. The second is an expulsive force, produced by the transmission of intra-abdominal forces to the bladder, which must be resisted by the urethra if opening is to be prevented.

The urethra resists this primarily by intrinsic closure of the pudendally innervated striated sphincter, aided by vaginal support.

3D ultrasound has recently introduced new insights into the image of urethral sphincters. Athanasiou et al. [308], using a transvaginal approach, reported a close correlation between the urethral sphincter volume and the degree of incontinence assessed on videocystourethrography ($r = -0.65; P < 0.001$).

With the use of three-dimensional ultrasound Athanasiou et al. [308] evaluated the urethra and the urethral sphincter in women with stress incontinence. These authors reported that this group of women have urethral sphincters that are shorter, thinner, and smaller in volume compared to controls.

Urethral vasculature has also been postulated to play a role in the continence mechanism and different Doppler parameters have been studied to evaluate correlation with stress urinary incontinence. However, Tsai et al [309] reported that urethral vasculature, and in particular the anterior branch of the middle urethral vessels is less likely to be seen after the menopause (89.1% vs. 79.2% pre- and postmenopause, $P = 0.030$). In the postmenopausal women hormone replacement therapy did not affect the appearance of the urethral vessels.

Results are controversial since some authors [280] reported less periurethral vessels and flow in women suffering from stress urinary incontinence whereas others [310] could not find any difference in the appearance of the urethral vasculature in subjects with or without stress urinary incontinence.
It is likely that these shearing and expulsive forces are generated simultaneously as intra-abdominal pressure rises. One can easily imagine that the urethra can be brought to a continence threshold beyond which urethral closure cannot be maintained. One can further imagine that repeated episodes of prolapse may eventually stretch, tear or attenuate sphincter mass and contribute to a chronically weakened urethra manifested by low VLPP or low urethral closure pressures, characteristic of ISD. After severe or prolonged untreated prolapse and stress incontinence, vaginal support alone may not be sufficient to correct the deficiencies of an exhausted sphincter. Although theoretical rather than evidence-based, such considerations may direct future research efforts towards a more integrated hypothesis regarding stress incontinence in women. The relative contributions of abnormal vaginal mobility and intrinsic urethral function should be considered as part of a continuum rather than a dichotomy. Current research and interest has concentrated mostly on ISD as the primary cause of SUI in women, but the relationship of the many factors affecting urethral support and function should remain a perspective in interpreting emerging findings.

V. CONCLUSIONS

We are approaching a new classification of stress incontinence which will integrate hypermobility and urethral dysfunction as inter-related elements on a spectrum of change. Certain concepts have stood the test of time, and they are included below, along with conclusions:

1. Many patients with urodynamic stress incontinence show urethral mobility (Level 2), although it is not yet known what it is about that mobility which permits urethral opening during stress.
2. Some patients who present with minimal mobility have primary or residual sphincter insufficiency.
3. Sphincter insufficiency is related to a decline in striated sphincter muscle mass and function as measured by electrophysiological studies of pudendal nerve and sphincter function, and MRI and sonographic estimates of muscle mass (Level 1). If repeated episodes of vaginal traction can be shown to enhance sphincter damage, then the effect of early treatment of stress incontinence and prolapse on future development of ISD should be investigated, since advanced ISD remains difficult to treat.
4. Successful operations can restore urethral position but do not restore urethral function. A good surgical outcome probably requires a certain reserve of urethral function. It is in the area of functional understanding of urethral anatomy that the greatest progress is likely to be made.

### D. PELVIC ORGAN PROLAPSE

Anatomical support of pelvic viscera is mainly provided by the levator ani muscle complex and connective tissue attachments of the pelvic organs: vaginal support arises from the connective tissue attachments between the vagina and the pelvic sidewall, the vaginal wall, and the levator ani muscles [311, 312].

Two mechanical principles explain how the uterus and vagina are normally held in place. First, the uterus and vagina are attached to the walls of the pelvis by the endopelvic fascia that suspends the organs from the pelvic sidewalls. Second, the levator ani muscles costrict the lumens of these organs closed, forming an occlusive layer on which the pelvic organs may rest [313].

The levator ani complex consists of the pubococcygeus, the puborectalis, and iliococcygeus muscles [314]. These muscles are tonically contracted at rest and act to close the genital hiatus and provide a stable platform for the pelvic viscera. Decline of normal levator ani tone by denervation or direct muscle trauma, results in an open urogenital hiatus, weakening of the horizontal orientation of the levator plate, and a bowl-like configuration [315, 316].

The supportive connective tissues are a continuous, highly interdependent sheet in which all components interact to achieve support of the vagina and, therefore, of the pelvic organs. DeLancey has introduced the concept of dividing the connective tissue support of the pelvis into three levels, with level I, II and III representing apical, midvaginal and distal support respectively. The upper portion of the paracolpium (Level I) consists of a relatively long sheet of tissue that suspends the vagina to the pelvic side wall, and it is responsible for suspending the apex of the vagina after hysterectomy.

In the middle third of the vagina, the paracolpium attaches the vagina laterally, to the arcus tendineus and fascia of the levator ani muscles (Level II). This attachment stretches the vagina transversely between the bladder and the rectum. The structural layer that supports the bladder (pubocervical fascia) is composed of the anterior vaginal wall and its attachment through the endopelvic fascia to the pelvic side wall. Similarly, the posterior vaginal wall and endopelvic fascia (rectovaginal fascia) form the restraining layer that prevents the rectum from protruding forward. The vagina’s lower third (Level III) fuses with the perineal membrane, levator ani muscles and perineal body, without any intervening paracolpium (Figure 11) [313, 317]. Damage to the upper suspensory fibres of the paracolpium causes a different type of prolapse from damage to the mid-level supports of the vagina. Defects in
the support provided by the mid-level vaginal supports (pubocervical and rectovaginal fascia) result in cystocele and rectocele, while loss of the upper suspensory fibres of the paracolpium and parame trium is responsible for the development of vaginal and uterine prolapse. These defects usually occur in varying combinations and this is responsible for the diversity of clinical problems encountered within the overall spectrum of pelvic organ prolapse [313].

For conceptual purposes the supportive connective tissue has been related to structural elements of the pelvic floor: the uterosacral ligaments (level I); the paravaginal attachments (endopelvic fascia) that connect the lateral vaginal walls to the arcus tendineus fasciae pelvis (ATFP) and the fascia of the levator ani muscles (level II); the perineal membrane and the perineal body (level III) [317]. Table 1 lists the structural elements of pelvic organ support, their possible damage and subsequent site of pelvic organ prolapse.

The integrity of muscular, connective and nerve structures is essential to guarantee normal pelvic organ support. If one of these factors fails, the other might be able to compensate to a certain degree.

In an American gynaecological clinic population (18-83 years), approximatively 3-6% of women had pelvic organ prolapse descending beyond the vaginal opening on routine pelvic examination [319]; an estimated 11% of women will undergo surgery for pelvic organ descent and urinary incontinence sometime in their lifespan [320].

The aetiology of pelvic organ prolapse is thought to be multifactorial with contributions from both environmental and genetic risk factors. Environmental factors that contribute to POP include vaginal delivery, chronic increases in intra-abdominal pressure, obesity, advanced age and oestrogen deficiency [321, 322]. Evidence for a genetic contribution to pelvic organ prolapse has been found in family-based studies, candidate gene association studies, expression studies and linkage studies [323]. Table 2 lists anatomical and functional determinants of normal pelvic organ support. It also summarises the possible nature of failure and its potential causes as well as the established and theoretical risk factors.

Vaginal delivery has been considered the main causal factor in the development of pelvic organ prolapse for some years [112, 320, 324-327]. However, if it is true that all women undergo pelvic floor stretching during vaginal delivery, not all of them develop a further prolapse; moreover, pelvic floor dysfunction has also been described in women who gave birth by caesarean section only [112, 322] and in nulliparous women [328]. Therefore, vaginal delivery does not totally explain the origin and progression of pelvic floor descent in all women. This supports the hypothesis that other causes, besides obstetrics, are involved in the aetiology of pelvic organ prolapse: connective tissue deficiencies, genetic predisposition, sexual hormones, pregnancy, ageing, menopause, obesity, neuropathies, ethnicity and family history.

In the last decade, attention has increasingly focused on understanding the molecular basis of POP and the recognition of the potential molecular markers and their modulators in pelvic floor supportive tissues in order to identify women predisposed to develop POP.

1. INHERITANCE, GENETIC AND ETHNIC PREDISPOSITION

Several studies have recently focused their attention on the inheritable predisposition for pelvic organ prolapse.

In the large case-control study carried out by Chiafarino et al. [329], a higher risk of prolapse was reported in women whose mother (OR: 3.2; 95% CI: 1.1-7.6) or sister (OR: 2.4; 95% CI: 1.0-5.6) were affected by the same condition; their data support that first-degree family history of prolapse is a risk factor for POP.

Jack et al. [330] demonstrated that the risk of POP among siblings of young women (average age: 37 years) with stage III and IV POP was five times higher than in the general population. Genetic analysis of the inheritance pattern within these families showed that pelvic organ prolapse segregated in a dominant fashion with incomplete penetrance.
Table 1. Structural elements of pelvic organ support, their possible damage and subsequent site of pelvic organ prolapse. The levels of support and anatomical defects are derived from the anatomical studies of DeLancey [313, 317].

The recent findings of high concordance in the POP stage between nulliparous women and their parous sisters strongly support the hypothesis of a familial basis for POP. Buchsbaum et al. [331] investigated the role of familial factors in the development of pelvic organ prolapse by comparing the prevalence of this condition in nulliparous postmenopausal women and their parous sisters. By compartment, there was a 74.3% to 91.1% concordance in prolapse stage within sister pairs. In discordant sister pairs, the parous sister was found to have the more advanced prolapse 88% of the time. Based on these results, the authors conclude that a high concordance of pelvic organ prolapse in nulliparous and parous sister pairs suggests a familial predisposition toward developing this condition. However, vaginal delivery appeared to confer a risk for more advanced pelvic organ prolapse. LEVEL OF EVIDENCE: II-2.

Some studies have drawn attention to the role of familial factors in the development of pelvic organ prolapse by comparing the prevalence of this condition in nulliparous postmenopausal women and their parous sisters. Based on these results, the authors conclude that a high concordance of pelvic organ prolapse in nulliparous and parous sister pairs suggests a familial predisposition toward developing this condition. However, vaginal delivery appeared to confer a risk for more advanced pelvic organ prolapse.

LEVEL OF EVIDENCE: II-2.

Some studies have drawn attention to the incidence of pelvic organ prolapse amongst identical twins. In the larger Swedish twin registry of 3,376 monozygotic and 5,067 dizygotic female twin pairs, a greater twin similarity among the monozygotic twins was found, indicating the influence of a genetic component to the aetiology of pelvic organ prolapse. Genetic and non-shared environmental factors seemed to contribute equally to the development of pelvic floor disorders in these women, about 40% for each factor [332].

Buchsbaum et al. [333] even reported that vaginal delivery was not associated with clinically relevant differences in relaxation of the pelvic support system within four sets of postmenopausal identical twins with different parity status.

Genetic variants that run in families with an increased incidence of pelvic organ prolapse have been documented.

A recent study provides strong scientific evidence for a genetic contribution to pelvic organ prolapse: using a genome-wide association study, Allen-Brady et al. [334], demonstrated that 6 single-nucleotide polymorphisms (SNPs) are significantly associated with POP in high-risk familial case group participants. LEVEL OF EVIDENCE: II. Their results showed that two of the six SNPs are located within the genes ZFAT and COL18A1, both with Mendelian inheritance in man. The ZFAT has been found to play a transcriptional regulator role for immune regulation and apoptosis and, hence, may affect development of the muscle and connective tissue of the pelvic floor. The COL18A1 gene (precursor of the collagen XVIII) may play a role in the structural organisation of basement membranes. The other four SNPs identified are intergenic, but one of them is close to the ANTXR2 gene, which binds intravenously to collagen and laminin, suggesting that it may be involved in extracellular matrix adhesion. The authors identified at least three strong candidate genes for POP that warrant follow-up.

Recent data suggest a role of genetic influence in early onset of POP. In a family in which three generations of female relatives suffered from prolapse at a very young age, a polymorphism in the promoter of LAMC1 gene has been found that seems to increase the susceptibility to early onset pelvic organ prolapse, as an autosomal dominant transmission [335].

One study examined gene expression of structural proteins that are related to actin and myosin in five women with, and five women without, pelvic organ prolapse in the pubococcygeal muscle. Several genetic differences between subjects and controls with gene under- and overexpression were found [336].

In mice, HOXA11 has been identified as an essential gene for the development of the uterosacral ligaments [337]. In HOXA11-null mice, the uterosacral ligaments were absent. Women with POP might have weakened connective tissue due to changes in a signalling pathway involving HOXA11 [337].

Increasing evidence supports a genetic aetiology of POP, also with respect to abnormal extracellular matrix remodelling [338]. A genetic predisposition to POP specific to elastin metabolism was noted in the rodent model, in which genetic mutation of the LOXL1 or the fibulin-5 gene in mice are involved in the altered elastic fibre assembly and then in the pathogenesis of the pelvic prolapse [339]. Altered gene expression of elastin has also been described in women with POP [340].

Genetic screening would certainly be an essential future tool for identifying the woman at risk of developing POP and for refining the counseling of women deemed to be increased risk. The primary prevention tool could be the adaptation of mode of delivery in at-risk groups. These patients could also benefit from changing their management such as whether surgery should be considered early or late in the woman’s lifespan.

Race is another demographic factor that seems to be associated with the development of POP. Some studies reported that Hispanic and European women appear to be at higher risk for POP than those of African, Asian or other descent [319, 322, 326, 341, 342]. This is also supported by evidence suggesting that women of Asian descent have reduced inherent pelvic organ mobility. In a cadaveric study, Zacharin [343] reported that Chinese women have stronger and thicker pubourethral ligaments, endopelvic fascia and endopelvic attachment to the obturator fascia compared to Caucasian women. More recently, Dietz et al. [342] confirmed these results using pelvic floor ultrasound, showing that Asian women have significantly less pelvic organ mobility than Caucasian women both antepartum and postpartum.

In cohort analysis of 27,342 women, Hendrix et al. [326], confirmed previously reported differences between white and African-American women. Hispanic
women had the highest rate of uterine prolapse (OR: 1.24, 95% CI: 1.01-1.54) and an increased risk for cystocele (OR: 1.20, 95% CI: 1.05-1.36) but not rectocele (OR: 0.95, 95% CI: 0.82-1.11).

The reasons for these ethnic differences are unclear; however, some evidence indicates that African-American women have smaller pelvic outlets than those of European descent [344].

Other connective tissue deficiencies such as hernias may share common pathophysiological mechanisms with POP. In a group of 60 women with advanced prolapse, the total prevalence of hiatal and inguinal hernias was significantly higher than in a control group of 60 women with mild or no prolapse (31.6% vs. 5%, p<0.001) [345].

A population-based, cross-sectional study of 5,489 Stockholm women found an OR of 1.8 for a positive association with symptomatic prolapse in women with a history of conditions suggestive of deficient connective tissue (varicose veins/hernia/haemorrhoids) [346].

McLennan et al. [347] demonstrated that the risk of prolapse was 1.4 (95% CI 1.2-1.8) times higher in women with a family history of prolapse and/or hernia, after adjusting for vaginal deliveries, hysterectomy and incontinence. The authors confirm that heredity is a risk factor for prolapse and suggest that history taking should include both male and female family members.

Taken together, this evidence suggests that there is a familial or genetic basis for POP in some women, and that heritable or genetic factor play a role in its development.

2. ALTERATION OF COLLAGEN, ELASTIN AND SMOOTH MUSCLE OF THE VAGINAL AND SUPPORTIVE TISSUE.

It has been demonstrated that young women with POP are more likely to have connective or neurological tissue diseases and congenital abnormalities [348].

Women with Marfan or Ehlers-Danlos syndrome have high rates of POP. Intrinsic joint hypermobility is another well recognised connective tissue disease that is associated with pelvic descent [349-352]. This finding supports the hypothesised aetiological role of connective tissue disorders as a factor in the pathogenesis of this conditions [353].

The vaginal wall is comprised of four layers: a superficial layer of non-keratinised stratified squamous epithelium; a subepithelial dense connective tissue layer composed primarily of collagen and elastin; a layer of smooth muscle referred to as the muscularis; and a layer of adventitia, composed of loose connective tissue. The subepithelium and muscularis together are thought to confer the greatest tensile strength to the vaginal wall. In the normally supported vagina, the supportive connective tissues pull the vagina up and back away from the vaginal introitus over the levator ani muscles. A normally supported vagina, in turn, provides support to the bladder, urethra, uterus and rectum. Disruptions of - or damage to - these connective tissue structures and injury to the vaginal wall are thought to be two important mechanisms causing prolapse.

The connective tissue of the vagina and supportive tissues contains a fibrillar component (collagen and elastin) and a non-fibrillar component (non-collagenous glycoproteins, hyaluronan, and proteoglycans). In addition, and with the exception of the arcus tendineous, these tissues contain a significant amount of smooth muscle. The fibrillar component is thought to contribute the most to the biomechanical behaviour of these tissues. The quantity and quality of collagen and elastin are maintained through a precise balance between synthesis, post-translational modification, and degradation.

Therefore, the integrity of the vagina and its supportive connective tissues are essential for keeping the pelvic organs in their normal anatomic position. Evaluation of these tissues from a biochemical perspective enables us to better discern the complex interplay between structural composition and supportive capacity.

Collagen types I, III and V are the main structural components of vaginal epithelium and endopelvic fascia and they are thought to be the principal determinants of tissue strength. Type I collagen confers strength to tissues while type III contributes to elasticity. Type III collagen is the primary collagen subtype in the vagina and its supportive structures. The ratio of collagen I to III is an indicator of tensile strength: the higher the amount of collagen type III, the lower is the mechanical strength. To our knowledge the role of type V collagen, which is found in small quantities in the vagina, is still unknown.

The turnover of connective tissues throughout the body is maintained by a family of highly conserved, zinc-dependent endopeptidases referred to as matrix metalloproteinases (MMPs). The MMPs are involved in both normal physiological and pathological proteolytic processes, which are an integral part of tissue remodelling in both women with and without prolapse. An excessive tendency towards connective tissue degradation may underlie the predisposition of some women to prolapse.

Interstitial collagens (types I, II and III) are cleaved by MMP-1, 8 and 13. The cleaved collagen fragments are susceptible to rapid gelatinase (MMP-2 and 9) degradation into amino acids. These gelatinases (MMP-2 and 9) also degrade elastin.

Reports of decreased total collagen in pelvic tissue from women with POP suggest that collagen degradation may contribute to POP. Collagen degradation depends on the activity of MMPs produced by connective tissue cells. MMP proteolytic activity is specifically regulated by their inhibitors, TIMPs, which
bind stoichiometrically to MMPs to inhibit their activity. The balance between MMPs and TIMPs defines the collagenolysis.

In women with prolapse, MMP-2 mRNA expression is increased with a concurrent decrease in the inhibitor TIMP-2 [354]. Recent data also indicate increased MMP-1 expression and decreased collagen I in the uterosacral ligaments of women with POP [355]. In contrast, collagen I and III mRNA expression was increased in vaginal tissue from women with POP [356]. Discrepancies in the literature can be due to the different methodological issues (different tissues targeted or a different method of protein quantification) used. Mismatches between mRNA and protein data are often found when examining proteins in the extracellular matrix. Thus, gene expression should always be confirmed with protein expression. These issues contribute to significant variations in the reported data and underscore the importance of careful research methodology. These discrepancies also suggest the possibility that different pathways in the extracellular matrix may be activated depending on injury type and severity, mechanical load and environmental factors [338].

Despite discrepancies in the precise MMP/TIMP or collagen type, the reported data and numerous other publications indicate that women with POP show an abnormal pelvic extracellular matrix metabolism with increased collagen remodelling.

Takano et al. [357] demonstrated that the general amount of collagen in the parametria is reduced in pre- and postmenopausal women with pelvic organ prolapse compared with women without prolapse. Moalli et al. [358] showed that collagen III is increased in vaginal subepithelium and muscularis in patients with prolapse relative to patients without prolapse, independent of age and parity. LEVEL OF EVIDENCE II-2. Increase in collagen III has also been reported in the uterosacral and cardinal ligaments of women with prolapse [359, 360]. The Moalli’s group [361] demonstrated that collagen III is the primary subtype in the arcus tendineus fascia pelvis; a decrease in the ratio of collagen I/(III+V) is associated with menopause in the absence of hormone therapy and a restoration of this ratio to premenopausal levels with hormone therapy. From these data the authors suggested that sex steroid hormones may improve the biomechanical properties of the supportive tissues of the vagina.

As all studies involving the procurement of human tissue are by necessity cross-sectional, it is impossible to determine whether the increase in collagen III reflects the causes or effects of prolapse. In either case, the increased flexibility and distensibility plus the decreased tensile strength associated with an increase in collagen III are likely to contribute to the progression of POP.

Elastin is primarily laid down during fetal development and rarely synthesised in adult tissues. In contrast to the other tissues in which elastin fibres do not experience a turnover in a lifespan, there is cyclical remodelling of elastin fibres in the reproductive tract. A massive degradation of elastin occurs at the time of parturition, followed by postpartum re-synthesis, allowing recovery of reproductive tissues to their pre-pregnancy state [362]. Mice deficient in LOX (lysyl oxidase) fail to replenish mature elastin fibres in the reproductive tract following parturition and develop spontaneous prolapse [363]. Yama-moto et al. [340] found a marked decrease in elastin mRNA and tropoelastin protein in the cardinal ligaments of women with pelvic organ prolapse relative to women without prolapse. Chen et al. [364] demonstrated a significant decrease in the endogenous inhibitors of elastases with increase in elastolytic activity in vaginal tissue from women with stress urinary incontinence and pelvic organ prolapse compared with control subjects. Therefore, these data suggest that the proper degradation, synthesis, and regeneration of elastic fibres are essential for maintaining pelvic organ support.

If damaged or destroyed, metabolically repaired elastin frequently results in malformed and dysfunctional repair products. Proteolytic enzymes capable of degrading elastin include the serine proteases, such as neutrophil elastase, the cysteine proteases, and MMP-2, 9 and 12. Marked decreases in elastin gene transcripts and elastin synthesis in pelvic fibroblasts were noted in women with POP [340], suggesting that altered elastin metabolism may contribute to prolapse. In rodent models with genetic disruption to LOXL1 or fibulin-5 gene, prolapse develops due to failure to synthesise and assemble functional elastic fibres [363]. Elastin content was decreased in the uterosacral ligaments of women with POP, as were LOX, and LOXL1 and LOXL2 gene expression [365].

A recent study by Moon et al. [366], evaluated the alteration of elastin metabolism in women with pelvic organ prolapse in a prospective case-control study: their results showed that expression of neutrophil elastase and matrix metalloproteinase-2 mRNA was higher in women with than in those without POP. Compared to before menopause, neutrophil elastase and matrix metalloproteinase-2 showed a significant decrease in postmenopausal women without POP, although they remained increased in postmenopausal women with POP. Alpha-1-antitrypsin was significantly lower in postmenopausal women with pelvic organ prolapse than in postmenopausal women without. The activities of neutrophil elastase, matrix metalloproteinase-2 and matrix metalloproteinase-9 were increased in women with POP, and these trends were similar to neutrophil elastase and matrix metalloproteinase-2 expression even after adjusting for age, parity and menopausal status. This study demonstrates that after menopause increased elastolytic protease has a significant role in the development of POP.
The strongly heritable connective tissue diseases, in which pelvic organ prolapse predominates as a result of an elastinopathy, highlight the importance of elastic fibres for maintaining vaginal support. Marfan’s syndrome, characterised by mutations in the fibrillin-1 gene, and cutis laxa with mutations in the elastin and fibrulin-5 genes, are notable for an increased incidence of POP in affected women [367-370].

Childbirth is an important risk factor for POP, not only for the mechanical trauma that the pelvic floor is submitted to: inflammatory pathways are activated during the complex process of tissue healing after birth trauma. During healing proteinases, growth factors such as TGF-β, cytokines and chemokines are secreted into the extracellular matrix by surrounding cells. TGF-β is one of a family of 25 kDa polypeptide growth factors that is currently viewed as the most important fibrosis promoting cytokine. It is responsible for extracellular matrix synthesis in fibroblasts, the differentiation of fibroblasts to myofibroblasts and the inhibition of matrix degradation by inhibiting MMP expression and up-regulating TIMP expression. Thus, it is important in extracellular matrix metabolism and affects tissues or organs in various ways. There is sparse but growing evidence of TGF-β modulation in pelvic connective tissue. Large quantities of TGF-β1 are stored in readily available form in the extracellular matrix. Release and activation of stored latent TGF-β1 by proteases can generate rapid, highly localised signals. Therefore, the modulation of TGF-β1 activity by extracellular proteases provides faster signal transduction than alterations in gene expression. This is important for tissue remodelling during pregnancy and repair after birth trauma [338].

3. NEUROLOGICAL FACTORS

Integrity of the pelvic innervation is essential for normal pelvic function. The changes in neurophysiological parameters seen after childbirth were interpreted to reflect neuromuscular injury caused by forces exerted on the sacral plexus, pudendal nerves, and pelvic floor muscles.

Abnormal findings have also been found in women with prolapse or stress incontinence. Histologically, there were smaller and fewer nerve bundles in women with posterior vaginal wall prolapse compared with women without prolapse [371]. It has been demonstrated that the density of peptide-containing nerves in the periurethral tissue and in the levator ani muscle in women with prolapse is reduced [372, 373].

Between 1985 and 1987, Allen et al. [177] found that 80% of primigravidae developed evidence of partial denervation of the pelvic floor following delivery. However, evidence of reinnervation and increased fibre density 2 months after vaginal delivery has been detected [177, 374]. Snooks et al. investigated 14 multiparous women from their previous studies [176, 374] 5 years after first vaginal delivery and demonstrated that pelvic floor striated sphincter muscle denervation progressed, indicating that age is a contributory factor [178]. Similarly, progressive denervation with time up to 15 years postpartum was found in another prospective study, corroborating the ageing factor [375].

The pudendal nerve innervates the voluntary urethral and anal sphincters, but it does not innervate the levator ani muscles, which receive their own nerve supply from the sacral plexus. Therefore, there is currently no clear evidence whether the neurological damage is responsible, together with the mechanical damage of stretching, for the visible levator defects.

Information from electrodiagnostic studies has demonstrated that birth causes changes in mean motor unit duration after vaginal birth and changes in pudendal nerve conduction patterns [177, 178, 376-378]. Prolongation of the pudendal nerve terminal motor latency (PNTML) is thought to be a result of pudendal nerve damage during vaginal delivery. Significantly prolonged mean PNTML’s have been found in women two to three days after vaginal delivery, compared to a multiparous [176] and a nulliparous control group [374]. At follow-up five years later, prolongation of PNTML persisted [178]. Two prospective analyses demonstrated a prolongation of PNTML antenatally to six to eight weeks after vaginal delivery, particularly after the first delivery [379, 380]. But, again, many of these changes seem to be temporary, as two-thirds of the women with an abnormally prolonged PNTML after delivery had normal measurement six months later [379].

Little recent electrophysiological work has been added to the literature, probably due to the technical difficulty of the nerve function tests in clinical practice.

Although it has not been proved in studies, it is reasonable to assume that periods of pain and discomfort after childbirth (e.g., perineal tears and episiotomy) and especially pain related to attempted PFM contraction could lead to a temporary nonactivation of the PFM. This could be the origin of disturbances in behavioural patterns, which would need to be re-adjusted. In combination with a particularly vulnerable pelvic floor neural control, whose complexity only evolved phylogenetically after the attainment of the upright stance, such a temporary disturbance of neural control after childbirth may persist, although the pelvic tear(s) resulting from vaginal delivery would have fully recovered.

Therefore, the effects of vaginal delivery on pelvic floor nerves are still controversial. While it seems logical that vaginal delivery causes some neuromuscular injury which would predictable to the development of pelvic organ dysfunction, many details are uncertain.
4. PREGNANCY AND PELVIC FLOOR MUSCLE REMODELLING

Several of the changes occurring prior to delivery are in all likelihood normal physiological changes and may be secondary to hormone-induced collagen alterations. Hormonal alterations are essential to prepare the body and to adjust the musculature and connective tissue for vaginal birth.

The high progesterone levels during pregnancy influence the pelvic floor structures: progesterone has smooth muscle-relaxing and oestrogen-antagonising effects, reducing the tone in the ureters, bladder and urethra [381].

Relaxin, increases markedly during pregnancy and it modifies the connective tissue: its collagenolytic effect, that allows appropriate stretching during vaginal birth, has been demonstrated in guinea pigs [382]. As a likely result of connective tissue remodelling in preparation for birth, Landon and colleagues found that the connective tissue of the rectus sheath fascia and the obturator fascia could be stretched to greater length during pregnancy, but it is also much weaker. In some women, these changes may be irreversible and further stretching beyond physiological limits may result in permanent dysfunction [383].

Recently, several studies have focused on the effect of pregnancy on the pelvic floor and on the development of prolapse.

Rahn et al. [384] identified pregnancy-induced changes in biomechanical properties of the vaginal wall and compared these with fibrin-5 knockout mice (Fbn5−/−) with and without prolapse. Compared to nonpregnant mice, vaginas of pregnant and Fbn5−/− (with prolapse) mice exhibited decreased maximal stress, increased distensibility and strain, plus decreased stiffness. Tissues from Fbn5−/− mice without prolapse were similar to non-pregnant animals. The authors concluded that pregnancy confers remarkable changes to the vaginal wall that include increased distensibility, decreased stiffness and maximal stress. Elastinopathy alone is insufficient to cause significant changes in these properties, but prolapse confers additional alterations in distensibility and stiffness that are similar to those changes that have been observed in pregnancy. These changes may contribute to the poor durability of many restorative surgical procedures for prolapse.

The effect of pregnancy on the development of pelvic organ prolapse was evaluated by O’Boyle et al. [385]: in a series of 135 nulliparous pregnant women, POPQ stage appears to increase during pregnancy and does not change significantly following delivery. POPQ stage assignments and POPQ component measurements were compared for first-, second- and third-trimester examinations. Overall, POPQ stage was significantly higher in the third trimester than in the first. These findings probably represent normal physiological changes of the pelvic floor during pregnancy, but suggest that significant changes may be objectively demonstrated prior to delivery. In nulliparous women, pregnancy is associated with increased POPQ stage compared with non-pregnant control subjects [386].

Sze reported that 46% of 94 nulliparous women had pelvic organ prolapse at their 36-week antepartum visit. Of them, 26% had a stage II prolapse [387].

5. CHILDBIRTH

Undoubtedly, vaginal delivery constitutes a traumatic event for the pelvic floor: it may affect the pelvic nerves, the pubococcygeus-puborectalis muscle complex, the pelvic fascial structures or the anal sphincter. However, all women sustain trauma to their pelvic floor during vaginal birth, but only some experience long term injury.

Several attempts have been made to define fascial trauma after vaginal delivery. In the anterior compartment, childbirth may result in disruption of the ‘endopelvic fascia’, in particular of paraurethral and paravaginal structures. Analogous to increased bladder descent after childbirth, there is a highly significant increase in caudal displacement of the rectal ampulla after childbirth [388]. The rectovaginal septum and Denoviller’s fascia are the connective structures involved in the posterior compartment damage that appears as a rectocele. It has recently been shown that vaginal childbirth also results in an increased prevalence of true rectoceles, i.e. presumed defects of the rectovaginal septum [389]. Such defects are strongly associated with symptoms of pelvic organ prolapse and obstructed defaecation [390].

Specific features of injury during vaginal birth influence whether a woman develops prolapse later in life. Several factors, that can be grouped together as descriptors of difficult vaginal delivery, are associated with increased occurrence of prolapse: forceps delivery, a prolonged second stage of labour, and large infant birth weight. Unfortunately, because of the overlapping nature of these different factors, it is difficult to determine which of them is causal and which of them is associated (e.g., forceps delivery is used when there has been a prolonged second stage of labour, and both of these factors increase in large-sized infants).

The role of childbirth in causing damage to the levator ani muscle (LAM), which is associated with both vaginal delivery and with pelvic organ prolapse, is probably the mediating mechanism in these injuries. Recent investigations using techniques such as magnetic resonance imaging (MRI) and three-four dimensional ultrasound have focused on the morphology of the levator ani complex and its integrity after delivery.

The occurrence of levator trauma postpartum is reported to be between 15-39.5% with ultrasound [151-157] (Figure 12) and between 17.7%-19.1% with MRI [159-161].
Figure 12. Levator ani defect early postpartum in a patient had spontaneous vaginal delivery (acquisition screen GE Voluson-e ® System).
A. In the multiplanar mode, the axial plane (lower left) and the rendered image (lower right) show an unilateral levator discontinuity (**) on the right side of pubococcigeal-puborectalis muscle.
B. Eight slices obtained with TUI in coronal-C plane in the same patients: the discontinuity (arrow) is demonstrated in at least three consecutive slices at and above the plane of minimal hiatal dimension (frames *, -1, -2, -3).
From Albrich et al, BJOG 2011 [156]
An observational study in women 2–4 weeks before and 2–6 months after vaginal childbirth provided direct proof for the hypothesis that childbirth is responsible for certain morphologic abnormalities of LAM observed in parous women and suggests that older age at first delivery is a risk factor for such trauma. LEVEL OF EVIDENCE II-3 [155].

To estimate the risk of prolapse associated with levator avulsion injury among a urogynaecological clinic population, Dietz et al. [165] retrospectively considered 781 women, with a mean age 53 years (range 15–89 years), and a median parity of 2 (range 0–12). Significant prolapse (stage II or higher) was diagnosed in 415 (53%) women, and 181 (23%) women were found to have levator avulsion defects. Prolapse was seen in 150/181 (83%) women with avulsion and in 265/600 (44%) women without avulsion, giving a RR of 1.9 (95% CI: 1.7-2.1). The association was strongest for cystocele (RR 2.3, 95% CI: 2.0-2.7) and uterine prolapse (RR 4.0, 95% CI: 2.5-6.5). The authors concluded that women with levator avulsion defects were about twice as likely to show pelvic organ prolapse of stage II or higher than those without, with an increased risk of cystocele and uterine prolapse.

Pelvic organ prolapse seems considerably lower after caesarean section [112, 344] but it has been described in prospective study in 35% of 26 women after caesarean section during active labour compared to 32% of 41 women who had spontaneous vaginal deliveries [387]. On the other hand, one epidemiological study using validated questionnaires negated the influence of labour versus no-labour caesarean delivery on pelvic organ prolapse [391] LEVEL OF EVIDENCE: II-2. Recent studies [156, 158] reported cases of early levator abnormalities after emergency caesarean section, and hypothesised a possible role of active labour in the occurrence of lesions damage to the pelvic floor muscle.

A recent study by Leijonhufvud et al. [113] considered a cohort of women having their first and all subsequent caesarean deliveries (n = 33,167), and an age-matched sample of women having only vaginal deliveries (n = 63,229). Women who had only vaginal deliveries had an overall increased risk for prolapse surgery (HR, 9.2; 95% CI: 7.0–12.1) compared with women who only had cesarean deliveries. They concluded that having only vaginal deliveries was associated with a significantly increased risk of pelvic organ prolapse surgery later in life compared to having caesarean deliveries.

There seems to be sufficient proof for the hypothesis that pelvic organ support can be impaired by vaginal delivery. It is unclear whether this effect is due to stretching or avulsion of structures and whether the observed changes are primary (i.e. directly due to childbirth) or the medium-term or long-term consequence of levator impairment. Several mechanisms may well coexist in one individual [392].

Furthermore, it has been shown that any delivery-related changes occur against the background of marked variations in pelvic organ support in young nulliparous women [393]. As the most significant changes are observed in those with the least organ mobility antenatally [394], the effect of childbirth may be a partial equalisation of those interindividual differences.

6. OBSTETRIC AND MATERNAL FACTORS

Increasing vaginal parity was the strongest risk factor for pelvic organ prolapse in women younger than 60 years in the Oxford Family Planning Study [325]. Compared with nulliparous individuals, the relative risk of developing prolapse was 8.4 for a woman who had delivered two children and 10.9 (95% CI: 4.7–33.8) for someone with four or more children [325]. The Women’s Health Initiative reported that single childbirth was associated with raised odds of uterine prolapse (OR 2.1; 95% CI: 1.7–2.7), cystocele (OR 2.2; 95% CI: 1.8–2.7), and rectocele (OR 1.9; 95% CI: 1.7–2.2) [326]. Every additional delivery up to five births increased the risk of worsening prolapse by 10–20% [326]. Similarly, the Progetto Menopausa Italia study showed that the risk of pelvic organ prolapse rose with increasing parity [395].

Caesarean section seems to protect against prolapse development whereas forceps delivery increases the risk [391, 396]. Findings of a cross-sectional study of 3050 women randomly selected from a large southern California Health Maintenance Organisation showed that women who had undergone one or more vaginal deliveries had a significantly greater risk of developing symptomatic pelvic organ prolapse than did those who had only caesarean sections (OR 3.21; 95% CI: 1.96–5.26), after adjusting for age, parity, and obesity [391]. The attributable risk of vaginal delivery for development of symptomatic prolapse, or the proportion that could have been prevented with a policy of routine elective caesarean section, was 46% in this population. LEVEL OF EVIDENCE: II-2 [391].

Other obstetric factors that have been associated with an increased risk of pelvic organ prolapse, albeit less consistently, are high infant birth weight (>4500 g), vaginal delivery of a macrosomic infant, prolonged second stage of labour, and age <25 years at first delivery [396, 397]. Somewhat more controversial is whether pregnancy itself, distinct from mode of delivery, alters the risk of pelvic organ prolapse. In a small case-control study, pregnancy was associated with worsening prolapse compared with non-pregnant controls matched for age and ethnic origin [386]. A substantial proportion of pregnant nulliparous women show progression from stage 0 or I support in the first trimester to stage I or II in the third trimester [385]. This loss of vaginal support does not seem to return to baseline in the postpartum period.

To date, the studies are controversial considering younger age (25 versus 28 years of age) [396] as well as older age (more than 30 years) [398] at first delivery as a risk factor for the development of pelvic organ prolapse. Another large study did not reveal an association at all [322].
Despite the strong relationship between obstetric factors and pelvic organ prolapse, most cases of symptomatic cases arise a long time after vaginal childbirth, and most women who bear children do not have symptomatic prolapse [399].

7. AGE

Both incidence and prevalence of pelvic organ prolapse increase with advancing age. In a cross-sectional study of 1004 women (age 18–83 years) who attended for their yearly examination, the relative prevalence of this disorder rose by about 40% with every decade of life [319]. In the Women’s Health Initiative, American women aged 60–69 years (OR 1.2; 95% CI: 1.0–1.3) and 70–79 years (OR 1.4; 95%CI: 1.2–1.6) had a higher risk of prolapse than did those aged 50–59 [326]. Similarly, findings of a cross-sectional study of 21449 menopausal Italian women showed an augmented risk of pelvic organ prolapse in women aged 52–55 years (OR 1.3; 95% CI:1.1–1.5) and those 56 years or older (OR 1.7; 95%CI: 1.5–2.0) compared with those younger than 51 years [395]. Surgery for prolapse is uncommon in women younger than 30 and older than 80 years; for women between these ages, the incidence rises steadily [320].

8. HORMONES

As age has been clearly shown to affect the prevalence and progression of POP, it is intuitive to believe that declining sex hormone levels observed with ageing may contribute to biochemical changes observed within tissue. However, several researchers studying hormonal status and prolapse have failed to find an association between oestrogen status and prolapse [325, 329, 344, 395].

The female lower urinary tract is a target organ for the action of the two sex steroid hormones, oestrogen and progesterone.

Steroidal hormones exert their effect on tissue through an interaction with specific intracellular receptors. Hormone receptor affinity may be at the root of the differences between women with pelvic floor diseases and normal controls. Progesterone receptors have been found to have greater expression in women with POP than in women without POP [400]. Several polymorphisms are present in the progesterone receptor gene that can alter its expression. A specific genotype (PGR rs484389) was significantly associated with the risk of having POP in a multivariate analysis [401]. Similarly, the oestrogen receptor β gene also contains multiple single nucleotide polymorphisms that affect its expression. A case-control study of 69 women with POP and 141 control subjects found that a specific haplotype for the oestrogen receptor β gene was associated with an increased risk of POP [402].

Studies have shown lower serum oestradiol (E2) levels in premenopausal women with SUI, with [403] and without concurrent POP [404], compared to control subjects. The impact of oestrogen on tissue may be related to its systemic or local levels, or altered sensitivity from a decreased number of receptors noted in genitourinary tissues [403, 405].

Skala et al. [406], evaluated the expression of oestrogen receptor (ER) alpha (α) and beta (β) and progesterone receptor (PR) in vaginal and periurethral tissue in women with genital prolapse. The expression of PR and ER varied with the extent of prolapse. For patients with prolapse >stage 1 (n=32), there was a significantly greater amount of PR in periurethral tissue (p=0.007) and a significantly lower expression of ER β in vaginal tissue (p=0.008) compared to patients with a low stage prolapse (n=15). Patients with stage II and III prolapse did not differ in their receptor expression. The authors concluded that the expression of PR in periurethral and ER in vaginal tissue varied with the extent of prolapse.

The current status of the literature suggests a hormonal impact on pelvic floor disorders, although the weak level of evidence emphasises the necessity for future research endeavours in this field to elucidate these complex relationships.

9. OBESITY

Increasing body-mass index also seems to have a role in the development of pelvic organ prolapse. An high BMI increases the risk of prolapse [319, 325, 396, 407, 408] and specifically for progressive rectoceles [409]. Increased waist circumference was associated with more pelvic organ prolapse in some studies [344, 409]. Handa et al. [409] demonstrated this for cystoceles. Women who are overweight (body mass index 25–30 kg/m²) and obese (>30 kg/m²) are at high risk of developing pelvic organ prolapse [326, 397]. Similarly, women with a body mass index of more than 26 kg/m² are more likely (OR 3.0; 95%CI: 1.6–5.7) to undergo surgery for prolapse than are those with a lower value [396].

10. CONSTIPATION

Repetitive straining, such as that seen in patients with chronic constipation or workers whose jobs entail heavy lifting, has also been associated with pelvic organ prolapse. Spence-Jones et al. [410] reported that straining at stool as a young adult was more typical in women with prolapse than in those without the disorder (61% vs 4%; p<0.001). Individuals with stage II or greater pelvic organ prolapse had an increased risk of constipation (OR 3.9; 95% CI: 1.4–11.9) compared to women with stage 0 or 1 prolapse [411]. However, findings of larger studies have disputed this association, and several groups have shown that neither overall stage of prolapse nor stage of the posterior vaginal wall correlate with bowel function [412-414]. Additionally, women with only urinary incontinence and no prolapse seem to meet Rome II criteria for constipation with the same frequency as those with advanced pelvic organ prolapse [414].
11. CHRONIC PELVIC FLOOR STRESS

Low socioeconomic status [415] and a labour-intensive occupation [329, 415, 416] are two demographic factors identified as risk factors for the development of POP.

Housewives, who perform more physically demanding work seem more likely to have prolapse (OR: 3.1; 95% CI: 1.6–8.8) than do professional managerial women [329]. Similarly, people with occupations involving heavy lifting might have a higher chance of undergoing surgery for pelvic organ prolapse [416].

12. PREVIOUS OPERATIONS

Although hysterectomy might increase the risk of subsequent POP, prolapse symptoms typically develop many years after this procedure [320, 325, 396, 417, 418]. In the Oxford Family Planning Study, surgical incidence for prolapse in women who had undergone a previous hysterectomy was 29 per 1000 women-years versus 16 per 1000 women-years for the entire cohort [325]. The cumulative risk of surgery for pelvic organ prolapse rose from 1% at 3 years after hysterectomy to 5% at 15 years. Risk was highest in women who had undergone a previous hysterectomy for prolapse (158 per 1000 women-years). In a prospective cohort study of 149,554 women aged 20 and older, the mean interval between hysterectomy and surgery for pelvic organ prolapse in those who developed the disorder was 19.3 years [320, 419]. Contrary to findings of many other studies, the prevalence of prolapse in women with a uterus in the Women’s Health Initiative was slightly higher than for those who had undergone hysterectomy, suggesting that previous prolapse of pelvic organs might have been repaired at the time of the procedure in this study population [326]. The surgical technique performed during hysterectomy, including performance of prophylactic culdoplasty, can lessen the development of a subsequent prolapse [420].

13. THE BONY PELVIS

There is evidence from several case control studies that variations in axial and pelvic skeletal structure can be associated with increased POP risks. These include increasing severity of thoracic kyphosis, a decrease in lumbar lordosis and in vertical orientation of the pelvic inlet, and an increase in the transverse diameter of the pelvic inlet [421-423]. In a case control study, Handa [424] compared 59 women with pelvic floor disorders with controls using standardised pelvimetry techniques during MRI. After controlling for age, race and parity and using a multiple logistic regression analysis, pelvic floor disorders were significantly associated with a wider transverse inlet (OR 3.4) and a shorter obstetrical conjugate (OR 0.23). The association between young age, advanced stage POP and severe disruption of pubic bone and pelvic muscle structure in women with bladder exsanguine is well recognised [425].

14. ASSOCIATED PELVIC FLOOR CONDITIONS

During a woman’s lifespan, the pelvic floor is responsible for urinary and the faecal continence as well as for sexual function. If the anatomy of the pelvic floor is altered, each one of these functions may be compromised. Pelvic organ prolapse is a common condition that often leads to lower urinary tract symptoms (LUTS) and may require surgical intervention to alleviate those symptoms. Therefore, the clinical evaluation of women with POP symptoms also requires the assessment of urinary and faecal incontinence symptoms as well as of sexual disorders. Physicians, who examine women seeking care for one condition, should inquire about symptoms of other disorders.

The relationship between LUTS and pelvic organ descent however, is not completely understood.

In a recent study, Costantini et al. [426] evaluated the correlation between LUTS and POP. They retrospectively reviewed 256 patients presented with POP and LUTS and underwent POP surgery. Most of 50% of patients reported two or more symptoms and only 4.2% had no LUTS. 73.8% patients had voiding symptoms, 15% urodynamic detrusor overactivity, 5% suffered from hydronephrosis. 57.8% had SUI. The authors concluded that urologists and gynaecologists should be aware of the high frequency of the association between POP and LUTS. POP repair may restore normal anatomy but LUTS may continue following surgery or develop “de novo.”

a) Bladder function

In a large community-based questionnaire survey, 44% (104/239) of women who had prolapse symptoms (239/3799) also complained of SUI and 37% of overactive bladder [427].

SUI can be functionally masked by POP. SUI may be uncovered by POP surgery and clinically continent women are at risk of developing symptomatic postoperative SUI. Many agree on the importance of preoperative urodynamic assessment with the prolapse reduced to assess potential occult SUI and detrusor overactivity. Preoperative identification of occult (and overt) SUI will facilitate the decision making by the surgeon and counselling of the patient regarding the possibility of an anti-incontinence procedure after prolapse repair or, in some specific cases, even at the same time.

Evidence of reduced peptide-containing innervation of perineal and periurethral muscles in women with SUI and POP has emerged [364], suggesting a neural abnormality in their pathogenesis. Connective tissue alterations such as decreased a-1 antitrypsin expression and altered elastin metabolism [364], decreased collagen concentration [428], and decreased oestrogen receptors [405, 429] have been described in women with urinary incontinence and/or POP.

Failure of bladder, bladder neck, and urethral support is often part of a more extensive defective
pelvic organ support. Poor pelvic organ support can lead to pathological pelvic relaxation in one or more compartment(s). Marinkovic and Stanton [430] published a review of 97 articles regarding incontinence and voiding difficulties associated with POP: they described the incidence, pathophysiology, anatomical changes and resultant consequences, evaluation and imaging of cystocele, rectocele, enterocele, and ureter and vaginal vault prolapse in combination with urinary incontinence. The authors concluded that POP appears to have significant clinical effects on urethral and voiding function that should be quantified preoperatively to allow appropriate surgical intervention, with the aim of restoring vaginal function and correcting concurrent incontinence, whether overt or occult. Not uncommonly, POP can lead to bladder outlet obstruction, detrusor overactivity, and latent SUI that is unmasked only with reduction of the POP (potential, latent, or unmasked SUI) [431]. It is recognised that POP surgery can improve voiding dysfunction and unmask occult SUI by alleviating the urethral kinking causing outlet obstruction [432].

Burrows et al. [433] described symptoms of bladder, bowel, and sexual function in 330 women with POP, comparing different degrees of prolapse staged by the POP-Q system. Women with SUI symptoms had less advanced prolapse (median 5 cm less prolapse in the apical compartment) than those without SUI. Women who needed to manually assist micturition had more advanced prolapse (median 3.5 cm more prolapse in the most severe compartment) than those who did not. Women with urgency and urgency incontinence had less advanced prolapse (median 3 cm or less) but the differences were smaller than those for SUI. Severity of prolapse was not associated with bowel or sexual symptoms in this study. The most important finding was that there are few strong associations between specific symptoms and severity of prolapse. LEVEL OF EVIDENCE: II-2.

Women without anterior prolapse on POP-Q exam rarely (<10%) report urinary splinting (digitally reduction of prolapse to aid with voiding) but ranged between 23 and 36% for stage III and IV. Urinary splinting is 97% specific for anterior prolapse. Seventy-seven percent of women with stage II POP report a symptomatic bulge, and report of a bulge has an 81% positive predictive value and a 76% negative predictive value [434]. It seems therefore that if women present with symptoms of vaginal/perineal bulge, then careful assessment for POP is warranted. However a woman with SUI, presents with no symptoms of POP, then surgical treatment of asymptomatic and incidental anterior POP is not indicated.

The surgical management of women with POP and with latent SUI remains controversial and challenging. Maher et al. [435] aimed to determine the effects of surgery in the management of POP by searching the Cochrane Incontinence Group trials register (as of June 2004) for randomised or quasi-randomised controlled trials that included surgical procedures for POP. The metaanalysis on the impact of POP surgery on continence was ‘limited and inconclusive’, but they reported that 10% of women developed new incontinence symptoms postoperatively.

Levin et al. [436] prospectively evaluated 313 women who underwent a TVT procedure for overt (228 women) or occult (85 women) SUI. About 50% women also underwent POP surgery concurrently. Overall, for 241 women with at least a follow-up of 12 months, 6.6% had persistent mild SUI, an additional 7% had urodynamic evidence of asymptomatic sphincter incontinence, whereas 8% developed de-novo urgency incontinence.

Among 130 women who underwent surgical treatment for an enterocele (75% the vaginal wall protruded through the introitus), 77% presented with SUI or detrusor overactivity. Sixty-seven percent of patients underwent Burch colposuspension with enterocele repair. Postoperative SUI requiring further treatment occurred in 10% after a mean period of follow up of 10 months, and cystocele developed in 1.5% [437].

Urologists and urogynecologists are faced with the challenge of determining which women with POP associated with SUI will benefit from concurrent surgical intervention for the POP. A comprehensive and anatomic approach to pelvic floor reconstruction is recommended, but no high-level evidence-based studies exist in the contemporary literature.

The intended goal of surgical correction of SUI and POP is durable restoration of normal anatomy and function, with symptomatic relief and avoidance of morbidity. At present, few evidence-based conclusions can be drawn about when to surgically intervene for SUI in women who present with POP. The available contemporary studies are few with a small number of patients; however, it seems prudent to recommend repairing symptomatic POP in women who present with SUI. So far, routine performance of anti-incontinence procedures at the same time as reconstruction of the anterior compartment does not seem to be justified by the current evidence. In women with symptomatic SUI and incidental, asymptomatic POP, one must balance any potential treatment associated morbidity with the intended clinical/surgical outcome.

Recently, Ramanah et al [438] compared changes in urinary symptoms before and after POP surgery, using either laparoscopic sacrocolpopexy (LSC) or transvaginal porcine dermis hammock placement with sacrospinous ligament suspension (VS). Out of the 151 patients included, 87 patients underwent LSC, and 64 VS. Overall, after a median follow-up of 32.4 months, POP surgery improved urinary frequency ($P = 0.006$), voiding difficulty ($P = 0.001$), stress urinary incontinence ($P = 0.001$), but not urgency ($P = 0.29$). VS was more effective in treating SUI ($P < 0.001$ vs. 0.52) while LSC more effective for voiding difficulty ($P = 0.01$ vs. 0.08). Postoperative de novo symptoms were observed in 35.8%
of patients with no difference between the groups (P = 0.06). UDI (P = 0.04) and UIQ (P = 0.01) scores were significantly lower after surgery. However, LSC significantly improved UDI (P = 0.03) with no effect on UIQ (P = 0.29) scores while VS significantly improved both scores (P = 0.02 and 0.001, respectively). Using multivariate analysis, only the improvement in the impact of urinary symptoms on daily living was independently associated with VS (OR 5.45, P = 0.01). The authors concluded that most preoperative urinary symptoms decreased after POP surgery with equivalent proportion of de novo symptoms after vaginal and laparoscopic approaches.

The prevalence of OAB symptoms in relation to signs and symptoms of POP is reported to be between 22.5-36.8% in community based studies [427, 439-441] and between 16-88% in hospital based studies [431, 442-444]. The prevalence of OAB with POP is greater in the hospital-based studies than in the community-based studies, which is not surprising, given the selected nature of the hospital samples. Only three studies, one community-based and two hospital-based, were identified that presented data specified per compartment and showed conflicting results: in the study by Miedel et al. [441], there is a clear relationship between anterior and posterior compartment prolapse and OAB symptoms in contrast to central compartment prolapse. In the studies by Bradley and Nygaard [445] and Sobhgoz and Charandabee [446] a such a relation could not be identified. In a study by Ellerkmann et al. [447] no correlation between worsening of the anterior compartment and urgency incontinence could be found. Data regarding the relationship between the stage of prolapse and OAB are very sparse. Burrows et al. [433] found that urgency and urgency incontinence occurred more often in women with a less advanced overall prolapse. Another study using ultrasound reached the same conclusion; women with a higher grade of bladder descent were less likely to suffer from urgency incontinence [448].

The pathophysiology of OAB in women with POP is unclear. Several theories exist: bladder outlet obstruction; release of various chemical factors (ATP, Ach, and P2X3) by bladder distension stimulating the detrusor receptors; traction on the urethra due to prominent cystocele resulting in an open urethra with urine entering the urethra that causes detrusor contractions. Bladder outlet obstruction is likely to be the most important mechanism by which POP induces OAB symptoms and DO signs. However, several other mechanisms might also play a role. However, strong indications show a causal relationship between OAB and POP [449].

b) Anorectal function

Prolapse of the posterior vaginal wall, alone or in combination with other compartment defects, can be challenging for the pelvic surgeon. Pelvic pressure, vaginal/ perineal splinting to defecate, difficult defaecation, faecal incontinence and impaired sexual function are some of the symptoms associated with posterior POP. Whether the prolapse is the cause of the symptoms or is a result of straining and stretching of support structures in women with defaecation disorders, remains unclear.

Bowel symptom like incontinence of flatus and obstructed defecation are common in women with POP. In several surveys, the incidence of anal incontinence ranges from 15-50% [412, 427, 450-457]. Faecal incontinence was reported in 5-22% of women with prolapse [332, 450, 456] which was significantly more than bowel symptoms in a control group [456]. There were no associations found between the stage of the prolapse and symptoms after adjusting for age and BMI [412, 455].

Meschia et al. [452] reported that among 881 women with symptoms of urinary incontinence and pelvic organ prolapse, the prevalence of anal incontinence was 20%. Urinary incontinence and severe rectocele were found to be associated with anal incontinence.

Disparities have been shown between the degree of pelvic organ prolapse, pelvic floor symptoms and defecography results [332, 458]. Two series of defaecographies in consecutive patients with prolapse and/or evacuation disorders described defaecographic findings that changed the patients diagnosis (although not always the management) in 46 of 62 cases and noted enteroceles that were not found on physical examination in approximately 50% of cases [459-461]. Sigmoidoceles are present in 4-11% of reported series, and are nearly always missed on physical examination [461, 462]. Their clinical impact and management remain unclear. Defaecography is not a routine investigation in women with POP and interpretation may be difficult in some cases since normal asymptomatic women may have focal defaecographic abnormalities [458]. The prevalence of abnormal colonic transit time is approximately 20% in patients presenting with evacuation disorders [463]. An abnormal preoperative colonic transit study is the most consistently cited risk factor for failure of rectocele repair to relieve evacuatory symptoms, regardless of the surgical technique [464-466]. Goh et al. [467] reviewed the management of rectocele and clearly described the complexity of clinical conditions resulting from the possible combination of various gynaecological and colorectal symptoms with anatomical abnormalities and the different surgical approaches.

Recently, Ramanah et al. [468] evaluated changes in anorectal symptoms before and after pelvic organ prolapse surgery, using laparoscopic sacrocolpopерineopecty. Preoperative and postoperative anorectal symptoms, colorectal-anal distress inventory (CRADI) and colorectal-anal impact questionnaire (CRAIQ) scores were prospectively compared from 90 consecutive women undergoing laparoscopic sacrocolpoperineopecty. After a median follow-up
of 30.7 months, laparoscopic surgery significantly worsened CRADI (p=0.02) with no effect on CRAIQ (p=0.37) scores. Post-operative and de novo strain (27%) and the need for digital assistance (17%) were the most frequent anorectal symptoms. No correlation was found between laparoscopic surgery and anorectal symptoms after multivariate analysis (OR 2.45, p=0.05). The authors conclude that anorectal symptoms are not improved after POP surgery by laparoscopic sacrocolpopereineopexy.

**c) Sexual function**

Patients who present with pelvic organ prolapse symptoms should be questioned about their sexual function. Surgical treatment in these patients may help their sexual disorders (e.g., by curing incontinence in patients with coital incontinence) but may also have undesired effects on sensation, blood flow, and anatomy. These effects can affect sexual arousal and orgasm or cause dyspareunia.

Dyspareunia, coital incontinence and vaginal dryness are common complaints in women with pelvic floor disorders [469, 470]. Although sexual dysfunction appears to be more frequently observed in these women, pelvic organ prolapse does not seem to negatively impact on sexual satisfaction when controlled for confounders like age [470-472].

Clinical populations are likely to have more severe pelvic floor symptoms and more advanced pelvic organ prolapse, with a greater potential for discernible impact on sexual function, whereas community populations may have mild symptoms and prolapse, with minimal impact. These conflicting results may also be the result of population differences in other related factors, such as age, menopause, or the woman's sexual relationships. Other challenges in studying the factors associated with sexual function in women with POP include a limited characterisation of female sexual function in some studies and difficulties assessing sexual function among women who do not have intercourse.

Handa et al. [473] reported that, with respect to anatomical prolapse, women with stage III–IV prolapse were more likely to report decreased libido and infrequent orgasm than women with stage 0 support. Adjustment for other characteristics attenuated the strength of these associations, although the association between prolapse and infrequent orgasm remained statistically significant. In the final adjusted model, the odds of infrequent orgasm were increased more than three times for women with stage III–IV prolapse (P=0.02). The authors concluded that women with anatomical prolapse stage III–IV were more likely to report infrequent orgasm but they were not at increased risk of other sexual problems. An important observation is that women with stage II support were not more likely to report any sexual complaint than women with stage 0 support. This suggests that the physical presence of stage II prolapse alone is not associated with sexual dysfunction. In contrast, women with prolapse symptoms (as reflected by a high score on the prolapse scale of the Pelvic Floor Distress Inventory) were much more likely to report sexual complaints. Thus, one can conclude that sexual function is worse in women with symptomatic prolapse. LEVEL OF EVIDENCE II.

In 305 women over 40 years seeking outpatient gynaecological care has been investigated the association between sexual complaints and perceived sexual distress. Women with sexual distress were also more likely to report sexual difficulty related to pelvic floor symptoms, sexual avoidance due to vaginal prolapse (13.9% vs. 1%, P=0.001) [474].

A better understanding of the anatomy of this area and of the sexual function will guide us in a more targeted approach to the management of these conditions.

**II. CONCLUSION AND RECOMMENDATIONS**

The aetiology of POP is thought to be multifactorial with contributions from both environmental and genetic risk factors. Undoubtedly vaginal delivery is the most traumatic event for the pelvic floor during a woman's lifespan, recent growing evidence underlines the possible genetic influence in the aetiology of POP. High concordance in the stage of POP between nulliparous and parous sisters suggests a familial predisposition toward developing this condition [331]. LEVEL OF EVIDENCE II-2. Recent studies provided strong scientific evidence of a genetic contribution to pelvic organ prolapse: 6 single-nucleotide polymorphisms are significantly associated with POP in high-risk familial case group participants [334]. LEVEL OF EVIDENCE II.

Also with respect to abnormal extracellular matrix (difference in collagen type and metabolism, elastin turnover), increasing evidence supports the genetic aetiology of POP. LEVEL OF EVIDENCE II. This has been confirmed by severe inherited connective tissue disorders, in which POP predominates [367-370].

Hormonal and mechanical physiological changes during pregnancy affect the pelvic floor support, but it has still to be demonstrated whether this is a reversible factor.

Even though it has been demonstrated that vaginal delivery is the major traumatic event for the pelvic floor caesarean section does not seem to be completely protective (LEVEL OF EVIDENCE II). Forceps, vaginal parity, prolonged second stage of labour, infant birthweight >4500 g are obstetrics risk factors for development of POP. The neurological sequelae of vaginal delivery on the pelvic floor are still controversial.

Declining sex steroid hormone level, ageing, age, obesity, constipation, chronic pelvic floor stress are associated with pelvic organ prolapse.
Although it has been documented that most patients with POP experience, in addition to symptoms of prolapse, urinary, faecal and sexual symptoms, their anatomical and functional relationship remains unclear. Moreover, recent findings show that there are few strong associations between specific symptoms and severity of prolapse. **LEVEL OF EVIDENCE: II-2.**

It is important to have better understanding of the pathophysiology of concomitant SUI and POP, in order to decide on the surgical management of these patients.

The complexity of the anorectal function in patients with POP needs to be clarified, as well as sexual function, which seems to be worse in women with symptomatic prolapse but not with the physical presence of stage II prolapse alone.

New research focuses on the identification of at-risk populations to develop pelvic organ descent. Establishing the inheritance of POP may identify populations that can be targeted for primary and secondary prevention studies, such as elective caesarean delivery. If specific genes can be identified, we may understand why some patients do not respond to certain therapies. Moreover, biomarkers or novel proteins, are expected to be related to various POP phenotypes.

The research priorities in pelvic organ prolapse are:
- to understand the mechanical and functional aspects of the vaginal birth
- to clarify the effects of labour on the pelvic floor and consequently the benefits of the emergency caesarean section
- to quantify the importance of genetic information on POP using Twin Models
- to investigate racial and ethnic background with genetic studies
- to determine possible explanation for related conditions (e.g. hernia, bowel dysfunction)

**E. PATHOPHYSIOLOGY OF FAECAL INCONTINENCE**

Faecal continence is maintained by a complex, poorly elucidated process involving the structural and functional integrity of the anorectal unit, the central and peripheral nervous system and pelvic organs. Continence requires a closed anal canal at rest, sensory function to detect the presence of flatus or stool in the rectum, intact reflex response of the appropriate muscles, cognitive recognition of the sensory signal, adequate storage capacity in the rectum and adequate function of the puborectalis and sphincter muscles. In addition, other factors such as stool consistency and physical mobility play a role. Disruption of the normal anatomy or physiology in any of these areas may lead to incontinence. Often, multiple factors contribute in patients with significant faecal incontinence [475-479].

**I. STRUCTURE AND FUNCTION OF THE ANORECTUM**

The anus is a muscular tube 2 cm to 4 cm long consisting of the internal anal sphincter, conjoined longitudinal muscle, external anal sphincter and puborectalis muscle.

1. **MUSCLES**
   
a) **Internal anal sphincter (IAS)**

The internal anal sphincter (IAS), an involuntary smooth muscle, is a 0.3 cm to 0.5 cm thick expansion of the circular smooth muscle layer of the rectum. The IAS ends about 10 mm proximal to the distal end of the external sphincter. It is primarily responsible for closure of the anal canal at rest through both myogenic and sympathetic excitatory activity. Studies disagree about the relative contribution of myogenic and nerve induced activity to the resting tone [480, 481]. The IAS generates slow waves occurring 6-20 times per minute; about 10 % of asymptomatic people also have ultra-slow waves with pressures fluctuating between 20 mmHg and 50 mm Hg [482-484]. The significance of variations in recordings between controls and incontinent patients is not well understood [485]. The internal anal sphincter contains non-adrenergic, non-cholinergic (NANC) fibres which contribute to contraction of the muscle mediated by nitric oxide [486-488]. The possible roles of other neurotransmitters and of the interstitial cells of Cajal are currently being studied in animal models [489-493]. Other animal studies have focused on the cellular regulation of basal tone in the IAS. Up regulation of RhoA/Rho kinase in the smooth muscle cells of the IAS plays a significant role in the maintenance of the basal tone [494]. The RhoA/Rho kinase components are responsible for the inhibition of myosin light-chain phosphatase of resulting in high level of myosin regulatory light chain [495].

b) **External anal sphincter (EAS)**

The external anal sphincter, a 0.6 cm to 1.0 cm thick cylinder of striated muscle covers the whole length of the internal sphincter and extends more distally into the subcutaneous tissue. The external sphincter contributes to the resting tone. Its primary function, however, is to contract to preserve continence when stool or flatus is present in the rectum or intra-abdominal pressure increases. The contraction may be voluntary or reflex with increased abdominal pressure from coughing or distension [496]. The muscle also relaxes to facilitate evacuation. The separation of the external sphincter into sections is controversial [497]. Many authors describe three sections termed superficial, subcutaneous and deep but they have also been described as subcutaneous, main body
and deep winged portion based upon MRI imaging [498, 499]. On MRI images, the subcutaneous portion is visibly distinct from the other portions with less clear separation between the middle and deeper portions [498]. Others argue the EAS functions as a single muscle unit. The EAS is a predominantly slow-twitch, fatigue resistant muscle with a majority of Type I fibres although there are also Type II rapidly contracting fibres as well [500, 501].

c) Conjoined longitudinal muscle

The outer longitudinal muscle layer of the rectal wall joins with fibres of the levator ani muscle to become the conjoined longitudinal muscle. The muscle extends distally between the internal and external anal sphincter and then splits into extensions that traverse the superficial portion of the external sphincter to attach to the perianal skin and medially through the internal anal sphincter to join the submucosal smooth muscle [502]. Suggested roles for this muscle include provision of supporting meshwork for the anal sphincters and assistance in maintaining anal closure. A more functional role is suggested by the differential response of the longitudinal muscle to neurotransmitters when compared to the internal anal sphincter [488]. One suggested role is that contraction of the muscle flattens the anal cushions and shortens the anal canal [503].

d) Puborectalis muscle (PR)

The puborectalis muscle, the most medial portion of the levator ani muscle, is a U-shaped loop of striated muscle that encircles the anorectal junction and attaches to the posterior aspect of the pubis. The puborectalis muscle is a mixture of Type I and Type II fibres but has fewer Type II fibres than the EAS [504]. It functions to close the upper anal canal [505, 506]. It is situated immediately cephalad to the external sphincter. The configuration of the puborectalis muscle results in the anorectal angle between the distal rectum and anal canal. At rest, the anal canal forms an angle with the axis of the rectum of approximately 90°; during voluntary squeeze the angle becomes more acute, approximately 70°; during defaecation, the angle becomes more obtuse, about 110° to 130°. Some data support the concept that the puborectalis muscle is part of the levator ani muscle (embryology, in vitro stimulation studies, innervation) [507-513] while other information suggests that it is part of the external anal sphincter (anatomic dissection, function during cough and straining [514-516]). The puborectalis muscle responds to increased abdominal pressure (coughing or straining) and rectal distension by contraction.

e) Levator ani

The levator ani muscles are a pair of broad sheets of striated muscle lying below the pelvic organs. There are three major components with different attachments. The iliococcygeus muscle arises from the ischial spine and attaches to the lateral aspect of the lower sacrum and coccyx. The pubococcygeus muscle runs from the posterior aspect of the pubis, mixes with fibres from the contralateral muscle at the anococcygeal raphe and inserts at the distal sacrum and coccyx. The third component is the puborectalis muscle which is described above. The urethra, vagina and rectum pass through an opening between the levator ani muscles called the levator hiatus.

2. NERVE STRUCTURE AND SENSATION

The somatic nerve supply arises from the second, third and fourth sacral spinal segments. The lower motor neuronal cell bodies for those nerves are located in Onuf’s nucleus of those sacral spinal segments. The primary nerve is the pudendal nerve which has both motor and sensory functions [517]. The pudendal nerve divides into three main branches. One branch, the inferior rectal nerve, supplies the external sphincter. The levator muscles including the puborectalis receive innervation directly from those spinal segments [510, 511, 513, 518]. However, the puborectalis muscle frequently receives an auxiliary supply from the inferior rectal and perineal branches of the pudendal nerve on its inferior aspect [519]. Both the EAS and levator ani muscles may be controlled voluntarily through corticospinal descending motor pathways [504]. They are also under reflex control through sacral reflex pathways. Pudendal nerve block creates a loss of sensation in the perianal and genital skin and weakness of the anal sphincter muscle, but it does not affect rectal sensation [520]. It also abolishes the rectoanal contractile reflexes, suggesting that pudendal neuropathy may affect the rectoanal contractile reflex response.

The anorectum also has a rich nerve supply through the enteric, sympathetic, parasympathetic and extrinsic spinal sensory neurons. Enteric motor neurons control most aspects of rectal motility; parasympathetic and sympathetic influence is mediated largely through modulation of the enteric neuronal circuits [521]. Within the myenteric plexuses there are motor, sensory and interneurons. The sympathetic supply of the rectum arises from the first three lumbar spinal segments. The innervation is carried through the preaortic plexus to the upper rectum and through the presacral nerves to the hypogastric plexus and then through the hypogastric nerves to the pelvic plexus. The parasympathetic fibres originate in the sacral parasympathetic nucleus in the sacral spinal cord and emerge through the sacral foramen as the nervi erigentes. They join the sympathetic fibres at the pelvic plexus and pass through rectal nerves to the rectal wall. The parasympathetic pathways have a role in propulsive activity of the colon and defaecation.

Extrinsic sensory innervation of the rectum seems to be responsible for sensory perception of rectal distension. Sacral afferents have cell bodies in the dorsal root ganglia of the sacral segments. Specialised sacral afferents have mechano-sensitive transduction sites within the myenteric ganglia of the rectum.
The amplitude and duration of this relaxation increase with the volume of rectal distension [546]. It has been suggested that bowel contents are periodically sensed by anorectal “sampling,” [547-549] the process by which transient relaxation of the IAS allows the rectal contents from the rectum to come into contact with specialised sensory organs. This process allows discrimination between flatus and stool.

### b) Cough reflex

Abrupt increases in intra-abdominal pressure, such as those caused by coughing or laughing, are associated with increases in anal sphincter pressure. [496, 550-553]. The increased pressure may be achieved through multiple mechanisms, including reflex contraction of the puborectalis [554]. The response is relative to the intensity of the cough [550]. It is unclear whether the response is a polysynaptic spinal reflex [496, 551] since it is preserved after spinal cord transection [555] or also requires central integrative centres [552].

### c) Rectoanal contractile reflex (sensori-motor response)

The rectoanal contractile reflex (or rectal anal excitatory reflex or inflation reflex) is the contraction of the EAS in response to rectal distension [556-558]. The amplitude and duration of the rectoanal contractile reflex increases with rectal distension up to a maximum volume of 30 ml [546].

### 5. RECTUM

The rectum is a hollow muscular tube, 12 cm to 15 cm long, composed of a continuous layer of longitudinal muscle that interlaces with the underlying circular muscle. These muscles are a mixture of smooth muscle cells and several types of interstitial cell of Cajal [521]. A network of interstitial cells of Cajal joined by gap junction connections coupled to smooth muscle cells trigger mechanisms that give rise to large, slow repetitive depolarisation of the smooth muscle, the slow waves [559]. The proximal end is defined either as the sacral promontory, the third sacral vertebrae or the area where the colonic taenie splay out and end. The distal end is the dentate line or anorectal ring. The rectum serves as a reservoir for storage and a “pump” for evacuation of stool facilitated by several characteristics. The rectal walls are compliant maintaining a relatively low pressure with increasing volumes. Its innervation allows the sensation of increasing volume [475, 521].

### 6. ANAL ENDOVASCULAR CUSHIONS

The submucosa of the anal lining contains blood vessels, connective tissue, smooth muscle and elastic tissue. They typically form three separate complexes of smooth muscle fibres and vascular channels called the anal cushions [560, 561]. A recent study of women demonstrated the normal variation in size; the size did vary with posture and parity but not age, history of obstetrical trauma or mild hemorrhoid symptoms [562]. Their contribution to continence is poorly studied and controversial.
7. STOOL CONSISTENCY

Considerable evidence exists that evacuation of formed stool is more easily deferred than loose stool (discussed in detail under diarrhoea). While theories exist about the reason, physiological proof is not available.

8. PHYSICAL MOBILITY

The ability to defer evacuation until a socially acceptable time and place requires physical mobility to reach a bathroom in the required time frame. The contribution of physical mobility to continence is largely inferred from studies identifying lack of physical mobility as a risk factor for incontinence [563-565]. There is limited information about the relative role for mobility in continent patients.

II. CONTINENCE MECHANISM

Complete continence is most likely with normal transit of formed stool, anal closure at rest, sufficient reservoir capacity and sensation in the rectum, functional reflexes for sampling and sphincter contraction, adequate cognitive function to recognise the urge to defaecate and physical mobility to reach the bathroom in time.

The anus is normally closed by the tonic activity of the IAS with contribution from the EAS and PR at different levels of the anal canal [506, 566]. Studies of the relative contribution of the IAS to the resting tone yield results varying from 55-85% [481, 520]. Some of that variation is likely to be related to the measurement technique utilised but it has also been found that resting pressure varies during the day [567] and with posture, increasing with the upright position [568]. The IAS contribution is also influenced by rectal distension [520, 569]. Some postulate that the anal cushions provide a tight seal based upon studies showing that the sphincter muscles in their circular configuration cannot contract sufficiently to provide complete closure [570, 571]. An in vitro study showed that even during maximal involuntary contraction, the internal sphincter ring was unable to close the anal orifice completely and a gap of approximately 7 mm was left open. This gap was filled by the anal cushions [572]. Anal cushions may exert pressures of up to 9 mmHg and thereby may contribute 10% to 20% of resting anal pressure [573]. These barriers are further augmented by the puborectalis muscle, which pulls the anal canal forward forming the anorectal angle. The extent to which the anorectal angle contributes to continence is controversial [566, 574-578]. One study suggests that it is important to the control of semi-solid material more than the control of liquid [579].

With rectal distension or increased intra-abdominal pressure, this barrier is reinforced by reflex or voluntary contraction of the EAS and PR. The contraction requires functional peripheral, spinal and cerebral function to sense and recognise the distension, activate the reflex and voluntary responses. In addition, adequate muscular contraction to increase the anal pressure is required. The rectal wall must distend to allow accommodation to the increased pressure. Finally, the mobility to reach an appropriate setting before the muscle fatigues is required.

III. DEVELOPMENT OF INCONTINENCE

Clearly there are a number of potential areas of injury or dysfunction in the complex mechanisms required for continence that might result in incontinence. Faecal incontinence occurs when one or more mechanisms that maintain continence is disrupted to an extent that other mechanisms are unable to compensate. Hence, faecal incontinence is often multi-factorial [475-479]. In a prospective study, 80% of patients with faecal incontinence had more than one pathogenic abnormality [476]. The interaction of those factors and when they result in clinical incontinence is poorly understood.

1. PASSIVE INCONTINENCE

Compromise of anal closure and loss of sensation may result in soiling or incontinence without awareness. Prolapsing tissue (either mucosal or full thickness rectal prolapse, rectal lesions) prevents closure of the anus. Some believe that resection of the anal cushions may result in passive incontinence [571]. Injury secondary to trauma, surgery or childbirth and weakness of the IAS are other causes. IAS atrophy occurs in systemic sclerosis and may contribute to a faecal incontinence [580, 581] although neuropathy appears to be a contributing factor as well [582]. Loss of sensation occurs from peripheral neuropathy, spinal cord and cerebral cortex events or after transection of the nerve supply by surgical or other trauma. Increasing evidence suggests that rectal hyposensitivity significantly contributes to passive incontinence [583-587]. Interestingly faecal seepage in men occurs despite normal anorectal physiology testing [583, 588, 589].

2. URGENCY INCONTINENCE

Incontinence occurs when the ability to hold stool or flatus is overwhelmed. If the rectum cannot distend to hold stool or the muscles do not contract adequately incontinence results. Changes in the reservoir function of the rectum from disease processes, radiation therapy or surgical resection. Pelvic floor muscle dysfunction may result from direct injury causing a defect or weakness. Iatrogenic or obstetrical trauma to the IAS is the most common cause of injury to that muscle. Direct injury to the EAS occurs most frequently from obstetrical injuries which are comprehensively presented elsewhere but may also occur from surgery or other trauma. The puborectalis and levator ani muscles may also be injured and the presence of defects appears to correlate with poor contractility and symptoms in
several studies [159, 590-593]. Major levator ani muscle injuries are more frequent in women with EAS obstetrical injuries and those with combined injuries are more likely to be symptomatic [159]. However, other investigators found no relationship between the presence of levator ani injuries and faecal incontinence [456, 594].

Rectal hypersensitivity, a lower threshold for the urge to defaecate, also contributes to urgency incontinence [477, 478, 595-599]. Complex, poorly understood mechanisms mediate rectal hypersensitivity. Variables include decreased compliance, increased sensitivity of extrinsic peripheral pathways or central afferent mechanisms [597].

IV. RISK FACTORS FOR FECAL INCONTINENCE

Many events and conditions impact on the mechanisms of continence often in multiple ways. The next section covers the conditions that most frequently contribute to incontinence.

1. AGING

Multiple studies document the increasing incidence of faecal incontinence with aging in both men and women [479, 600-606]. One study of women in a community found that 70% of incontinence developed after the age of 40 [607]. Another study of women in the United States documented an initial 15% prevalence of incontinence in women over 50 years old and onset rate of 7% over the next 10 years [608].

While the rising incidence is well documented, understanding of the physiological impact of aging is less clear. Conflicting evidence exists about the effect of aging on anal resting pressure. While a number of studies report decreased anal resting pressures in older continent and incontinent persons [598, 609-612], some found lower pressures in patients with incontinence but not asymptomatic older persons [613, 614]. Increased thickness of the internal anal sphincter is associated with aging [598, 615-618]; this finding is thought to represent increased fibrosis although that hypothesis is not proven. Animal studies of smooth muscle contraction demonstrate decreased contractility with aging [619]. Studies of the internal sphincters of aging animals found changes in translocation of signaling molecules as well association and phosphorylation of contractile proteins [619].

Most studies of the effect of aging on anal squeeze pressures found decreasing pressures with advanced age [610-614, 620, 621] but not all [598, 622, 623]. One report found decreasing anal squeeze pressures with age in women but not men [621]. The decrease in anal squeeze pressures does not correlate with easier fatigability of the external sphincter. Indeed, studies show no change with age [624] or that the external sphincter becomes more resistant to fatigue with age [625]. These findings are consistent with studies of skeletal muscle in general which show that reduction of muscle fibres with increasing age with a greater loss of Type II fibres which are less fatigue resistant [626]. The result is a weaker but more fatigue resistant muscle. Very little specific data about the external anal sphincter exist, however.

The decreased anal squeeze pressures might also be related to external sphincter atrophy. Thinning, presumed to be secondary to atrophy, of the external sphincter has been documented in both endoanal ultrasound and MRI studies [615-617, 627-629]. One study found excellent correlation between atrophy on imaging and the pathological changes of atrophy [630]. Some studies found that atrophy is related to aging [617, 628] but not all [598]. Faecal incontinence did correlate with external sphincter atrophy [598]. Data from studies of nerve injury in animals reveals that sphincter atrophy and decreased function develops after nerve injury [631-633]. It is known that muscle atrophy secondary to age related loss of anterior horn cell occurs [634]. Human studies demonstrate increased muscle fibre density suggesting reinnervation in the external sphincter with age [614, 635].

Finally several studies have shown a decrease in rectal sensitivity with increasing age [609, 620]. One study found that decrease only in women [612]. The relationship of this finding to faecal incontinence is not clear.

2. GENDER

Prevalence studies suggest that faecal incontinence occurs more frequently in young women but as people age, many studies report essentially equal incidence in men and women. [602, 604-606, 621, 636, 637] The mechanisms of faecal incontinence in men appear to differ from women [479, 583, 588, 589, 638, 639].

Oestrogen and progesterone receptors are found in the IAS and EAS. Because of this finding, some proposed that menopause is a factor for incontinence in women. However, since aging and menopause are closely related, an independent relationship is difficult to prove. Symptomatic improvement from oral oestrogen replacement supports the proposed relationship; however study of topical oestrogen compared to placebo showed no difference. In addition one study found a 30% increased risk of incontinence in patients currently taking oral oestrogens [640]. At the present, the role of the hormone receptors and relationship of menopause to the onset of incontinence is uncertain.

3. DIABETES

Diabetes is reported as a risk factor for faecal incontinence in several prevalence studies [605, 606, 640, 641]. One study reported a 40% increase in the risk of faecal incontinence [640]. Another population based study found that both occasional and frequent episodes of incontinence were more common in diabetic patients (OR 2.7) [642]. In a study of elderly
Korean patients, diabetes was associated with faecal incontinence in women but not men [643]. A review of incontinence in community dwelling men did identify diabetes as a risk factor, however [639]. A case control investigation found that diabetic patients had more frequent and severe episodes of faecal incontinence [644]. Several reports found that incontinence was more frequent in patients with other diabetic complications particularly neuropathy and retinopathy [644-646]. It is uncertain whether longer duration of disease increases the likelihood of incontinence as one study found an association [645] but two did not [644, 646]. Faecal incontinence was associated with poor glycemetic control in one report, [644] but not another [646].

The underlying mechanism for faecal incontinence in diabetic patients is not clear. One likely contributor is oral medication taken for diabetic control. Metformin has been shown to be independently related to faecal incontinence in diabetic patients [647]. In addition, withdrawal of metformin was reported to eliminate the incontinence [648]. One confounding factor is that diarrhoea, a known risk factor for faecal incontinence, occurs in 5-35% of patients with diabetes [642, 645, 649, 650].

One hypothesis is that microvascular changes associated with diabetes result in damage to pelvic floor innervation and muscles [651]. A comparative study of anorectal physiology of controls, incontinent patients with diabetes and continent and incontinent patients with multiple sclerosis found that the incontinent, diabetic patients had higher sensory thresholds and lower resting and squeeze pressures [652]. An anal physiology study compared findings of patients with the diagnosis of diabetes for less than 10 years to those with the diagnosis for longer than 10 years [653]. Both groups of patients had lower resting and squeeze anal pressures (P < 0.01), impaired rectoanal inhibitory and anocutaneous reflexes, and reduced sensitivity to rectal distention. Although both groups had statistically significant differences from the control group, the patients with the longer duration of disease had lower sphincter pressures and more blunted sensation in addition to more frequent episodes of incontinence. The latter group also had more evidence of microvascular disease and neuropathy. Blunted rectal sensation and internal sphincter dysfunction were identified in diabetic patients in two separate studies [532, 654]. These findings would be consistent with underlying neurologic and/or microvascular changes. It is unclear how to reconcile that hypothesis, however, with the lack of association of incontinence with neuropathy in some epidemiology studies [649, 655].

4. GASTROINTESTINAL DISORDERS

a) Diarrhoea

Diarrhoea is consistently reported as a risk factor for faecal incontinence. For many patients symptoms of diarrhea include loose consistency of the stool and rectal urgency. Loose stool is an independent risk factor for incontinence and is additive to other risk factors such as obstetrical sphincter injury [479, 600, 602, 603, 608, 636, 639, 640, 656, 657]. Diarrhoea has a significant impact on the development of incontinence with OR 53 in one study [600]. Loose stool is also reported to result in incontinence after treatment with pelvic radiation [658].

b) Rectal urgency

Rectal urgency is reported as an independent risk factor for faecal incontinence [602, 659] as well as a factor in worsening symptoms in patients with incontinence [597]. It is unclear whether the aetiology is rapid transit into the rectum overwhelming the reservoir function or hypersensitivity or some combination of factors [602, 636]. Several investigators have shown that rectal hypersensitivity is a common finding but incontinence developed only in patients with associated sphincter weakness [477, 597]. Rectal hypersensitivity has also been found to be associated with an abnormal colonic motility pattern in the sigmoid colon in incontinent patients [660]. The relationship between this finding and irritable bowel syndrome remains to be clarified.

c) Constipation/impaction

Constipation and incomplete evacuation of the rectum are associated with faecal incontinence in several studies [601, 608]. A study of hospitalised elderly patients found that faecal impaction and diarrhoea were strongly associated with faecal incontinence [661]. Uncertainty exists regarding whether these two factors result in incontinence in patients with otherwise normal anorectal function. Overflow incontinence occurs in some patients with faecal impaction. The use of laxatives may exacerbate the problem [662]. One study of elderly patients with impaction, compared to controls, found that they had blunted rectal sensation and less frequent external sphincter contractions in response to rectal distension [663]. In addition the internal sphincter relaxed at lower levels of rectal distension. Studies of impacted patients without incontinence have not been reported.

d) Irritable bowel syndrome

A number of studies found irritable bowel syndrome to be a risk factor for faecal incontinence [600-602, 640, 664-666]. Proposed mechanisms include loose stool consistency, rapid colonic motility and rectal hypersensitivity [660, 667].

5. NEUROLOGICAL/PSYCHIATRIC CONDITIONS

a) Dementia

The prevalence of faecal incontinence is higher in patients with dementia compared to others of similar age. One study reported a prevalence of 32% in older patients with dementia [668]. Another study reported a rate of 34% in patients with dementia compared to 6.7% in those without dementia [669].
Although diarrhoea was the greatest risk factor for incontinence in a study of nursing home residents, dementia also contributed to the development of incontinence [670]. In the study of community-living older adults in the United States, the prevalence odds ratio of fecal incontinence decreased by 51% with each unit improvement in cognitive score [671]. A Japanese study of community dwelling older adults found dementia to be a risk factor for double incontinence [672]. There is limited information available about the relationship between intellectual disability and faecal incontinence [673]. Proposed mechanisms for the specific contribution of dementia include lack of recognition or understanding of the urge to defaecate and lack of ability to articulate the need for the bathroom.

b) Depression

Several studies identified depression as a risk factor for faecal incontinence [603, 605, 636, 639, 674]. Many assume that the association occurs because of the psychological burden of the symptoms while it is also possible that side effects of anti-depressant medication contribute to the symptoms. Recently, however, an editorial challenged investigators to “clarify the link between the cerebral impact of neurotransmitters and anorectal physiology” given the role of serotonin in depression and gastrointestinal function [675]. Depression and faecal incontinence are both associated with poor nutritional status in the elderly [676]; that association confounds understanding of any true causal relationship between any two of the conditions.

c) Spinal Cord Injury

Patients with spinal cord injuries frequently report difficulty with both constipation and incontinence [677, 678]. The level of the injury determines the effect on continence. Supraconal lesions lead to delayed colonic transit and exaggerated rectal contractions and anal relaxation in response to rectal distension. Cauda equina lesions interrupt the effenter limb of the reflex arc which results in loss of rectal sensation and tone as well as impaired sphincter function [679]. Paraplegics or people with sacral neuronal lesions may retain some degree of sensory function, but virtually no sensation is felt if lesions reach the higher spine [530, 555].

d) Stroke

In several large surveys, stroke has been identified as a risk factor for incontinence [605, 636, 639, 672]. Studies of stroke patients demonstrate fairly consistent rates of faecal incontinence from 30-40% on admission [668, 680-683]. The rates decreased to 20% by the time of discharge [680, 682] and 7-11% at 6-12 months [668, 681, 683]. The Copenhagen Stroke Study found that abnormalities in patients with incontinence were more likely to be hemorrhagic, larger in size and involve the cerebral cortex than stroke patients without incontinence [683].

6. NUTRITION

a) Obesity

Population based studies of faecal incontinence identify obesity as a significant risk factor [600, 601, 640]. In addition studies of pelvic floor symptoms in obese patients find a higher incidence of faecal incontinence than generally found in the non-obese population with rates ranging from 16-68% [684-691]. A non-significant trend towards worsening incontinence was found in another study [692]. Four studies investigated the relationship between the rate of incontinence to the BMI; two found increasing rates of incontinence with increasing BMI [640, 689, 693]. One did not [691]. The relationship is further supported by data that weight loss after bariatric surgery decreases the incidence of faecal incontinence [685, 689, 694, 695]. While the findings of these studies are quite consistent a recent systemic review of obesity and pelvic floor disorders found the number of studies to be limited, primarily focused upon women, and usually lacking control groups and physiology testing [696]. Two confounding factors were noted in studies of this relationship. One is that diarrhoea, an independent risk factor for incontinence, is also frequently associated with obesity [696]. The second is the association of faecal incontinence with low fibre intake in obese women raising the question of dietary contribution to the increased incidence of faecal incontinence with obesity [687]. Chronically elevated intra-abdominal pressure, known to be associated with obesity [697, 698], is typically proposed as the reason for pelvic floor dysfunction in obesity. Other factors including diabetes, neurological changes and intervertebral disc herniation which are common in the obese population may very well contribute.

b) Vitamin D

Vitamin D deficiency is associated with urinary incontinence in men and women [699, 700]. One small study of ten patients with faecal incontinence found that all had either vitamin D deficiency or relative vitamin D insufficiency [701]. These rates are much higher than the 36-57% rate of deficiency or relative insufficiency from historical data of the general population. In a large study of 1881 women in the US, there was a non-significant trend towards an association between lower vitamin D levels and faecal incontinence [699]. It is known that vitamin D absorption and synthesis in the skin declines with age [702, 703]. Any association between lower levels of vitamin D and faecal incontinence may represent only the factor that both are common in the elderly; the significance is at present uncertain but potentially could represent a easily remediable factor.

7. OBSTETRICAL INJURY

The impact of pregnancy and vaginal delivery on continence is described in the section on obstetrical injury. While those injuries occur with reasonable
frequency, quite often the patient does not develop clinical incontinence until later in life. The reasons for the onset of symptoms and the required combination of factors are poorly understood. However the contribution of EAS defects to incontinence is supported by data demonstrating that clinical improvement after sphincteroplasty is more likely in patients with successful anatomical repair seen on ultrasound [627, 704-706]. The frequency of puborectalis or levator ani muscle injury as well as the degree to which it contributes to faecal incontinence is unclear but is being more actively investigated [591, 592, 594, 707].

8. PHYSICAL MOBILITY

Intuitively, adequate physical mobility to reach the toilet in a timely manner in response to the urge to defaecate is necessary for continence. Limited mobility was found to be a risk factor for incontinence in one population based study [636] and an investigation of nursing home residents [564]. In a study of urban dwelling older people, the odds of prevalent incontinence increased by 20% for each unit decrease in the physical performance measure [671]. In a study of long-term care patients, immobility was one of the strongest predictors of incontinence [708]. In another study, the use of physical restraints (maximal limitation of mobility) was found to be the most significant cause of incontinence when the data were adjusted for other risk factors [709].

9. RADIATION

Faecal incontinence occurs after pelvic irradiation for prostate, gynaecological and rectal cancer [710-713]. Radiation therapy adds to the risk of incontinence associated with rectal resection [714-717]. It appears that short course radiotherapy carries a higher risk than long term irradiation [718]. Direct comparison trials powered to answer the question are currently in progress [719, 720]. In a study of the relationship of radiation dosage to symptoms after prostate radiotherapy, faecal incontinence was associated primarily with radiation to the EAS and PR [721]. The exact mechanism(s) by which radiation therapy causes incontinence is uncertain. The rectum may be stiffer and less compliant [722] and the anal pressures reduced either from muscle or nerve injury by the radiation [715, 723, 724].

10. RECTAL PROLAPSE

a) Mucosal, internal and full thickness rectal prolapse.

A significant proportion (48-63%) of patients with prolapsing haemorrhoids or mucosal prolapse report soiling [725, 726]. Symptoms resolve with successful treatment [725-728].

External rectal prolapse is associated with faecal incontinence in up to 66% of patients [729-732]. Diminished anal resting tone commonly accompanies rectal prolapse [555, 730, 733]; that finding suggests that internal sphincter dysfunction perhaps from repeated stretching is one mechanism for incontinence. Other considerations include the presence of neuropathy; it is unclear if the prolapse results in prolonged pudendal nerve latencies [734, 735] or if both share a common aetiology. The exact mechanism or combination of causes is uncertain. Other investigators, however, found that patients with rectal prolapse and persistent incontinence had evidence of sphincter defects either from surgical or obstetrical injury [736, 737].

Internal rectal prolapse is also associated with faecal incontinence [738, 739] and decreased anal pressures [733]. While surgical intervention for internal rectal prolapse is controversial, several studies report improvement in their incontinence after rectopexy [740-742].

11. SURGERY

a) Anorectal surgery

Lateral internal sphincterotomy, is the recommended surgical procedure for refractory anal fissures. The surgery involves the division of the internal sphincter and may result in incontinence of flatus and stool [743-748]. Quite variable rates of post-operative incontinence from none to 36% are reported. The definition of incontinence, type of follow-up and length of sphincterotomy contribute to the variability. Some authors suggest that pre-existing sphincter injury might predispose to incontinence [749, 750]. Another author found evidence for increased sphincter asymmetry in patients with incontinence after sphincterotomy compared to continent post-operative patients but no differences in pre-existing sphincter defects [751]. A recent report suggests that the development of symptoms of incontinence may be delayed similar to women with obstetrical sphincter injuries [752].

Incontinence is reported in 0-14% of patients after hemorrhoidectomy [753-756]. In the limited studies available, increased risk of incontinence has been related to previous vaginal deliveries [754], number of hemorrhoids excised [755] and post-operative internal sphincter defects [754, 757]. Some have argued that excision of the anal cushions is the reason for incontinence [571].

Surgery for anal fistula may result in faecal incontinence. The frequency depends upon the anatomy of the fistula, baseline sphincter function and the surgical procedure performed. The reported rates of post-operative incontinence range from 0-50% [758-770]. The definition and measurement of incontinence varies among the studies. Treatment of high fistulas involving more sphincter muscle is more likely to be followed by incontinence [744, 758, 765, 770]. Injections of fibrin glue and endorectal advancement flaps have lower post-operative incontinence rates than other fistula procedures [761]. Age over 45 years old [758] and gender [760, 769] were found to increase the risk in some studies. The mechanism appears to be iatrogenic (and sometimes intentional) sphincter injury.
b) Rectal resection

In a recent meta-analysis of functional outcomes after resection for rectal cancer including studies reported between 1978 and 2004, faecal incontinence of any kind occurred in 3-79% of patients [713]. Rates of incontinence of solid stool ranged from 0-40%, liquid 0-60% and flatus 9-76%. The pooled proportion of incontinence of solid stool was 14 % and liquid stool 29%. The risk of incontinence appears to depend upon the tumor location and level of the anastomosis 29%. The risk of incontinence appears to depend upon the tumor location and level of the anastomosis [771]. Theoretically loss of the rectal reservoir contributes to incontinence. The goal of replacing the reservoir function led to the development various types of reconstruction following resection (coloplasty, colonic J pouch, ileoanal reservoir). While long –term data are sparse, in the first 18 months post-operatively colonic J pouches result in lower rates of incontinence than straight anastomoses or coloplasty according to a recent Cochrane review [772]. Damage to the internal sphincter occurs during this type of resection presumably from transanal introduction of stapling devices and may contribute to incontinence as well [773, 774]. However a recent study comparing patients undergoing handsewn anastomoses to double stapled ones found no difference in faecal incontinence post-operatively or anorectal manometry results [775]. Diminished rectal sensation and changes in motility seen post-operatively indicate that nerve damage may also contribute [775-777]. Rectal sensation and the ability to defaecate can be abolished completely by resection of the nervi erigentes [778]. If parasympathetic innervation is absent, rectal filling is only perceived as a vague sensation of discomfort. Cadaver studies after total mesorectal excision reveal the close proximity of the levator ani nerve and pelvic splanchnic nerves to the plane of dissection particularly for low rectal resections [779]. Damage to those nerves would impact on the function of the puborectalis muscle. It is likely that multiple factors contribute to incontinence after rectal resection and difficult to assign relative importance.

c) Hysterectomy

Several reports identified hysterectomy as a risk factor for faecal incontinence [600, 636]. However, another study found a reduced risk of incontinence [640] and one found no association [601]. In addition to conflicting results, the mechanism is not understood.

d) Cholecystectomy

Cholecystectomy results in diarrhoea in some patients. It is often assumed that incontinence occurring after cholecystectomy is related to the onset of diarrhoea. However, two studies identified cholecystectomy as a significant independent risk factor for incontinence [600, 780]. The underlying mechanism, if not associated loose stool, is uncertain but perhaps could be related to rectal urgency secondary to bile salt irritation.

12. SMOKING

A study from the Mayo Clinic reported an association between incontinence in older adults and current smoking with an odds ratio of 4.7 [600]. An earlier study reported the same finding in post-partum patients with faecal incontinence. The reason is unclear [116]. Chronic obstructive pulmonary disease has been associated with faecal incontinence [640] but in The Mayo Clinic study pulmonary disease was not found to be a factor. Other proposed mechanisms include the anti-oestrogen effect of nicotine [781] or accelerated colonic transit secondary to nicotine induced high amplitude contractions in the colon [782].

13. URINARY INCONTINENCE

Many studies report an association between urinary and faecal incontinence. It is likely that it is not a causative relationship but rather that the two conditions result from a common aetiology [414, 600, 603, 606, 636, 640, 657, 783, 784].

V. SUMMARY AND RESEARCH RECOMMENDATIONS

Multiple factors play a role in the development of faecal incontinence. More information is now available about the impact of aging on the sphincter muscles and pelvic nerves. The role of rectal urgency and hypersensitivity in the onset of incontinence, perhaps in conjunction with an underlying abnormality that alone did not result in symptoms, has received more attention. Recent work has also focused on remediable risk factors such as nutritional factors and lifestyle choices. However the complex interaction of the pelvic floor is not fully understood and requires more investigation. More information about the aging process including the potential for reversible changes would be of interest. In addition, little data exist to demonstrate whether changes in theoretically remediable risk factors will decrease incontinence.

F. CHILDBIRTH AND FAECAL INCONTINENCE

Pregnancy and childbirth have a significant impact on the emotional and physical wellbeing of a woman. It is reported that as many as 91% of women report at least one new symptom eight weeks post-partum [785]. A fall in maternal mortality accompanied by an increase in female life expectancy (86 years in Japan) has now shifted the focus of attention towards identification of factors that may minimise morbidity. Although pre-existing bowel symptoms may be aggravated during pregnancy and childbirth, the development of symptoms de novo is a more frequent occurrence. Obstetric trauma is the most common cause of faecal incontinence. However, the onset of symptoms may occur many years after delivery with a peak incidence in the perimenopausal years. This
may reflect the effect of contributory factors such as the process of aging, the effect of the menopause or progression of neuropathy. This section focuses on the association between obstetric trauma and faecal incontinence. The term ‘anal incontinence’ is used to include incontinence to flatus, liquid and solids.

Anal incontinence has been reported to occur between 5 [202, 786] to 26 [119] % of women during the first year following vaginal delivery. In a Canadian study [787] involving 949 consecutive women who delivered vaginally, 26% reported anal incontinence while 3% reported faecal incontinence. They identified forceps delivery and third/fourth degree tears as independent risk factors. In a population based study of 8774 women in Oregon, USA, more than 25% reported faecal incontinence within 6 months of childbirth [116].

### I. NEUROGENIC TRAUMA

The mechanism that maintains continence is complex and affected by various factors such as mental function, lack of a compliant rectal reservoir, rectal hypersensitivity, enhanced colonic transit and changes in stool consistency and volume. However, the ultimate barrier is the anal sphincter. Anal incontinence may ensue if there is mechanical disruption to the anal sphincter muscles, disturbance in neurological function or a combination of both factors. In about 80% of women with presumed “idiopathic” anorectal incontinence there is histological evidence of denervation of the striated pelvic floor muscles, particularly the puborectalis and external anal sphincter (EAS) [788]. This feature has also been demonstrated electro-physiologically by means of an increased fibre density in patients with idiopathic faecal incontinence indicating re-innervation following denervation [789].

Another finding in these patients is a conduction delay in pudendal nerves as measured by pudendal nerve terminal motor latency (PNTML) [790].

Although Hertz in 1909 suggested that pelvic floor damage may result from a normal vaginal delivery, objective scientific evidence for this was only produced in 1984 [176] and a follow-up of 14 patients 5 years later [178]. These authors studied 122 women, 71 after delivery with manometry, perineometry, PNTML and EMG, and 51 before and after delivery with EMG. This study demonstrated an increase in anal sphincter striated muscle fibre density in the vaginal delivery group at 2 months post-partum indicating evidence of re-innervation following denervation. The fibre density was not altered following elective caesarean section. Thirty three percent of primiparae and 50% of multiparae had prolonged PNTML within 48 hours of delivery. However, by 2 months, the PNTML had returned to normal in 60% of these women, indicating that damage to pudendal nerve conduction is reversible. Multiparity, forceps delivery, increased duration of the second stage of labour, third degree perineal tears and high birth weight were important factors leading to pudendal nerve damage. In the five year follow-up study of 14 women, only multiparae who did not have a forceps delivery were selected; the denervating process was found to be progressive in the majority of women and 5 women suffered from stress urinary incontinence, 3 of whom were also incontinent to flatus.

In another prospective neurophysiological study, Allen et al. [177] studied 96 nulliparous women with EMG, PNTML and vaginal pressure measurements during pelvic floor contraction. They found evidence of re-innervation in the pelvic floor muscles of 80% of primiparae 2 months after vaginal delivery. The only obstetric factors associated with re-innervation were a high birth weight and a longer active stage of labour. Forty five of the original 96 women were studied again 6 years later and they concluded that changes in pelvic floor neurophysiology occur with time and do not appear to be related to further childbearing.

A third prospective study [791] measured anal pressures, anal sensation and the perineal plane in 72 antenatal women and repeated 72 hours post-partum and in 41 women 2 months postpartum. Anal sensation was unchanged. Cornes et al. [792] measured anal sensation in 96 primiparae within 10 days after delivery and measurements were repeated in 74 women 6 months after delivery. They found that at 6 months anal sensation had returned to normal. Anal sensation remained unchanged after cesarean section. In women who had a torn EAS, only impairment of sensation in the upper anal canal persisted at 6 months. More than half the women who admitted to persistent anal incontinence had normal anal sensation. Chalifa et al. [793] measured anal electro-sensitivity before and after childbirth and found it unchanged. Anal sensation in isolation therefore probably plays a minor role in the development of obstetric related faecal incontinence.

### II. MECHANICAL TRAUMA

Until the advent of anal endosonography, mechanical trauma to the anal sphincters was only suspected when there was a history of third or fourth degree tears collectively known as obstetric anal sphincter injuries (OASIS). Consequently, when anal endosonography was performed in patients believed to be suffering from “neurogenic” faecal incontinence unsuspected internal anal sphincter (IAS) and EAS defects were identified [794]. The sonographic appearance of EAS defects has been verified histologically to represent fibrosis [795] while the appearance of IAS defects have been validated prospectively in patients undergoing lateral internal anal sphincterotomy [750]. Trauma as identified by ultrasound may represent unrecognised OASIS (previously referred to as occult) or the consequence of recognised and repaired OASIS.

### 1. UNRECOGNISED (“OCCULT”) ANAL SPHINCTER TRAUMA

Sultan et al. [202] performed the first prospective study (before and after childbirth) to demonstrate
both “occult” anal sphincter trauma (Figure 13) and pudendal nerve damage during childbirth in both primiparous and multiparous women (n=150). In 35% of primiparous and 44% of multiparous women anal sphincter defects were identified at 6 weeks postpartum by anal endosonography that were not present before vaginal delivery. Thirteen percent and 23% respectively developed defecatory symptoms (faecal urgency and/or anal incontinence) after delivery. Only two of the 150 women (both primiparous) had recognised tears of the anal sphincter at the time of delivery. A strong association was demonstrated between the presence of any defect and the development of symptoms. Only 4% of multiparous women sustained new sphincter damage following a subsequent delivery. The single independent factor associated with anal sphincter damage was forceps delivery. The 23 women delivered by cesarean section remained asymptomatic and none developed sphincter defects. No relationship was demonstrated between PNTML measurements and defecatory or urinary symptoms.

Donnelly et al. [796] interviewed 219 nulliparae in the third trimester regarding bowel habits and performed anal vector manometry. At 6 weeks postpartum 184 women returned and the same bowel symptom questionnaire was completed and anal vector manometry plus PNTML measurements were performed. Anal endosonography was performed in 81 women with altered faecal continence or abnormal physiology. Instrumental vaginal delivery and a passive second stage of labour prolonged by epidural analgesia were significantly associated with the greatest risk of anal sphincter trauma and impaired faecal continence. As instrumental delivery is a known risk factor (8 fold increased risk of sphincter trauma), early use of oxytocin was recommended to shorten the second stage. A continuation of the same study [797] reported that PNTML was prolonged and the squeeze pressure increment was reduced in women who had a cesarean section in the late first stage (>8cm cervical dilatation) or second stage.

Chaliha et al. [793] measured anal sensation and manometry in 286 nulliparae during the third trimester and repeated in 161 women postpartum when anal endosonography was also performed. Anal endosonography revealed sphincter defects in 38% of women and this was associated with the presence a lowering of anal squeeze and resting pressures. Threshold anal electrosensitivity remained unchanged and bore no relationship to symptoms. Postpartum sphincter defects were associated with perineal tears and vaginal delivery.

Abramowitz et al. [798] undertook a prospective study of 233 women who had anal endosonography performed before and 6 to 8 weeks after childbirth. Of the 233 women (118 primiparae), 202 had a vaginal delivery. Postpartum anal incontinence in the 233 women was reported by 13% of primiparae and 8.5% of multiparae and anal sphincter defects in 21% and 12% respectively. However, the prevalence of anal sphincter defects amongst those who had a vaginal delivery (n=202) was 26% and 13% respectively. Previous studies [799, 800] including others mentioned in Table 1 and 2 have shown that the

Figure 13. Anal ultrasound image of the mid anal canal
EAS = external anal sphincter. IAS = internal anal sphincter. The area between the black arrows at 11 and 2 o’clock represents an external anal sphincter defect while the area between the white arrows between 9 and 3 represent an internal sphincter defect
first delivery is most likely to be associated with anal sphincter trauma but this study is at variance as it claimed that secundiparous females have the same risk as primiparous women. However, this finding remains unsubstantiated and is further disputed by a subsequent prospective study [801].

Fynes et al. [800] undertook a prospective study of 59 previously nulliparous women through 2 successive pregnancies and found that 34% had anal sphincter injury after their first delivery but only 2 new injuries occurred after the second delivery confirming the findings in Sultan’s study [202]. An important finding in this study was that 42% of women (5 of 12) who had a severe ‘occult’ sphincter injury during their first delivery (squeezing pressure increment < 20mmHg or anal sphincter defect > one quadrant) developed anal incontinence after the second delivery.

Willis et al. [802] performed anal vector manometry, endosonography, PNTML and rectal sensibility at the 32 weeks and 6 weeks postpartum. Using the Kelly-Holschneider score they reported anal incontinence in 5% and identified occult injuries in 19%. PNTML and rectal sensibility was unaffected by vaginal delivery.

Table 3. Prospective studies before and after vaginal delivery of “occult” anal sphincter injury (using 2D ultrasound) and anal incontinence but excluding faecal urgency

* modified continence score questionnaire used and may include urgency

Nazir et al. [803] performed vector manometry and endoanal ultrasound in 73 nulliparous women at 25 weeks and 5 months postpartum (Table 3). There was no correlation between vector manometry and anal endosonography or clinical variables.

Belmonte-Montes [804] performed anal endosonography in 98 nulliparous women 6 weeks before and 6 weeks after delivery and after excluding 20 third degree tears found occult sphincter injuries in 13%. Seventy five percent of women with defects were symptomatic and there was a good correlation between defects and symptoms. However, it is not clear as to how many with ‘occult’ defects were symptomatic (Table 3).

In 3 further studies [805-807] anal ultrasound was performed only after delivery and defects were identified in 11.5 to 34% (Table 4). Varma et al [805] studied 159 postnatal women (105 primiparous and 54 secundiparous) and found occult anal sphincter defects in 11.5% of primiparous and 19% of secundiparous vaginal deliveries but 80% of forceps deliveries. None of their patients suffered faecal incontinence but only 72% of questionnaires were returned. However, their cohort was recruited before 1998 and had a high cesarean section rate (25%) and a low forceps rate (4%).

Williams et al [808] performed a prospective study
in 45 nulliparous women before and after vaginal delivery using 3 dimensional endosonography. There was evidence of perineal trauma in 29% (external sphincter 11%, puboanalis 20%, transverse perineal muscle 7%). Sudol-Szopińska et al. [809] performed 3 dimensional endoanal ultrasound in 112 primiparous women and found only 2.6% sonographic injuries. However, their obstetric practice was different in that they had a 77% episiotomy rate and a 59% epidural rate.

Oberwalder et al. [810] performed a meta-analysis of 717 vaginal deliveries and found a 26.9% incidence of anal sphincter defects in primiparous women and an 8.5% incidence of new sphincter defects in multiparous women. Although two thirds of these women with “occult” defects were asymptomatic in the postpartum period, the probability of faecal incontinence associated with a sphincter defect was 76.8 to 82.8%.

Some 15 years after having first coined the term “occult” OASIS based on anal endosonography, Sultan [202] began questioning whether the 28% sonographic anal sphincter defects (Table 5) identified some weeks after delivery were really genuine occult defects that were not identifiable clinically at delivery. They therefore conducted a prospective study [811] in which 241 women having their first vaginal delivery had their perineum re-examined by an experienced research fellow and endoanal ultrasound was performed immediately after delivery and repeated 7 weeks postpartum. When OASIS were identified by the research fellow, the injuries were confirmed and repaired by the duty registrar or consultant. The prevalence of clinically diagnosed OASIS increased from 11% to 25% (n=59). Every clinically diagnosed injury was identified by postpartum endoanal ultrasound. However, there were three women with sonographic defects in whom the injury was not identified clinically. Two of these had only small IAS defects that were not considered clinically significant. The other was a combined defect of both the IAS and EAS and while this could be classified as an occult tear, it is most probably a tear that was not recognised by the research fellow. At 7 weeks postpartum, no de novo defects were identified by ultrasound. This study concluded that virtually all sphincter defects that have previously been designated as “occult” injuries (Table 5) were in fact OASIS that could have been identified by a trained clinician [812] and that less than one percent are genuine occult OASIS (if indeed they exist). Interestingly, 87% of midwives and 27% of junior doctors failed to recognise OASIS clinically. Although it is likely that some of these injuries would have been detected at the time of suturing the tear, it is concerning that clinical recognition of OASIS is suboptimal [813]. However, this finding is not unique as Groom and Patterson [814] also found that the rate of third degree tears rose to 15% when all “2nd degree tears” were re-examined by a second experienced person.

These studies [811, 814] confirm the lack of adequate training as previously highlighted by Sultan et al. [815] who reported that 91% of doctors who had done at least 6 months of training in obstetrics and 60% of midwives indicated inadequate training in perineal anatomy and 84% and 61% respectively reported inadequate training in identifying 3rd degree tears. Another possible reason for under-diagnosis is that tears of the anal sphincter have been wrongly classified and therefore anal sphincter tears have been under-reported. Any involvement of the anal sphincter should be classified as a third degree tear. However 41% of doctors and 16% of midwives classified a torn anal sphincter as a 2nd degree tear [815]. Sultan and Thakar [816] reviewed every relevant textbook (n=65) in the library of the Royal College of Obstetricians and Gynaecologists (RCOG) and found that there was a lack of consistency in classification and in about 40% the classification was omitted or wrong. Furthermore, previous classifications were incomplete because they did not

incorporate depth of EAS rupture or involvement of the IAS. This therefore has epidemiological, clinical and medicolegal implications. If a third degree tear is incorrectly classified as second degree, then inappropriate repair could result in sub-optimal outcome (see below). Sultan [817] has therefore proposed the following classification (Figure 14)[813] that has been incorporated into the 29th RCOG green top guidelines [818] and the first edition of this book:

First degree: laceration of the vaginal epithelium or perineal skin only.

Second-degree: involvement of the perineal muscles but not the anal sphincter.

Table 5. Prevalence of anal incontinence following primary repair of obstetric anal sphincter rupture (fecal incontinence ie. excluding flatus incontinence only is shown in parentheses).

Mean 39% (15%)

*Includes 2 with secondary sphincter repair
+ *Includes only 4th degree tears
Third degree: disruption of the anal sphincter muscles and this should be further subdivided into:

3a: <50% thickness of external sphincter torn.
3b: >50% thickness of external sphincter torn.
3c: internal sphincter torn also.

Fourth degree: a third degree tear with disruption of the anal epithelium.

An isolated rectal tear without involvement of the anal sphincter is rare and should not be included in the above classification.

2. RECOGNISED OBSTETRIC ANAL SPHINCTER INJURIES

Primary repair of OASIS are usually performed by obstetricians using the end-to-end repair technique [819]. However, as shown in Table 3, anal incontinence occurs in 39% (range 15% to 67%) and in addition, urgency can affect a further 6% [819] to 28% [820]. Frank faecal incontinence affected 14% [819] (range 2% [821] to 29% [822]). The reasons for persistent symptoms are unclear but there are five studies [819, 820, 823-825] demonstrating anal sphincter defects following repair in 40 to 91% of women. Although the extent of the sphincter injury appears to be related to outcome of repair, in some studies (Table 5) the data were not interpretable, [826] incomplete [824] or inclusive of symptoms other than anal incontinence [203]. Forceps delivery, first vaginal delivery, large baby, shoulder dystocia and a persistent occipito-posterior position have been identified as the main risk factors for the development of OASIS [798, 799, 817, 823].

The most popular method of EAS repair is the end-to-end technique but colorectal surgeons prefer the overlap technique for secondary repair because of better outcome [827]. It is now known that like other incontinence procedures, the outcome can deteriorate with time and one study has reported continence in 50% of women at 5-year follow-up. However, at least one third of women in this study had more than one attempt at sphincter repair and therefore these findings cannot be extrapolated to those following primary repair of acute injury [828]. In 1999, Sultan et al. [829] were the first to explore the feasibility of the overlap technique of repair for acute EAS rupture but more importantly advocated the identification and separate repair of the torn IAS. Until then, very little importance was given to the torn IAS during primary repair. However, subsequently in a study involving 500 consecutive women with OASIS it has been shown that sonographic evidence of IAS injury was predictive of faecal incontinence [830]. More recently Roos et al. [831] studied 531 consecutive women with OASIS and found that women who sustained an IAS tear were significantly more likely to suffer incontinence, have lower anal pressures, persistent IAS defects and a reduced quality of life. Increasing IAS defect size has also been shown to be related to symptoms of anal incontinence [832]. When a patient presents with faecal incontinence months or years after delivery, it is almost impossible to perform a successful IAS repair highlighting the importance of identification and repair immediately after delivery [813, 829]. Compared to matched historical controls [819] who had an end-to-end repair, Sultan et al. found that the rate of anal incontinence was reduced from 41% to 8% when the overlap technique was used for EAS repair with separate repair of the torn IAS [829] and therefore recommended the performance of a randomised controlled trial.
The first published randomised trial by Fitzpatrick et al. [820] reported no significant difference between end-to-end and overlap repair although there appeared to be trend towards more symptoms in the end-to-end group. However, there were methodological differences in that the torn IAS was not identified and repaired separately and they used a constipating agent for 3 days after the repair. Unfortunately, they included partial EAS tears in their randomised study. A true overlap [813, 828] is not possible if the sphincter ends are not completely divided and it would be expected that if an overlap is attempted, the residual intact sphincter muscle would have to curl up and hence there would be undue tension on the remaining torn ends of muscle that would be overlapped. This technique would therefore go against the general principles of surgery of deliberately placing tissue under avoidable tension [819].

Garcia et al. [833] also performed a randomised trial of the two techniques and took great care to include only complete ruptures of the EAS (full thickness 3b,3c and 4th degree tears). There were 23 women in the end-to-end group and 18 in the overlap group. Unfortunately, only 15 and 11 women respectively returned for follow-up which was only at 3 months. No significant difference was found between the groups in terms of symptoms of faecal incontinence or transperineal ultrasound findings. However, the authors acknowledged that the major limitations of their study were that randomisation was inaccurate and that their study was underpowered.

Williams et al. [834] performed a factorial randomised controlled trial (n=112) in which women were randomised into 4 groups: overlap with polyglactin (Vicryl; Ethicon, Edinburgh, UK); end-to-end repair with Vicryl; overlap repair with polydioxanone (PDS; Ethicon, Edinburgh, UK); end-to-end repair with PDS. This trial was specifically designed to test the hypothesis regarding suture related morbidity (need for suture removal due to pain, suture migration or dyspareunia) using the two techniques. At six weeks, there were no differences in suture related morbidity. The authors claimed that there were no differences in outcome based on repair technique. Unfortunately, the majority of patients included in this trial were partial tears of the EAS (70% were 3a tears) and as mentioned above, a true overlap [812, 829] cannot be performed if the EAS is only partially torn. Furthermore, their follow up rate at 12 months was only 54%. These data therefore need to be interpreted with caution.

Fernando et al. [835] performed a randomised controlled trial of end-to-end vs overlap technique. The study had adequate power (n=64) and the primary outcome was faecal incontinence at one year. All repairs were performed by two trained operators and Grade 3a EAS were excluded. At 12 months (81% follow-up rate), 24% in the end-to-end and none in the overlap group reported faecal incontinence (p=0.009). Faecal urgency at 12 months was reported by 32% in the end-to-end and 3.7% in the overlap group (p=0.02). There were no significant differences in dyspareunia and quality of life between the groups. At 12 months 20% reported perineal pain in the end-to-end and none in the overlap group (p=0.04). During the 12 months period 16% in end-to-end and none in the overlap group reported deterioration of defaecatory symptoms (p=0.01). Further calculation

---

Figure 15. Flow chart demonstrating a pathway of the management of a subsequent pregnancy following OASIS (MSP= maximum squeeze pressure; CS =caesarean section)
revealed that four women need to be treated with the overlap technique to prevent one woman with OASIS developing faecal incontinence. On the basis of this randomised trial it would appear that the overlap technique of EAS repair accompanied by separate repair of the torn internal sphincter, performed by trained clinicians is associated with a good outcome. In 2006, the Cochrane review [836] concluded that as the surgeon’s experience was not addressed in two of the three randomized studies, it would be inappropriate to recommend one type of repair over the other.

Farrell et al. [837] performed a randomised controlled trial with a 6 month follow-up of end-to-end (n=62) vs overlap (n=63) EAS repair in primiparous women. They reported significantly higher rates of flatal but not faecal incontinence in the overlap group. However, there were more 4th degree tears in the overlap group and therefore more IAS injury that could explain the increased flatal incontinence in this group [838]. At 3 year follow up there was no significant difference in anal incontinence between the groups [839]. This supports the findings of Fernando et al. [835, 836] who demonstrated a significantly higher risk of deterioration in anal incontinence over time in the end-to-end group and highlights the importance of longer term follow-up.

Rygh and Korner [840] performed another randomised controlled trial (n=101) with the primary outcome measure ‘of at least weekly solid stool incontinence’. They concluded that the overlap technique was not superior to the end-to-end repair. However, there were more women with symptoms of anal incontinence with the end-to-end repair (34% vs 20%).

Therefore, until the Cochrane review is updated the current recommendation is that as the surgeon’s experience was not fully assessed in all the studies, it would be inappropriate to recommend one type of repair in favour of another [836].

Management of subsequent pregnancy after OASIS

All women who sustained OASIS should be assessed in hospital by a senior obstetrician 6 to 12 weeks after delivery. Some centres have established dedicated multidisciplinary perineal clinics. In 2010, 30% of UK hospitals had such a dedicated clinic (Sultan AH, unpublished data). It is important that a comprehensive history is taken regarding bowel, bladder and sexual function. As these symptoms are embarrassing, a structured questionnaire may be useful. A proper vaginal and rectal examination should be performed to check for complete healing, scar tenderness and sphincter tone [809, 813, 841]. Mild incontinence (faecal urgency, flatus incontinence, infrequent soiling) may be controlled with dietary advice, controlling agents (loperamide or codeine phosphate), physiotherapy or biofeedback. However, women who have severe incontinence should, in addition, be offered secondary sphincter repair by a colorectal surgeon. Asymptomatic women must be advised to return if symptoms develop [812]. There are no randomised studies to determine the most appropriate mode of delivery. Women who have had a successful secondary sphincter repair for faecal incontinence should be delivered by cesarean section [842]. Some women with faecal incontinence may choose to complete their family prior to embarking on anal sphincter surgery. It would appear that these women could be allowed a vaginal delivery as the damage to the sphincter has already occurred and risk of further damage is minimal and probably insignificant in terms of outcome of surgery. The risk of worsening or de novo neuropathy has not been quantified and in practice, does not appear to be clinically significant.

Until recently [821] the management of a subsequent pregnancy after OASIS has not been described in any detail [816].

It has been suggested that a cesarean section should be performed even after transient anal incontinence [843] but this has been questioned [844].

In order to counsel women with previous OASIS appropriately, Sultan et al [812] find it useful to have a symptom questionnaire, anal ultrasound (Figure 7) and manometry results (Fig 3). It has been shown that clinical assessment alone has a poor sensitivity for detecting anal sphincter defects [845]. If vaginal delivery is contemplated then these tests should be performed during the current pregnancy unless performed previously and found to be normal. In a prospective study over a 5 year period, Scheer et al. [846] followed the protocol shown in Figure 15 and found that when women who had no evidence of significant anal sphincter compromise based on anal endosonography and manometry were allowed a vaginal delivery (the others offered cesarean section) there was no deterioration in symptoms, anorectal function or quality of life. Although 11% of textbooks recommend a prophylactic episiotomy [816] there is limited evidence that an elective episiotomy prevents subsequent anal sphincter disruption [116] while other studies have indicated that episiotomy may increase the prevalence of anal sphincter disruption.

III. INSTRUMENTAL VAGINAL DELIVERY

Although only 4% of women delivered by forceps sustain a 3rd/4th degree tear, up to 50% of those that do tear have an instrumental delivery [819]. Vacuum extraction is associated with fewer OASIS than forceps and this view is supported by two large randomised studies [847, 848]. A UK study [847] where mediolateral episiotomy is practised reported severe vaginal lacerations in 17% of forceps compared to 11% of vacuum deliveries and a Canadian study [848] where midline episiotomy is practised reported OASIS in 29% of forceps compared to 12% of vacuum deliveries. In a Cochrane review [849], forceps were less likely than the vacuum extractor to fail to achieve a vaginal birth (risk ratio 0.65, 95% CI: 0.45-0.94).
However, with forceps there was a trend to more cesarean sections, and significantly more third- or fourth-degree tears (with or without episiotomy), vaginal trauma, use of general anaesthesia, and flatus incontinence or altered continence. Facial injury was more likely with forceps (RR 5.10, 95% CI: 1.12-23.25). Serious neonatal injury was uncommon with either instrument.

A 5 year follow-up of infants who participated in a randomised trial of forceps and vacuum delivery has confirmed that there is no difference in terms of neurological development and visual acuity with use of either instrument [850]. "Occult" trauma to the anal sphincter has also been identified more frequently in forceps delivery occurring in up to 80 percent [202, 805, 851]. A small randomised study (n=44) confirmed this by identifying occult anal sphincter defects in 79% of forceps compared to 40% of vacuum deliveries [851]. Trauma occurs more frequently when a second instrument is used to attempt vaginal delivery [851] and therefore if no descent of the head occurs following appropriate cup selection and application technique of vacuum extraction, one should resort to a cesarean section. Metal cups appear to be more suitable for ‘occipito-posterior’, transverse and difficult ‘occipito-anterior’ position deliveries [852]. The soft cups seem to be appropriate for straightforward deliveries as they are significantly more likely to fail to achieve vaginal delivery (OR 1.65, 95% CI 1.19-2.29). Although, they were associated with less scalp injury (OR 0.45, 95% CI 0.15-0.60), there was no difference between the two groups in terms of maternal injury. Farrell et al. [853] performed a prospective study of 690 primigravid women and found that forceps delivery was associated with a higher incidence of flatus incontinence (RR 2.6) compared to spontaneous vaginal delivery and a higher incidence of both flatal (RR 2.6) and faecal (RR 3.6) incontinence compared to cesarean delivery. Vacuum delivery did not increase the risk of flatus incontinence. MacArthur et al. [786] performed the largest questionnaire based multicentre study to establish the prevalence of faecal incontinence at 3 months post-partum. They reported a prevalence of 9.2%, with 4.2% reporting it more often than rarely. Compared to vacuum extraction, forceps delivery was associated with almost twice the risk of developing faecal incontinence. Thakar and Eason [854] performed a meta-analysis and demonstrated that one anal sphincter injury is avoided for every 18 women delivered by vacuum extraction instead of forceps.

IV. EPISIOTOMY

There is now considerable observational data to indicate that a reduction in episiotomy rate is not associated with an increase in OASIS [855]. The Cochrane database [200] shows that restricting the use of episiotomy is associated with less posterior trauma. Although there was an increase in anterior perineal trauma it had no effect on the development of urinary incontinence. Henriksson et al. [856, 857] performed an observational study in which they noted that when midwives who previously had a high episiotomy rate reduced their rate, the prevalence of OASIS also reduced. However, this beneficial effect was abolished when midwives with a low rate of episiotomy attempted to reduce it even further. Based on this evidence, it was suggested that the ideal episiotomy rate should lie between 20 to 30% and no more. Midline episiotomies are more popular in North America as it is believed that they are more comfortable and recovery is less complicated. However Coats et al. [858] performed a quasi-randomised study of 407 primiparae and found 24% of midline episiotomies extended into the anal sphincter (partial or complete tears) compared to 9% of mediolateral episiotomies. Although the perineum was significantly less bruised in the midline group and sexual intercourse commenced earlier, pain and wound breakdown was similar in both groups. However, care needs to be taken to ensure that mediolateral episiotomies are performed correctly as Andrews et al [859] have shown that only 22% of doctors and no midwife made the incision commencing from the posterior fourchette with a 40 to 60 degree angle from the midline. Another study demonstrated that for every six degrees away from the midline there was a 50% reduction in OASIS [860]. It has also been shown that the angle of incision when the head is crowning is underestimated such that a 60 degree angle measures 45 degrees after delivery [205].

V. DELIVERY TECHNIQUES

Pirhonen et al. [861] compared the frequency of OASIS in low risk deliveries between two Scandinavian countries (26 541 vaginal deliveries) and found the risk to be 13 times higher in Sweden (Malmö vs Finland (Turku). They speculated that the only explanation for this was a difference in manual support given to the baby’s head during crowning and pushing the perineum under the chin. Jonsson et al. [862] performed a randomised trial between the Ritgen’s manoeuvre and standard delivery but found no significant difference in OASIS rates. However, only 50% of the eligible women were assigned and almost 20% of the women randomised to the Ritgen’s manoeuvre did not have this method of delivery. The following interventions with randomised controlled trials evidence regarding effectiveness demonstrated no effect on OASIS: antenatal perineal massage, pelvic floor exercises in pregnancy, water births, positions during labour and birth, epidural analgesia, early vs delayed pushing with epidural and second stage pushing advice [854]. Although one small randomised trial showed otherwise [788] other large observational studies, have shown that duration of the second stage of labour is an independent risk factor for the occurrence of OASIS [796, 799, 863, 864].
VI. TRAINING

McLennan et al. [865] who surveyed 1177 fourth year residents and found that the majority of residents had received no formal training in pelvic floor anatomy, episiotomy or perineal repair and supervision during perineal repair was limited. Stepp et al. [866] found that textbooks used in American practice offered little in terms of prevention and repair of perineal trauma. There is evidence from one study [815] that perineal anatomy is poorly understood by midwives and trainee doctors, who perform the bulk of deliveries in the UK. In this study 41% of trainees and 16% of midwives incorrectly classified a partial or complete tear of the EAS as ‘second degree’. Inconsistency in classification of tears would allow many injuries to pass, unrecognised. In another study conducted in the USA, the majority of residents demonstrated substandard skill in repairing OASIS [867]. It has been shown that hands-on workshops on perineal repair (www.perineum.net) can change practice [868-870] and intensive and focused training in perineal anatomy and repair should therefore become an essential module in the programme for trainees and midwives. Hals et al. [871] provided the best available evidence to show how an interventional program in four Norwegian hospitals can reduce the frequency of OASIS. The program involved a 2-3 day course at the delivery suite of each hospital that included training on delivery with perineal support and delivery of the neonates chin. In addition, restrictive mediolateral/lateral episiotomy was recommended. OASIS reduced from 4.16 -5.25% before intervention to 1.73% during the last year of intervention.

VII. IRRITABLE BOWEL SYNDROME (IBS)

IBS affects 3-17% in selected populations and the cause remains unknown. Donnelly et al. [872] recruited 312 primiparous women and reported that 11% of young primiparous women (n= 34 of 208) suffered from pre-existing IBS prior to their first pregnancy. Twenty four percent reported symptoms of impaired faecal continence in the puerperium but symptoms were found significantly more frequently in those with IBS compared to those with normal bowel habit (71% vs 18%). However, women suffering from IBS are no more likely to incur mechanical or neurological injury to the anal sphincter. Women with IBS delivered by cesarean section did not have altered continence postpartum. However, 6 months postpartum there were no symptomatic differences between those with IBS and those without but only 90 of the 107 women who had either impaired faecal continence or abnormal anal manometry were studied. Treatment is directed towards the predominant symptom and although antispasmodics such as hyoscine, mebeverine and dicyclomine are used widely to relax intestinal smooth muscle, they should be avoided during pregnancy.

VIII. CONCLUSIONS AND RECOMMENDATIONS

a) Compared to forceps the vacuum extractor is associated with less perineal and anal sphincter trauma. (Level 1)
b) Compared to midline episiotomy, mediolateral episiotomy is associated with a significantly lower risk of 3rd/4th degree tears. (Level 1)
c) Liberal use of episiotomy is not beneficial (Level 1) and restricting the rate of episiotomy to about 30% may reduce the risk of trauma to the anal sphincter. (Level 4)
d) A prolonged active second stage of labour is associated with denervation of the pelvic floor and one study has suggested that this also occurs with a prolonged passive second stage of labour with epidural analgesia. In these circumstances, early use of oxytocics in the second stage of labour may be useful. (Level 4)
e) Selective use of cesarean section may be beneficial particularly in those who have evidence of compromised anal sphincter function and those who have had previous successful continence or prolapse surgery. (Level 4)
f) Modification in techniques of delivery of the baby may reduce anal sphincter injury and further research is needed. (Level 3)
g) A more focused training program for doctors and midwives needs to implemented. There is a poor understanding of perineal and anal sphincter anatomy and hence identification of anal sphincter trauma, incorrect classification and poor outcome of repair. (Level 4)
h) There is increasing evidence supporting the identification and repair of the internal anal sphincter. Repair techniques of the external sphincter (overlap versus the end-to-end) are inconclusive and one technique cannot be recommended over the other. (Level 1)

G. PATHOPHYSIOLOGY OF INCONTINENCE IN MEN

Urinary incontinence (UI) in men, as in women, which is subdivided into three major groups as there is urgency, stress and mixed UI, may be caused by either an abnormality of the bladder (UUI), an abnormality of the bladder outlet (SUI) (bladder outlet which includes the internal (IUS) and distal to the prostate the external urethral sphincter (EUS)), or a combination of both (MUI) [873-875]. Changes in bladder ultrastructure and function that can occur as a result of neurological disease or aging (that can cause detrusor overactivity or underactivity) occur in men [876].
Many of these problems are associated with benign and/or malignant diseases of the prostate and their treatment. For example, in men the prevalence of detrusor overactivity and impaired compliance causing incontinence is not associated with the bladder outlet obstruction caused by benign prostatic obstruction [876, 877].

Key outlet functions are; maintaining closure for urine storage, increased closure (guarding) during exertion, sustained opening for voiding, transient opening for territorial marking in animals and orthograde male ejaculation. These are coordinated by several spinal and higher CNS centres, with overlap of the somatic, sympathetic and parasympathetic nervous systems [878]. Also sphincter insufficiency resulting in stress urinary incontinence (SUI) does not generally occur as the result of aging, but rather as a side effect of surgery (for benign or malignant conditions) or radiation of the prostate followed by transurethral resection or neurological injury. Ectopic ureter in the male does not cause incontinence as its insertion into the lower urinary tract is always proximal to the external urethral sphincter. Extra-urethral incontinence in men is only known as a result of a fistula, where as it can occur in women because of congenital (developmental) abnormalities. Fistulae in men are most often iatrogenic (surgery, radiotherapy, cryotherapy, HIFU (High-intensity focused ultrasound)) or inflammatory (diverticulitis).

This section will focus on the pathophysiology of incontinence as it relates to prostatic obstruction and its treatment and the treatment of prostate cancer.

I. CONTINENCE MECHANISM IN THE MALE

The internal urethral sphincter (IUS) has its source at the urinary bladder’s inferior neck (smooth muscle) continues through the prostatic urethra above the verumontanum and remains under autonomic control. The external urethral sphincter (EUS) located distal to the prostate at the level of the membranous urethra as the secondary sphincter to control the flow of urine. It contains mainly striated muscle and is therefore under voluntary control by the somatic nervous system. Opposite to the female sphincter (Figure 16), the male closing mechanism of the bladder is separated by the prostate.

At the boundary between the IUS and EUS, the striated and smooth muscle fibres intertwine to some extent. The external urethral sphincter (EUS) extends from the prostatic urethra below the verumontanum through the membranous urethra. EUS includes the rhabdosphincter (intrinsic skeletal and smooth muscle) and extrinsic paraurethral skeletal muscle. At the prostatic level, the superior part of the striated EUS is largely confined to the anterior side of the urethra and prostate. Inferior to the prostate, the EUS is horseshoe-shaped (although named as the rhabdosphincter, omega shaped) with the opening on the dorsal side. The dorsal muscle fibres of the left and right sides approach the midline and sometimes cross the prostate [227, 880, 881].

For simplicity, the normal male urinary sphincter mechanism may be divided into two functionally separate units, the internal urethral sphincter (IUS) and the external urethral sphincter (EUS) [882]. The IUS consists of the bladder neck, prostate and prostatic urethra to the level of the verumontanum. The IUS is innervated by autonomic parasympathetic and sympathetic fibres from the inferior hypogastric plexus (Figure 17). The EUS extending from the verumontanum to the proximal bulb is comprised of a number of structures that help to maintain continence.

![Figure 16](image-url)

Figure 16. a: Rhabdosphincter and urethra of a female fetus (transverse section). Both ends of the omega-shaped rhabdosphincter (RS) and the urethra (U) are anchored in the ventral wall of the vagina by the help of a strong dorsal connective tissue raphe (T). Ventrally and laterally the rhabdosphincter and the urethra are surrounded by loose connective tissue (and vessels). P, pubic bone; N, nerves; b: Rhabdosphincter and urethra of the same fetal specimen as in (transverse section). The level of this section is more caudal than in (a). P, pubic bone; U, urethra; RS, rhabdosphincter; UF, ventral urethral fascia; T, strong dorsal connective tissue raphe (T); the tendinous arch of the pelvic fascia is marked with arrows.

The male EUS complex is composed of the prosta-
to-membranous urethra, cylindrical rhabdosphincter (external sphincter muscle) surrounding the prosta-
to-membranous urethra, and extrinsic paraurethral musculature and connective tissue structures of the pelvis. The rhabdosphincter is a muscular structure consisting of longitudinal smooth muscle and slow-
twitch (type I) skeletal muscle fibres, which can main-
tain resting tone and preserve continence [227, 883, 884]. The striated muscle of the rhabdosphincter is considerably thicker ventrally and thins dorsally. Stri-
ated muscle fibres of the rhabdosphincter have been shown to intermingle with smooth muscle fibres of the proximal urethra, suggesting a dynamic and coordi-
nated interaction. The rhabdosphincter is invested in a facial framework, and supported below by a mus-
culofascial plate that fuses with the midline raphe, which is also a point of origin for the rectourethralis muscle [885]. Superiorly, the fascial investments of the rhabdosphincter fuse with the puboprostatic liga-
ments [886]. This dorsal and ventral support probably contributes to the competence of the sphincter. The striated fibres of the extrinsic paraurethral muscle (levator ani complex), on the other hand, are of the fast-
twitch (type II) variety [883]. During sudden increases in abdominal pressure, these fibers can contract rapidly and forcefully to provide continence. Continence maintains even after inducing paralysis of the striated sphincter [887] indicating that this structure is not sole-
ly responsible for continence. In addition, unlike in the female where urethral support can be compromised as a result of childbirth and aging [888], in the majority of the cases the male rhabdosphincter functions as a result of prostate surgery [889]. The striated muscle fibres of the rhabdosphincter intermingle with smooth muscle fibres of the proximal urethra and in fact have been shown to be inseparable from each other [880]. In the past related to the approach of radical prosta-
tectomy the smooth muscle fibres inserting into the bladdernec (IUS) were resected, which interrupted innervation. It is worth noting that impaired detrusor contractility seems to be frequently associated with intrinsic sphincter deficiency. With increasing knowl-
edge of the periprostatic nerves and the improvement of preservation of the bladder neck (IUS) the functional outcome has improved even further [890].

The EUS is innervated by the autonomic (via the pelvic nerve) and somatic (by the pudendal nerve) nervous systems. Nerve fibres are seen proximally in a dorsal position (5 to 7 o’clock), while more distally, they are located primarily laterally [885, 891]. The intrinsic smooth muscle of the proximal urethra receives parasympathetic innervation from pelvic nerve branches of the inferior hypogastric plexus [891, 892]. The rhabdosphincter may also receive somatic innervation. Hollabaugh et al. described the so-called “putative continence nerves” as branches of the pelvic nerve travelling under the endopelvic fascia picking up intrapelvic branches of the pudendal nerve, given off before it enters the pudendal canal, which was further verified by Castello et al. [891, 893]. It has also been proposed that somatic innervation from the pudendal nerve after it exits the pudendal canal is primarily sensory in origin, facilitating reflex contraction of the sphincter complex to maintain continence. [894] (Figure 17).

An elegant histological and immunohistochemical study with 3-D reconstruction in the male fetus has confirmed mixed autonomic and somatic innervation [880]. Unmyelinated (autonomic) nerve fibres desti-
tined for smooth muscle fibres run alongside of the myelinated (somatic) fibers. The majority of the unmy-
elinated fibres approach the smooth muscle layers at 5 and 7 o’clock while the majority of myelinated fibres penetrate the striated sphincter at 3 and 9 o’clock.

![Figure 17. The innervation of the bladder outlet is better investigated with its internal urethral sphincter than the external sphincter, which is substantial for the continence.](image-url)
Structure and innervation are important components of sphincter function. In addition, Tuygun et al. [895] have found a much higher incidence of periurethral (or peri-sphincter) fibrosis in incontinent vs. continent men after prostatectomy. Using MRI at least 6 months after prostatectomy they discovered that all 22 incontinent men had periurethral fibrosis while only 4/14 (29%) continent men did [896, 897]. This might lead to the importance of the corpus spongiosum, which surrounds the bulb urethra and supports with its blood filling in addition to the sphincteric function.

In summary, sphincter continence in the male is dependent on the integrity of the IUS and/or EUS, its support structures and neural innervation and probably the prostate, as long it is not enlarged to cause obstruction. Following the removal of the IUS during radical prostatectomy, continence seems to be mainly maintained by the EUS mechanism, consisting of soft tissue supportive structures, smooth muscle, and striated muscle. This outcome has improved in relation to surgical techniques which preserve the IUS. The smooth muscle and slow twitch striated muscle of the rhabdosphincter (EUS) are probably mostly responsible for sphincter continence; however, striated muscle contractions of the periurethral and paraurethral muscles are likely to assist. Damage to the innervation (parasympathetic and somatic) of the smooth and striated muscle may indirectly contribute to post-prostatectomy incontinence. In addition, compromise of the sphincter support mechanism or post-operative changes such as fibrosis can compromise sphincter function (Figure 18).

II. INCONTINENCE ASSOCIATED WITH BPH AND ITS TREATMENT

Benign prostatic hyperplasia (BPH) and benign prostatic obstruction (BPO) and their treatments have long been associated with incontinence in men. Detrusor Overactivity (DO), impaired compliance and urgency incontinence are prevalent in men with BPO. The prevalence of OAB ranges in adult males from 10% to 26% and in adult females from 8% to 42%. It increases with age and is often associated with other LUTS [898]. In men undergoing urodynamic testing detrusor overactivity is present in 40-80% of patients with obstruction [899-901]. In addition, impaired compliance, another potential cause of incontinence, has been shown to have a high correlation with outlet obstruction in men [902, 903]. Thus even before treatment of BPH and BPO there is a notable incidence of bladder dysfunction and incontinence.

Incontinence after the treatment of BPH may be related to persistent bladder dysfunction, new onset bladder dysfunction or sphincter dysfunction (injury). However, one European survey of 840 men reported lower prevalence of UI after transvesical prostatectomy for BPH compared to other studies [904]. Turner-Warwick et al. [905] first directed attention to the relationship of bladder outlet obstruction, the symptoms of frequency, urgency and urgency incontinence (now commonly known as LUTS; Lower Urinary Tract Symptoms) and the correlation of these symptoms with detrusor overactivity seen on cystometry. They noted that in 75% of men, symptoms resolved after relief of the obstruction. Leng and McGuire [906] showed improvement in compliance after removal of obstruction in 7/9 men with severely impaired compliance (<5 ml/cmH²O), but only one man regained “normal” bladder compliance. Several contemporary explanations for the cause of persistent overactivity after obstruction exist. These include denervation supersensitivity of the bladder muscle [11, 907, 908], alterations in collagen composition of the obstructed bladder [909], emergence of altered and increased sensory reflexes mediating the micturition reflex [910, 911] and physical changes in detrusor myocytes affecting electrical transmission [912] or even the remaining influence of CRP as investigated by Kupelian et al [73]. In addition, the bladder itself and particularly the trigone may be inadvertently resected during surgery, causing bladder dysfunction or even without prior surgical treatment. Causes of sphincter damage related to transurethral or open prostatectomy include direct damage because of surgical technique and electrocautery or thermal injury to the sphincter [913].

Recently, Han et al [914] conducted a retrospective data analysis using a managed care data set (Integrated Healthcare Information Services National Benchmark Database) from 1997 through 2003. They identified a cohort of men with BPH using International Classification of Diseases, Ninth Revision (ICD-9) codes. From a total of over 12 million men, 411,658 men with BPH (3.3%) were identified. The group then determined the nature of incontinence in these men with BPH focusing on its incidence, prevalence, and management. Furthermore they stratified patients into therapeutic subgroups of watchful waiting, alpha-blockers, 5-alpha-reductase inhibitors and surgery. Of the total cohort, 2.7% had a diagnosis of incontinence. Most of these men (87.5%) did not have prior BPH surgery, but those who did have surgery 12.5% were diagnosed with incontinence. The rates were almost identical whether the procedure was transurethral resection or incision, laser, transurethral needle ablation, transurethral microwave therapy. Newer data suggest that open prostatectomy might be more effective and safer than the transurethral approaches, which probably depends to the size of the prostate and the experience of the surgeon [915, 916]. The rate of incontinence after surgical treatment was 1.4% for both stress and mixed incontinence, 4.5% for urgency incontinence and 6.5% for unspecified incontinence whereas the incontinence rates for men on watchful-waiting, alpha-blockers, 5-alpha-reductase inhibitors and combination therapy were 6.4%,
5.7%, 5.1%, and 6.5% respectively [914]. This study provides some interesting data but must be interpreted with caution. The diagnosis of incontinence was limited by what the patient and provider considered to be incontinence and was not often confirmed by objective testing.

Nevertheless, the relationship between BPH and incontinence can clearly be inferred. Until the last decade, transurethral resection of the prostate and open prostatectomy accounted for the majority of surgical procedures to treat BPO. In 1989, the American Urological Association published two major series on TURP and its complications. The AUA cooperative study included 3,885 patients from 13 teaching centres and private practices [917], while the second consisted of a survey of all practicing urologists in the United States of whom 2,716 urologists responded [917]. Rates of post-TURP incontinence requiring a pad or collection device were 0.4% in the first and 3.3% in the second study. The AUA Cooperative study also reported mild stress

![Figure 18. The external urethral sphincter (EUS) and internal urethral sphincter (IUS) in a male fetus (12 wk of gestation). Three-dimensional reconstruction in (A) anterior view, (B) posterior view, (C) right-lateral view, (D) superior view, and (E) inferior view. The EUS is shown in blue, and the IUS is shown in pink. The urethra and prostate are shown in light grey. Anterior and posterior directions are represented by the letters “a” and “p.” Immunohistochemically stained sections: Sections from inferior (F) to superior (H) stained immunohistochemically for striated muscle, showing the EUS (black arrowheads). Panels (I) through (K) are from the same level as sections (F) through (H), stained immunohistochemically for smooth muscle, showing the IUS (red arrowheads). Note the smooth muscle tissue at the dorsal side of the urethra, where the striated muscle of the external sphincter is lacking; see red arrow in (J). Red lines in (C) illustrate the level of the sections as seen in (F) through (H). L = levator ani muscle; PB = pubic bone; R = rectum; U = urethra; bar = 0.5 mm. From Wallner et al, Eur Urol 55(4):932-944, 2009 [227]]
incontinence in 1.2% [918]. In 1994, the Agency for Health Care Policy and Research published clinical guidelines for the diagnosis and treatment of benign prostatic hyperplasia. The guidelines panel reviewed 27 articles about transurethral prostatectomy and 30 articles reporting open prostatectomy to analyse treatment outcomes. The panel reported that the risk of total incontinence, defined as complete loss of voluntary control over micturition was of great concern to patients facing a treatment decision for BPH. In an overall ranking of 15 different outcomes, the panel’s proxy judges ranked total incontinence of urine as the fourth most important outcome influencing a treatment decision. After TURP, 2.1% of patients experienced stress incontinence, 1.9% had urge incontinence, and 1.0% reported total incontinence. The panel attempted to abstract data on urgency incontinence, but found very few studies reporting this particular outcome, therefore a statistical analysis was not performed. For open prostatectomy stress incontinence occurred in 1.9%, urgency incontinence in 0.5% and total incontinence in 0.5% of patients.

Most studies evaluating post TURP and open prostatectomy incontinence have found a significant incidence of sphincter and bladder dysfunction. The incidence of sphincter dysfunction ranges from 20-92% and bladder dysfunction from 56-97% [919-924]. The relatively high incidence of sphincter dysfunction may seem somewhat surprising as the incidence of DO before treatment is so high and it persists in 18-59% after surgery to relieve obstruction [900, 905]. Therefore one might expect that a large number of patients would have persistent detrusor overactivity and urgency incontinence. However, in large series, sphincter dysfunction appears to be the main cause of incontinence. The high incidence of sphincter dysfunction is likely to represent a selection bias, e.g. large numbers of patients referred to tertiary centres for treatment of stress incontinence. Nitti et al. [925] evaluated patients with voiding dysfunction after TURP and found that of those who had incontinence 75% had bladder dysfunction, while only 20% had sphincter dysfunction (the cause of incontinence could not be identified in 5%). Twenty-seven percent of incontinent patients with bladder dysfunction also had obstruction. In the past decade, alternatives to TURP for the treatment of BPH have emerged. Most notable are thermal therapies and laser resection/enucleation of the prostate. Thermal therapies are considered “less invasive” and outcomes in most series are not comparable to traditional TURP with respect to efficacy. However some laser treatments provide similar efficacy in well-selected patients, at least in the short term. Studies that have evaluated that holmium laser resection (HoLRP) and potassium titanyl phosphate (KTP) laser vaporisation of the prostate have shown a similar incidence of incontinence. Two randomised controlled trials of holmium laser versus TURP have shown rates of stress incontinence to be very similar.

Westenberg, et al [926] showed the incidence of stress incontinence with or without urgency incontinence to be 7% for HoLRP versus 6.7% for TURP at a minimum of 4 years follow-up. Kuntz and colleagues [927] found just 1% stress incontinence in each group at 12 months. They also showed a similar rate of resolution of preoperative urge incontinence for both groups (81% versus 85%). Two other prospective non-randomised trials of HoLEP found 0.6% -2.5% incidence of stress [928]. Two randomised controlled trials of KTP (green light) laser versus TURP reported 0% and 1% stress incontinence in each group respectively [929, 930] while a third randomised trial did not mention incontinence [931]. Retrospective studies on Greenlight showed a 2-3.3% incidence of stress incontinence [932, 933]. Te, et al. [934] reported 1 year results of Green Light in the first US multicentre prospective trial. At 12 months 2 of 139 men had persistent new onset UI. They reported no stress incontinence. Others report no better outcome than standard management apart from length of hospitalisation [935].

In addition to the surgical treatment, it needs to be borne in mind that males with urinary tract infections (UTIs) had higher adjusted rates of UI with a pooled odds ratio of 3.5 (95% CI: 2.3; 5.2) [936-940]. Acute genitourinary toxicity, enuresis, incomplete urination (residual), and other urological conditions were associated with higher adjusted odds of UI in all studies that examined the relationship [936, 941-943].

III. CONTINENCE ASSOCIATED WITH RADICAL PROSTATECTOMY

1. INCIDENCE

The incidence of incontinence after radical prostatectomy has been a source of controversy over the past several decades as reported rates have varied greatly depending on the definition and methodology of data collection. The incidence has probably declined over the past two decades, owing to advances in surgical technique and to earlier recognition of lower stage disease in younger patients, however the prevalence of post-prostatectomy incontinence has risen; paralleling the increase in surgical procedures performed annually [944]. In 1991, Foote et al tabulated data from series published between 1977 and 1990, and reported a range of incontinence rates from 2.5 to 87% after radical prostatectomy [945]. In general, older single-institution studies utilizing physician assessments to determine incontinence rates report relatively low rates (5-8%) [946-951]. Another study with a follow-up of up to 5 years reported frequent leakage in 14% or no urinary control in men 60 months after diagnosis [952]. A variety of definitions of incontinence were used, making comparison of data difficult. Since then, validated patient questionnaires have been developed, which help to standardise definitions of incontinence, allow easier comparison between in-
tions, and assess the impact of incontinence on quality of life. This eliminates physician bias perhaps improving accuracy [953-955], although it introduces the cavee at that questionnaire-based data may reflect subjective urine leakage but does not correlate with bother or actual urine, especially for mild degrees of incontinence [956, 957]. As expected these studies show the incidence of incontinence to be significantly higher, 13-65%, depending upon the definition.

In the past few years robotic radical prostatectomy has gained popularity and now, probably the majority of radical prostatectomies are performed with the support of robot surgical assistance. This surgical approach (trans- vs. extraperitoneal) has been further developed so that even in this instance, the outcome related to the approach needs to be evaluated periodically by further developments [958]. Similar to what has been observed with open radical prostatectomy, the continence rates tend to increase with longer follow-up and may continue to improve even beyond 12 months [959]. The continence rates from several large recently published series ranged from 68 to 97% at 12 months post surgery [959-964], reaching the laparoscopic data with longer experience (continence range 12 months post op: 84.9 – 94 (mean72)% [965], Jacobson et al reported in their prospective study that there were no differences in urinary functional outcomes one year after open radical retropubic prostatectomy or laparoscopic radical prostatectomy [966] with 20 - 27% reported to have achieved immediate continence following catheter removal [960, 962, 963]. Recently anterior vesicourethral reconstruction [967], posterior vesicourethral reconstruction [968] and total reconstruction [969] have been described to increase the continence rate and hasten time to recovery of continence. As in earlier open prostatectomy series, robotic series tend to be single institution studies with physician reported outcomes and continence status based on 0 or 0-1 pads.

In 1993, The American College of Surgeons Commission on Cancer reviewed the reported results of 2,122 patients treated by radical prostatectomy performed at 484 institutions in 1990 [970]. Only 58% reported complete continence, 23% reported occasional incontinence not requiring pads, 11.2% wore 2 or fewer pads per day, 4% wore more than 2 pads per day, and 3.6% were completely incontinent. Fowler et al [971] published the results of an outcomes study on a series of Medicare patients with less encouraging results. In this series patients age >65 surveyed by mail, telephone, and personal interview, over 30% reported currently wearing pads or clamps to deal with wetness; over 40% said they dripped urine on coughing or when the bladder was full; 23% reported daily wetting of more than a few drops. Six percent had surgery after the radical prostatectomy to treat incontinence.

There appear to be differences in physician vs. patient reported outcomes and centres of excellence versus community surgeons’ outcomes [972]. When trying to interpret all of the data, it is clear that the varying definitions of incontinence make comparisons impossible. Even using the definition of pad free totally continence has its limitations. Rodriguez et al [964] found that 70% of men who attained “pad-free continence” after radical prostatectomy have occasional incontinence. Conversely, Lepor et al [973] asked the single question “Do you consider yourself continent?” at 3-24 months after surgery where 97.1% of men answered yes. They found that the best correlation of objective measures with a positive response were 0 or 1 pad, total control or occasional dribbling, and no or slight problem from incontinence on the UCLA/RAND questionnaire [973]. There is a wealth of good quality prospective studies evaluating incontinence after prostatectomy in an objective manner. One such study compared continence in patients undergoing open versus laparoscopic radical prostatectomy at one year, using a 24-hour pad test, symptom scores and quality of life measures [689]. Incontinence was defined as a pad weight of > 8 grams/24 hours. There were no differences in objective and subjective measures between the two groups. Urinary incontinence was present in 13% of open and 17% of laparoscopic cases. In practical terms incidence of incontinence that produces bother, no matter what its degree, is the true parameter of interest. However, because of the individual variability of bother and the way data have been collected, we must be aware of the limitations of the historical data in the literature.

2. RECOVERY OF CONTINENCE AFTER RADICAL PROSTATECTOMY

While the majority of patients experience incontinence immediately following RRP, for most this is transient with a gradual improvement over time. It needs to be kept in mind that there is even a group of about 4% who might be incontinent prior to surgery (≥8g) although they might not consider themselves as incontinent [974]. Most studies report progressive return of continence up to one year after surgery and in general intervention for incontinence is usually delayed until one year after surgery unless absolutely no progressive improvement is seen. Thus, most prostatectomy series report continence rates at 1 year. Lepor and Kaci [973] showed that continence may continue to improve up to 24 months based on objective and subjective measures. They showed modest improvements in bother (UCLA RAND questionnaire) pad usage and total control rates between 12 and 24 months. Pad weights were not determined so it is possible that some “improvement” could have been related to patient tolerance and expectations over time. Smither et al. [975] objectively assessed the natural history of post radical prostatectomy incontinence using a standardised I hour pad test. They showed a rapid improvement in urinary control during the first 18 weeks post-RRP with a flattening of the recovery
curve beyond that point. Minimal incontinence defined as < 1 g on a 1 hour pad test was as demonstrated in 3, 3.67%, 65, 87 and 91% of patients at 2, 6, 18, 30, 42, and 54 weeks. They concluded that the 18-week marker appears to be the time point after which the majority of patients have achieved urinary control, although a small percentage will have continued objective improvement. This estimation is echoed by Socco et al. reporting the progressive improvement of continence until 2 years following RRP but some patients may become incontinent even later [976] whereas others reported that the peak level of continence was already reached at 3 months [974].

3. RISK FACTORS

An increased risk of post-prostatectomy incontinence in older men is supported in theory by anatomical observations. With advancing age, there is evidence of atrophy of the rhabdosphincter [885] and neural degeneration [977]. Several studies have shown advancing age to be a risk factor for postoperative incontinence [946, 947, 949, 951, 978, 979]. Steiner, et al [950] found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older. Catalona et al. [946] reported that “Recovery of urinary continence occurred in 92% (1,223 of 1,325 men) and was associated with younger age (p<0.0001) which might be related to surgical approach (nerve sparing), which might be performed more in the younger than in the older patient, although they ultimately reach a similar outcome [980]. Most large series have found no correlation between the stage of disease and incontinence rates [946, 947, 953, 957], whereas Loeb reported the benefit of the younger patient in the high risk group to maintain continence [981]. However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing) and rates may be higher, but this appears to be a reflection on surgical technique and not disease stage [947].

Authors of several single-institution studies have argued that surgeon experience and surgical technique are important determinants of post-operative incontinence rates [891, 921, 947, 982, 983] and many have found that changes in their own technique have led to reduced rates of incontinence or a reduced time to continence recovery [891, 947, 969, 984-986].

This includes procedural modifications such as, nerve sparing (probably secondary to a more careful dissection [987, 988] bladder neck preservation, preservation of anterior urethral ligamentous attachments and urethrovesical junction reconstruction (Figures 19, 20).

Patients who have undergone previous irradiation for prostate cancer are at high risk of developing incontinence after radical prostatectomy with the possible need of a postoperative radiation therapy [981]. Rates of significant incontinence after salvage prostatectomy range from 57-64% [991, 992]. Sanderson and colleagues [993] reported that 45% of men underwent artificial urinary sphincter placement after salvage prostatectomy and another 31% without an artificial sphincter had incontinence greater than occasional dribbling. This has prompted some to recommend urinary diversion at the time of salvage radical prostatectomy [708].

4. AETIOLOGY AND PATHOPHYSIOLOGY OF POST RADICAL PROSTATECTOMY INCONTINENCE: SPHINCTER VS.BLADDER DYSFUNCTION

There is fairly extensive literature on urodynamic investigation of post prostatectomy incontinence. While it is well established that both bladder and sphincter dysfunction may be present after radical prostatectomy, most studies agree that sphincter dysfunction (stress incontinence) is the main cause [994]. In these series the incidence of sphincter dysfunction ranges from 88-98.5%, with associated bladder dysfunction (detrusor overactivity and less commonly impaired compliance) in 26-46%. Bladder dysfunction, on the other hand, was present in 34-45% of patients, but was the sole cause of incontinence in only 1.5-4%. Bladder dysfunction when present in association with sphincter dysfunction may not always be clinically significant. Ficazzola and Nitti [995] found that although 46% of patients had bladder dysfunction, incontinence on urodynamic study was demonstrated in only 27%. Even in those patients, sphincter dysfunction was the main cause of incontinence in the overwhelming majority. Groutz and colleagues [996] found a 33% incidence of bladder dysfunction, but found that it was the main cause of incontinence in only 7.25%. Two earlier series reported a higher incidence of bladder dysfunction [920, 921]. Some authors feel that in some patients with severe intrinsic sphincter deficiency, bladder dysfunction may occur as a result of filling the bladder to volumes that it is not accustomed to holding [995]. The study of Giannantoni et al. reported that after RRP a high proportion of patients (70.3%) were affected by DO and about the half of these patients complained of overactive bladder symptoms of which DO was also observed in 61.2% of patients before surgery, which indicates that the abnormality can be attributed to the surgical damage in a small percentage of patients. At the 36-month follow-up, the dysfunction persisted in 56.3% of 32 men, and about 40% of these presented with overactive bladder symptoms. At three year follow-up, the dysfunction persisted in 25% of cases. [997]. Filling to capacity may produce detrusor overactivity or decreased accommodation. Thus, bladder dysfunction is in a sense an artefact, but one possibility is partial de-
Figure 19: By projecting the found concourses of the periprostatic nerves (B, [989]) and the structure of the external urethral sphincter (C,[227]) in the common given anatomical knowledge (A) demonstrates the necessary protection of the periprostatic nerve concourses to ensure the postoperative fast recurrence of urinary continence (E,[888]). The extraprostetic innervation continues into the external urethral sphincter, surrounding the apex of the prostateal most completely. The external urethral sphincter function, and the related continence, is secured through the Lig. Pubovesicale, anchored by the tendinous arch and the detrusor (D)[879]).

Figure 20. Surgical anatomy of the urethral sphincter complex. (A) Fixation of the urethral sphincter (modified from Luschka [16]). (B) Lateral aspect of the urethral sphincter after nerve sparing. PPL = puboprostatic ligament; PVL = pubovesicalis ligament; PP = puboperinealis muscle; DA = detrusor apron; B = bladder; FSS = fascia of the striated sphincter; ML = Mueller’s ligaments (ischioprostatic ligaments); NVB = neurovascular bundle; R = rectum; MDR = medial dorsal raphe; RU = rectourethralis muscle; OI = Os ischiadicum; SS = striated sphincter (rhabdosphincter); PB = pubis bone.

From Schlomm et al, Eur Urol 2011 [990]
centralisation of the bladder as a result of its mobilisation during prostatectomy [996], combined with somatic denervation, because the branches of the pudendal nerves innervating the pelvic floor muscles and the striated urethral sphincter split before reaching the urogenital diaphragm [950]. This may explain why the outcomes for artificial urinary sphincters for the treatment of stress incontinence are not adversely affected by the presence of detrusor overactivity [998, 999]. In addition bladder dysfunction may be chronic and stem from obstructive uropathology present before prostatectomy. It must be emphasised that patient selection, urodynamic technique and timing of urodynamic evaluation maybe responsible for the differences seen among the different studies. It is also important to note that most of these studies are preformed in men seeking treatment for their incontinence. However, it appears that sphincter dysfunction is the primary cause of post-radical prostatectomy incontinence, but bladder dysfunction may be present in a significant number of men (though rarely alone) and must not be completely discounted when planning treatment.

The majority of evidence in the literature supports the conclusion that sphincter damage is the primary cause of incontinence after total prostatectomy. Direct exposure and manipulation of the sphincter during radical prostatectomy would suggest that sphincter damage is the most likely cause of incontinence. Successful treatment with the artificial urinary sphincter and male sling procedures also indirectly suggests that primary sphincter injury is the major cause of incontinence, since outcome is usually not complicated by bladder dysfunction. It might be helpful to include urodynamics and especially the urethral pressure profile as suggested by Bentzon et al. [1000]. They suggested that postoperative urodynamics after 6 months may be predictive for persistent incontinence at the bladder, sphincter, and both, that immediate intervention is more appropriate than watchful waiting. They found that sphincter insufficiency was diagnosed by stress incontinence with maximal urethral closure pressure below 30 cmH2O, decreased functional length and a distinctive profile. Bladder dysfunction after prostatectomy may have been present preoperatively, for example due to pre-existing outflow obstruction, may be caused by the operation itself, or may be due to age related changes in bladder function. Many patients who have prostate surgery have pre-existing bladder dysfunction, which may or may not be symptomatic. While it is more obvious how an overzealous TURP (with resection into the trigone) can cause detrusor overactivity, it is less apparent how radical prostatectomy affects detrusor function. Some have suggested that denervation of the urethra or the bladder may occur during radical prostatectomy. John et al [1001] studied trigonal innervation by biochemical markers and found that “urinary incontinence was associated with decreased trigonal innervation, a high sensory threshold and low maximal urethral closure pressure” which was evaluated differently by the same author slightly differently [877].

IV. INCONTINENCE RELATED TO RADIATION THERAPY FOR PROSTATE CANCER

Radiation therapy, whether external beam or brachytherapy, can be a cause of voiding dysfunction and incontinence [1002]. Sometimes this is a direct effect of the radiation or it can be related to the treatment of other sequelae such as urinary retention. The initial response to it is primarily oedema and then gradually degeneration, fibrosis and disorganisation overcome the bladder musculature. While radiation is primarily delivered to the prostate, portions of the bladder may also be affected. Perivascular fibrosis of blood vessels may then cause vascular occlusion followed by ischemia of the bladder wall, which can then progress to fibrosis within 6 to 12 months [1003]. Choo et al. [1004], found that urodynamic bladder capacity decreased by an average of 54 ml, 18 months after radiation therapy. Blaivas et al [1005] evaluated 47 men with symptomatic LUTS after brachytherapy and found that 71% were incontinent and 85% had detrusor overactivity. Similarly, radiation can cause damage to the distal urinary sphincter, which can result in incontinence. In addition there is a dose-effect relationship for individual pelvic floor muscles and anorectal complaints after prostate radiotherapy, which was related to incontinence-related complaints showing specific dose-dependent effects to individual pelvic floor muscles [721].

Urinary retention and increased obstructive LUTS are other common problems of radiation therapy, particularly brachytherapy resulting in urinary retention. The incidence of retention has been reported to range from 2% to 30% after brachytherapy [1006-1009]. Most patients with retention will have resolution of their obstruction within weeks while others may require surgical procedures. A retrospective review of over 2,100 Medicare patients who underwent brachytherapy for prostate cancer found that 8.3% required a surgical procedure to relieve bladder outlet obstruction post-brachytherapy [1010]. Flam, et al [1011] reported that 19 of 600 (3.1%) patients receiving brachytherapy required TURP. Kollmeier and colleagues [1012] reported a similar rate of 2% in 2050 men. Most authors have found significant rates of post TURP incontinence after radiation. Incontinence following TURP after brachytherapy has been reported in 0-70% and is often severe. [1011-1013]. External beam radiation is also a risk factor as Green et al [1014] reported a 33% incidence of incontinence following TURP in patients post-irradiation for prostate cancer. Some authors have emphasised that incontinence can be
Incontinence in the male as in the female can be broadly divided into causes related to bladder and/or sphincter dysfunction. The pathophysiology of incontinence as it relates specifically to the male is fairly well described; however, advances in science and anatomy will undoubtedly provide a more intricate understanding in the future. For example, the causes of sphincter insufficiency are known (i.e. damage to muscle, nerve and/or supporting structures) but clinicians are not able to accurately assess the exact cause of sphincter insufficiency in any given patient. Therefore much of our understanding of post treatment incontinence “pathophysiology” is derived from reports of incontinence (incidence/prevalence) after surgery or radiation. In addition, investigators have not adequately defined the incidence of incontinence related to interventions for prostatic disease, whether benign or malignant. Some work has been undertaken to understand and discriminate the issue of pre- and post operative related incontinence, but because of the shortened hospitalization those prospective investigations, which are mandatory for the understanding of the physiological functioning and the pathophysiology, which might become clinically significant after the intervention. Problems have been two-fold: first in defining incontinence and what is bothersome/significant and second in accurately reporting data. New technologies for the treatment of BPH have provided us with Level 1 evidence regarding the incidence of incontinence in trials comparing new technology to TURP and Level 2 evidence through meta-analysis and prospective series. Data regarding the incidence of post-radical prostatectomy and postradiation incontinence has been less robust and of a lower quality - level 2-4.

V. CONCLUSIONS

Incontinence in older people, continence status may not be absolute, especially in those who are frail. Infrequent leakage of small amounts may appear and disappear, and reporting accuracy varies as well [1030]. Sometimes the changing status of incontinence is the initial symptom of LUTS, neurological disorder (Parkinson’s disease, MS etc.), cardiac changes or diabetes. Furthermore, ethical constraints and methodological issues preclude robust investigations of the conditions commonly impugned as causes of transient incontinence. Thus, it is not surprising that evidence supporting the association between these conditions and transient incontinence consists predominantly of case reports and case series.

2. RESULTS OF LITERATURE REVIEW

Transient causes of incontinence in older people are shown in Table 6 and can be recalled using the mnemonic DIAPPERS (Deliurium, Infection, Atrophic vaginitis, Pharmaceuticals, Psychological condition, Excess urine output, Reduced mobility, Stool impaction) [1024, 1031-1033].

a) Delirium

"D" is for delirium, a confusional state characterised by fluctuating inattentiveness and disorientation. Its onset occurs over hours to days, as contrasted with dementia, which develops over years. Delirium can result from almost any medication and from virtually any acute illness, including congestive heart failure, deep vein thrombosis, or infection. Many of these conditions may present atypically in older patients, and if the patient becomes confused because of them, incontinence may be the first abnormality detected [1034]. Delirium leads the list because, if unrecognised, it is associated with significant mortality [1035]. Thus, in this case, meticulous medical evaluation - not cystometry - is crucial [1036].

b) Urinary infection

Symptomatic urinary infection is another cause of incontinence, although it is suppose uncommon one [1022]. However, asymptomatic urinary infection, is much more common in older people [1037, 1038]. Women with recurrent urinary tract infection had the highest increase in UI by 230% for weekly UI [1039] and for monthly UI [1040], 220% for UI in the past year [936], and by 470% for ever having UI [1041]. In addition Arya et al. reported that women with recurrent UTIs have greater urinary frequency and increased perceived bladder sensation in the absence of an active infection than control women [1042].

c) Atrophic vaginitis

Atrophic vaginitis in older women is frequently associated with lower urinary tract symptoms, which occasionally include incontinence [1043]. As many as 80% of such women attending an incontinence clinic are reported to have physical evidence of atrophic vaginitis, characterised by vaginal mucosal atrophy, friability, erosions, and punctuate haemorrhages. While the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritus and dyspareunia, greater improvement in cytological findings, and higher serum oestradiol levels [1044]. Atrophic vaginitis has been associated with urgency and occasionally a sense of "scalding" dysuria, but both symptoms may be relatively unimpressive. More recent epidemiological and clinical studies have called these beliefs into question since they have demonstrated an association with systemic oestrogen treatment and the onset of incontinence [Sievert et al ICI-RS paper 2012]. Unfortunately, limitations in their design allow for the possibility of both bias and confounding factors. Further research is warranted.

d) Medications

Pharmaceuticals are one of the most common causes of incontinence in older people, with several categories of drugs commonly implicated [1045, 1046]. Of note, many of these agents are also used in the treatment of incontinence, underscoring the fact that most medications used by older people are "double-edged swords." The first category of relevant drugs is the long-acting sedative/hypnotics, such as diazepam and flurazepam, which can cloud an older patient's memory. "Loop" diuretics, such as furosemide or bumetanide, by inducing a brisk diuresis, can also provoke leakage. Drugs with anticholinergic side effects are a particular problem and include major tranquillizers, antidepressants, anti-Parkinsonian agents (e.g., benztropine mesylate or trihexyphenidyl), first generation (sedating) antihistamines, antiarrhythmics (disopyramide), antispasmodics, and opiates. By decreasing detrusor contractility, they can cause urinary retention and overflow incontinence. They also can cause confusion. Anticholinergic agents are particularly important to ask the patient about for two reasons. First, older patients may often take more than one of them at a time. Second, they are contained in many non-prescription preparations that older people frequently take without consulting a physician.

Adrenergically-active agents have also been associated with incontinence. Many alpha-adrenoceptor antagonists (used mainly for treatment of hypertension) block receptors at the bladder neck and may induce stress incontinence in women [1047]. Older women are particularly at risk because their urethral length and closure pressure normally decline with age. Thus, prior to considering other interventions for stress incontinence in a woman taking such a drug, substitution of an alternative agent should be tried and the incontinence re-evaluated. Calcium channel blockers can cause incontinence. As smooth muscle relaxants, they can increase residual volume, especially in older adults with impaired detrusor contractility. The increased residual urine may occasionally lead to stress incontinence in women with a weak urethral sphincter, or to overflow incontinence in men with concurrent urethral obstruction. Finally, angiotensin converting enzyme inhibitors, by inducing cough (the risk of which is age-related), may precipitate stress incontinence in older women whose urethra has shortened and sphincter weakened with age [1048].
e) Diuresis
Excess urinary output can also cause incontinence, especially in individuals with impaired mobility, mental state, or motivation, particularly if they also have detrusor overactivity. Causes of excess output include excess intake, diuretics (including theophylline-containing fluids and alcohol), and metabolic abnormalities (e.g., hyperglycemia and hypocalcaemia). Nocturnal incontinence can be caused or exacerbated by disorders associated with excess nocturnal excretion, such as congestive heart failure, peripheral venous insufficiency, hypoalbuminemia (especially in malnourished older people), and drug-induced peripheral oedema associated with NSAIDs, thiazolidinediones, and some calcium channel blockers (e.g., dihydropyridines such as nifedipine, isradipine, and nicardipine). In addition, certain foods are natural diuretics like asparagus, parsley, beetroot, grapes, green beans, leafy greens, pineapple, pumpkin, onion, leeks, and garlic, as well as juices such as orange juice. The role of caffeine and timing of drinking fluids (e.g., in the evening or before bedtime) is still not clear, but should nonetheless be considered a possible contributing cause for nocturia and nocturnal incontinence, whereas it is known to increase the bowel motility [1049-1051].

f) Restricted mobility
Restricted mobility is an easily understood but frequently overlooked cause of incontinence [1052]. In addition to obvious causes, restricted mobility may be associated with orthostatic or postprandial hypotension, poorly-fitting shoes, poor physical state, or fear of falling, all of which are common geriatric conditions. All of these reasons together with restricted mobility might be the cause of incontinence due to nocturia.

g) Nocturia
For frail/older people with bothersome nocturia, assessment should focus on identifying the potential underlying cause(s), including (GR: C):
- Nocturnal polyuria;
- Primary sleep problem (including sleep apnoea);
- Conditions resulting in a low voided volumes (e.g. elevated post-voiding residual) co-morbidity.

Post-void residual (PVR) volume
A post-void residual volume (PVR) is impractical to obtain in many care settings. However, there is compelling clinical experience for measuring PVR in selected frail/older persons with:
- Diabetes mellitus (especially if longstanding);
- Previous episodes of urinary retention or history of high PVR;
- Recurrent UTIs;
- Medications that impair bladder emptying (e.g. anticholinergics);
- Chronic constipation;
- Persistent or worsening UI despite treatment with antimuscarinics;
- Previous urodynamic study demonstrating detrusor underactivity and/or bladder outlet obstruction (GR: C).

h) Faecal impaction

II. FAECAL INCONTINENCE

1. BACKGROUND
The prevalence of faecal incontinence in older adults ranges from 3.7-27% in community-dwelling elderly persons to over 50% in nursing home residents [602, 603, 605, 606, 636, 637, 672, 709, 1053, 1054]. In addition, faecal incontinence is a common reason for referral of elderly persons to a nursing home. [565, 1055] Underreporting is an issue with both urinary and faecal incontinence [656, 1054, 1056, 1057]; memory-loss and dementia exacerbate that the problem in the elderly. While the prevalence is fairly well documented, the percentage of those people who have transient as opposed to long-term incontinence is not well known. There is significant financial and social cost associated with management of faecal incontinence in the community and nursing homes [607, 656, 1058-1062]. Identifying transient and remediable causes would benefit patients, caregivers and the healthcare system. One confounding aspect in the discussion of transient incontinence is the largely unknown natural history of faecal incontinence. It is clear that the symptom is intermittent in some patients and spontaneously resolves in others. As noted earlier in this chapter, continence for stool is a complex mechanism involving the consistency and transit time of stool, rectal capacity and pelvic floor function. Rectal capacity and pelvic floor function are less likely to undergo transient changes but stool consistency, transit time of the intestinal tract and other medical conditions may change. It is well established that the prevalence of faecal incontinence increases with age, even if the mechanism is not completely understood; the increase in prevalence suggests progressive deterioration of some aspect of anorectal function [602-604, 606, 607, 636, 640, 1056]. Theoretically, alterations in stool consistency, transit time and medical conditions would be more likely to result in incontinence in the elderly although that there is minimal confirmatory data. The literature on transient faecal incontinence is limited with a dominance of case series and retrospective reports. Some information is inferred from data from large studies of prevalence and risk factors. Treatment recommendations are frequently based upon an empirical rather than evidence-based approach.

2. CAUSES
Faecal incontinence occurs when the propulsive forces in the colon and rectum overwhelm the resistant forces of the pelvic floor. Continence for stool requires the receipt and recognition of the urge to defaecate, mobility to reach the toilet in time, and the ability to postpone defaecation until reaching the bathroom.
Delaying defaecation requires sufficient rectal capacity and compliance and adequate neurologic and anal sphincter function.

**a) Altered mental status**

Acute medical illness, hospitalisation, surgery and medications such as opiates and sedatives may result in delirium or disorientation in the elderly. The reported rates of mental status changes to as high as 74% after surgery and from 11 to 42% during medical hospitalisation [1063, 1064]. In a systematic review of delirium associated with medication, opioids, benzodiazepines, and dihydroxyridines were found to clearly increase the risk of delirium. There was uncertainty regarding antihistamines, tricyclic antidepressants, anti-Parkinson medications, steroids and non-steroidal anti-inflammatory medication [1065]. Delirium, confusion and other transient changes in cognitive function may impair a patient’s ability to recognise the urge to defaecate and/or their motivation to remain continent. The limited investigations of the relationship between delirium and incontinence studied patients with chronically altered mental status; any relationship of acute delirium and/or confusion with faecal incontinence is inferred from those data. Studies of the impact of delirium on continence show that delirium plays an important role in the development of incontinence [670, 708]. The impact of altered mental status on continence has also been inferred from studies showing improvement in continence with scheduled toileting programs [1066, 1067]. Ignoring the urge to defaecate combined with the effect of medications may result in faecal impaction followed by incontinence. Delirium may require the use of restraints. Need for a restraint has been reported as an independent factor in incontinence [709].

**b) Impaired mobility**

Lack of adequate mobility may prevent a patient from reaching the bathroom in time to avoid incontinence. In addition to the causes described in the urinary incontinence section, musculoskeletal ailments, such as arthritis and bone fractures, occur more commonly in the elderly and limit mobility. During the recovery phase from joint replacements ambulation may be slow and unsteady. Acute neurological conditions such as stroke may affect a patient’s gait as well as debilitated states from other illness. Faecal incontinence is fairly common (up to 30% in first week) immediately after a stroke; with rehabilitation, the rate decreases [605, 681, 1068]. The use of anti-cholinergic medication and requiring assistance to reach the toilet were significant independent factors [681]. For patients temporarily requiring assistance to reach the bathroom, the timeliness of the assistant may affect their continence.

**c) Stool consistency**

Change in stool consistency affects continence; both constipation and diarrhoea may result in faecal incontinence.

**d) Diarrhoea**

Loose stool is clearly a risk factor for incontinence [606, 608, 636, 640, 674, 1054, 1068-1070]; one study identified loose stool as the most important independent risk factor [607]. Any condition or medication resulting in loose stools may also lead to incontinence including acute infection, intestinal inflammatory processes, medication and supplements (Table 7). Medications with the side effects of diarrhoea and/or steatorrhea may result in faecal incontinence. Table 8 lists the medications, which cause diarrhoea or steatorrhea with reasonable frequency. [605, 1071, 1072] Laxatives and the medications used for bowel preparation for colonoscopy and surgery frequently result in temporary incontinence in older patients.

Although rarely described in the literature, intuitively cessation of the causative medication should decrease the incontinence. In a case report, withdrawal of the offending medication, metformin, resolved the incontinence [648].

**e) Constipation**

Paradoxically faecal incontinence may occur in patients with faecal impaction. [641, 662, 1073-1075] Immobility, inadequate dietary and fluid intake, depression, metabolic disorders neurological conditions, connective tissue disorders and medications contribute to constipation. [641, 662] Impaction may result in overflow incontinence with loose stool leaking around the faecal bolus. [663] Evaluation of impacted patients compared to elderly controls revealed similar resting and squeeze pressures although both groups had lower pressures than younger healthy controls. However perianal and rectal sensation was impaired in 74% of the impacted patients. [613, 1076] The theory is the patients with impaired sensation do not experience the urge to defaecate with the typical volume of stool. The stool bolus causes the usual reflex relaxation of the internal anal sphincter but the lack of perception prevents the normal contraction of the external sphincter muscle. Incontinence is often aggravated by the use of laxatives to relieve constipation.

Apart from data for alpha-adrenergic agents (Level of Evidence = 2), the level of evidence for most of these causes is Level 3-4. Nonetheless, because many are easily addressed and contribute to morbidity beyond the lower urinary tract and perianal area, they are worth identifying even if the evidence is not strong.

III. SUMMARY

Despite the lack of robust data about the incidence and causes, transient urinary and faecal incontinence are clinically common problems. Since in most cases treatment is relatively straightforward, it is important to consider the causes discussed in this section when elderly patients present with new onset incontinence. Moreover, addressing them may improve the incontinence even if it does not eliminate it, and it may make the incontinence more amenable to subsequent therapy. (Grade of recommendation C)

IV. RECOMMENDATIONS

Further research should be performed on the mechanisms, prevalence, incidence, and remission rates of each of the known causes of transient incontinence, and possible additional causes should be identified as well. Since the clinical circumstances of older people are heterogeneous, studies should be conducted among several subgroups, including independent and homebound and community-dwelling older people, bedbound and mobile institutionalised older people, and acutely hospitalised older people.

V. RESEARCH PRIORITIES

Further research should be performed on the mechanisms, prevalence, incidence, and remission rates of each of the known causes of transient incontinence, and possible additional causes should be identified as well. Since the clinical circumstances of older people are heterogeneous, studies should be conducted among several subgroups, including independent and homebound and community-dwelling older people, bedbound and mobile institutionalised older people, and acutely hospitalised older people.

The aim of this report is to present an update of the evidence-based recommendations from the 4th ICI regarding the initial assessment of urinary incontinence (Committee 5A) and outcome measurements (Committee 5B) of UI for adult men and women.

I. INTRODUCTION

The Standardisation Steering Committee (SSC) of the International Continence Society (ICS) “establishes terminology and methodology in the ICS’s areas of activity, to underpin professional standards of clinical management and research. The value of the SSC is in promoting best standards when clinicians and allied professionals communicate with patients and colleagues, undertake diagnostic tests, proceed to therapeutic interventions and undertake research. Precise use of agreed terminology ensures clear understanding for collaborating centres and readers of publications. Adherence to the diagnostic testing standards gives patients and clinical colleagues confidence that conclusions on which important therapeutic decisions are based are reliable. Development of future insights into mechanisms and treatments of the disease areas relevant to the ICS is enhanced where research studies employ internationally standardised approaches.” (http://www.icsofice.org/ViewCommittee.aspx?ViewCommitteeID=7) The reports of the SSC are posted on the internet for reference (http://wiki.icsofice.org).

The term “urinary incontinence” refers to the complaint of any involuntary loss of urine. The symptom of urinary incontinence can be volunteered by or elicited from the individual or may be described by the individual’s caregiver. Urinary incontinence can be categorised into several distinct sub-types based on associated characteristics and circumstances surrounding episodes of urine leakage. Although defining the type of incontinence will not establish a definitive underlying diagnosis, it will ultimately guide investigation and treatment. The
following are the accepted ICS definitions of these conditions unless referenced [1].

**a) Types of urinary incontinence**

a) Stress (urinary) incontinence: Complaint of involuntary loss of urine on effort or physical exertion e.g., sporting activities), or on sneezing or coughing. (Sporting activities)

b) Urgency (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency.

c) Postural (urinary) incontinence: Complaint of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position.

d) Mixed (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing.

e) Incontinence associated with chronic retention of urine: Complaint of involuntary loss of urine which occurs in conditions where the bladder does not empty completely as indicated by a significantly high residual urine volume and/or a non-painful bladder which remains palpable or percussable after the individual has passed urine. (Note: The ICS no longer recommends the term overflow incontinence. A significant residual urine volume denotes a minimum volume of 300 mls, although this figure has not been well established.)

f) Nocturnal enuresis: Complaint of involuntary loss of urine which occurs during sleep.

g) Continuous (urinary) incontinence: Complaint of continuous involuntary loss of urine.

h) Insensible (urinary) incontinence: Complaint of urinary incontinence where the individual is unaware of how it occurred.

i) Coital incontinence (for women only): Complaint of involuntary loss of urine with coitus. This symptom can be further divided into that occurring with penetration or intromission and that occurring at orgasm.

j) Functional incontinence: Complaint of involuntary loss of urine that results from an inability to reach the toilet due to cognitive, functional or mobility impairments in the presence of an intact lower urinary tract system. (see Cmte. 11, Frail Elderly)

k) Multifactorial incontinence: Complaint of involuntary loss of urine related to multiple interacting risk factors, including factors both within and outside the lower urinary tract such as comorbidity, medication, age-related physiological changes and environmental factors. (see Cmte. 11, Frail Elderly)

Urinary incontinence can exist in isolation or may be associated with other lower urinary tract symptoms. The ICS classifies lower urinary tract symptoms (LUTS) into bladder storage, voiding and post-micturition, and pelvic organ prolapse symptoms. The following section summarises the definitions of LUTS described by the ICS-SSC.

**b) Bladder storage symptoms**

Bladder storage symptoms are experienced during the bladder filling phase:

a) Increased daytime urinary frequency: Complaint that micturition occurs more frequently during waking hours than previously deemed normal. Traditionally seven episodes of micturition during waking hours was considered as the upper limit of normal, although it may be higher in some populations.

b) Nocturia: Complaint of interruption of sleep one or more times because of the need to void. Each void is preceded and followed by sleep. (Note: The number of nocturia episodes and the degree of bother based on number has been questioned and the threshold of 2-3 per night has been suggested.) [5,6,7]

c) Urgency: Complaint of a sudden, compelling desire to pass urine which is difficult to defer. (Note: The ‘all or none’ nature of ‘urgency’ has been questioned) [8].

d) Overactive bladder syndrome (OAB): Urinary urgency, usually accompanied by increased urinary frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology.

**c) Bladder sensation**

Asking patients about bladder sensory symptoms during bladder filling may be helpful in characterising certain types of incontinence.

a) Increased bladder sensation: Complaint that the desire to void during bladder filling occurs earlier or is more persistent to that previously experienced. This differs from urgency by the fact that micturition can be postponed despite the desire to void.

b) Reduced bladder sensation: Complaint that the definite desire to void occurs later than that previously experienced despite an awareness that the bladder is filling.

c) Absent bladder sensation: Complaint of both the absence of the sensation of bladder filling and a definite desire to void.

**d) Voiding and postmicturition symptoms**

Voiding symptoms are experienced during the voiding phase and post-micturition symptoms are experienced immediately after micturition.
2. ASSESSMENT OF SUB-POPULATIONS REVIEWED BY OTHER COMMITTEES

The targeted assessments and specific outcome measures for conditions of UI in Children (Cmte 9), Neurogenic Patients (Cmte.10), Frail Elderly (Cmte.11), Painful Bladder Syndrome (Cmte.19) and Faecal Incontinence (Cmte.16) are presented separately in the respective reports. The requirements of specific sub-populations negate the ability to recommend a 'universal' initial evaluation. Within the initial assessment of UI, these sub-populations / subgroups are recognised because of the differences within patient groups or the interrelationship between the conditions. Congenital and maturational issues are critical considerations in children. Specific risks for combined storage and emptying abnormalities and upper urinary tract deterioration in the neurogenic population demand a more involved initial and complex evaluation. The effects of ageing on the lower urinary tract, altered toileting functions, and medical co-morbidities in the frail elderly group present unique challenges. These subgroups also include patients with LUTS with and without incontinence but the presence of pelvic pain or faecal incontinence.

The sub-sections in this report should be utilised in conjunction with other population or condition specific Committee Reports of the Consultation and with the final recommendations of the Consultation which are presented in simplified form in the Appendix (1.Definitions). Recommendations for initial evaluation have been developed by the International Scientific Committee and are also published in the Appendix (2.Evaluation). In addition, History and Symptom Assessment recommendations are further detailed as the initial steps in the evaluation of the index adult male (3. Initial Management, II. Male), and adult female (3. Initial Management, III. Female). The reader is encouraged to refer to these recommendations and algorithms in combination with this report.

3. EVIDENCE BASED RECOMMENDATIONS

The recommendations presented in this report are evidence-based and utilise the ICUD - EBM grades. A search of the available literature in English obtained from Medline© and Pubmed© up to January 2012 by the individual committee members employed multiple search terms related to the initial assessment of the patient with urinary incontinence and patient reported outcomes assessment.

III. INITIAL ASSESSMENT

1. PURPOSE OF INITIAL ASSESSMENT
(EXPERT OPINION OF THE COMMITTEE)

As will be noted, especially in this committee report (5A), the amount and sophistication of the literature that is applicable for the development of evidence-based guidelines is limited. For this reason, the grade of recommendation in the area of "initial assessment" will often rely on 'expert opinion of the panel'. For the purpose of subsection 5A, the 'initial assessment' represents the components of the history, physical examination, laboratory tests, and basic office testing to:

1) Establish a presumptive or condition specific diagnosis, and exclude underlying organ-specific related or unrelated conditions that would require intervention.

2) Assess the level of bother and desire for intervention from information obtained from the
4) Prompt the recommendation of additional more complex testing or specialist referral (when indicated).

5) Assess the level of improvement after intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes (Cmte. 5B).

Once the type of UI with associated LUTS has been established, elaboration of a differential diagnosis can occur, and further investigations may be elected and an eventual treatment plan can be formulated to address or modify the effects of the underlying cause(s). The success of the treatment plan can be measured by patient-reported outcomes (from a simple “yes” or “no” to more complex questionnaires), and/or other objective measures of urinary leakage events (including bladder diaries, pad tests, or urodynamics studies).

The initial assessment must consider the degree of bother, and the costs of further evaluation, balanced against the consequences of a failure to diagnose an underlying condition, the risks and benefits of empirical conservative management or pharmacological therapy, and the need for an accurate diagnosis before more complex intervention or empirical therapy. The burden of these conditions and the availability of resources for individual patients, caregivers, physicians, and health care systems requires that primary intervention strategies be formulated, when available, from evidence based findings and decisions emanating from the initial evaluation.

Of note, LUTS cannot be utilised with confidence to make a definitive diagnosis of a specific lower urinary tract condition or lower urinary tract disease (LUTD), as these symptoms may suggest and indicate pathologies such as urinary tract infection (UTI) or more serious underlying conditions. Basic laboratory tests, such as testing for UTI or blood (haematuria), and appropriate screening for malignancy should be considered before the decision is made to choose therapy for incontinence. Urinary retention with overflow voiding may present as urinary urgency, frequency, and nocturia with urinary loss mimicking OAB.

Concomitant pathology may affect urine production as a co-morbid contributory factor, by affecting fluid balance or renal function (fluid intake and output regulation) and may need to be addressed prior to or in combination with bladder or bladder outlet therapy. A thorough review of medications which alter fluid production or lower urinary tract function should be addressed. The physician should elicit a history of pelvic pathology or surgery and neurological symptoms and signs that may indicate alterations in the control of lower urinary tract function or be responsible for the cognitive, motivational, or physical factors that determine the ability to perform toileting functions effectively. The physical examination and the appropriate laboratory tests are necessary to refine the differential diagnosis and therapeutic course.

2. INITIAL ASSESSMENT – GENERAL RECOMMENDATIONS

1. Lower Urinary Tract Symptoms (LUTS) cannot be used to make a definitive diagnosis; they may also indicate pathologies other than Lower Urinary Tract Disease (LUTD). Specific to this report, LUTS includes Overactive Bladder (OAB) a syndrome which is associated with urgency incontinence (OAB-wet) or without incontinence (OAB-dry). (Level 5 - Grade D)

2. Urinary incontinence should be described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage and whether or not the individual seeks or desires help. (Level 5 - Grade D)

3. Urinary incontinence should be categorised by symptoms into urgency incontinence, stress incontinence or mixed incontinence and conservative (non-invasive) therapies may then be started based on this classification to treat the most troublesome component, or either component of the incontinence. (Level 5 - Grade D) More sophisticated testing (e.g., urodynamics studies) is not required prior to the institution of conservative therapy (see indications for urodynamics in the Committee Report on Dynamic Testing Committee 6). (Level 3 - Grade C)

4. Both objective (bladder diary) and subjective (patient reported outcomes – PROs) are recommended for assessment and measurement of the degree of symptoms and bother of UI at baseline, and for the assessment of the impact of therapy. (Level 3 – Grade D)

5. Normal lower urinary tract function requires the ability of the bladder to adequately store urine at low pressure while the bladder outlet remains competent, and the bladder to contract until completely empty while the bladder outlet remains open. In addition to an evaluation of LUT function, a thorough evaluation for co-morbid conditions which affect fluid intake and output should be undertaken. Diseases of the nervous system and pelvic disorders, as well as medications
3. INTIAL ASSESSMENT – GENERAL RESEARCH RECOMMENDATIONS

1. Standardisation of the 'definition of symptoms' and the 'measurements of symptom frequency, severity and bother' are essential for patient care and research. Continued research into the appropriate scales and metrics should be accompanied by a significant attempt to establish best practice guidelines for their use and a consensus on the adoption of universal standards.

2. Recognition and resolution of the differences in common language usage and scientific utilisation of terms should continue. Resolution of the differences in definitions and metrics between recognised societies and regulatory agencies is essential for communicating data with respect to patient care, research, and treatment outcomes.

3. Research into the development of accurate measures to objectify subjective symptoms such as "urgency" and other bladder sensory symptoms.

4. Development, standardisation, and universal adoption of symptom assessment tools (questionnaires) to improve the diagnostic accuracy of lower urinary tract symptoms. (Refer to section 5B of this committee’s report)

5. Validation of the accuracy of specific components of the history and physical findings to establish an accurate diagnosis and initiate non-invasive conservative or pharmacological therapy. In addition, to further identify components that would indicate the need for more invasive testing, complex therapeutic interventions, and indications prior to / or as a result of referral.

6. Creation and institution of evidence based guidelines for the referral of patients to a specialist are needed to improve the efficiency of the healthcare system in treating the large burden of disease. (See Epidemiology, Committee 1). The institution of conservative measures and pharmacology are in the domain of the primary caregiver. Further improvement in the ability to define the index patient, but more importantly the sub-groups of patients who will require more complex specialist therapy, will aid in counselling and referral at the primary level. In addition, refining the true risks for significant underlying disease noted while obtaining the history, or during the examination or laboratory findings will improve resource utilization.

IV. GENERAL POPULATIONS

1. INITIAL ASSESSMENT OF URINARY INCONTINENCE

Individuals with UI can be identified through routine screening, or the patient may initiate discussion about incontinence problems. The initial assessment of UI should help the health care provider understand the type of incontinence, while identifying potentially modifiable contributing factors. Most primary treatment options, such as lifestyle modifications and behavioral treatments, do not vary by type of UI. However, it is important to determine the type of UI since some treatment options do vary according to incontinence. Equally important, establishing the type of UI will lead the health care provider to a list of possible underlying causes, or differential diagnosis of the urinary symptoms. Most causes of UI are non-life threatening, however symptoms of incontinence may also herald life-threatening or more severe disease such as bladder cancer when associated with haematuria; when more specialised testing will be required immediately. Finally, assessing the level of bother and desire for intervention from information obtained from the patient or caregiver is essential for guiding the nature of the treatment plan.

a) History

The general history should include questions relevant to precipitating and aggravating factors of urinary loss, time of onset and duration of symptoms, and degree of bother. Acute symptoms can be defined by documenting patterns of fluid intake and output, acute infection, recent surgery or trauma. Chronic symptoms should prompt queries about a history of congenital abnormalities, neurological disease, relevant surgery or general health. Information should be obtained concerning medications with known or possible effects on the lower urinary tract. The general history in women should also include assessment of menstrual, obstetric, sexual and bowel function. The reader is referred to the report on Epidemiology (Cmte. 1) for specific risk factors to be considered during the medical history, and to the report on Frail Elderly (Cmte. 11) for a list of co-morbidities and medications that can cause or contribute to UI.

A later section of this Committee Report (5B) presents a complete review and evaluation of questionnaires that are applicable for clinical and research use in evaluating patient symptoms. Structured condition specific questionnaires may be utilised, and
may be either clinician or self-administered. Use of questionnaires may facilitate disclosure of embarrassing symptoms, ensure that symptoms are not omitted, and standardise information for audit and research. In the absence of questionnaire use, Table 1 summarises key questions for the initial assessment of urinary incontinence based on the expert opinion of this committee. Note that the committee strongly encourages the use of standardised questions.

### b) Diaries

The micturition time chart records the timing of voids in 24 hours; the frequency-volume chart (FVC) additionally includes the urinary volume voided, and the bladder diary which may include incontinence episodes, pad usage, fluid intake, and the degree of urgency and incontinence. Documentation of the frequency of an individual’s lower urinary tract symptoms and the voided volume for at least 24 hours can be extremely helpful both in the initial assessment of urinary incontinence, may be therapeutic as it provides insight into bladder behaviour, can be utilised to monitor the effectiveness of treatment during follow-up. Two main methods of documenting this information are in use, and a sample frequency-volume chart and bladder diary are illustrated with the instructions for use in the appendix in Annex 1: Bladder Charts and Diaries. The frequency-volume chart is used to describe a chart that records the time of each micturition and the volume voided for at least 24 hours, although 2-3 days of recording generally provide more useful clinical data. The bladder diary refers to a more comprehensive instrument that may include the individual’s daily type and volume of fluid intake, pad usage, incontinence episodes, and the degree of incontinence. Episodes of urgency and sensation might also be recorded, as might be the activities performed during or immediately preceding the involuntary loss of urine. A frequency-volume chart or bladder diary, if properly completed, can confirm all of the following information.

**Table 1: Key questions in the initial assessment of urinary incontinence**

<table>
<thead>
<tr>
<th>Stress urinary incontinence: Do you sometimes leak urine when you cough or sneeze or when you exert yourself, such as when lifting a heavy object?*</th>
</tr>
</thead>
<tbody>
<tr>
<td>Urgency urinary incontinence: Do you sometimes feel an urge to void that is so sudden and strong that you sometimes don’t make it to the bathroom on time?*</td>
</tr>
<tr>
<td>How long have the symptoms been present?</td>
</tr>
<tr>
<td>How often do you leak urine and how much do you leak?</td>
</tr>
<tr>
<td>Circumstances surrounding urine leakage e.g. sexual activity, change in position, provocation by running water or ‘key in the latch’?</td>
</tr>
<tr>
<td>Nocturnal symptoms or enuresis?</td>
</tr>
<tr>
<td>Association with other lower urinary tract or pelvic organ prolapse symptoms?</td>
</tr>
<tr>
<td>Impact on personal and social life?</td>
</tr>
<tr>
<td>Amount and type of fluid intake e.g. coffee, tea, alcohol?</td>
</tr>
<tr>
<td>Episodes of urinary tract infection or haematuria?</td>
</tr>
<tr>
<td>Previous treatment attempts (successful and unsuccessful)?</td>
</tr>
<tr>
<td>Mobility problems?</td>
</tr>
<tr>
<td>Cognitive deficits?</td>

<tr>
<td>Neurological deficits?</td>
</tr>
<tr>
<td>Problems with constipation or faecal incontinence?</td>
</tr>
<tr>
<td>Number of pregnancies and the type of delivery, with complications?</td>
</tr>
<tr>
<td>Previous prostate, pelvic or abdominal surgeries or radiation treatment?</td>
</tr>
<tr>
<td>Coexisting diseases (diabetes, heart disease, neurological impairment)?</td>
</tr>
<tr>
<td>Types of medications consumed?</td>
</tr>
</tbody>
</table>

*Evidence regarding the reliability of these questions for diagnosing stress or urgency urinary incontinence is detailed below.
a) Daytime urinary frequency: Number of voids by day (wakeful hours including last void before sleep and first void after waking and rising).

b) Nocturnal frequency/nocturia: Number of times sleep is interrupted by the need to micturate. Each void is preceded and followed by sleep.

c) Twenty-four-hour frequency: Total number of daytime voids and episodes of nocturia during a specified 24-hr period.

d) Twenty-four-hour urine production: Summation of all urine volumes voided in 24 hr.

e) Maximum voided volume: Highest voided volume recorded.

f) Average voided volume: Summation of volumes voided divided by the number of voids.

g) Median functional bladder capacity: Median maximum voided volume in everyday activities.

h) Polyuria: Excessive excretion of urine resulting in profuse and frequent micturitions, defined as over 40 ml/kg body weight during 24 hours or greater than 2.8 L of urine for an individual weighing 70 kg.

i) Nocturnal urine volume: Cumulative urine volume from voids after going to bed with the intention of sleeping to include the first void at the time of waking with the intention of rising (excludes last void before sleep).

j) Nocturnal polyuria: Excess (over 20–30% age dependent) proportion of urine excretion (nocturnal voided volume/total 24 hr voided volume x 100%) occurring at night (or when the patient is sleeping). [9]

However, it should be noted that there are some limitations to the use of a frequency-voiding chart or bladder diary. There is no evidence that the results of these charts provide a valid prediction of the type of urinary incontinence experienced by each patient.[10, 11] Some patients may have difficulty completing the diary in a reliable, meaningful or timely fashion, especially when increasing the complexity or the amount of time (days) required to complete the diary. [12] The bladder diary may not be helpful for gleaning information about the evolution of incontinence episodes that occurs less frequently than once per day. [12,13]

- **Recommendations - Bladder Diary**

| 1) A bladder diary is recommended in order to document and communicate both objective information and to objectify observations by the patient during the diary period. Although never completely diagnostic, diary patterns may characterise normal and abnormal states. (Level 3 – Grade C) |
| 2) The ideal duration of a diary is not clear. (Level 4) A 1-day frequency volume chart (FVC) which includes the first morning void the following day is a reasonable tool to gain insight into voiding habits during normal daily routine. A 3-day FVC or diary is recommended for accurate assessment of LUTS and for confirming a consistent clinical pattern in day-to-day practice. (Level 3 – Grade C) For atypical clinical patterns or clinical research, a 7-day diary may be recommended (most pharmacological studies now employ a 3-day diary as a standard to improve patient compliance). |

- **Bladder Diaries - Future Research**

1) The ideal duration of a bladder diary based on accuracy, compliance, and the utility of the diary for diagnosis, the selection of therapy, and improving the outcomes of therapy requires further investigation.

2) The utility of paper versus electronic methods of recording voiding patterns requires further research.

- **Urinalysis**

“The urinalysis is a fundamental test that should be performed in all urological patients. Although in many instances a simple dipstick urinalysis provides the necessary information, a complete urinalysis includes both chemical and microscopic analysis.” [14] Urine dipstick testing, as opposed to microscopy, is satisfactory for urinalysis in the diagnosis of acute uncomplicated cystitis. [15] In relation to urinary incontinence, dipstick urinalysis is not a diagnostic test, but a screening test, utilised to detect haematuria, glucosuria, pyuria and bacteriuria. Haematuria can indicate important pathology such as urothelial carcinoma in situ, leading to lower urinary tract storage symptoms including incontinence. [16] Glucosuria is relevant, as a potential indicator of diabetes mellitus. This can cause symptoms via several mechanisms including polyuria secondary to osmotic diuresis. Diabetic peripheral autonomic neuropathy affecting bladder innervation may be associated with impaired bladder emptying and chronic urinary infection[17] The examiner should note that a patient does not generally demonstrate glucose into the urine until the blood sugar is >180 mg/dl. Consequently, a dipstick urinalysis may fail to reveal intermittently high sugars or mild diabetics. [17] If diabetes is suspected, then a random or fasting blood sugar is preferred. [18]

Pyuria and bacteriuria, detected from urinary dipstick leukocyte esterase and nitrite tests respectively, are important signs of urinary tract infection. The specificity and sensitivity of these latter tests for UTI is increased when used together compared to either individual test. [19,20] Even in the absence
of controlled studies, there is general consensus that the benefits of urinalysis clearly outweigh the costs involved, although the use of urinalysis should always be associated with prognostic significance. A positive dipstick urinalysis will prompt formal urine microscopy and culture to detect UTI prior to antibiotic treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence and lower urinary tract symptoms, the value of urinalysis can be illustrated by the finding that 60% of women without detrusor overactivity will develop detrusor overactivity at the time of UTI. The importance of urinalysis in the basic assessment of patients with urinary incontinence and lower urinary tract symptoms is not dependent on gender, age or aetiology. Indeed, it has been recommended in the evaluation of geriatric patients including nursing home residents who are incontinent, in peri- and postmenopausal women, and in older women reporting urinary incontinence. In the latter context, it has even been observed that clinically significant urine samples can even be obtained from disposable diapers in elderly incontinent women. The clinical relevance of asymptomatic bacteriuria (without pyuria) and pyuria (without bacteriuria) in the elderly is controversial, as eradication of bacteriuria appeared to have no effect on the resolution of incontinence, and may not deserve any treatment.

1. Urinalysis - Recommendation

1. It is considered standard to perform a urinalysis by either using a dipstick test or examining the spun sediment in incontinent patients. (Level 5 - Grade D)

2. If a dipstick test is used, it is recommended that a “multi-property” strip that includes fields for haematuria, glucose, leukocyte esterase and nitrite tests be chosen. (Level 5 - Grade D) Dipstick is not as accurate as urine culture, being specific for infection but not sensitive. (Level 2 - Grade C)

3. Additional tests available on urine dipstick strips, such a protein, bilirubin, ketones and pH, may be helpful in the broader medical management of patients. However, they are not essential in the context of evaluation of the patient with urinary incontinence or lower urinary tract symptoms. (Level 5 - Grade D)

d) Post Voiding Residual in the Female and Male Patient

1. General

The post voiding residual urine (PVR) is the volume of urine remaining in the bladder following a representative void. Both bladder outlet obstruction and low bladder contractility contribute to the development of PVR. PVR measurement can be accomplished within a few minutes of voiding either by catheterisation, or by calculation of bladder volume using a portable ultrasound scanner or formal ultrasonography.

It is difficult to determine the value of post-void residual determination in the initial assessment of urinary incontinence since most studies producing data on PVR have not been in patients with UI. However, the populations studied have included women with UI, and incontinent patients with neurogenic bladder disease. Several studies have compared volumes measured with portable ultrasound scanners versus catheterisation and found portable scanners to be 85-94% accurate. A study has imaged the bladder volume after catheterisation and found that the volume of urine remaining in the bladder after catheterisation accounted for most of the difference between the two measurements. Bimanual palpation cannot reliably estimate the post-void residual urine volume.

Since PVR may vary, one measurement of PVR may not be sufficient. PVR should probably be measured several times to increase its reliability. Griffiths et al found a significant variability in PVR measurement depending on the time of the day, with the greatest volume occurring in the morning. A non-representative PVR is particularly common if the patient’s bladder is not full enough to yield an urge to void. Special consideration is required in male patients with incontinence and bladder outlet obstruction, incontinent neurogenic patients who may demonstrate combined disorders of storage and emptying, and preoperatively in patients being considered for incontinence surgery.

An increased PVR alone is not necessarily a clinical problem, but if combined with high pressure storage pressures in the bladder it can lead to upper urinary tract problems. If the PVR is associated with urinary tract infections (UTIs), the PVR may need to be treated since UTIs may be more difficult to eradicate in the presence of an infected residual. A significant PVR also decreases the functional bladder capacity and contributes to urgency/frequency, urgency incontinence and nocturia. Of note, a Scandinavian study in nursing home residents found that an elevated PVR was not associated with bacteriuria and incontinence. Since recurrent UTI’s [due to elevated PVR] can be associated with urinary incontinence it is suggested that PVR in incontinent patients with recurrent UTIs should be measured.

Review of the literature does not demonstrate an evidence-based specific maximum PVR that is considered normal, nor is there a minimum PVR that is considered abnormal. The amount of residual urine that precludes treatment by various therapies has not been determined. The AHCPR guidelines state that, in general, a PVR less than 50 ml is considered adequate bladder emptying and over 200 ml is considered inadequate emptying (expert opinion of the panel members – Level D).
2. POST VOIDING RESIDUAL (SPECIFICS IN THE FEMALE PATIENT)

“Normal values” of PVR have been determined in several groups of non-incontinent and incontinent women. Gehrich et al studied 96 women (mean age 60 ± 11 yrs) that were seen in a well-women clinic. These women had no history of incontinence, retention, symptomatic prolapse or neurologic disorders. Most (97%) had a minor (asymptomatic) degree of prolapse, 80% were post-menopausal and 30% had had a hysterectomy. The median PVR was 19 ml (range 0-145 ml; mean 24 ± 29 ml); only 5% had PVR > 100 ml. Only, age > 65 yrs was associated with higher PVR [37]. Tseng et al studied 107 women with urodynamic stress incontinence. They found a mean PVR of 62.5 ml by bladder scan and 38.5 ml by catheterisation. Only 15.9% had a PVR greater than 100 ml. The PVR determined by bladder scan offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 ml [38]. Haylen et al studying women with lower urinary tract dysfunction found that 81% had a PVR of less than 30 ml [39]. Fitzgerald et al studied women with urgency, frequency and urgency incontinence: 10% had an elevated PVR of > 100ml. In these women with OAB, the following independent risk factors for increased PVR were found: vaginal prolapse, symptoms of voiding difficulty and absence of stress-incontinence [40]. Lukacz et al found that only 11% of women with pelvic floor disorders had an elevated PVR [41]. Wu and Baguley studied 319 consecutive patients (196 women, 123 men) in a predominantly geriatric subacute general rehabilitation unit. Twenty two patients had been admitted with a catheter and were excluded. Of the 297 “asymptomatic” patients, 21.5% had PVR volumes of 150 mL or more. Patients with elevated PVR (> 150 ml) were significantly more likely to have a urinary tract infection at admission and have urinary incontinence on discharge [42]. Millemann et al retrospectively reviewed 201 women (mean age 55; range 20-90) who presented with complaints of urinary frequency, urgency and/or urgency incontinence. 19% had an elevated PVR of more than 100 ml (mean 211 ml; range 100-997 ml). On multivariate analysis the following independent predictors of raised PVR were identified: age > 55 yrs [OR 3.71], prior incontinence surgery [OR 4.32], a history of multiple sclerosis [OR 15.32] and pelvic organ prolapse grade 2 or greater [OR 3.61] [43]. In summary, an elevated PVR > 100 ml was found in 5% of women visiting a well-women clinic, in 10-19% of women with OAB, in 11% of women with pelvic floor disorders and in 15.9% of women with urodynamic SUI. Overall, incontinent women have a slightly higher risk of elevated PVR compared to asymptomatic subjects. There are insufficient data on incontinent men to draw conclusions.

Does a significant PVR have an impact on the outcome of treatment in patients with incontinence?

Nager et al studied the predictive value of urodynamic measures on stress continence outcomes after surgery for stress urinary incontinence. They found that urodynamic measures do not predict outcomes. However, since women with PVR > 150 ml were excluded in this study, one can only conclude that PVR volumes < 150 ml did not have an adverse impact on stress continence outcome [44].

3. POST VOIDING RESIDUAL (SPECIFICS IN THE MALE PATIENT)

A PVR measurement is especially recommended in men with symptoms suggestive of bladder outlet obstruction. A PVR less than 50ml is considered adequate bladder emptying and over 200ml is suggestive of obstruction. As in the female patient, PVR can be measured within a few minutes of voiding by catheterisation to confirm that the bladder is empty [45] or by ultrasonography [46]. A dedicated ultrasound system has been developed for automatic measurement of PVR, thereby improving the accuracy and increasing comfort in the male patient. The International Consultation on BPH defined a range of 50 to 100 ml as the lower threshold to define abnormal PVR [48]. Both the AUA and the EAU guidelines suggest a threshold of 300 ml to identify patients at risk of unfavorable outcome following LUTS / BPO treatment [49,50].

There is no consensus about the relation between PVR and UTI in the male patient. Although the negative role of large residuals has been reported, the evidence is controversial. Elevated residual urine volume has been considered a bad prognostic factor for disease progression. However, in the standard patients, renal failure, acute retention and UTIs are uncommon in men with large, chronic residuals [51]. No factors are available to identify patients, with significant residual urine, who are at risk of progression [52]. Therefore, based on these trials, untreated LUTS may place the male patient at risk for potential clinical deterioration. Thus, periodic measurements of PVR are recommended in such patients.

- Post Voiding Residual - Recommendations

1. Varying degrees of decreased bladder emptying or urinary retention may be a cause of LUTS that are associated with symptoms of decreased urinary storage. The decision to perform a PVR in disease specific sub-groups of incontinent patients should be based on an association of the condition with poor bladder emptying (Grade D), whereas in individual patients this decision may be based on symptoms or physical findings. (Grade C).

2. Female patients who present with storage specific symptoms, with normal sensation and no complaints of decreased bladder emptying, and no anatomical, neurological, organ-specific, or co-morbid risk factors for retention may be assessed for...
V. SPECIFIC POPULATIONS:
EVALUATION OF THE FEMALE PATIENT

1. ESTABLISHING THE TYPE OF URINARY INCONTINENCE IN WOMEN

a) The reliability of simple history questions for women

A meta-analysis was conducted by Holroyd-Leduc et al. using literature abstracted from 1960-2007 to determine the reliability of several questions for establishing the type of urinary incontinence in women. [53] An updated literature search was performed using the same search criteria from July 2007-January 2012 to determine whether new evidence was available to add to existing data. Among 794 new citations, no new relevant articles were found to contribute additional evidence. According to the results of the meta-analysis by Holroyd-Leduc et al, simple questions to diagnose stress or urgency urinary incontinence have high reliability in women (kappa=0.8; 95% CI, 0.3-0.9), with the percent agreement between repeated questioning estimated at 90% (95% CI, 84%-95%) for stress, urgency and mixed urinary incontinence sub-types. [54] The reader is referred to the systematic review for a list of all studies included in the analysis for each type of incontinence. In summary, if a woman responds “yes” to the question, “Do you lose urine during daily activities?” she is twice as likely to experience stress urinary incontinence compared to a woman who responds “no” to this question (positive likelihood ratio [LR], 2.2; 95% confidence interval [CI], 1.6-3.2; negative LR, 0.39; 95% CI, 0.25-0.61). The question to diagnose urgency urinary incontinence is even more reliable. A woman who responds “yes” when asked “Do you ever experience such a strong and sudden urge to void that you leak before reaching the toilet?” is four-times as likely to have urgency incontinence than a woman who does not experience feelings of urgency associated with urine leakage (positive LR, 4.2; 95% CI 2.3-7.6; negative LR, 0.48; 95% CI, 0.36-0.62). Positive answers to both these questions strongly suggest mixed urinary incontinence.

Martin et al performed a systematic review of methods of assessing urinary incontinence from 1996-2002, with findings similar to those reported by Holroyd-Leduc et al. [55] The clinical history alone in diagnosing stress urinary incontinence in women was found to have a sensitivity of 0.92 and specificity of 0.56, and for urgency urinary incontinence a sensitivity of 0.61 and specificity of 0.87. No evidence was provided by either review on the reliability of other questions to diagnose additional symptoms of incontinence.

Although positive answers to the questions noted by Holroyd-Leduc et al. increase the likelihood that a woman will have a certain type of urinary incontinence, the history alone is insufficient to establish diagnostic certainty. Sufficient diagnostic certainty has been defined as a positive likelihood ratio > 5 to confirm the diagnosis and a negative likelihood ratio < 0.2 to exclude the diagnosis, which is greater than the values obtained in the meta-analysis. As such, diagnostic interviews need to be complemented by a targeted physical exam and sound clinical judgment to establish a probable diagnosis. According to the meta-analysis by Holroyd-Leduc...
et al., comprehensive assessment including the
detail the most value for diagnosing stress urin
continence (positive LR, 3.7; 95% CI, 2.6-5.2; nega
tive LR, 0.20; 95% CI 0.08-0.51) and ur
continence (positive LR, 4.6; 95% CI, 1.7-12.6; nega
tive LR, 0.11; 95% CI 0.04-0.33) in female patients.

b) Accuracy of the general physical examination
in women

No studies were found that addressed the accuracy
of components of the general physical examination
for diagnosing the type of urinary incontinence
in women. Nonetheless, it is recommended that a
thorough physical examination, including but not
restricted to the abdomen, rectum, gynaecologi
cal/ pelvic regions and neurological system be per
formed for ruling out certain risk factors as well as
significant associated or underlying pathology, such
as significant prolapse, obstruction, neurological
disease and malignancy. Height and weight should
be recorded so that the body mass index can be
calculated (Kg/M2).

1. ABDOMINAL EXAMINATION

Observation of the abdomen may yield evidence of
scars from previous surgeries or increased abdomi
nal striae. Increased abdominal striae may be found
in association with other markers of abnormal colla
gen metabolism, and are more likely in patients with
prolapse and stress incontinence. [56] An attempt
should be made to palpate the kidneys, particularly
where a voiding dysfunction or neurogenic bladder
dysfunction are suspected. A distended bladder
may be identified by abdominal palpation or by su
prapubic percussion. In one study designed to look
at the clinical utility of basic assessment in elderly
women, palpable enlargement indicated a post-void
residual volume of at least 300ml. [57]

2. NEUROLOGICAL EXAMINATION

A neurological examination should be performed with
particular attention to the sacral neuronal pathways.
Saddle anesthesia will occur with lesions affecting
S2-S4. (See Cmte. 10, Neurogenic Patients) As
sessment of gait, abduction and dorsiflexion of the
toes (S3) and sensory innervation to the labia mi
ora (L1-L2), sole and lateral aspect of the foot (S1),
posterior aspects of the thigh (S2), and cutaneous
sacral reflexes (bulbocavernosus and anal reflexes)
are additional features of the neurological exam that
may be assessed. A rectal examination will provide a
subjective assessment of resting and voluntary anal
tone (S2-S4). For patients with possible neurogenic
lower urinary tract dysfunction, a more extensive
neurological examination is required. In the elderly,
full cognitive and mobility assessments are also rec
ommended. An evaluation of hand dexterity should
be performed when self-catheterisation is being con
sidered as a treatment option for incontinence asso
ciated with chronic urinary retention.

3. GYNAECOLOGICAL EXAMINATION

Gynaecological examination should include inspec
tion of the perineal and genital regions as well as a
digital vaginal examination to evaluate pelvic floor muscle strength. Inspection of the
vulva and perineum allows a description of the
skin and the presence of any abnormal anatomi
cal features, of atrophy or excoriation, features of
prolapse, and erythema due to incontinence and
the wearing of pads.

Presently there are few scientific data document
ing the parameters of a normal pelvic examination
in women of various ages and with various obstet
rical histories. The components of the examination
have not been universally agreed upon. It seems
intuitive that the examination should include an
assessment of the bony architecture, pelvic floor
muscle tone and muscle mass, connective tissue
support, the epithelial lining of the vagina, the size,
location, and mobility of the uterus, the adnexal
structures, and innervation of the pelvic floor struc
tures. It is important to establish the oestrogen sta
tus as oestrogen receptors are present within the
lower urinary tract, [58] and have been shown to
influence cell proliferation. [59] Women with oes
trogen deficiency may complain of urgency and
frequency and recurrent urinary tract infections
may develop because of loss of urethral mucosal
coaptation. In women of reproductive age, symp
toms may vary with the menstrual cycle. [60]

The well-oestrogenised vagina has a thickened
epithelium, with transverse rugae in its lower
two-thirds. The poorly oestrogenised vagina has
a thinned epithelium with loss of transverse ru
gae. Signs of moderate to severe vaginal atrophy
include the presence of pale and dry vulvovagi
nal mucosa with petechiae. [61] A urethral car
uncle, a small, soft, smooth friable red outgrowth
along the edge of the urethra, may also develop.
A thin watery yellow vaginal discharge may be
observed. The appearance of thicker, white or
other coloured vaginal secretions may suggest a
vaginal infection; urine within the vagina suggests
genitourinary fistula.

Urethral diverticula are occasionally congenital but
most are acquired. They may have either a simple
or a complex sacculation. Many patients with ure
thral diverticula are asymptomatic and need no
treatment. Symptomatic patients report recurrent
cystitis, frequency, dysuria, dyspareunia, urinary in
continence and voiding difficulties. On clinical ex
amination a suburethral mass may be palpable; the
urethra is usually tender; and, if the sacculation com
municates with the urethra, it may be possible to ex
press a purulent exudate from the urethra. Occasion
ally, a stone may develop within the diverticulum. [62]
4. Specialised tests for diagnosis UI in Women

Three special manoeuvres can be performed during the initial assessment of urinary incontinence: the stress test, the Q-tip test, and the pad test. The post-void residual urine volume and use of a urinalysis in the initial assessment of women with urinary incontinence are also discussed.

• Stress Test

The stress test involves observation for urine loss with coughing or Valsalva manoeuvre.

This procedure can be performed while the patient is in the lithotomy position or standing. Instantaneous urine leakage on coughing or during aValsalvamanoeuvre is considered a positive test, and a sign of stress urinary incontinence. [2] Holroyd-Leduc et al. reviewed existing evidence on the diagnostic accuracy of the stress test for stress urinary incontinence. [53] Results from the meta-analysis revealed that a positive stress test increases the likelihood of a diagnosis of stress urinary incontinence (summary LR, 3.1; 95% CI, 1.7-5.5), while a negative test result decreases the likelihood (summary LR, 0.36; 95% CI, 0.21-0.60). The results obtained during a filled-bladder test are more accurate than the results obtained during an empty-bladder test. Doing a more complicated stress test that uses a step-wise approach to bladder filling and combines supine and standing testing does not further improve diagnostic accuracy for stress urinary incontinence. The stress test performed with coughing appears to be a reliable test. Reliability data are not available for tests performed using the Valsalva manoeuvre. Price and Noblett recently compared the accuracy of the cough stress to the pad test for diagnosing stress urinary incontinence. [63] The cough stress test demonstrated superiority over the pad test with a sensitivity, specificity, and positive and negative predictive values of 90%, 80%, 98%, and 44% for diagnosing stress urinary incontinence.

• Q-tip test

The Q-tip test has traditionally been used to assess mobility of the urethro-vesical junction. The test involves placement of a lubricated cotton swab or Q-tip in the urethra to the level of the bladder neck while the woman is in the lithotomy position. Change in the axis of the free end of the swab is then measured while the woman performs a Valsalva manoeuvre. The free end should remain horizontal if no anatomical defect is present. If the free end moves above the horizontal, urethral hypermobility is suspected, this can occur in patients with stress urinary incontinence. [64] In a meta-analysis by Holroyd-Leduc et al. that examined the accuracy of the Q-tip test for diagnosing stress urinary incontinence, only two relevant studies met the inclusion criteria. [53] Results of the analysis suggested that a positive Q-tip test does not accurately predict the diagnosis of stress urinary incontinence in women. More specialised testing with pelvic floor ultrasound and other imaging techniques appears to be gradually replacing the Q-tip test for a more advanced assessment of bladder neck hypermobility. The reader is referred to the Report by the Committee on Imaging and Other Investigation (Cmte 7).

• Pad test

A pad test involves the continuous wearing of continence pads for a set period of time. The objective of pad testing is to quantify the volume of urine lost by weighing a perineal pad before and after some type of leakage provocation. This test has also been used in an attempt to distinguish continent from incontinent women, rather than for distinguishing the type of urinary incontinence. Holroyd-Leduc et al. reported that a positive pad test increases the likelihood of an incontinence problem (LR, 3.3; 95% CI, 2.0-5.4), while a negative pad test makes an incontinence problem much less likely (LR, 0.11; 95% CI, 0.05-0.27). [53] Pad tests can be divided into short-term tests, usually performed under standardised office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a full bladder or with a fixed known volume of saline instilled into the bladder before beginning the series of exercises. A pad weight gain >1 g is considered positive for a 1-hour test, and a pad weight gain >4 g is positive for a 24-hour test. There is wide variation in the pad weight gain in incontinent women participating in clinical trials. Although some studies have found high test-retest correlations in pad tests, [65, 66] other studies have reported low inter-subject and intra-subject reliability. [67, 68] The correlation coefficient between total leakage during two long-term tests appears to exceed that of standard 1-hour tests. [69, 70]

2. Pelvic Assessment: Pelvic Floor Strength and Pelvic Organ Prolapse

a) Assessment of pelvic floor muscle strength

According to the recent 2010 joint guidelines published by IUGA/ICS in 2010, pelvic floor muscle strength is qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, normal, weak or absent, or by a validated grading symptom. [2] Voluntary pelvic floor muscle contraction should be evaluated during the initial assessment by vaginal digital palpation. Any or all of the following factors can be assessed including muscle strength (static and dynamic), voluntary muscle relaxation (absent, partial, complete), muscular endurance (ability to sustain maximal or near maximal force), repeatability (the number of times a contraction to maximal or near maximal force can be performed), duration, coordination, and displacement. If possible, it is desirable to document findings for each side of the pelvic floor separately to allow for any unilateral defects and asymmetry. The ICS report on the
standardisation of terminology of pelvic floor muscle function and dysfunction provides a fuller description of the assessment of pelvic floor muscle function including the following:[71]

a) Normal pelvic floor muscles: Pelvic floor muscles which can voluntarily and involuntarily contract and relax.

b) Overactive pelvic floor muscles: Pelvic floor muscles which do not relax, or may even contract when relaxation is functionally needed, for example, during micturition or defaecation.

c) Underactive pelvic floor muscles: Pelvic floor muscles which cannot voluntarily contract when this is appropriate.

d) Non-functioning pelvic floor muscles: Pelvic floor muscles where there is no action palpable.

b) Assessment of Pelvic Prolapse

Urinary incontinence and pelvic organ prolapse are separate clinical entities that often coexist. Significant protrusions of the vagina can obstruct voiding and defaecation. It is important to assess pelvic organ prolapse in a woman with incontinence, because repair of one pelvic support defect without repair of concurrent asymptomatic pelvic support defects can predispose to accentuation of unrepaired defects and new symptoms. The term stress incontinence on prolapse reduction (occult or latent stress incontinence) was recently introduced to describe the development of stress urinary incontinence after of reduction of co-existent prolapse by surgical repair or pessary insertion. [2]

Assessment of pelvic organ prolapse described in this section is in accordance with the recent 2010 joint guidelines produced by IUGA/ICS in 2010.[2] All examinations for pelvic organ prolapse should be performed with the woman’s bladder empty (and if possible an empty rectum). [2] The patient should be examined in the position (for example, left lateral (Sims), supine, standing, or lithotomy) that best demonstrates prolapse according to the patient. The degree of prolapse may be worse later in the day (after a lengthy time in the erect position) than it is earlier in the day. The hymen always remains the fixed point of reference for prolapse description. Pelvic organ prolapse is defined as the descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix), or the apex of the vagina (vaginal vault or cuff scar after hysterectomy) at the level of the hymen or beyond. Most clinicians are generally comfortable with the terms cystocele, rectocele, vaginal vault prolapse, and enterocele, which have historically been used interchangeably with the terms anterior, posterior or apical vaginall prolapse. [2, 71]

a) Stage 0: No prolapse is demonstrated.

b) Stage I: Most distal portion of the prolapse is more than 1 cm above the level of the hymen.

c) Stage II: Most distal portion of the prolapse is 1 cm or less proximal to or distal to the plane of the hymen.

d) Stage III: The most distal portion of the prolapse is more than 1 cm below the plane of the hymen.

e) Stage IV: Complete eversion of the total length of the lower genital tract is demonstrated.

1. Pelvic organ prolapse quantification (POP-Q)

Different systems have been used to describe pelvic organ prolapse (POP), however lack objectivity and validation [73, 74]. The need for an objective, site-specific method of quantifying and staging POP lead to the design and validation of the POP-Q system. The original description of the POP-Q was by Bump et al [72] in 1996 and is shown in figures 1 and 2. The POP-Q records defects relative to the hymenal remnants in centimetre gradients. These measurements are further staged according to the distal-most defect (Figure 3).

Anterior vaginal wall prolapse is defined as descent of the anterior vagina so that the urethra-vesical junction (a point 3cm proximal to the external urinary meatus) or any anterior point proximal to this is less than 3cm above the plane of the hymen. The well-supported anterior vaginal wall should not cross the longitudinal axis of the vaginal canal. Hypermobility of the urethro-vesical junction is demonstrated by having the patient perform a maximum Valsalva effort. In women with hypermobility, the increase in intra-abdominal pressure causes descent of the urethro-vesical junction (bladder neck).

On vaginal examination, there may be loss of the transverse crease between the lower and middle thirds of the anterior vaginal wall and descent of the anterior vaginal wall. Anterolateral protrusion into the vaginal canal may represent unilateral or bilateral detachment of the pubocervical fascia along the anterolateral vaginal sulcus from its attachment to the arcustendineus fascia pelvis (white line). Central protrusions of the anterior vaginal wall may represent defects in the pubocervical fascia below the trigone and base of the bladder. Advanced prolapse of the upper anterior vaginal wall may obstruct a well-supported bladder neck.

Prolapse of the apical segment of the vagina is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix, below a point that is 2cm less than the total vaginal length above the plane of the hymen. Descent of the cervix or of the vaginal apex following hysterectomy, below the level of the ischial spines is evidence of a defective vaginal suspension mechanism. In some women, the intravaginal portion of the cervix may become elongated and cause the cervix to extend into the lower vaginal canal, simulating prolapse; however the fundus may have good support. In other women, the uterus may prolapse fully outside the hymen as uterine procidentia. Following hysterectomy, the vaginal cuff
may be well supported or may prolapse fully outside the hymen, along with other vaginal segments.

Posterior vaginal wall prolapse is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3cm above the level of the hymen or any posterior point proximal to this, less than 3cm above the plane of the hymen. The well-supported posterior vaginal wall should not cross the longitudinal axis of the vaginal canal. Posterior protrusions into the vaginal canal are most commonly caused by defects in the recto-vaginal fascia allowing protrusions of the small bowel (enterocoele) and/or rectum (rectocele). Normally, the anterior vaginal wall lies upon the posterior vaginal wall. Therefore, protrusions of the posterior vaginal wall can affect the function of the urethra and blad-
system of the original scale was retained. Only four measurement points were suggested; i.e. the anterior and posterior vaginal walls, the cervix and the vaginal apex. Measuring the descent of a half-way point between the hymenal remnants and the vaginal wall, cervix or vaginal apex similar to the original POP-Q was described [77]. The inter-observer correlation of the simplified POP-Q was investigated in a secondary analysis of data from a large multicentre study. Weighted kappa statistics for the four POP-Q sites ranged from 0.53 (indicating poor agreement) to 1.0 (denoting excellent agreement) [78].

A review of the POP-Q with the aim of simplifying the assessment tool is underway by the standardisation committees of the International Continence Society (ICS) and International Urogynaecology Association (IUGA) [2].

Despite the difficulties highlighted with the adoption of the POP-Q, reproducibility and reliability of the assessment system have been demonstrated [75, 79, 80]. Hall et al demonstrated that the examination could be completed within four minutes by new learners and two minutes by clinicians experienced with the assessment [81]. With experienced practitioners, POP-Q staging performed using the measurement technique and estimation based on clinical examination are not significantly different [82]. Parnell et al have described a POP-Q model in order to teach the POP-Q examination [83]. The POP-Q has gained popularity in the quantification of POP in clinical research protocols and is quoted in 80% of articles on POP [84].

A retrospective study by Collins et al showed that a point Bp value of >-.5 on the POP-Q was found to be strongly correlated with defaecatory dysfunction with symptoms of stool trapping and incomplete evacuation; leading to the need for perineal splitting in women with POP [85]. The POP-Q has been used for the linguistic validation of condition specific health related quality of life questionnaires such as the Pelvic Floor Distress Inventory, Pelvic Floor Impact Questionnaires [86], Prolapse Quality of Life questionnaire [87-89], Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ12) [90] and validation of the Patient Global Impression of Improvement (PGI-i) for urogenital prolapse [91].

The POP-Q measurements have been validated in the dorsal lithotomy, standing and upright positions. Digesu et al. investigated the reliability of the POP-Q in the left lateral position in a sample of 218 patients. Compared with digital examination, the POP-Q system showed a higher degree of reliability (Kappa coefficients of 0.54 and 0.88 respectively) [92].

The POP-Q has been used to define improvement in POP after surgical interventions in a number of studies; including novel laparoscopic techniques such as uterine suspension to the anterior abdominal wall [93], colpocleisis [94], sacrospinous fixation [95, 96], vaginal mesh or abdominal mesh [97-124], animal derived mesh [125-128] and collagen coated mesh repairs [129]. An advantage of the widespread adoption of the POP-Q system is the ability to compare results and surgical outcomes of different studies.

A recent study involving 311 women with symptomatic prolapse aimed to investigate the influence of increasing age, body mass index (BMI) and parity on POP-Q measurements [130]. The results of the study showed no correlation between BMI and POP-Q measurements. Increasing parity was associated with greater scores on point Aa. Aging was associated with worsening global POP-Q scores. The correlation between POP-Q measurements and symptoms of prolapse were found to be poor in a study of 64 patients with stage ?or greater prolapse [131]. This study reported that higher BMI was associated with experiencing fewer symptoms of prolapse.

An observational study of 94 women underwent POP-Q and pelvic ultrasound assessment of their type of cystocele [132]. The aim of the study was to investigate the agreement between physical POP-Q and the Green radiological classification of cystocele. Kappa co-efficients ranged between 0.56-0.54 and 0.32-0.79 for clinical and ultrasound diagnosis respectively. The clinical utility of these findings has not been established. The quantification of POP using the POP-Q was compared with dynamic MRI and perineal ultrasonographic imaging; the results showed that correlations of the anterior compartment were good to moderate, compared with central and posterior compartment that were poor to moderate. Correlations were independent of the Pop-Q staging measurements [133].

Sexual function in women with prolapse before and after treatment has been investigated in a number of studies, using the POP-Q as an objective measure of prolapse. One study of 68 women undergoing transvaginal mesh repair found improvement in POP-Q scores postoperatively, however dyspareunia was a significant factor for pre-menopausal women [134]. Another study looking at sexual function in women after pelvic floor surgery found significant improvement in both POP-Q scores and sexual satisfaction in women after surgery – interestingly, none of the women had undergone mesh repair [135].

3. GENERAL RECOMMENDATIONS IN THE FEMALE PATIENT

1. In order to diagnose female incontinence, interviews need to be complemented by a targeted physical exam and sound clinical judgment to establish a probable diagnosis. LEVEL 1, Grade B.

   a) A positive response to the question “Do you lose urine during physical exertion, lifting, coughing, laughing, or sneezing?”, increases
the ratio to 2.2 times that a woman has stress incontinence than to the woman who responds negatively.

b) A positive response to the question “Do you ever experience such a strong and sudden urge to void that you leak before reaching the toilet?”, increases the ratio to 4 times as likely that a woman has urgency incontinence than to the woman who responds negatively.

c) Positive answers to the questions in (a) and (b) strongly suggest mixed incontinence.

d) Of note, a response ratio of 5 times as likely is generally accepted as a positive likelihood ratio.

2. There are no studies which address the components of the general physical examination for diagnosing the type of urinary incontinence in women. LEVEL 1 Grade B.

a) Urinary leakage with a cough or Valsalva maneuver increases the likelihood by 3.1 times over a stress test that demonstrates no leakage.

b) The cough test is more reliable than a pad test for diagnosing stress incontinence.

3. An assessment of pelvic floor anatomy and strength should be performed during a routine pelvic examination. LEVEL 5 Grade D.

a) A simple description of the relationship of the anterior, superior and posterior walls at rest and with straining is recommended.

b) The degree of prolapse has not been correlated with the presence or degree of urinary loss.

c) Although the POP-Q examination has been reviewed by this committee on Initial Assessment and has been shown to be reproducible and reliable, this committee does not recommend the routine use of the POP-Q by primary caregivers.

4. RESEARCH RECOMMENDATIONS IN THE FEMALE PATIENT

1. Investigations to correlate the accuracy of the history (simple questions) and physical examination (stress test, pelvic anatomy, and pelvic strength) for the diagnosis of stress (effort), urgency (compelling urge), and mixed (combined) incontinence are recommended.

2. Investigations which correlate the accuracy of combining the history and physical findings for predicting the treatment response to empiric therapies involving conservative and pharmacological intervention are recommended.

3. A simplified, accurate and reproducible system for grading anatomic changes, and establishing the likelihood or presence of stress (effort) incontinence are needed. Investigations into the development of specific maneuvers which involve the reduction of prolapse and the “unmasking” of leakage and the reliability of these maneuvers in both the diagnosis of stress incontinence, and response to empiric conservative therapy should be undertaken.

VI. SPECIFIC POPULATION: EVALUATION OF THE MALE PATIENT

1. CHARACTERISTICS OF MALE INCONTINENCE

In the male patients, lower urinary tract dysfunction, and obstruction from benign prostatic enlargement presents a multi-factorial paradigm for assessing symptom aetiology. Lower urinary tract symptoms (LUTS: voiding, storage and post-micturition symptoms) in men have a significant effect on quality of life (QOL), as compared with the unaffected general population [136]. The aetiologies of voiding symptoms may vary, from benign prostatic hyperplasia (BPH), urethral stricture, primary bladder neck dysfunction, or abnormal voiding dynamics of the detrusor. Several epidemiological reports have demonstrated that storage symptoms (including urgency and urgency incontinence) defined as OAB syndrome also increases with age in men [137,138]. In men with bladder outlet obstruction and idiopathic detrusor overactivity, older age and a higher grade of obstruction has been reported [139]. Chronic prostatic pain syndromes (e.g. non-bacterial chronic prostatitis) and other pelvic floor dysfunctions can also present with a component of symptoms compatible with storage symptoms. In younger men, primary bladder neck dysfunction is a common cause of LUTS, with or without pelvic pain [140]. Functional abnormalities of striated sphincter relaxation may also occur in young men [141].

The complexity of the presenting symptoms and the various differential diagnoses mandate a thorough basic assessment of the lower urinary tract in men to plan optimal therapeutic intervention.

a) Prevalence of OAB (male)

In the NOBLE study, a different sex-specific pattern emerged for OAB with or without urgency incontinence [142]. The prevalence of OAB with urgency incontinence displays a steeper age-related increase among women than among men and the gender difference is statistically significant. In women, OAB with urgency incontinence increased more than nine-fold from 2.0% in those 18-24 years of age to 19.1% among those 65-74 years of age. In contrast, a substantial increase in prevalence of OAB with urgency incontinence among men did not occur until 65 years of age, reaching 8.2% for ages 65-74 years and 10.2% for those 75 years and older. In men, OAB without urgency incontinence increased approximately three-fold, from 8.5% below 45 years
of age to 21.8% after 55 years of age, whereas OAB without urgency incontinence gradually increased in women less than 44 years of age and reached a plateau in women over the age of 44 years.

Prevalence ratios for OAB with urgency incontinence and for OAB without incontinence were significantly elevated for men who self-reported a history of prostate problems. Thus, the evaluation of men with symptoms of OAB syndrome depends on the identification and assessment of lower urinary tract obstruction that may be a cause (in part or in entirety) of the presenting symptoms.

Recently, Markland et al. estimated trends in the prevalence of urinary incontinence in the adult population of the United States from 2001 through 2008 before and after adjusting for other potential associated factors. They analyzed data on 17,850 adults 20 years or older who participated in the 2001 to 2008 cycles of the National Health and Nutrition Examination Survey. The age-standardised prevalence of urinary incontinence in the combined surveys was 13.9% in men, and 51.1% in women. Prevalence in women increased from 49.5% in 2001 to 2002, to 53.4% in 2007 to 2008 (Ptrend = 0.01) and in men from 11.5% to 15.1%, respectively (Ptrend = 0.01). In women, the increased prevalence was explained in part, by differences in age, race/ethnicity, obesity, diabetes and select chronic diseases across the survey periods. In men, an adjustment for possible associated factors did not explain the increasing prevalence of urinary incontinence [142].

Recent epidemiological surveys have demonstrated a significant association between metabolic syndrome (MS) and lifestyle factors, and LUTS, including incontinence. Well-known lifestyle factors, such as food; meat, fat for example, are widely known high risk factor of BPH. It has been revealed that lifestyle factors associated with metabolism — including obesity, blood glucose, exercise, and diet — also contribute substantially to the development of these conditions [143]. In the Third National Health and Nutrition Examination Survey conducted on men older than 60 yr, the odds of having LUTS increased significantly in men with three or more components of MS when compared with their control counterparts [odds ratio (OR) 1.80; 95% confidence interval (CI) 1.11–2.94] [144]. Patients with MS also had an increasing rate of prostate growth, which might account for the increasing prevalence of LUTS [145].

Boston Area Community Health (BACH) survey is a population based epidemiological survey of a broad range of urological symptoms and risk factors in a randomly selected 1,899 men [146]. Using ATP III guideline to characterise MS and AUA symptom index (AUASI) to assess LUTS, it showed that there is a significant association between MS and voiding symptoms rather than storage symptoms of LUTS. The overall prevalence of MS in this study was 29% and demonstrated the association of each LUTS and individual components of MS. Statistically significant associations between LUTS and type 2 diabetes and/or increased blood sugar were observed. Recent studies [147, 148] showed that administration of statins, which are medications currently prescribed for prevention of coronary heart disease, stroke, and peripheral artery diseases, may help prevent common urological problems in aging men.

b) Prevalence of Incontinence after surgery (male – the prostate)

Another important issue in male patients is incontinence after surgery or intervention for BPO and prostate cancer. A survey in England of 5276 patients who had undergone TURP found that one-third of men (n=1759 men) who were continent before surgery reported some incontinence 3 months post TURP [149]. Recently, a systematic review of the literature revealed that many minimally invasive techniques and surgeries for management of BPO result in urinary incontinence, which was observed more often following TURP (1.4%). The rate of urinary incontinence after other techniques are as follows: HIFU; 0.0%, ILCP: 0.1%, TUMT: 0.1%, TUNA: 0.0%, TUVP: 0.9%, VLAP: 0.2%, HoLEP: 1.2% [150]. (All these abbreviations need to be spelt out in full first) Carson et al. reported that incontinence occurs in 0.5 to 1.0% of all patients undergoing open prostatectomy for benign prostatic disease [151].

Urinary incontinence after radical prostatectomy continues to be a widespread and difficult problem for urologists to treat. After radical prostatectomy, Donnellan et al. reported that 6% of men were mildly incontinent, 6% were moderately incontinent and 4% were severely incontinent at 1 year after surgery [152], Wei et al reported rates of 6% to 69% [153]. Flynn et al. reported that the rate of post-radical prostatectomy urinary incontinence ranges greatly in the published literature, from 3% to 74% after surgery, with varying definitions. Long-term incontinence after radical prostatectomy that significantly affects quality of life and requires surgical treatment occurs in approximately 5% of cases [154]. Catalona et al. showed that incontinence after prostate surgery was primarily dependent on the age of the patient. The older the patient, the more likely he is to be incontinent and to never regain urinary control. For 40-49 year olds, permanent incontinence is 8% (4/53) 50-59 year olds 3% (12/358) 60-69 year olds 8% (48/632) while after 70 it is 13% (or 38/282) making an overall 7.7% (102/1325) [155]. Laparoscopic and robotic prostatectomies have been reported to have lower rates of urinary incontinence [156]. After permanent prostate brachytherapy, urinary incontinence was reported in 0-19% of patients [157].

Although radical prostatectomy has a clinically significant beneficial effect on LUTS with significant
improvements of AUA symptom index and flow rate, [158,159] urinary leakage can have a major impact on QOL. Greater degrees of urinary loss have been correlated with greater bother and more significant lifestyle changes [162]. A Medicare survey by Fowler showed that in 1072 patients, more than half of the patients with urinary leakage considered it to be a medium or large problem [160]. In spite of these findings, many investigators have been encouraged by overall patient satisfaction with surgery and patients’ willingness to undergo surgery again, if faced with the same situation [160].

In the immediate postoperative period, stress and urgency incontinence are common. These symptoms have been attributed to varying degrees of oedema and inflammation that may be present in the healing prostatic urethra. The majority of men achieve continence without invasive intervention following radical prostatectomy. Final continence status should be measured using self-administered disease specific instruments at 24 months after operation [160]. No factors (age, severity of LUTS, Gleason score, bilateral nerve sparing surgery and estimated blood loss) were identified that predicted early return of continence [1152].

Post-prostatectomy incontinence may be caused by sphincter malfunction and/or bladder dysfunction [161, 162]. Urinary control in the adult male depends on integrity of both the internal and external sphincters. Even during TURP, the internal sphincter mechanism is virtually destroyed, and in some cases, the external sphincter is also damaged. Thus post-prostatectomy stress incontinence may result.

In a recent study of patients undergoing radical prostatectomy that specifically evaluated detrusor dysfunction [163] de novo detrusor underactivity and impaired or poor compliance, presumed to be a consequence of bladder denervation, occurred in a limited proportion of patients (28.6% and 18.4% respectively). However, it may cause urgency and urgency incontinence, which may be resolved in the majority within 8 months. Detrusor underactivity and decreased bladder compliance are also preexisting conditions in about 30% and 20% of patients. The conditions relate to the presence of BOO, and they do not appear to be influenced by prostatectomy. Persistent detrusor overactivity after obstruction relief is probably related to concomitant sphincter deficiency and stress urinary incontinence, which increase afferent nerve activity of the proximal urethra and induce involuntary detrusor contractions [164].

Obstruction after prostatectomy, resulting from an anastomotic stricture or residual prostatic tissue (post TUR-P), may also play an important role in the development of post-prostatectomy incontinence. Obstructing stricture often causes increase in post-void residual urine, resulting in urinary leakage and/or a weak urinary stream. It has been reported that the anastomotic stricture treatment rates after radical prostatectomy are 16% to 33% [165,166].

2. GENERAL MEDICAL HISTORY (MALE)

The medical history should focus on the urinary tract, previous surgical and radiation therapy history, medical condition and symptoms that may cause bladder dysfunction, familial history of prostate diseases (BPH and cancer), and a review of sexual and bowel habits. If the patient has experienced prostatic surgery, surgical history, current stage of the prostatic cancer, co-morbid conditions, and type of prostatic surgery (retropubic, perineal, laparoscopic, or robotic) should be assessed. Radiation therapy types are also assessed.

Urinary incontinence is rare in men without a history of previous trauma or prostatic or pelvic surgery; therefore, neurogenic bladder dysfunction (neurogenic bladder) must be considered in men with no history of surgery or trauma.

A critical assessment of current medications is recommended to exclude the effects of any pharmacological agents on lower urinary tract function. For example, angiotensin-converting enzyme inhibitors cause chronic cough, which can exacerbate activity-related (stress) incontinence. Alpha-adrenergic blockers cause decreased urethral resistance. This can exacerbate activity-related (stress) incontinence. Alpha-adrenergic agonists cause increased urethral resistance, resulting in exacerbation of urinary retention. Anticholinergics cause detrusor relaxation, which can cause straining to void and possible urinary retention. Diuretics have no direct effect on detrusor function, but can cause an increase in urinary volume, leading to frequency and urgency. Calcium channel blockers relax smooth muscles, causing straining to void may contribute to urinary retention. Psychotropic medications relax smooth muscles of detrusor, causing straining to void and may contribute to urinary retention. Sedatives have no direct affect on the bladder but can contribute to sedation and delirium [167]. All this is relevant to women as well as men so should not be in the male section.

3. SYMPTOM ASSESSMENT (MALE)

Symptom assessment in men with incontinence should aim to identify and exclude patients with complicated incontinence that need to be referred for specialised management. Complicated incontinence comprises patients with recurrent incontinence after failed previous surgery, with total urinary incontinence, and/or with associated symptoms such as pain, haematuria, recurrent urinary tract infection, voiding symptoms, and/or a history of previous pelvic radiotherapy or radical pelvic surgery [168].

Because the occurrence of LUTS in men does not necessarily indicate concomitant prostate enlargement and/or obstruction, specific modalities should be
utilised to ascertain the potential for the aetiological role of these entities. A variety of symptom scores has been described to assess male patients with LUTS. In men, the American Urological Association symptom score for BPH (AUA-7) is most commonly used in North America for assessment of subjective symptoms. However, equally reproducible data can be obtained from the International Prostate Symptom Score (IPSS), the ICSmale questionnaire (now renamed the ICIQMLUTS, long and short forms, as part of the ICIQ modular questionnaire: www.iciq.net).

The IPSS has been the most widely used (in many countries and languages), but neglects the symptom of urgency incontinence, a symptom that produces significant bother. The ICIQMLUTS (ICSmale-SF) is slightly longer, but takes into account the symptom of urgency incontinence, and in fact may be divided into voiding and incontinence sub-scores. To date, it has not been as widely used as the IPSS, but may see more use that is widespread as part of the ICIQ Modular Questionnaire.

Overactive bladder symptom scores are also very useful for male patients with storage symptoms including urgency incontinence [169,170].

Among LUTS, urgency, nocturia, and hesitancy are most bothersome, whereas weak stream, urgency, and frequency are the most prevalent in pooled populations being evaluated for BPH [171]. Postmicturition dribbling is often provoked by an obstructing disease such as BPH or urethral stricture but can also be a symptom of a urethral diverticulum.

Many studies have stressed the lack of the reliability of urodynamics testing in order to determine the cause of post-prostatectomy incontinence, [172,173]. Nevertheless, valuable information can be gained from a careful history with regard to incontinence, especially when related to sphincter dysfunction. The symptom of stress incontinence is highly predictive of the presence of sphincter dysfunction. Chao and Mayo found that 67 of 71 men with post-prostatectomy incontinence secondary to sphincter dysfunction complained of the symptom of stress incontinence [174]. Similarly, Ficazzola and Nitti found 95% positive predictive value and a 100 % negative predictive value for symptom of stress incontinence [161]. Urgency incontinence as a predictor of bladder dysfunction does not seem to be as valuable, and the presence of bladder dysfunction cannot be determined accurately without urodynamics testing [161, 174].

An important aspect of the assessment of male incontinence should be a description of the type and severity of incontinence and precipitating events. Severity may be determined by the number of episodes per day, the need for protection (e.g., pads, penile clamp, external catheter), and the impact of incontinence on activities of daily living. Bladder diaries and pad tests can quantify severity. A bladder diary (or frequency volume chart) kept for 3 to 5 days may be useful in almost all male patients, especially in those with OAB. (refer to section VII, A, 1,a frequency-volume chart and bladder diary, and the Appendix Annex 1). The time and voided volume are recorded for each micturition during several 24-hour periods. Bladder diary completion by the patient provides useful evidence about the normal urinary habits of the patient, including giving some estimate of bladder capacity and diurnal and nocturnal frequency, urgency and stress incontinence. It also helps to identify patients with nocturnal polyuria or excessive fluid intake that are common in the aging male. The data obtained from a frequency-volume chart provide a strong correlation to cystometric capacities and are reasonably immune to the effect of detrusor overactivity in men with LUTS [175].

The 24-hour pad test is an excellent test to quantify the amount of urine leakage in men. Since most patients use different size and type of pad, it is difficult to compare number of pad/day per patient. Furthermore, some patients are very disturbed by any leakage at all and change the pads very frequently, before they are saturated. The other distinction is between a safety pad and true urinary incontinence. In general, the each 1g weight equals 1ml urine loss. A cut-off value of 250g of urine has been proposed to categorise minor from more troublesome or severe leakage [176]. Recently, Macchard et al. suggested that the technical feasibility of the 20-min pad test to evaluate post-prostatectomy incontinence was excellent. The results correlated significantly with both the self-assessment via questionnaire (r =0.63; p<0.001) and the 1-hour pad test (ICS; r =0.66; p<0.001). Moreover, it was highly reliable (r = 0.74; p<0.0005) with excellent patient acceptance. [177]

4. PHYSICAL EXAMINATION (MALE)

The assessments focus on general physical examination, digital rectal examination (DRE) and neurological testing of the perineum and lower extremities. In general a physical examination should include a specific evaluation of the surgical wound, the presence or absence of a distended bladder, or excoriation of the genitals secondary to urinary incontinence. Abdominal palpation to evaluate bladder distension, especially in elderly incontinent men, who may have overflow leakage due to obstruction, is recommended. A post-void residual volume should be measured in patients suspected of urinary retention. The examination should also include external genitalia, location of the urethral meatus, a retractable foreskin and evidence of congenital malformation. The evidence of urethral discharge after abdominal straining (a Valsalva manoeuvre) or coughing in either the supine or upright position should be performed so that the presence of stress incontinence can be ascertained.
A focused neurological examination is also highly recommended. In a patient suspected of ne-urogenic bladder, evaluation of perineal sensation and lower extremity neuromuscular function, and anal sphincter tone, which is often decreased in neurogenic patients [178] is important. A focused neurological examination should also assess the patient’s general mental status and ambulatory status.

A DRE should include palpation of the prostate to assess size, symmetry and consistency of the gland and its relation to the pelvic sidewall and the rectum. An enlarged, indurated and painful prostate may imply BPH, prostate cancer and prostatitis, respectively. Locally advanced prostate cancer can also produce OAB-like symptoms. DRE may ex-clude prostatic cancer, although its specificity and sensitivity is low [179]. DRE tends to underestimate the true prostatic size: if the prostate feels large by DRE, it usually also is found to be enlarged by ultra-sound or other measurement technique [180,181]. Prostate volume has been associated with the risk of BPH progression [182] and response to treat-ment [183]. It has been reported that men with BPH with idiopathic detrusor overactivity showed a significantly higher incidence (54%) of intravesical protrusion of the prostate [184]. This finding sug-gests that intravesical protrusion may in some way increase afferent impulses from the prostate and alter the stability status of the bladder. Occasionally tumours of the anal canal can be diagnosed while performing DRE of the prostate.

5. URINALYSIS AND URINE CYTOLOGY (MALE).

Bladder cancer, carcinoma in situ of the bladder, urinary tract infections, urethral strictures, and bladder stones can cause OAB-like symptoms in aged men. Although haematuria or pyuria is not universally present in those conditions, urinalysis is important to rule out these diseases. Urinalysis is not a single test; complete urinalysis includes physical, chemical, and microscopic examinations. Dipstick urinalysis is certainly convenient but false-positive and false negative results may occur. It is considered an inexpensive diagnostic test able to identify patients with urinary tract infection as indicated by the presence of leucocyte esterases and nitrites. A substantial proportion of older patients with chronic OAB-like symptoms have significant bacteriuria, sometimes accompanied by pyuria. In men, recent urinary tract infections were associated with OAB without urgency incontinence (prevalence ration=2.9; 95% CI: 1.6-5.0) [138]. However, infec-tion may exist in the absence of pyuria and, in the elderly population, pyuria may develop in the ab-sence of urinary tract infection. Microscopic haema-turia can be easily identified by dipsticking because of the presence of haemoglobin. The detection of haematuria is important because the condition is associated with a 4-5% risk of diagnosing urological disorder or malignancy within 3 years. Because of the high prevalence of urinary tract infection and the increase of LUTS in the presence of urinary tract infection, all guidelines on the management of pa-tients with LUTS suggestive of BPO, and urinary in-continence, endorse the use of urinalysis in primary care management [185,186].

Urine cytology is also recommended in male pa-tients with haematuria and a predominance of stor-age symptoms, especially with a history of smoking or other factors, to aid in the diagnosis of bladder carcinoma in situ and bladder cancer This applies to both men and women. [185,186].

6. MEASUREMENT OF THE SERUM CREATI-NINE (MALE)

Epidemiological studies in community dwelling men have shown the absence of any association be-tween BPO/BPE/BPO and chronic kidney disease [187] suggesting that screening for renal function is not justified in male patients. Recently, data from the MTOPS study showed that the risk of develop-ing de novo renal failure in men with LUTS is low (less than 1%) suggesting that is not necessary to monitor renal function in patients with LUTS / BPO [188].

7. MEASUREMENT OF THE SERUM PROS-TATESPECIFIC ANTIGEN (PSA) (MALE)

In most patients, a normal DRE may be sufficient to exclude locally advanced cancer as a cause of LUTS or OAB. There is no consensus as to the measurement of prostate specific antigen (PSA) in patients with LUTS. The rationale for measur-ing PSA is twofold: to screen for prostate cancer [189] and to measure a parameter with prognostic value for the progression of BPH and the response to treatment [192, 193]. Because prostatic cancer is one of the potential causes of LUTS or OAB in men, PSA (together with DRE) is a relatively sensi-tive way to exclude prostatic cancer as a diagnosis [190, 191]. PSA measurement is recommended in men with LUTS and a life expectancy of over 10 years in whom the diagnosis of prostate cancer would change the management of patient’s symp-toms. Given the uncertainties, surrounding prostate cancer detection physicians must use clinical judg-ment in determining which patients should or should not undergo transrectal ultrasonography and prostate biopsy in response to a particular PSA [192].

However, it is important to understand that about 25% of men with BPH have a serum PSA greater than 4 ng/ml. Because of the overlap between serum PSA values in men with BPH and those with clini-cally localised prostate cancer, other parameters (PSA velocity, free/total PSA ratio, complexed PSA and PSA density) will assist diagnostic specificity [193, 194]. It has been suggested that a relationship between initial PSA level and subsequent prostate cancer detection with a stepwise increase in cancer detection rate (from <1% to 58%) in patients with
<1.0 ng/ml, 1.1-2.5, 2.6-4.0, 4.1-10.0 and >10 ng/ml PSA value in over 26,000 patients enrolled in a screening programme [156]. In addition, Thompson reported data on prostate cancer prevalence from the prostate cancer prevention trial [157]. This trial confirmed a stepwise increase in the risk of having a prostate cancer in patients with serum PSA from 0.5 to 4.0 ng/ml, but showing the limitation of the current threshold of 4.0 ng/ml. Change of PSA threshold from 4.0 to 2.0 ng/ml has been proposed but currently no consensus exists [197].

In addition, serum PSA is a reasonable predictor of prostate volume in men with LUTS and may be utilised in this capacity in making clinical decisions [192]. The role of the IPSS score in the assessment of BOO is questionable, and that the grade of obstruction correlates better with prostate volume, PVR, and Qmax [198]. Moderate-to-severe LUTS in men can result in urinary retention. The incidence of retention in men with untreated LUTS in community-based trials is 6.8 per 1000 during longitudinal follow-up of 4 years [199]. If only patients with moderate-to-severe symptoms are considered, the rate of retention increases to 25 per 1000 [200]. In a meta-analysis of predictors of retention in pooled groups of placebo patients from clinical trials of men with LUTS undergoing active interventions (4300 patients), Roehrborn et al. found PSA and prostate volume to be strong independent predictors of urinary retention and the need for surgery in men with LUTS followed up longitudinally in clinical trials [181, 201].

Laniado et al [202] have also tested the hypothesis that PSA level be utilised to predict the presence or absence of BOO, evaluated by pressure flow studies. In patients with LUTS, those with a PSA more than 4 ng/ml are significantly more likely to have some degree of BOO. Conversely, patients with PSA less than 2 ng/ml have a 33% risk of BOO.

8. RECOMMENDATIONS

1. Male patients differ from female patients in the presentation of LUTS. The incidence of OAB wet is lower until the 7th decade. (Level 2)
2. Stress urinary incontinence is primarily associated with surgery of the prostate in male patients. (Level 2)
3. Disorders of bladder emptying from benign prostatic enlargement should be considered before treating male patients for OAB symptoms. (Level 2) (Grade B).
4. In addition to DRE, PSA measurement is recommended in selected male patients with OAB.

9. FUTURE RESEARCH

1. Improve the understanding of the underlying pathophysiology and contributory clinical factors involved in the development and treatment of detrusor overactivity in the male patient, especially in differentiating the condition from female patients.
2. Develop simple, non-invasive, cost-effective methods to determine the contribution of bladder storage and bladder emptying abnormalities in male patients.

I. INTRODUCTION

The last update of the International Consultations on Incontinence reports broadened the scope of this review to include all patient-reported outcomes, not just health-related quality of life. This update will continue in the same vein to extend and update the prior literature reviews of PROs, for lower urinary tract symptoms (LUTS) and bowel incontinence outcome measures, and provide recommendations for questionnaire selection for use in clinical practice and research. In addition, this summary will review the purpose and content of the ICI questionnaire (ICIQ) modules. The expansion in scope of this review to include all types of patient reported outcomes (PRO) is an important step in recognising the inherent conceptual differences of various PROs each with different assessment goals. A PRO is “any report of the status of a patient’s health condition that comes directly from the patient, without interpretation of the patient’s response by a clinician or anyone else”([1], page 2). PROs measure different aspects of disease and therapeutic impact such as: symptom frequency or symptom bother, health-related quality of life (HRQL), treatment satisfaction, or work productivity measures (Figure 1).

An essential component of selecting a PRO for use is to ensure that the selected PRO is consistent with the objective of the study or clinical purpose. For example, if the goal is to assess treatment satisfaction, then a treatment satisfaction measure should be incorporated into the study design or as a clinical outcome. The matching of appropriate PRO selection with one’s desired outcomes is critical to success when assessing PRO’s and will be reviewed further in this chapter.

Ultimately, the last decade has been one of tremendous growth in the area of PROs with influences from scientific and regulatory communities. As such, the ICI will endeavour to continually update the recommendations it offers on the basis of emerging data and published evidence based on the sound and rigid recommendations of the prior reviews.

1. SELECTING PRO MEASURES FOR CLINICAL TRIALS AND CLINICAL PRACTICE

How does a researcher choose which instruments are most appropriate for a particular research study and/or clinical assessment? The following section provides general guidelines for use in conducting PRO assessments in clinical trials or other research investigations related to urinary or faecal incontinence.

As there are many available PROs, it is of utmost importance to select the PRO measure that is relevant and applicable to one’s desired outcome. If an intervention is designed to reduce symptom bother, then a relevant PRO would be a symptom bother measure. Multiple PROs can be included in clinical practice or in a research study; however the designation of the PRO as a primary, co-primary, secondary,
tertiary or exploratory endpoint must be noted. In addition, issues of staff and participant burden, time constraints, and resources should be considered in the selection of a PRO measure. Once it has been decided which outcomes are to be assessed it is important to choose a questionnaire that has been scientifically developed and validated. Principles of validation and questionnaires that have been validated are presented in this chapter.

2. SELECTING PRO MEASURES FOR RESEARCH STUDIES

a) Study Design

There are several protocol concerns that must be taken into account when using PRO measures in research studies, including the length of the study, the frequency of contact with the study participants, the timing of clinical assessments, the complexity of the study design, the number of participants enrolled, and participant and staff burden. The goal of the PRO assessment is to "fit" the PRO measures to the protocol without compromising either the study objective or design. For example, if the study design is complex with frequent participant contacts and multiple clinical measures, it may be necessary to keep the PRO measures at a minimum or to reduce the number of times the PRO is assessed (e.g. baseline and end of study rather than during all participant contacts) to minimise participant and staff burden. At the same time, however, PROs must be viewed as an important variable in the overall trial design and cannot be devalued in the data collection process. Consequently, PRO measures cannot be altered or reduced to accommodate study design as such alterations may yield less reliable measures or may seriously diminish the integrity of the overall study design and yield useless information. Having well developed research goals and questions regarding PROs will help to guide you in the selection of measures for a study. The aim is to develop a conceptually adequate, yet practical PRO battery given the study population, the specific intervention, and the study design.

The frequency with which PRO will need to be assessed in a research study will depend upon the nature of the condition or intervention being investigated and the expected effects (both positive and negative) of treatment. At a minimum, as with all measurements collected in a research study, a baseline and end of study assessment should be completed. In addition, PRO assessments should be timed to match expected changes in functioning due to either the intervention or the condition or the disease itself. Timing follow-up assessments to coincide with typical patient follow-up visits, if appropriate, may also reduce the costs involved in follow-up PRO assessments.

b) Study Population

It is critical to specify key population demographics that could influence the choice of instruments, the relevant dimensions of the PRO to be assessed, and the mode of administration. Thus, age, gender, educational level, the language(s) spoken, and cultural diversity should be carefully considered prior to selecting PRO measures. For example, a cohort of patients over the age of 70 may have more vision problems than middle-aged persons, making self-administered questionnaires potentially inadvisable. Ethnically diverse groups also require measures that have been validated across different cultures and/or languages.

In clinical trials, it is also as important to consider how the disease or condition will progress and affect the outcomes of patients in the control group as it is to understand the effects of the study treatment. For example, in patients with incontinence assigned to a placebo-control arm of a study, one might expect a symptom to worsen and thus have an effect on daily functioning. The point is to select PRO measures that are sufficiently sensitive to detect changes in both the treatment and the control group patients. Use of the same measures for both groups will ensure an unbiased and comparable assessment.

c) Intervention

There are three major factors related to the intervention that are relevant to PRO assessment, and therefore require careful consideration: 1) the positive and adverse effects of treatment; 2) the time course of the effects; and 3) the possible synergism of the treatment with existing medications and conditions. It is crucial to understand how a proposed treatment can affect patient outcomes in both positive and negative ways. For example, some drug therapies may relieve LUTS but produce side effects like dry mouth or sexual dysfunction.

In addition, the time course of an intervention’s effects on PROs is also critical both in terms of the selection of measures and the timing of when PRO measures are administered to study participants. For example, in a trial comparing coronary artery bypass graft (CABG) surgery to angioplasty, an assessment of PRO one week post-intervention might lead to an interpretation that the surgical arm had worse outcomes than angioplasty for PRO since the individuals in this arm of the trial would still be suffering the effects of the surgical procedure (for instance, sore muscles and surgical site discomfort) which could overwhelm any benefits associated with CABG. However, at six months post-intervention, the benefits of CABG surgery such as, relief from angina might be more profound than the benefits received from angioplasty. Thus, when PROs are assessed could influence how one interprets the benefits (or negative effects) of the interventions.

Finally, it is important to have a clear understanding of the current medications the patient population is likely to be taking prior to randomisation to the study treatment, and how these medications might
interact with the trial intervention, (either a pharmacological or behavioural intervention), to influence patient outcomes.

3. TYPES OF PRO MEASURES

There are two types of PRO measures: generic and condition-specific. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both healthy as well as ill individuals). These instruments are generally multidimensional, and assess at least the physical, social and emotional dimensions of life. An example of this type of instrument is the Medical Outcomes Study SF-36 Health Status Profile [2]. A second type of measure is condition-specific (e.g., instruments designed to assess the impact of specific diseases, conditions, age groups, or ethnic groups). Condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions, but condition-specific measures also include items more specific to the particular condition or population being studied. Examples of condition specific instruments in urology include the Incontinence Impact Questionnaire [3], the King’s Health Questionnaire [4], and the OAB-q [5].

In general, the growing trend has been to include condition-specific outcome measures in clinical trials due to their enhanced sensitivity to change and the need to minimise participant burden. Importantly, the type of instruments selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed. In practice, clinical trials that include PROs usually incorporate a combination of PRO measures most relevant to the study population and intervention, if applicable, being mindful of resource constraints and staff and participant burden.

Quality-adjusted Life Year (QALY)

Increasingly HRQL outcome measures are being used in the development of quality-adjusted life year (QALY) measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs. QALYs are widely used for cost-utility analysis[6]. In the past decades, economic evaluation has been increasingly important for the decision maker to decide which treatment or intervention is more cost-effective, in order to allocate limited healthcare resources soundly. Economic evaluation aims to compare interventions in terms of their costs and benefits, including their patient outcome impact. Health benefits can be quantified as QALYs (pronounced “qualies”), which have become a standard measure and are now recommended in most of health economics guidelines as the method of choice [7]. The economic chapter contains additional information regarding QALYs, as do the following references: [8, 9].

4. LITERATURE SEARCH STRATEGY

For the current version of this chapter the previous literature search was updated. A number of databases were accessed, electronically, with specific search criteria, such as validation work from the period January 2006 through August, 2011. Age and gender limits were not specified. Databases used included Pub-Med/MEDLINE, and websites accessed included oab.com, proqolid.com, ncbi.nlm.nih.gov and mapi-institute.com. The following keywords were used separately and/or in combination: “urinary incontinence”, “urinary symptoms”, “urgency”, “overactive bladder”, “stress incontinence”, “incontinence,” “questionnaire,” “epidemiology,” “prostate,” “prolapse(d),” “faecal,” “bowel,” “anal,” “quality of life,” “sexual,” “geriatric,” “paediatric,” “satisfaction,” “symptom bother,” “goal attainment”, “screener,” and “generic.” Questionnaires evaluated in this chapter were updated with any new information if new validation work was found. New questionnaires not in the previously updated resource tool were added to appropriate sections if they were validated and relevant with regard to the search terms specified above. Grades were evaluated for correctness, based on previous and new validation work, and modified if and when necessary to demonstrate any changes with respect to instrument validation.

II. THE MEASUREMENT OF PATIENT-REPORTED OUTCOMES (PROS) OF INCONTINENCE, OTHER LOWER URINARY TRACT SYMPTOMS, AND BOWEL PROBLEMS

Incontinence and other lower urinary tract symptoms (LUTS) as well as bowel problems and their impact on patients and their lives can be assessed in a number of ways. Traditionally, the clinical history has been used to gain a summary view of the symptoms experienced by patients and in some cases the impact on their lives. Increasingly however, patient-completed methods of measuring incontinence and LUTS are being used, including voiding diaries and questionnaires.

Patient self-completed questionnaires or patient reported outcomes (PROs) represent the most important clinical review of symptom impact and treatment benefit from a patient perspective. PROs provide a method for the standardised collection of data, or an objective assessment of subjective phenomena, from patients relating to incontinence, other LUTS, and bowel problems. Clinicians’ assessments of patients’ outcomes have often been shown to underestimate the degree of bother perceived by patients, and to focus on issues of lesser importance to patients [10].

1. PRO QUESTIONNAIRE DEVELOPMENT AND VALIDATION

PRO questionnaires can be used to record the presence and severity of urinary and bowel symptoms,
as well as the impact of symptoms on everyday activities and health-related quality of life (HRQL) and satisfaction with treatment, etc. To ensure that the results obtained with PROs are clinically useful, data must be gathered using valid and reliable instruments. Questionnaire design and development is not a simple process. Developing such instruments requires a multistep, structured process that incorporates cognitive psychology, psychometric theory, and patient and clinician input. The process begins by determining the intent and purpose of the PRO and culminates in studies that demonstrate the measure’s validity, reliability, and responsiveness. The specific steps required for developing a PRO questionnaire are outlined in the following section and are shown in Figure 2.

The development of a PRO is a rigorous, scientific process to provide confidence that the PRO is measuring what it is intended to measure, that it does this reliably, and is appropriate for use in the patient or population group under investigation. The final instrument must have demonstrated validity and reliability in the intended target population. PROs need to be developed with patient and clinician input and have the psychometric, or measurement, properties of the PRO evaluated to determine that it is a valid outcome measure. To be a useful measurement tool, a PRO instrument must also be easy to administer, reliable, and valid. Only PROs that have undergone this process and have published validation data are discussed in this chapter.

a) Determining Questionnaire Intent and Purpose

The first task in developing a PRO measure is to determine why the instrument is needed. Given the current number of disease-specific questionnaires available in the field of incontinence and related pelvic disorders, a new PRO measure must fill a need that has not already been met by an existing instrument. Once the need for the measure is recognised, its purpose and clinical usefulness need to be considered because the purpose dictates the validation design process. For example, a symptom- and a treatment-satisfaction measure would be developed and validated differently because the outcome is different.

The development stage would focus on the outcome of interest (e.g., symptoms patients experience and the significance of each symptom, or what issues patients consider when determining how satisfied they are with treatment) with the items derived from the patient perspective and relating to the outcome

Figure 2. The development of a patient reported outcome is a multistep process
of interest. Validation efforts would include designing a study focused on the outcome of interest with the appropriate patient inclusion/exclusion criteria to enhance generalisability while maintaining internal consistency and providing opportunities to test—at a minimum—reliability and validity.

b) Developing the Items

Designing a clinically useful PRO measure involves more than just developing a series of questions. In addition to clinician input and literature review, questionnaire items must be generated from a patient perspective and include the patient voice. This is obtained through focus groups or one-on-one interviews to provide qualitative data on issues pertinent to patients and to identify the words patients use to describe their symptoms or disease impact. Focus groups and one-on-one interviews should be carefully planned to address the goals of the questionnaire being developed. For example, if a measure is intended to assess symptom bother, interview questions should pertain to the patient’s symptom experience. Importantly, rather than using clinical terminology which patients may not comprehend, the words used during the focus groups or interviews should be common to patients. The results of the qualitative patient interviews lead to item generation. After items are generated, the newly drafted questionnaire should be reviewed by other patients and experts to ensure its readability and content validity.

An alternative approach to questionnaire development is to adapt an existing measure to meet the needs of the desired questionnaire. Patients need to be involved in the questionnaire adaptation to ensure that the revised measure is pertinent to the population of interest. The adapted questionnaire must be validated on its own in the target population as the validity of the original questionnaire does not apply to an adapted measure.

For newly developed and adapted questionnaires, think-out-loud interviews or cognitive interviews should be used to ascertain the correctness and validity of the revised questionnaire. In a think-out-loud interview, patients are asked to review a question and describe what they are thinking as they cognitively process the question; the patients think out loud about what the question means to them and how they think through their response to the question. For a cognitive interview approach, patients review and respond to the questionnaire items, and then they are interviewed about what each item meant to them as they completed the questionnaire. Both approaches provide information about what patients consider when responding to each question.

c) Determining the Mode of Administration of a Questionnaire

When generating the PRO items, the mode of administration must be considered. Will the measure be completed by the patient (i.e., self-administered) or administered by an interviewer (i.e., interviewer-administered)? How the questionnaire will be completed needs to be determined before the validation stage because mode of administration can affect patient responses. For highly personal or intimate questions, a self-administered questionnaire is recommended to avoid response bias. Questionnaires that are self-administered are preferable to interviewer-administered questionnaires because the data collection burden is reduced and patients are more likely to provide unbiased information on self-administered questionnaires. Importantly, if a questionnaire has been validated for a particular mode of administration (self-administered pen and paper), this does not make the questionnaire valid for all modes of administration (e.g. electronic administration via web or handheld device). Should the mode of administration change from the original validation, processes must be undertaken to ensure no change in meaning or content have occurred with the format change. Guidelines for this type of adaptation are clearly outlined by Coons et al (2009) [11].

d) Questionnaires’ Psychometric Properties

All PRO measures must demonstrate reliability, validity, and responsiveness, which are described in detail below. This can be accomplished in several ways:

1. Perform a stand-alone cross-sectional study to validate the questionnaire in the patient population for which it was designed;
2. Administer the untested questionnaire in a clinical study and use the baseline data to perform psychometric validation (the end-of-study data can also be used to evaluate responsiveness); or
3. Perform a stand-alone longitudinal study with an intervention to determine the instrument’s psychometric performance and responsiveness in a non-clinical trial setting.

The following psychometric properties must be tested for and demonstrated in a validated questionnaire.

Reliability refers to the ability of a measure to produce similar results when assessments are repeated (i.e., is the measure reproducible?). Reliability is critical to ensure that change detected by the measure is due to the treatment or intervention and not due to measurement error [12]. One measure of reliability is the questionnaire’s internal consistency, which indicates how well individual items within the same domain (or subscale) correlate. Cronbach’s alpha coefficient is used to assess internal consistency reliability, with higher alphas indicating greater correlation. Typically, Cronbach’s alpha should be greater than 0.70 to indicate good internal consistency reliability [12, 13]. If the item-to-total alpha is less than 0.20, the question should be removed or rewritten.

Test-retest reliability, or reproducibility, indicates how well results can be reproduced with repeated
testing. To assess test-retest reliability, the same patient completes the questionnaire more than once, at baseline and again after a period of time during which the impact of symptoms is unlikely to change (e.g., a few days or weeks) [12, 13]. The Spearman’s correlation coefficient and intraclass correlation coefficient are used to demonstrate reproducibility. For group data, a Spearman’s correlation coefficient or an intraclass correlation coefficient of at least 0.70 demonstrate good test-retest reliability [12, 13].

**Interrater reliability** indicates how well scores correlate when a measure is administered by different interviewers or when multiple observers rate the same phenomenon [12]. Demonstration of interrater reliability is not necessary for self-administered questionnaires but is necessary for instruments based on observer ratings or using multiple interviewers. A correlation of 0.80 or higher between raters indicates good interrater reliability [12].

**Validity** refers to the ability of an instrument to measure what it was intended to measure [12, 13]. A measure should be validated for each specific condition or outcome for which it will be used. For example, a measure designed to assess stress incontinence typically are required to validate a questionnaire [12, 13]. Content validity is a qualitative assessment of whether the questionnaire captures the range of the concept it is intended to measure [12, 13]. For example, does a measure of symptom severity capture all the symptoms that patients with a particular condition have, and if so, is the measure capturing the items in a manner meaningful to patients in language patients can understand? To obtain content validity, patients review the measure and provide feedback as to whether the questions are clear, unambiguous, and comprehensive.

**Convergent validity** is a quantitative assessment of whether the questionnaire measures the theoretical construct it was intended to measure [12, 13]. Convergent validity indicates whether a questionnaire has stronger relationships with similar concepts or variables. Stronger relationships should be seen with the most closely related constructs and weaker relationships seen with less-related constructs [12, 13].

**Discriminant validity** indicates whether the questionnaire can differentiate between known patient groups (e.g., those with mild, moderate, or severe disease) [12, 13]. Generally, measures that are highly discriminative are also highly responsive.

**Criterion validity** reflects the correlation between the new questionnaire and an accepted reference, or gold standard [12, 14]. One difficulty in establishing criterion validity is that a gold-standard measure might not be available [12, 14]. When criterion validity can be established with an existing measure, the correlation should be 0.40 to 0.70; correlations approaching 1.0 indicate that the new questionnaire may be too similar to the gold-standard measure and therefore redundant [12, 14].

**Responsiveness** indicates whether the measure can detect change (for better or worse) in a patient’s condition [15]. An aspect of responsiveness is determining not only whether the measure detects change but whether the change is meaningful to the patient. This can be done by determining the minimal important difference (MID) of the measure. The MID is the smallest change in a PRO questionnaire score that would be considered meaningful or important to a patient [16]. A treatment that is statistically significantly better than another may not necessarily have made a meaningful difference to the patient; the MID indicates whether the treatment made such a difference from a patient perspective.

Unfortunately, there is no scientific test for MID as it is an iterative process that involves two methodologies to determine the MID of a questionnaire: an anchor-based approach and a distribution-based approach [17, 18]. With the anchor-based approach, the MID is determined by comparing the measure to other measures (or “anchors”) that have clinical relevance [17]. With the distribution-based approach, the MID can be determined by the statistical distributions of the data [17], using analyses such as effect size, one-half standard deviation, and standard error of measurement [17-19].

Another methodology to evaluate treatment benefit is to examine the cumulative distribution function (CDF) of responses between treatment groups. The CDF provides plots to examine the treatment effect and mean improvements by treatment group to see if the mean improvement varies by patient subsets [1, 19].

e) **Linguistic and Cultural Validation**

Increasingly, PRO questionnaires are required to be used in a number of different populations and settings, however, questionnaires and their psychometric properties are not necessarily transferable [20, 21]. A measure that is valid and reliable for a particular language and culture may not prove to be so after translation. Linguistic and cultural adaptation of a questionnaire can occur during the development phase before validation, or it can be done after the questionnaire is validated in the language in which it was initially developed, with the latter being the more common approach. Ensuring the linguistic and cultural validity of a questionnaire is especially important for measures used in multinational clinical trials [20, 21].

The principal steps in adapting a measure for different languages and cultures are as follows:
(1) two forward translations of the original instrument into the new language;

(2) quality-control procedures that may include a backward translation (translating the instrument back into the original language) [21];

(3) adjudication of all translated versions;

(4) discussion by an expert panel to ensure clarity of the translated questionnaire; and

(5) testing the translated instrument in monolingual or bilingual patients to ensure that it measures the same concepts as the original instrument [21, 22].

However, if a backward translation of the measure does not produce a semantically equivalent instrument, then the instrument may need to be developed in the target language, rather than just translated [21].

After cultural and linguistic validation, PROs should also be psychometrically validated within the target language. Thus, reliability, validity, and responsiveness need to be assessed with each language translation to confirm the same measurement properties are present in the translated language(s) to ensure psychometric equivalence. If psychometric equivalence is not present (e.g., not achieving similar or better results in new language translation), the cultural and linguistic translations need to be re-evaluated and perhaps a new instrument may need to be developed.

The ICIQ questionnaires and many of the other questionnaires discussed in this chapter have multiple linguistically validated versions making them useful for International implementation. It is also important to note that the step after linguistic validation, demonstrating psychometric equivalence, should also be demonstrated to ensure that the PRO performs equivalently in different languages and cultures (e.g., Coyne et al. 2008 [23]).

f) Regulatory Oversight

As clinicians and scientists have begun to appreciate and accept PROs as appropriate outcome measures, regulatory authorities have issued guidance documents on current best practices in the development and implementation of PRO in clinical trial settings [1, 24, 25]. For PROs to be acceptable outcome measures for regulatory authorities, documentation of measurement properties must be present as well as evidence of inclusion of the patient perspective and understanding of the PRO and a cohesive conceptual framework that stipulates how the PRO is related to the intervention. While PROs within this document may have a “recommended” status, they may not meet all of the required regulatory guidelines and may require additional validation work either from a qualitative or quantitative perspective. It is strongly suggested that regulatory authorities be contacted early in the process of selecting a PRO for clinical trials to ensure regulatory acceptance of the PRO.

g) Questionnaire Development - A Conclusion

PROs are the most suitable method for assessing the patient’s perspective of their lower urinary tract, vaginal and bowel symptoms [26]. Questionnaires may be long and detailed for use in research, but need to be short and easy to use to be relevant for clinical practice. In addition to being valid and reliable, they need to be easy to complete, and, if they are being used to measure outcome, sensitive to change. Developing a new questionnaire and testing it thoroughly takes a great deal of time and is only necessary if there is not an existing instrument available.

There are many questionnaires currently available for use and these have been reviewed and described with recommendations from the Committee for their use in the last three ICI reports.

The major purpose of the ICI has been to provide a definitive international review and consultative opinion regarding the recommended measures to assess patient reported outcomes within the area of urinary incontinence and LUTS. To this end since the First Consultation, the ICI has worked to develop a modular format for the various patient reported outcomes allowing clinicians and researchers to select internationally recommended questionnaires for the assessment of their patients in both clinical practice and clinical trials. In this fifth ICI review, the ICIQ modular questionnaires (supported by the International Consultation) are presented in detail and their use evaluated. Whilst some of the modular questionnaires are still currently under full evaluation their content and format are presented within this chapter.

III. RECOMMENDED PRO QUESTIONNAIRES

Grades of Recommendation for Questionnaires 2012

As with previous Consultations, the Committee continues to use three grades of recommendation. However, we have added a + sign to indicate when published content validity is available for an instrument:

• Questionnaires were ‘highly recommended’ and given a Grade A if the Committee found “Published data indicating that the questionnaire is valid, reliable and responsive to change following standard psychometric testing. Evidence must be published on all three aspects and questionnaires must be relevant for use with persons with incontinence. Grade A + indicates there is additional evidence of published content validity.”

• Questionnaires were “recommended” and given a Grade B if the Committee found “Published data..."
indicate that the questionnaire is valid and reliable following standard psychometric testing. Evidence must be published on two of the three main aspects (usually validity and reliability). Grade B + indicates there is additional evidence of published content validity.”

• Questionnaires were considered to have “potential” and given Grade C if the Committee found “Published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing. Grade C + indicates there is additional evidence of published content validity.”

The Committee decided that evidence published in abstracts or posters could be used to indicate a developing questionnaire’s potential, but was not sufficiently peer-reviewed to provide the basis for a stronger recommendation.

As decided in the Fourth Consultation the recommendation will be to preferably utilise questionnaires from the ICIQ modules described in detail below. Many, but not all, of these questionnaires are Grade A or A+ questionnaires by previously stipulated criteria. Within the description of the ICIQ modules below the grade assigned to each module is indicated.

Should none of the modular questionnaires be deemed appropriate for specific research or clinical purposes, ICI’s recommendation is to use a Grade A+ or A questionnaire as previously recommended. When no suitable instrument exists a Grade B or C questionnaire, performing additional validation as indicated prior to use if feasible, should be used.

For UI and UI/LUTS, the Committee examined the quality of the psychometric evidence. Only where published data were scientifically sound was the label ‘with rigor’ allowed. Where the Committee had concerns about the quality of evidence, this is noted in the descriptions of the questionnaires below. The Committee considered that the number of high quality questionnaires means that there are now sufficient questionnaires for most purposes and it is not necessary to encourage the development of new questionnaires, except for particular patient groups (see below).

IV. INTERNATIONAL CONSULTATION ON INCONTINENCE MODULAR QUESTIONNAIRE (ICIQ): WHAT IS THE ICIQ?

The ICIQ modular questionnaire was developed to meet the need for a universally applicable standard guide for the selection of questionnaires for use in clinical practice and clinical research [27, 28]. The decision to develop standard questionnaire modules was taken by the Committee after the first ICI meeting in 1998, and resulted in the development of the ICIQ core questionnaire discussed in this section. It was recognised at that time that there were many good validated questionnaires each developed for a specific purpose and each subtly different. Although developers of the questionnaires were familiar with their content and use, the increasing number of questionnaires made appropriate selection difficult and limited the ability to compare similar clinical and research data due to different data collection methods.

An international advisory board was established to continue the development of the modular ICI questionnaire outside the limits imposed by triennial convening of the ICI Committee. Early discussions with the advisory board resulted in the decision to expand the concept to include wider urinary symptoms, bowel symptoms and vaginal symptoms. The advisory board consisted of clinicians and researchers with experience in the design and use of questionnaires representing the major societies involved in the assessment and research of lower genital tract, lower urinary tract and bowel function. The members of the advisory board of the ICI can be seen on the ICIQ website at www.iciq.net. The ICIQ modular questionnaire was then established. Researchers who have developed questionnaires that they would like to be reviewed by the advisory board for inclusion should send the questionnaires and relevant publications to www.iciq.net. The project is a series of living documents that will be continually updated.

1. AIMS AND OBJECTIVES

The ICIQ’s objective is to provide international consensus on the use of patient completed questionnaires for the assessment of lower pelvic symptoms and their impact on patient’s lives. Three aims underpin the ICIQ in order to achieve clarity over questionnaire use:

• To recommend high quality self-completion questionnaires according to evidence of validation as stipulated by the three prior ICI Committees;

• To promote wider use of questionnaires to standardise assessment of lower urinary tract and pelvic dysfunction and its impact on patients’ lives, in order to;

• Facilitate communication in different patient settings and different patient groups both in clinical practice and wider clinical research.

The ICIQ recognised that many high quality published questionnaires already existed and, with permission from the authors, those instruments were adopted into the modular project. It was not possible to adopt all available questionnaires and where more than one option existed, the most appropriate questionnaire for the purpose was included. Where high quality questionnaires were not available, the need to develop a new questionnaire/s was acknowledged. Collaborative efforts to develop new questionnaires are welcome and encouraged.
The ICIQ’s international nature requires that linguistically validated translations are available. More than 50 language versions of various modules have been validated to date, conducted according to established protocol.

Fourteen ICIQ modules/questionnaires are currently available for use, with further modules in development (discussed in detail below). Clinicians or researchers are able to select module(s) to meet the particular requirements of their study or clinical practice. In order to simplify this selection process, modules have been categorised as shown in Table 1. It must be stressed that although multiple questionnaires can and probably should be used they must be used in the format in which they were originally designed and the questionnaires cannot be merged together.

In recent years, increasing advances have been made in the area of electronic documentation, particularly with regard to patient care. It is recognised that questionnaires requiring written completion by hand may lack versatility and therefore prevent uptake of the ICIQ, hampering

attempts to promote standardisation of evaluation. Evaluations of electronic ICIQ modules are currently underway. Cognitive interviewing is being conducted among the potential populations of interest to ensure the appropriateness of these formats, for example, adults with varied lower urinary tract symptoms [11]. Quantitative comparison studies of equivalence are also planned to ensure the robustness of their measurement capabilities is not compromised.

In this chapter, questionnaires forming part of the ICIQ modular format are referred to as those preferred for usage. Although many of the modules are Grade A or A+ questionnaires, others are still under various phases of development and are graded appropriately. Questionnaires that are in early stages of development and have yet to reach Grade C are described as “in development”. Where an ICIQ module is not available it is recommended that a Grade A or B or C questionnaire is used.

2. ICIQ MODULES

a) Core Modules

Questionnaires to assess the core symptoms and impact on health related quality of life (HRQL) of lower pelvic dysfunction are contained in this section, in addition to impact on sexual matters. Core modules (Table 2) provide evaluation of:

- Lower urinary tract symptoms
- Urinary incontinence
- Vaginal symptoms
- Bowel symptoms

Each symptom module is intended for the comprehensive yet succinct measurement of symptoms and associated ‘bother’. The bother item attached to each symptom enables the individual to indicate areas that cause the greatest negative impact on HRQL as perceived by them. This can be a more sensitive indicator of treatment goals than frequency of symptoms alone. The HRQL questionnaires cover specific issues that are a consequence of symptoms, such as life limitations and emotional impact.

b) Specific Patient Group Modules

Questionnaires to assess specific conditions or symptom complexes such as nocturia and overactive bladder are contained in this section along with HRQL modules for these specific symptom complexes. This category also includes specific patient groups, for example, children. These instruments contain only question items characteristic of the symptom complex or have been developed specifically for use in a diverse group making the items/questionnaire only utilisable in that population.

- Nocturia
- Overactive bladder
- Patients with spinal cord disease
- Patients using long term catheters
- Lower urinary tract symptoms in children

c) Optional Modules

This category lies within the core symptoms and includes lengthier questionnaires for more in-depth (maybe in-depth evaluation is more accurate) evaluation of lower pelvic dysfunction. Whilst these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of broader associated symptoms may be desired.

- Lower urinary tract symptoms
- Urinary incontinence

d) Post-treatment Module

The ICIQ module for post-treatment satisfaction is in the early stages of development. Assessment of a patient’s satisfaction with treatment (behavioural, surgical or medication) provides information on treatment impact on their condition and life and includes their perception of effectiveness, tolerability and convenience. It is not yet clear if satisfaction following treatment can be characterised by a set of common question items that are applicable to all lower pelvic health conditions. As with HRQL, there are generic and disease specific questionnaires that assess satisfaction. Ongoing studies will provide further evidence on which to make suggestions regarding post treatment evaluation but it is likely that this will encompass both generic and condition specific measures. Ultimately, the development of post treatment modules will also rely on advice from regulatory authorities (e.g. FDA, EMA) to ensure that measures capture a recognised multidimensionality of satisfaction.

3. GUIDANCE FOR USE OF THE ICIQ

The ICIQ recommends the use of a symptom and HRQL module that match the intended purpose of a study in order to provide a comprehensive evaluation of these two perspectives. The extent of burden placed on the respondent and the study or clinical outcomes must be considered however and ultimately guide questionnaire selection. The characteristics of each module are summarised below, although more extensive information can be found on the project website, www.iciq.net. Modules currently under development are summarised in Table 3.

4. ICIQ QUESTIONNAIRE IMPLEMENTATION

The ICIQ modular questionnaire has attracted considerable attention from both clinicians and researchers worldwide since its structure was finalised in 2004. More than 1200 requests for use of the various modules have been documented and over 180 published studies were identified up to March 2012. The most widely applied module is the ICIQ-UI Short Form, particularly to evaluate female urinary incontinence. Reports on further validation and translations of the ICIQ and related educational projects are growing in number. This is essential in order to achieve standardised evaluation of pelvic floor dysfunction, which is a primary aim of the initiative.

The ICIQ has also been applied to clinical and general practice settings, and has been adopted in national guidelines for the management of urinary incontinence in primary care by the Scottish Intercollegiate Guidelines Network (www.sign.ac.uk/pdf/sign79.pdf) and in a primary care resource pack by the British Society of Urogynaecology.

5. CONCLUSION

The ICIQ modular questionnaire project (www.iciq.net) provides a series of standardized questionnaires for the patient reported assessment of lower pelvic dysfunction symptoms and their impact on patients lives. The ICIQ provides clarity over the selection of questionnaires by recommending only those with evidence of high quality and robust psychometric validation including validity, reliability and sensitivity to change. This assurance provides the user with confidence in the results obtained, which is important in clinical practice and research where treatment decisions or trial outcomes depend on this evidence. Increasing awareness of the ICIQ aims to promote increased use of standardised questionnaires, thereby facilitating communication between clinicians and researchers and enable more widespread comparisons between different treatments and patient groups worldwide. Collaboration with the ICIQ is encouraged among clinicians and researchers in order to conduct further evaluation and provide further translations of ICIQ modules.

V. PATIENT-REPORTED OUTCOME (PRO) QUESTIONNAIRES TO ASSESS THE IMPACT OF URINARY INCONTINENCE, OAB AND LOWER URINARY TRACT SYMPTOMS

There are a variety of PRO measures available for use in clinical practice and research that assess a range of concepts (e.g. HRQL, patient satisfaction, symptom bother, etc). This section and table series at the end of the chapter provides an overview and assessment of those measures. Importantly, clinical practitioners and researchers need to clearly determine their clinical and research objectives before selecting a PRO as it is these objectives and the target patient population that will help determine which validated PRO is appropriate to use. Appendixed Tables 4 through 8 provide a brief overview of all current PRO measures for urinary incontinence and LUTS, their purpose, psychometric properties, translation availability, and recommended ICI grade.

Please note, as instrument development and validation is an ongoing process, the tables below contain publications through August, 2011. As additional work may have been performed on an in-
strumet, it is always prudent to conduct a further literature search and/or contact the instrument developer prior to selecting an outcome measure for your clinical practice or study.

One trend that has become more apparent since the previous Consultations is the modification of more established urinary incontinence questionnaires for use in selected patient groups (e.g., pelvic organ prolapse; males; different cultural/language groups). When using a questionnaire in a patient group other than the group in which it was initially developed, cognitive interviews with the new patient population should be held to review the applicability of the questionnaire to the new patient group. Several of the main questionnaires to be discussed below have now had modified versions published in the literature. The Committee’s view is that although it may be appropriate to modify established questionnaires for use with some populations, it is advisable to keep such modifications to a minimum, and to use the original versions whenever possible. Any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument, and thus all modified instruments should be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument’s construct validity, reliability, and test-retest reliability, at a minimum, and sensitivity to change, in intervention studies.

For some of the more widely used instruments listed below, several modified, shortened versions have been published. Information regarding the modified versions is provided under the original source versions of the questionnaires, but the modified versions are evaluated and graded separately, based on the available information regarding their psychometric properties and performance.

1. HEALTH-RELATED QUALITY OF LIFE MEASURES

Health-related quality of life (HRQL) measures help to assess the impact of disease and treatment on those aspects of quality of life related to health. UI is a symptomatic condition that has been shown to affect many aspects of a patient’s life - physical, emotional, and social relations and cause concern and burden. As such, it is important to assess HRQL in clinical research and practice. Appendixed Table 4 at the end of the chapter provides a quick overview of the variety of HRQL measures available and their validity and characteristics to determine which measure is suitable for your objectives.

2. PATIENT SATISFACTION AND GOAL ATTAINMENT SCALING

Patient satisfaction and Goal Attainment Scaling are two important but separate types of PROs that allow for individualised assessment of disease impact and treatment. Patient satisfaction is the subjective, individual evaluation of treatment effectiveness and/or the service provided by the healthcare system. Goal attainment scaling (GAS) is a method developed to ascertain individual patient treatment goals and using those to facilitate patient-provider interaction and tailor the treatment plan based on those individual’s goals [41].

Measures of patient satisfaction can include evaluation of accessibility/convenience, availability of resources, continuity of care, efficacy, finances, humaneness, information gathering and giving processes, pleasantness of surroundings and perceived quality/competence of health care personnel [42]. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based on patient expectations and provider and treatment performance. As an outcomes measure, patient satisfaction allows health care providers to assess the appropriateness of treatment according to patient expectations. In chronic diseases, where patients must live with treatment, patient satisfaction may be the distinguishing outcome among treatments with comparable efficacy [43].

Two patient satisfaction methods of promise with Grade B criteria are the BSW and OAB-S [44, 45]. Generally responsiveness cannot be assessed as there is no baseline assessment of patient satisfaction with treatment as no treatment has been given. Appendixed Table 5 at the end of the chapter presents a summary of satisfaction instruments identified in UI, OAB and other LUTS.

GAS has been used to measure clinically important change in several therapeutic areas. Although it was originally developed to assess health outcomes in mental health settings, it has recently been expanded to include evaluations in urogynecology[46-50]. GAS has been linked to several possible benefits compared with traditional outcome measures, such as improved clarity concerning treatment objectives for both the healthcare provider and the patient, active involvement of the patient in problem-solving efforts, establishment of realistic patient and healthcare provider expectations of treatment, and increased motivation of patients towards improving their health condition [41]. The end result of GAS is to clarify patients’ expectations for their treatment, document goal achievement, and eventually increase patient satisfaction and improve therapeutic outcomes.

One GAS instrument for lower urinary tract symptoms has been well-developed, the Self Assessment Goal Attainment (SAGA) questionnaire. The development and pilot testing of the SAGA questionnaire has been published [46]. SAGA was developed in 3 phases: (1) a preparatory phase in which preliminary information on goal setting and attainment was gathered; (2) a goal elicitation phase that included qualitative interviews with 41 patients with OAB symptoms and/or other LUTS; and (3) cog-
nite debriefing interviews during which the draft questionnaire was administered to 11 patients with OAB and/or other LUTS. Numerous linguistically validated translations are available at: http://www.pfizerpatientreportedoutcomes.com [51].

3. SCREENING TOOLS

In order to improve the detection of incontinence, OAB and other LUTS, several screening tools have been developed (Appendixed Table 6). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the B-SAQ has been designed to screen for general lower urinary tract symptoms (LUTS) rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire which can detect more than one symptom complex may be more functional as a screening tool in clinical practice than a highly specific questionnaire. The Leicesther Impact Scale (LIS), OAB-V8, OAB-SS and QUID are all Grade A, short, simple to understand and complete, and easy to interpret. However the LIS is interviewer, not patient administered. Importantly, with screeners, responsiveness is not assessed, however the sensitivity and specificity of each tool is critical.

4. ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Measures that can be used to assess how bothered patients are by urinary symptoms are included in Appendixed Table 7. The Patient Perception of Bladder Condition [52] and the Urogenital Distress Inventory are the only Grade A recommend instruments. There are several Grade B and C measures which assess bother for incontinence and LUTS.

5. ASSESSING THE IMPACT OF URGENCY

Several instruments have been developed specifically to assess urinary urgency, which is defined by the International Continence Society as “the complaint of a sudden compelling desire to pass urine which is difficult to defer”[53]. Urgency is the hallmark symptom of OAB [54], thus assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficult-to-postpone need to urinate (urgency) [55, 56]. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein[57] make a case for describing urgency as a “compelling desire to void in which patients fear leakage of urine” as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced UUI (an event) rather than the strongest feeling of urgency (a sensation) itself. Several instruments have been developed to assess urinary urgency these are summarised in Appendixed Table 8.

VI. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HEALTH-RELATED QUALITY OF LIFE IMPACT OF PELVIC ORGAN PROLAPSE

Many women with lower urinary tract and bowel symptoms have pelvic organ prolapse (POP). The clinical assessment, standardized measurement, conservative and surgical treatment of POP is covered in Chapters 5A and 15. Increasingly with new surgical techniques for the treatment of POP standardized objective and subjective assessments are required. This chapter will review the standardised symptom assessment tools for POP. These tools do not allow the clinical staging or planning of prolapse treatment, nor do they assess the correction of prolapse following conservative or surgical treatments. As with many of the other sections in this chapter, it is apparent that clinical conditions affect patients differently. Ultimately, the decision to seek and offer therapy for POP and the evaluation of its success will best be measured by the patient and not necessarily by the physician assessed clinical findings. Whilst not as advanced as the assessment tools to evaluate LUTS, there has been progress in the development of POP specific assessment tools since the last triennial ICI report.

It is important to remember that where specific problems of the patient with POP require assessment (e.g., lower urinary tract symptoms, sexual function) it may be preferable to use one of the questionnaires designed specifically for that purpose.

In general questionnaires for POP tend to focus more on the symptoms related to the lower bowel and prolapse probably because of the wider availability of questionnaires to assess LUTS. The broad three categories of instruments for POP are:

1. Presence of symptoms and their severity;
2. HRQL
3. sexual function.

As prolapse is almost always multidimensional, selecting questionnaires in the modular format of the ICIQ (see above) may well be preferable for many clinical and research applications.

For POP, the Committee examined the quality of the psychometric evidence and only where published data were scientifically sound was the label ‘with rigor’ allowed. The Committee noted that this is a developing area and therefore three grades of recommendation were established (Table 9).
VII. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQL IMPACT OF FAECAL INCONTINENCE

A range of PROs have been developed to identify the severity of anal (AI) or faecal incontinence (FI) and its impact on HRQL. By comparison with the last triennial review, questionnaires are now being incorporated into research trials on a more regular basis recognising the importance of capturing the patient’s perspective. Less is reported regarding the patient’s perspective. Due to the close overlap between faecal incontinence and other pelvic floor disorders (in particular urinary incontinence), some of those questionnaires used for other pelvic disorders also include items to cover faecal incontinence. For similar reasons, items relating to faecal incontinence have often been included in questionnaires addressing general gastro-intestinal and colo-rectal function, as well as condition specific instruments in such areas as irritable bowel syndrome and inflammatory bowel disease, conditions which are commonplace in colorectal practice as well as in other specialties dealing with pelvic floor disorders [66, 67]. It is also important to remember that the normal range of bowel function is broad, that bowel function may be highly variable within individuals without significant pathology. Consequently instruments in this field are likely to lack a degree of sensitivity or specificity for the specific bowel disorders such as IBS, IBD evacuation disorder and constipation.

Anal/faecal incontinence and bowel evacuation are intrinsically related to pelvic floor function and it may be inappropriate to consider bowel function purely in terms of continence and constipation. Evacuatory dysfunction may result from a variety of underlying pathologies including outlet obstruction, slow transit or other mechanical, pharmacological, metabolic, endocrine and neurogenic abnormalities [68]. Anal incontinence occurs in both sexes and it is unclear whether there is any difference between genders in terms of prevalence. Studies to date suggest that in different age groups prevalence varies, with unique risk factors attributable at these stages of life [69]. Symptoms are considered crucial to diagnosis as specific symptoms are thought to reflect the underlying pathophysiology [70]. Thus, urgency (the inability to defer defaecation) and urgency faecal incontinence are thought to indicate loss of voluntary control due to impaired external anal sphincter function, whereas passive faecal incontinence is thought to indicate impairment of the smooth muscle of the internal sphincter.

For AI/FI, the Committee examined the scope of available measures and quality of the psychometric evidence. While this remains a developing area, the publication of the ICIQ-B questionnaire for the assessment of anal incontinence and associated impact on quality of life means that a questionnaire is now available that reaches the highest level of recommendation, including the qualitative development phase [32, 33]. Further evaluation of existing measures such as the Faecal Incontinence Quality of Life index (FIQL) has also resulted in an improved grade of recommendation [71].

The grades of recommendation are as outlined in previous sections and below. Table 10 summarises the questionnaires reviewed and grades of recommendation accordingly.

Appendixed Tables 11 through 13 at the end of the chapter provide details of the specific psychometric properties and development of each questionnaire.

VIII. QUESTIONNAIRES TO ASSESS SEXUAL FUNCTION/SEXUAL HEALTH AND URINARY SYMPTOMS

Sexual function may be regarded as a dimension or aspect of overall HRQL, for which a number of dimension-specific measures have been developed and validated. There is a wide choice of available instruments, the selection of which will depend on the clinical or research setting where the instrument is to be employed. Established and widely used measures that have been shown to be valid, reliable and responsive are clearly desirable, however the feasibility and appropriateness of using a particular instrument in a particular setting must also be considered. A large number of different instruments exist in this field, which aim to evaluate specific aspects of sexual function and sexual health. A number have been specifically developed or adapted to examine sexual function in patients with pelvic floor disorders such as incontinence.

Table 9: Recommended questionnaires for the evaluation of symptoms and health-related quality of life impact of pelvic organ prolapse

Table 10 summarises

Appendixed Tables 11 through 13 at the end of the chapter provide details of the specific psychometric properties and development of each questionnaire.
Clinicians who treat sexual problems often prefer to use unstructured rather than structured interviews or questionnaires in clinical practice as an unstructured approach allows the tailoring of questions to suit the couple or the individual being assessed. Unstructured interviews enable the clinician to support patients who feel vulnerable and encourage discussion. The experienced clinician hopes to have an appreciation of the information required to make the correct diagnosis and institute appropriate treatment. In this setting, vocabulary can be modified, as can the level of assertiveness and the depth of questioning to suit the needs of the individual. This flexibility is not readily achievable with questionnaires which individuals may also find difficult to complete due their impersonal nature or because of physical or mental impairment, cultural or language differences. However, some patients find the discussion of intimate issues with clinicians very difficult and questionnaires may allow these issues to be measured in private, at ease and more effectively before subsequently exploring questionnaire responses in the clinical interview itself.

Appendixed Table 14 at the chapter’s end outlines a number of sexual health measures with a Grade A or B rating based on the criteria provided above. Three measures are of particular note, obtaining an A+ rating, having demonstrated not only reliability and validity but also that content was derived with patient input and responsiveness to treatment has been shown: GRISS [84], FSFI [85], and IIEF [86]. Most of the identified measures are self-reported, easy and quick to administer and many have various language versions available. The majority have also been previously used in incontinence populations. There are various others measures that would be given a rating of C (e.g., Sexual Behaviour Inventory [87, 88], McCoy Female Sexuality Questionnaire [89]), but given the breadth of measures available with an A or B rating, researchers are encouraged to use these for assessing sexual function/sexual quality of life. Specific choice of measure will be dependent on research hypothesis. For instance, if you wanted to assess impact of OAB on sexual function e.g. arousal in women then you would want to use the FSFI rather than the SQOL-F [90] because the FSFI has a specific arousal domain whereas the SQOL-F assesses sexual quality of life.

### IX. QUESTIONNAIRES FOR SPECIFIC PATIENT GROUPS

Most studies and questionnaires have been developed for use with members of the general population or urology/gynaecology patients with incontinence or POP. However, some specific patient groups may experience particular problems with incontinence (for example, children, frail elderly or those who are severely disabled), which may require independent investigation and potentially the development of more specific measures or the addition of a new subset of items on already developed instruments. The Committee advises that researchers should use existing highly recommended or recommended questionnaires if possible as this aids comparison and to reduce the increasing proliferation of questionnaires. Many of the questionnaires developed below for particular conditions (e.g. prostate cancer) pre-dated the development of highly recommended questionnaires, and highly recommended questionnaires should be used preferentially.

#### 1. OLDER PEOPLE

Urinary incontinence symptoms play an influential role on the overall HRQL in older people (>65) and causes a significant decrease in HRQL, as severe as that of many chronic disease states. Since the elderly commonly have a number of associated co-morbid conditions, it may be difficult to measure the impact of urinary incontinence with generic HRQL measures. The use of incontinence specific tools to measure patient-reported outcomes in the elderly, therefore, is of considerable importance. Validated incontinence-specific PRO questionnaires, such as IQQ, I-QOL or KHQ, are used for clinical trials or research on urinary incontinence including elderly people, but their validity has not been specifically assessed in this age group. Okamura assessed symptoms and HRQL in older people (men and women)
with lower urinary tract symptoms including incontinence, using the KHQ and IPSS. They demonstrated that symptoms and HRQOL in the elderly with LUTS could be assessed by IPSS and KHQ and that urinary incontinence appeared to be more associated with a decreased HRQOL in elderly women [91].

On the other hand, there are a variety of factors affecting older people, including physical, social, mental, economic or environmental conditions, which are different from those of the young. In frail elderly people with dementia or physical impairment, it may be difficult to assess the impact of urinary incontinence alone. Questionnaires specifically developed for the elderly may be of great importance in this respect. However, there is little relating to the development or validation of particular questionnaires for older people with urinary incontinence. Two questionnaires dealing with older people were found and are described below. No questionnaires dealing with patient outcomes specifically for frail older incontinent people were found.

a) The Urge Impact Scale (URIS) [Grade B]

The Urge Impact Scale (URIS) was designed and tested specifically for older persons with urgency incontinence. The URIS was developed and validated by DuBeau et al. (1999) [92] and included 32 items, reduced to 24 items (URIS-24). The URIS-24 was psychometrically assessed for validity and reliability in community-dwelling older (>65y) men and women with urgency incontinence. Cronbach’s alpha was 0.84 for the URIS-32 and 0.94 for the URIS-24. In assessment of test-retest reliability, interclass coefficient (ICC) was 0.88. The URIS-24 had modest but nearly significant correlation with the number of urgency incontinence episodes (rho=-0.39, p=0.05). Factor analysis revealed 3 component structures corresponding to physiological burden, perception of personal control and self-concept. There was no analysis for responsiveness. They showed that the URIS-24 is an internally consistent, highly reproducible tool for the assessment of the QOL impact of urgency incontinence on older persons.

b) Caregivers

The Overactive Bladder Family Impact (OAB-FIM) scale was developed to assess the impact of OAB on family members of patients with OAB. This 19-item tool consists of 6 subscales [93]. Four subscales (Irritation, Activities, Travel, Concern) could be used for all family members; however 2 additional subscales (Sleep, Sex) should only be administered to spouses/significant others. The OAB-FIM was highly discriminating between OAB and control family members, with all OAB family members indicating significant impact (all p<0.0001). Internal consistency reliability (Cronbach’s alpha >0.71) and 2-week test-retest reliability (intraclass correlation coefficients >0.73) were high for all subscales. Concurrent validity of the OAB-FIM was demonstrated through statistically significant (p < 0.001) Spearman correlations with the OAB-q (coefficients ranging from 0.35 to 0.58) and the PPBC (0.31 to 0.56). No differences were noted on the OAB-FIM by patient incontinence status (none, urge vs. mixed). OAB-FIM scores also discriminated by family member perceptions of OAB severity, particularly among the Irritation, Activities and Travel subscales. Correlational analyses among the OAB-FIM and relationship quality measures suggest that greater OAB symptom impact on the family member was associated with increased problems in the patient–family member relationship. The responsiveness of the OAB-FIM is yet to be assessed. This measure can be found at www.pfizerpatientreportedoutcomes.com.

2. CHILDREN

Some questionnaires have been developed specifically to address issues for children, particularly enuresis. See Chapter 9 (Children) and section on ICIQ modular questionnaire.

3. SPINAL CORD INJURED/NEUROLOGICAL IMPAIRMENT

Individuals who have a spinal cord injury or are neurologically damaged can experience particular difficulties with incontinence and the use of various devices. It would be useful to investigate whether Grade A questionnaires, developed for people without neurological damage, can be used in this group, or whether additional modules or instruments are required. This is an area where a small number of questionnaires are being developed with the Qualiveen being a notable exception (Also see section on the ICIQ questionnaire and below).

Qualiveen: Quality of Life Related to Urinary Problems in Spinal Cord Injury [Grade A]

The Qualiveen was developed to evaluate the specific impact of urinary dysfunction on the quality of life of spinal cord injury patients in France [94]. The initial items were developed following patient interviews, and were then assessed for validity and reliability in 281 spinal cord injury patients with urinary difficulties. The Qualiveen contains 30 items and has demonstrated good reliability and validity [94]. Further validation of the Qualiveen has occurred in multiple sclerosis patients [95] and it has been translated and validated into English [96], German [97], and Portuguese [98]. The Qualiveen has demonstrated responsiveness in multiple sclerosis patients and has a suggested MID of 0.5 [99].

4. PROSTATE/BLADDER CANCER

Many PRO questionnaires are available for assessment in this area: Post-radical prostatectomy questionnaire [100, 101], Cancer Rehabilitation Evaluation System - Short Form (CARES-SF) [102], Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q) [103], PROSQOLI [104], Modified Southwest Oncology Group (SWOG) [105], Functional Assessment of Cancer Therapy - (FACT-G), Bladder form (FACT-B) and Prostate form (FACT-P) [106],
5. LOWER URINARY TRACT SYMPTOMS/BENIGN PROSTATE DISEASE

Many questionnaires have been developed to assess LUTS and benign prostate disease; however, most do not contain a full evaluation of UI. Perhaps the most widely known urology PRO is the AUA Symptom Index [110], I-PSS (International Prostate Symptom Score) [110, 111]. The IPSS has been utilised internationally to assess symptoms of prostate disease with documented reliability, validity and responsiveness. Additional PRO measures for BPH are as follows: Patient-completed modification of the Boyarsky[112], BPH Impact Index [113], and BPH Health-related QoL survey [114].

6. SUMMARY

In summary, some general points to consider in selecting PRO measures for urology studies:

- Ensure that the PRO research questions and study endpoints are clearly defined. Determine the PROs that are most critical to assess and which are most likely to be affected by a particular condition and/or its treatment.

- Make good use of prior literature searches in identifying past research in the area(s) of interest, as well as in identifying the types of PRO measures other researchers have used in past work. This information can provide valuable information on how particular outcome measures have performed in previous populations, as well as provide additional information to assist in defining research questions/issues regarding the PRO components of any given study.

- Consider the characteristics of the population in selecting measures. For example, are the study subjects to be children or older adults, well educated vs. those with limited education, or persons with low literacy? Ensure that the mode of data collection is appropriate for use with the study population. Furthermore, do not assume that an instrument validated for use with Caucasian, middle-class individuals in the U.S. will be appropriate for use in other countries, and/or those of a lower socio-economic status or of different educational backgrounds. This chapter has indicated, where possible, the extent to which specific PRO measures have been validated, and used reliably with different populations.

- Use the questionnaires recommended in this chapter whenever possible. Do not “reinvent the wheel.” Developing new PROs is a time-consuming and complicated process. If a new scale needs to be developed, ensure that the guidelines proposed by the FDA and EMEA on developing PROs are followed and that the appropriate expertise in questionnaire development and psychometrics is available to your research team in order to guide the questionnaire development process.

- Know the strengths and weaknesses of different types of PRO measures. In general, generic measures are useful in providing information on multiple patient outcome dimensions that can be compared across different populations. They may lack sensitivity, however, in addressing concerns of specific patient populations (e.g., OAB, UI, faecal incontinence). Condition-specific instruments, in contrast, do address areas of function more specific to the condition, and tend to be more responsive to changes in clinic status, due to their increased specificity in addressing the conditions of their patient populations. Weaknesses of condition-specific instruments, however, are that they are often not appropriate for use with multiple populations, and cannot be used to make direct comparisons across different patient groups.

- Know how to score your selected PRO measures and how to interpret the scores. Specifically, ensure that the scoring method of a measure provides you with the information you need to answer your research question?

- Finally, train and certify your staff to administer PRO measures using either patient interview and/or self-administration techniques, depending on the method to be used in the study. The administration process needs to be standardised and completely similarly across all participants.

X. RECOMMENDATIONS FOR RESEARCH

1. The selection of a PRO questionnaire must reflect study purpose and objectives
2. Grade A recommended questionnaires should be used in all clinical trials evaluating treatments
3. The inclusion of the ICIQ modules is preferred in all studies to standardise outcome assessment
4. Continued PRO development, refinement, and use should accurately and adequately report on the methods, samples, statistical analyses and psychometric properties of questionnaires in scientific journals (i.e. validity, reliability and responsiveness), so the quality of each study can be assessed

Researchers are encouraged to use existing questionnaires and refine for specific populations when needed (e.g. frail elderly, children)

5. Researchers are encouraged to collaborative with the ICIQ project on the development and refinement of modules and translations.

I. INTRODUCTION

The first two reports of the International Consultation on Incontinence (ICI) contained chapters on 'Urodynamic Testing' [Hommen 1999; Hommen 2002]. Urodynamics is the umbrella term used to describe measurements of the function of the lower urinary tract. These measurements can be used in the management of urinary incontinence (UI). The third and the fourth report of the ICI expanded the topic to include physiological measurements of the lower gastrointestinal tract in relation with faecal (or anal) incontinence. Consequently, the chapters were named 'Dynamic Testing.' [Griffiths 2005].

In this fifth consultation, ICI 2012, we have further updated the evidence for the technical performance, clinical utility and responsiveness to treatment of dynamic testing. However faecal incontinence is discussed in a separate committee for this 2012 consultation. Diagnosis of faecal incontinence and its measurement techniques is therefore not included in this chapter. Consequently, the chapters' name is Urodynamic Testing. We have used the chapter on 'Dynamic Testing' from the previous (2009) consultation as a template for this report; retaining some of the original text and tables where there has been no change since the previous consultation [Rosier 2010; Rosier 2010; Rosier 2010]. Nevertheless the use of the previous chapter as a template, this chapter is updated with more than 200 new references and ±300 outdated references have been removed. With the aim to use the 'test of time' we have however usually not included references of publications less than one year before the consultation. Also discussions of tests that have been presented as 'new' in the previous years, without follow-up manuscripts from other centres, and or without manuscripts that describe the clinical use in comparative studies, have been reduced in length.

Treatment of (stress) urinary incontinence (SUI) has changed considerably in the last decade and that has had its consequence on diagnostic testing. One of the effects has been that the paragraphs that discuss urethral pressures and or leak point pressures are reduced in length.

The primary aim of the chapter is to present what tests might be performed to elucidate the mechanism that causes UI in the individual, but a more predominant aim has been to make recommendations, and to give the strength of the recommendation (A to D), for what tests could or should be performed for certain groups of patients. Thus we present an overview of the best scientific evidence with regard to the role of urodynamic testing in clinical practice. On the basis of this, we provide recommendations for the current state of assessment of the patient with UI, and recommendations for future scientific evaluation of dynamic testing. We present the overview of scientific evidence in paragraphs, with conclusion(s) (with a level of evidence that follows the Modified Oxford Scale) from this evidence for each paragraph. Following on from that, we present our graded recommendation(s) and where deemed useful some topics(s) for research. These items are highlighted in the text and are therefore also suitable for 'express reading'.

The chapter considers urodynamics for patients with signs and symptoms of urinary incontinence. The tests are described with the clinical perspective as well as with normal values and reliability of the measured parameters in mind, followed by reviews of the literature regarding clinical urodynamic evaluation of different patient groups with UI; women, men, children, neurogenic lower urinary tract dysfunction (NLUTD), and the frail elderly. Urodynamics of micturition problems is not addressed specifically and only described where deemed relevant, when a combination with symptoms and signs of UI is present. Each section concludes with the committee’s recommendations.

A. URODYNAMICS

I. WHAT IS URODYNAMICS?

The term 'Urodynamic studies' (UDS) was defined by the International Continence Society (ICS) in 1988 as to 'involve the assessment of the function and dysfunction of the urinary tract by any appropriate method' [Abrams 1988; Schafer 2002]. The report in
2002 which revised the 1988 standard did not alter the definition of ‘urodynamic studies’ or ‘urodynamic observations’ [Abrams 2002]. Another update that adds specific terms for female pelvic floor dysfunction and -female- lower urinary tract dysfunction (LUTD) restates the 2002 ICS terminology report in a descriptive manner [Haylen 2010; Haylen 2010] and includes elements from the ICS good urodynamic practice report [Schafer 2002] as well.

The conventional experts view, endorsed in the previous standardisations and consultations, is that urodynamics is a series of more or less agreed-upon clinical tests, such as flow studies, filling cystometry, pressure-flow studies and urethral (closure) -function measurements. These measurements can be combined with simultaneous electromyography (EMG) recording and/or with imaging by either X-rays or ultrasound. Also implicitly agreed upon is that urodynamics is the way to determine, in an objective manner, which dysfunction causes people to have lower urinary tract symptoms (LUTS) and or signs of UI.

The attempt to gain understanding of an individual’s lower urinary tract (LUT) functioning, on the basis of test observations, in relation to what is known about normal, or expected abnormal, physiology, is what constitutes urodynamics.

Urodynamic studies can answer questions such as: ‘What is the cause, or causes of increased voiding frequency in this patient’ as well as: ‘Why does this patient have urinary incontinence?’ These questions not only can be posed for individual patients but also can form part of clinical or laboratory research [Toh 2006; Nager 2009; Gordon 2001; Gomes 2004].

Conventionally, UDS involves the patient being connected to equipment in the laboratory in order to measure physiological parameters, such as pressures, inside the patient. The data is monitored while the test is being carried out and adjustments can be made to prevent or correct for technical problems and artefacts as they arise. Ambulatory urodynamics may be employed in an attempt to answer the clinical (or fundamental or scientific) question [Pannek 2008]. In ambulatory urodynamics, pressures and other physiological parameters from the patient are fed into a data logger and the patient is free to move about and carry out normal activities. The advantage is that such tests can last for many hours in more ‘natural’ circumstances for the patient but the disadvantage is that prevention of, and control for artefacts and also integration of patients’ activity, sensations or perceptions is much more difficult. Videourodynamics (or ultrasound combined) is a technique to combine anatomical morphological information of the lower urinary tract with functional (pressure and flow) measurements.

II. WHAT SHOULD BE THE ROLE OF URODYNAMIC STUDIES IN CLINICAL PRACTICE?

It is frequently quoted that that the aim of urodynamic testing is to reproduce the patients’ symptom(s). This committee has a view that the ‘symptoms’ here referred to are the patients’ (or caregivers’) way of expressing that she or he notices UI and/or any other sign (or presumed sign) of LUTD. No evidence exists about the incidence of the presentation of the specific symptom ‘urinary incontinence’ in a referred population without that being true. It is the committees’ opinion that this incidence is however probably very, very low. It is therefore not the primary task to ‘solely’ confirm UI as a symptom but it is the doctors’ task to ‘translate’ the sign and or symptoms into a clinical diagnosis that leads to an effective treatment.

Urodynamic testing should be applied to objectively measure and document the entire lower urinary tract function and or dysfunction when it can have therapeutic consequences, bearing the individual patients’ symptoms, and all other relevant circumstances, in mind. Urodynamic testing can show signs such as (significant) residual urine or underactive detrusor which is often not specifically noticed by the patient, even when neurologically unaffected. Especially, but not uniquely in patients with relevant neurological abnormalities, upper urinary tract signs (dilatation) can exist or develop without any (new) symptom. Furthermore the patient can present with symptoms such as, ‘urinary frequency’, ‘nocturia’ or ‘recurrent urinary tract infections’, which are difficult or impossible to reproduce in the usual UDS-laboratory. The importance of urodynamic testing is thus to reproduce the dysfunction of the lower urinary tract and to determine the cause of the signs and or symptoms of urinary tract functional disease. The implicit consequence of this is also that ideally at least one complete filling (storage) and pressure-flow (voiding) cycle, that adequately represents the patients problem (e.g. with regard to volumes) including post voiding features, (residual urine, or after contraction) should be tested, analysed, and documented, even if only storage or voiding signs or symptoms have been expressed by the patient.

The role of urodynamic studies in broad clinical perspective can be:

a) to identify all factors that contribute to the LUT symptoms (e.g. urinary incontinence) and assess their relative importance;

b) to obtain information about all other aspects of LUT function or dysfunction whether or not expressed as a symptom or recognisable as a sign;

c) to allow a prediction of the possible consequences of LUT dysfunction for the upper urinary tract;
d) to allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment;

e) to confirm the effects of intervention or understand the mode of action of a particular type of treatment for a LUT dysfunction; especially a new and or experimental (pre-routine) one;

f) to understand the reasons for failure of previous treatments for urinary incontinence, or for LUT dysfunction in general (after unsatisfactory treatment).

**Conclusion (level 1)**

- Urodynamic testing in clinical practice is to evaluate a person’s lower urinary tract function with at least one complete and representative filling-voiding-post voiding cycle by testing with relevant pressures and flowmetry. Urodynamic testing includes quality control, subsequent analysis, and documentation. Auxiliary testing of urethral (bladder outlet) closure function or simultaneous registration of pelvic floor muscle activity and or simultaneous addition of anatomical or morphological information with ultrasound, roentgen or other imaging can complete, or augment the value of, urodynamic testing for specific indications.

**III. THE TESTS OF CONVENTIONAL URODYNAMICS**

1. **UROFLOWMETRY**

This is the non-invasive measurement of urine flow rate. The patient voids into a flow meter in private ideally with a normal to strong (but not uncomfortable) desire to empty their bladder [Schafer 2002]. Urine flow rate is continuously measured and displayed graphically. Various parameters from the trace are automatically calculated and printed out together with the trace. After control for artefacts in automated calculations, the maximum flow rate, the volume voided and shape of the curve are usually the principal determinants of whether or not the patient is emptying their bladder in a normal way. If an abnormal voiding is obtained, it is good clinical practice to repeat the assessment to check that the result is reproduced, or not. Several factors, such as patient apprehension, can give an abnormal recording in patients who have no voiding difficulty. Asking the patient about what she or he thinks about the voiding; whether the voiding (including the volume) was an adequate representation of the real voiding (compare with voiding diary) and if necessary further explanation is absolutely relevant and must be regarded as standard (good urodynamic) practice. Repeating the assessment can eradicate the effect of such confounding factors and will confirm or refute the validity of earlier assessment(s). Unambiguous and careful instruction of the patient, privacy and a short meatus to flowmeter distance are all inherently relevant [Adlja 2010].

2. **FILLING CYTOMETRY**

This is the measurement of the pressure inside the bladder to assess its storage capabilities. It is an invasive test which involves a catheter being placed into the bladder, usually transurethrally, and another catheter being placed rectally or vaginally (or sometimes through an abdominal stoma) to measure abdominal pressure. Subtracting the abdominal pressure, indirectly measured via vagina, rectum or stoma, from the pressure measured inside the bladder (intravesical pressure) gives a representation of pressure changes due to the action of the detrusor smooth muscle or due to the (lack of) viscoelasticity of the bladder to volume change, measured and expressed as bladder compliance.

During this assessment, the bladder is usually filled with normal saline solution, or x-ray contrast solution in the case of videourodynamic, either through a separate catheter placed transurethrally or through the filling channel of a dual lumen catheter if such is used to measure intravesical pressure. Usually the filling rate is much faster than physiological bladder filling so that, depending on the urodynamic capacity (and related to information from the voiding diary), the bladder is filled in about 10 min.

The intravesical and abdominal pressure and the calculated \((p_{\text{ves}} - p_{\text{pad}})\) detrusor pressure are monitored as the bladder is filled and before the patient has been given ‘permission to void’. The storage ability of the bladder is assessed in terms of the volumes required to elicit various sensations from the patient, its capacity, its compliance (passive muscle adaptation to volume stretch and detrusor muscle relaxation) as distinct from the absence of (phasic) detrusor pressure rises. The filling (storage) phase of cystometry is the method of demonstrating urodynamic stress incontinence (USI) by means of coughing or straining, on request of the clinician [Ward 2008]. Good urodynamic practice demands that abdominal pressure, and intravesical pressure, as well as subtracted detrusor pressure are evaluated to diagnose urinary bladder storage function.

3. **PRESSURE-FLOW STUDIES (VOIDING CYSTOMETRY)**

This is a measurement of the mechanics of micturition. When the filling (storage) phase of cystometry is complete, the patient is given ‘permission to void’ and will empty their bladder on a flow meter whilst intravesical, abdominal and detrusor pressures are being recorded. The simultaneous measurement of flow rate and pressure enables voiding to be assessed and pressure flow analysis can help determine whether slow urine stream is due to bladder outlet obstruction (BOO) or to an underactive detrusor contraction or to a combination of those.
4. URETHRAL PRESSURE PROFILOMETRY

This is a test to estimate the urethra and the surrounding (muscle and other-) structures’ ability to maintain the bladder outlet closed allowing the body system to contain urine within the bladder. By concept, a catheter is placed transurethrally into the bladder and then withdrawn along the urethra (usually by a mechanical puller at a constant rate). The pressure along the length of the urethra is measured and interpreted relative to the pressure inside the bladder (and or abdomen). The maximum pressure measured in the urethra is assumed to give an indication of the urethral closure function.

5. ABDOMINAL LEAK POINT PRESSURE

This is another concept to estimate the urethra’s (bladder outlet’s) ability to contain urine within the bladder. Intra-abdominal pressure is measured whilst the patient is asked to increase their abdominal pressure by valsalva or by coughing. The abdominal pressure required to produce leakage from the bladder gives an indication of the closure function of the urethra since higher closure pressures (‘better function’) require higher abdominal pressure increments to cause leakage.

IV. TECHNOLOGICAL INNOVATIONS IN URODYNAMICS

1. AIR-CHANGED CATHETERS FOR PRESSURE MEASUREMENT

Single-use, air-charged catheters have been developed and used for intravesical, intra-urethral and abdominal pressure measurement in urodynamics (T-Doc, Wenonah, NJ). Initial reports, presented at a meeting, from a female cadaver -study showed that these catheters gave more reproducible measurements of MUCP compared to micro tip catheters, water filled catheters and fibre-optic catheters [McKinney 2000]. In a clinical study in 2004 on 45 women, their performance has been shown to be comparable to micro transducers in the measurement of maximum urethral closures pressure and Valsalva leak point pressure (VLPP) [Pollak 2004]. However, the same study showed a difference in functional urethral length which was attributed to the different diameters of the two catheters. Following on from that, a randomised comparison of these air charged catheters with micro tip catheters in another 64 women, showed that measured maximum urethral closure pressure (MUCP) and functional urethral length were equally reliable. However, the air-charged catheter showed a systematically higher reading causing the conclusion that they cannot be used interchangeably [Zehnder 2008]. The measurement of VLPP by Pollak et al [Pollak 2004] suggests that they can be used to measure intravesical pressure [White 2009; Zehnder 2008]. To compare the response of two disposable clinical catheter systems: water-filled and air-charged, to controlled pressure signals in a laboratory set-up to assess their similarities and differences in pressure transduction using a transient step test and a sinusoidal frequency sweep test, has been carried out. Water-filled catheters were reported to act as an under damped system, and sensitive to (motion) artefacts, whilst air-charged catheters acted as an over damped system, were less sensitive to artefacts and slower in response [Cooper 2011]. Air-charged catheters have several practical advantages over fluid-filled pressure lines because there is no hydrostatic pressure effect to account for, so that there is no need to position external sensors at the level of the symphysis pubis. There is also no need to flush the system through to exclude air; a process that is essential in a fluid-filled pressure-sensing environment. Also, there are no fluctuation artefacts in pressure produced when the patients move [Kim 2010]. However, although air-charged catheters may make urodynamics easier to set up, the conduct and interpretation of a urodynamic study still requires an experienced, appropriately trained practitioner.

Conclusions (level 3)

- Air-charged catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra.
- There have been no studies to show whether air-charged catheters provide a superior alternative to fluid-filled lines for measuring intravesical and intra-abdominal pressure in urodynamics.

Recommendation (grade C)

- Investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure in urodynamics are advised to check for themselves that they have an equivalent performance to their current system for measuring pressure.
- Investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure in urodynamics are advised to check for themselves how the performance of their system compares to the standard reference values for clinical relevant limits (of pressures obtained with the classical systems).

Topic for research

- A study to compare the performance of air-charged catheters with fluid-filled pressure lines in the measurement of intravesical and intra-abdominal pressure during filling and voiding cystometry, to include ‘fast’ events such as coughing.

2. OBJECTIVE ASSESSMENT OF BLADDER SENSATION

Bladder sensation during urodynamics is usually recorded by the simple expedient of asking the patient to inform the investigator when they experience
different sensations. This is an ICS standardised, but subjective measurement which can be confounded by the investigators inadvertently distracting the patient whilst bladder filling is being carried out. Investigators can also bias the measurement by inadvertent prompting, or by causing too much 'concentration' and unrepresentative awareness of the patient [Frenkl 2011]. Bladder (filling) sensation has received increasing attention since (urinary) urgency and 'early' filling sensation are clinically important and some treatments are believed to or initiated to influence LUT sensation [Wachter 2011; Heeringa,R.2011].

A patient-activated, keypad 'urge score' device to measure sensations during bladder filling was introduced [Craggs 2005] to enable patient perceptions of bladder filling and the successive stages of increasing bladder sensation to be recorded without prompting or intervention by the investigator. The device provided reliable and repeatable measures of different bladder sensations. In a controlled setting with 11 healthy volunteers of both sexes, bladder sensations were recorded during non-invasive rapid bladder filling and related to bladder filling sensations during cystometry in the same healthy volunteers: bladder sensation was reported to be continuously incremental [Heeringa 2011].

Filling sensations during conventional urodynamics were marked on a body map in another prospective study. Results from this study suggested that women’s bladder sensations vary in relation to their bladder condition and suggested that this may provide clinicians with relevant information about bladder (dys)-function adding to the usual history and clinical examination [Digesu 2009].

Daily life bladder sensation can be evaluated by sensation related bladder diary and during cystometric bladder filling. 185 women with SUI, OAB or mixed UI filled out a 3-day bladder diary grading bladder sensation and measuring voided volume at each micturition. During UDS reported filling sensations were noted. The end -cystometric volumes were significantly larger than the diary voided volumes for corresponding bladder sensations, and this in all groups, leading to conclusion that symptoms relate more to the diary. [Naemovna 2009]

Imaging studies with regard to brain activity during bladder filling and emptying were reviewed [Fowler 2001]. Research, that started 1996 has provided the in vivo evidence for the existing indirect -neuro anatomical- knowledge of the brain areas involved in lower urinary tract function control and modulation, but cannot yet be regarded as a replacement of cystometry

Many studies consistently show that the correlation between objective and subjective features of detrusor adaptation to volume increment, bladder proprioception and the subjective interpretation of filling is weak [Chung 2011; Meel 2011; Clemens 2011; Tsunoyama 2011; Coyne 2011; Deffontaines 2010; Honjo 2010]. In fact these observations also demonstrate that urodynamic testing is adding new and objective diagnostic information to what has been gathered with history, voiding diary and clinical investigation. Both, UDI as well as signs and symptoms, are relevant, in combination, to select further treatment.

**Conclusion (level 3-4)**

- On the basis of published results, a significant variation exists in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity, despite the standardisation of terms.
- Strategies to derive bladder filling sensation parameters in a more automated and objective way, have been published and show plausible and applicable results, however are not yet sufficiently tested with regard to reliability, relevance, investigator independency or test retest robustness.

**Heart rate variability**

The use of heart rate variability was studied during conventional cystometry [Mehnert 2009]. Heart rate variability was evaluated to serve as a monitor of the autonomic nervous system and an objective measure for bladder filling sensation. Heart rate variability showed to reflect sympathico -vagal balance and to correlate with bladder filling sensation in 11 healthy subjects.

**Conclusions (level 3-4)**

- Monocenter uncontrolled studies have provided evidence for an association of heart rate variability monitoring and urodynamic observations.
- None of the analysis or testing methods of the autonomic nerve system has, to date, shown any relevance for the diagnosis of lower urinary tract function or dysfunction in neurologically unaffected persons. No direct evidence exists for lower urinary tract dysfunction as a sign of – otherwise sub clinical- autonomic failure. No evidence exists that any analysis of autonomic function can be specific enough to monitor lower urinary tract function.

**3. NON-INVASIVE PRESSURE (& FLOW) MEASUREMENTS**

Over recent years, groups in UK and The Netherlands have been developing non-invasive techniques to measure pressure-flow in males. The UK group has developed a penile cuff device that was tested in various preclinical and clinical validation studies but has not been reported as a true replacement of pressure flow cystometry and has not been reported to be relevant for the diagnosis of UI [Griffiths 2002; Drinnan 2001; Griffiths 2005; Drin-
The committee does not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis urinary incontinence, or of lower urinary tract dysfunction.

Recommendation (grade B)

- The committee recommends that non-invasive measurements of bladder or detrusor ‘voiding-pressure’ are considered in order to evaluate voiding function in clinical experiments when the male patient is not required to undergo an invasive assessment of the storage function of the lower urinary tract.

- The committee does not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis urinary incontinence, or of lower urinary tract dysfunction.

Conclusions (level 2)

- Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. None of these studies have however shown any applicability in the diagnosis of urinary incontinence.

- Near-infrared spectroscopy has in very selected recordings shown a relation with detrusor (over) activity and is reported to be applicable as a manner to detect detrusor overactivity.

4. URETHRAL RETRO-RESISTANCE PRESSURE

In the measurement of urethral retro-resistance pressure (URP), a small meatal plug is inserted just inside the female urethra and saline is pumped into the urethra until the pressure reaches the value sufficient to overcome the resistance offered by the urethra when the fluid flows into the bladder. The pressure required to achieve and maintain an open bladder outlet is taken to be a measure of urethral closure function. The basic principle behind the technique has its origins in 1923 when Bonney made an attempt to measure the efficiency of urethral closure [Bonney 1923]. In his first clinical paper, Slack et al studied 258 SUI women with the URP technique in comparison with MUCP and Valsalva leak point pressure (VLPP). They found that URP measurements correlated well with both standard assessments and found that only URP measurements correlated with UI severity [Slack 2004]. The URP, in a group of 61 women, without symptoms of UI and who had negative standing SUI tests, was significantly higher than in a group of women with SUI who had been tested previously [Slack 2004]. This study also provided some test-retest data which showed that URP measurements were consistent in individuals.

Measurements of URP on 165 women with various urodynamic diagnoses were published subsequently [Digesu 2006]. Women with USI had significantly lower URP than women with competent urethral sphincters. Women with mixed urodynamic incontinence had values of URP intermediate between women with DO and those with USI. In the mixed symptoms group, URP mean values were not significantly different from those with DO and competent sphincters, or those with USI. The authors concluded that whilst there are significantly different URP measurements between women with DO and those with USI, the URP is not a diagnostic tool.

An analysis of URP in 48 women with clinically and urodynamically proven SUI (USI) without pelvic organ prolapse (POP) before and after anti-incontinence surgery (colposuspension n = 8, tension-free vaginal tape n = 6, tension-free transobturator tape n = 34) and another study to compare URP with ‘established measures of incontinence severity’ showed that preoperative URP did not correlate with USI in all women, had no predictive value and did not correlate with the outcome of anti-incontinence surgery [Tunn 2007; Roderick 2009].

Conclusion (level 2/3)

- After positive first reports of urethral retro-resistance pressure measurements it was shown that this measurement does not give any better information about urethral closure function than the urethral pressure profile or volsalva leak point pressure.
Recommendation (grade B/C)

- The committee recommends that urethral retro-resistance pressure measurements are not used in clinical routine as an alternative to (cystometry or) urethral pressure measurements made with conventional urodynamic equipment to diagnose the type of (female) urinary incontinence.

5. URETHRAL PRESSURE REFLECTOMETRY

In 2005, Klarskov et al reported on an in vitro study of pressure reflectometry for the simultaneous measurement of cross-sectional area and pressure in a collapsible biological tube and subsequently the technique of urethral pressure reflectometry (UPR), to assess the female urethra, was presented in 2007. The team postulated that these parameters had the potential to provide more physiological information about the urethra than could be obtained from conventional urothral studies.

In the same year these investigators compared UPR with urethral pressure profilometry (UPP) in 143 women (105 patients and 38 healthy volunteers) [Klarskov 2007]. UPR was measured supine, both while relaxed and during ‘squeeze’, and while upright and relaxed, and compared with UPP using the perfusion technique, with the patient supine and relaxed. All measures were done twice to evaluate short-term reproducibility and 17 patients were assessed with both methods on two different days (long-term reproducibility). The authors showed that UPR measured the same pressure as UPP but the UPR was more reproducible. Subsequently UPR parameters of in 30 SUI women and 30 volunteers (23 ‘continent’ and 7 ‘nearly continent’) were reported and compared with UPP [Klarskov 2008].

Conclusion (level 3)

- Preclinical measurements of urethral pressure reflectometry opening pressure and cross sectional area (‘dynamics’) have provided some insight into urethral closure function and dynamics, but, as yet, have no clinical relevance in the diagnosis of (female) urinary incontinence.

Recommendation (grade C)

- The committee recommends that urethral pressure reflectometry is not used in clinical practice for the diagnosis of urinary incontinence before clinical relevance, non inferiority and or superiority over current urodynamic tests has been demonstrated.

6. ULTRASOUND IMAGING

Imaging and ultrasound in relation to UI will be discussed in a separate chapter. We will only give a short summary of ultrasound in relation with urodynamic observations.

The measurement of detrusor wall thickness has been used in a number of studies as a screening test for DO or BOO with a variety of measurement techniques using transvaginal, transabdominal or transperineal ultrasound. Different protocols were used and measured different parts of the bladder for example the dome, the trigone or the anterior bladder wall. This has resulted in contradictory data. Some data showed a smaller bladder capacity in overactive bladder (OAB) wet or DO, and an association between increased detrusor wall thickness and DO on urodynamic testing. Also, observations of an association of ultrasound detrusor wall thickness and BOO have been reported. Most researchers conclude that overlap of the results and the relatively low predictive value should be improved before bladder wall thickness is used in clinical practice [Lekskulchai 2008; Kuo 2009; Panayi 2009; Panayi 2010; Oelke 2009; Chung 2010; Ozawa 2010; Kuhn 2010; Almeida 2011; Serati 2010].

Conclusion (level 3)

- There is some evidence that detrusor wall thickness is related to bladder outlet obstruction as well as to detrusor overactivity.

- There is no evidence that ultrasound detrusor wall thickness analysis can discriminate between detrusor overactivity and bladder outlet obstruction and a relatively low predictive value to discriminate from normal lower urinary tract function.

- There is a large overlap between normal and abnormal values in detrusor wall thickness and a lack of standardisation in ultrasound detrusor wall thickness measurement.

Recommendation (grade C)

- The committee recommends that ultrasound detrusor wall thickness is not used in routine clinical practice for the diagnosis of lower urinary tract function related to urinary incontinence.

B. URODYNAMICS: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE

I. REPRODUCIBILITY OF FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS

1. INTER-OBSERVER, TEST-RETEST AND PRACTICE VARIATION

When different investigators judge urodynamic traces together with written clinical information in women, there is agreement between them regarding the final clinical diagnosis in about 80% of cases. In other words there is, depending on the diagnosis, some disagreement in 20% of cases when urodynamics is judged in combination with clinical
parameters [Whiteside 2006]. A few studies have concluded that there is good short time inter and intra-rater reliability. In a single centre series of 621 urodynamic pressure flow tracings of female patients, small average differences between parameters were observed by various investigators, which was interpreted as good inter-observer agreement [Digesu 2003]. Inter-observer variability has also been tested in other ways. In a study where 4 experienced practitioners, evaluated 17 paediatric urodynamic datasets, they failed to agree on aspects of detrusor function, including DO, in a quarter of the cases [Venhola 2003]. This result is reminiscent of a similar study of the interpretation of urodynamic recordings of male voiding function [Kortmann 2000].

To determine the reproducibility of same session repeated UDS in women with symptoms of UI, 152 women presenting with symptoms of UI underwent standardised UDS, which consisted of free uroflowmetry and two filling cystometries and pressure-flow studies. Overall, reproducibility of the urodynamic parameters were good to excellent (ICC range: 0.72-0.93), except for the bladder volume at FSF (ICC = 0.46) and the maximum Watt's factor (ICC = 0.68). The bladder volume at FSF and the MCC were systematically higher in the second run (mean difference (95% CI) = -45 (-73; -37) and -3 (-15; 10), respectively). Reproducibility of the diagnosis SUI and/or DO were good to excellent (median ICC = 0.76, p = 0.68 and p = 1.00, respectively). Reproducibility of the volume and amplitude at DO, however, were only poor (ICC = 0.18 and 0.25, respectively). The authors of this study concluded that reproducibility of same session repeated—standardised—UDS, in women with symptoms of UI was good to excellent [Broekhuis 2010].

In a survey to determine the variation in urodynamic practices in the United Kingdom 100 questionnaires were sent to units known to be performing urodynamic investigations. There was a significant variation in practices with only 51% of units having a protocol for what tests should be performed, under what circumstances and how [Adekanmi 2002]. Standardisation of urodynamic variables may result in a greater consistency of diagnosis, allowing easier comparisons of treatment regimes and outcomes, and is the conclusion of studies and reviews of this kind [Zimmern 2006; Ellis-Jones 2006]. Standardisation, education and training as well as auditing and evaluation are reported to be relevant in this regard [Ellis-Jones 2006; Singh 2010; Moore 2011].

In a review to examine the influence of position during (filling) cystometry with regard to the sensitivity for DO, sixteen relevant studies with good consistency were analysed. All but two showed a clear influence, with a higher incidence of DO in the vertical position (sitting or standing) or onset of DO when changing to a vertical position. Performing the UDS in a supine position would have missed a large proportion of DO diagnoses, ranging from 33% to 100%. The authors noticed a substantial practice variation in position during urodynamic investigation and suggested standardisation was needed [Al-Hayek 2008].

Some suggested that these findings are caused by difficulties of interpretation, included movement artefacts, and also criticise over-dependence on patients for suitable data recording without a medical assistant. This presumed lack of reliability has lead to the study of the additional value and reliability of ambulatory UDS, as it may improve diagnostic sensitivity and maybe specificity. The additional diagnostic value of ambulatory UDS in patients with LUTS was compared with conventional UDS [Koeveringe 2010]. A retrospective study was done in 108 patients between 2002 and 2007. Ambulatory UDS was shown to be useful in patients with OAB, or in patients with UI that was not demonstrated during conventional UDS, but the study is difficult to extrapolate to real values of amended diagnostic capability.

2. SHORT-TERM (WITHIN-SESSION) REPRODUCIBILITY

A number of authors have investigated the within-session reproducibility of cystometric measurements. Because such measurements are conducted within a short period of time, the possibility that the first measurement influences the second, for example through a direct effect on the mechanical properties of the bladder (hysteresis and/or viscoelasticity), has to be considered.

30 healthy women with a mean age of 52 years, underwent 2 consecutive medium fill rate (50 mL/min) cystometries in a single session [Brostrom 2002]. The volumes at first desire to void (FDV) and normal desire to void (NDV) increased significantly from the first to the second measurement, by 34 and 51 mL respectively. The MCC showed no difference. The proportion of these healthy subjects who showed DO changed from 4/30 (13%) in the first cystometry to 1/30 (3%) in the second; statistically insignificant.

In a similar study [Mortensen 2002] of short-term repeatability in 31 female patients aged 14-74 years, two consecutive cystometries were performed with body temperature liquid at a rate of 50 mL/min. On the first cystometry, FDV occurred at a median volume of 112 mL (range 26-503 mL). The cystometric capacity had a median value of 150 mL, with a range from 39-633 mL. The volume at FDV increased by 46 mL from the first to the second cystometrogram, while the MCC increased by 35 mL. These changes are similar to those seen in normal volunteers, but, as the authors point out, they are not clinically important because they are much smaller than the random variability within subjects, as measured by the 95% confidence limits of ±130 and ±106 mL respectively.
Chin-Peukert et al [Chin 2003] examined the variability between two consecutive cystometries in 32 male and 34 female children with a mean age of 7. Most suffered from spinal dysraphism. A smaller number showed DO on the second study than on the first (p< 0.05), and similarly the volume at which DO was first observed was larger on the second study (p<0.05). Interestingly, these results are similar to those obtained in children without overt neuropathy [Griffiths].

Hess et al [Hess 2002] did not perform repeated cystometries, but first measured the bladder pressure ‘as is’ at whatever volume was in the bladder initially, in 21 men and 1 woman with ‘neurogenic bladder’. They then drained the bladder and refilled to the same volume and again measured the pressure. The second ‘cystometric’ pressures were higher than the initial ‘physiological’ ones by approx 6 cm H$_2$O (p = 0.01), although strongly correlated.

In another study where fifty consecutive individuals with spinal cord injury had 2 trials (trial 1 and trial 2) of UDS done 5 minutes apart, differences in MCC, opening pressure, maximum detrusor pressure, volume (leaked) voided, and post void residual (PVR) volume were evaluated. The variation observed was ± 100-150 mL for the volume parameters and ±10-20 cm H$_2$O for the mentioned pressure parameters, all in both directions between 1st and 2nd [Chou 2006].

Sixty men with LUTS and 35 with NLUTD after spinal cord injury (SCI) were assessed, with symptom scores and uroflowmetry obtained and filling and pressure-flow cystometry carried out three times in succession. In men with LUTS, a significant decrease in the number and pressure of detrusor contractions in consecutive filling cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. In men with SCI, cystometric variables and DO remained consistent over sequential studies [Ockrim 2005].

Twenty asymptomatic women with a mean age of 42 years [30-55] agreed to undergo a urodynamic evaluation, repeated immediately without removing the catheters (a two-fill and void study) [Gupta 2004]. Sixteen women of this cohort returned for an identical assessment 1-5 months later. The short time variation was ± 5 mL/s for Q$_{max}$ and ± 10 cm H$_2$O for p$_{det}$Q$_{max}$. Voided volume (VV) and first sensation of filling (FSF) differed ±50 mL in the test re-test situation. The authors noted that the variation of parameters in these healthy women was larger than observed in other studies with patients.

3. INTERMEDIATE-TERM REPRODUCIBILITY

Homma et al [Homma 2000] found that, in 30 patients with DO, repeat cystometry carried out 2-4 weeks after initial testing showed a consistent shift towards normal. Bladder volumes increased by 10-13% (p<0.01), while DO disappeared in 10% of subjects and decreased in amplitude by an average of 18% in the remaining cases. The random variability of cystometric capacity was ± 57 mL (95% CI).

4. LONG-TERM REPRODUCIBILITY

10 healthy females (mean age 34 years), were investigated twice at an interval of 2 years in both, supine and sitting positions [Sorensen 1988]. FSF occurred at a mean volume of 378 mL supine and 354 mL sitting, with intra-subject variability over two years as quantified by the standard deviation (sd) of 76 and 100 mL (sd) respectively. MCC was 512 mL supine and 502 mL seated, with intra-subject sd of approximately 75 mL in both cases. Inter-subject sd’s were a little larger: 76-144 mL. No significant differences in volumes or compliance over two years could be demonstrated.

Post hoc analysis of urodynamic (pressure flow) tests of male treated for LUTS with enlarged (unspecified) prostate and BOO (for a not specified proportion) showed test retest reproducibility to be good on the basis of parameter correlations, but without kappa or Bland and Altman analysis [Kraus 2010].

A total of 48 children ±10 years were enrolled in a study to evaluate the influence of position during UDS in this patient group, with 60% neurologically affected. No difference was noted for maximum cystometric capacity, DLPP or pressure specific volumes at 20 and 30 cmH$_2$O between the supine and sitting positions. Statistically significant lower values were found for the volume of FSF and volume at which DO was first detected, with lesser difference for abdominal or Valsalva leak point pressure in the sitting position. Significant differences were also noted with position changes in regard to detection of DO and UI episodes, being more prevalent in the sitting position [Lorenzo 2007].

Summary

In patients and in healthy volunteers, if cystometry is repeated either during the same session or within about 4 weeks, the bladder volumes at which the various sensations are felt and the bladder capacity tends to increase by 30-50 mL, while the proportion of traces showing DO tends to fall. These systematic changes are fairly small in comparison with the random within-subject variability, which has an average range of about 50-60 mL.

Conclusions (level 2)

- A number of studies have reported test retest variation of ±10-15% for various parameters (volume, pressure or flow) and observations; this can be regarded as the physiological variation of urodynamic testing.
- Various studies have demonstrated clinically relevant practice variation and inter-rater/observer variation.
Recommendations (grade B)

- The committee recommends that investigators and clinicians take into account the inherent physiological variability of urodynamic testing.
- The committee recommends investigators and clinicians evaluate the ‘representativity’ of the tests (which is an evaluation based on the patient’s perception as to how well the tests have reproduced their usual lower urinary tract symptoms and function, helped e.g. by the voiding diary.) and the committee recommends that examiners strive towards maximal representativity.
- The committee recommends sitting position during cystometry, because that can increase sensitivity of the diagnosis of filling phase abnormalities.
- The committee recommends persistent attention to the standardisation of techniques, to education, and to practice quality evaluation, and consistency of interpretation of results, especially to reduce intra and inter-practice variation and inter–observer variability.

Topics for research

- The committee suggests further consideration of standardisation of urodynamic tests, procedures and evaluation, especially to reduce inter-practice variation.
- The committee suggests intensive dissemination of up-to-date standards and careful training of urodynamic investigators and suggests evaluation of the effect of these standards and training on health care quality.

5. REPRODUCIBILITY OF AMBULATORY URODYNAMICS

There is no published data on the reproducibility or test retest differences of ambulatory urodynamic studies. There is no report that evaluates the investigator dependency on the -post test- analysis of the recorded data.

II. CYSTOMETRY: NORMAL VALUES

1. NORMAL VALUES: FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS

Normal values for cystometric variables are reported by a number of authors. A striking observation is that there is great inter-centre variability, even for tests in nominally similar persons or patients. There is no evidence from these studies that these variations are strongly associated with differences in filling rate, infusate temperature, or patient position. In addition to and referring to the previous consultations we report only the relatively recent studies on volumes, pressures, compliance, capacity and sensations.

Wyndaele et al [Wyndaele 2002] examined 50 volunteers; The bladder was filled at 30 mL/min with body temperature saline. For males (n=18; mean age 22 ± 3 years), FSF occurred at 222 mL ± 151 mL; FDV occurred at 325 mL ± 140 mL; and strong desire to void (SDV) occurred at 453 mL ± 94 mL, which was taken as maximum capacity. For females (n=32; mean age 21 ± 2 years) FSF occurred at 176 ± 96 mL; FDV at 272 mL ± 106 mL; and SDV at 429 mL ± 153 mL. DO was observed in 7/50 (14%) of these normal volunteers. The group also published a study with symptom free ‘middle-aged’ female volunteers. Of their volunteers, a substantial number were excluded because of asymptomatic abnormalities. The remaining had an average capacity during cystometry of 586 mL (sd 193 m) with 258 mL and 1092 mL as extremes [Pauwels 2004].

Twenty-four women without a history of frequent urgency and without DO (mean age 50.2 years, range 22-80 years), including 7 pre- (29.2 years), 7 peri- (48.8 years), and 10 postmenopausal (66.0 years) women were studied with uroflowmetry and video urodynamics to determine normative data for LUT function in asymptomatic continent women without DO across the age span. For all subjects, median maximum single VV in bladder diary was 500 mL and median MCC was 580 mL. SDV was reported at 287, 366, and 425 mL for pre-, peri-, and post-menopausal groups, respectively. The maximum flow rate was 25, 32, and 23 mL/sec in uroflowmetry and 23, 24, and 18 mL/sec during the pressure-flow study, respectively. Median PVR was below 20 mL in all groups. At maximum flow rate subjects voided with detrusor pressures of 29, 26, and 24 cm H₂O, respectively and MUCP was 94, 74, and 42 cm H₂O, respectively [Pfisterer 2007].

Thirty healthy males aged 21-32 years volunteered for an ambulatory urodynamic 24 h investigation, with a suprapubic catheter, to study natural fill urodynamics during normal and increased fluid intake. The recorded micturition data were: frequency (f), VV, voiding time, maximum flow rate (Qmax) and time to Qmax. The number of sensed and not-sensed detrusor contractions, and their duration and time in relation to voiding were also recorded. During the recording day, subjects were randomized to normal (30 mL/kg body weight per day) or larger (60 mL/kg body weight per day) fluid intake. There was a larger urine production and an increased voiding frequency in the fluid-loaded group (p<0.0001). The detrusor pressure (pdetQmax) was significantly higher in the fluid-loaded group (73 cm H₂O, range 57-94) than in the normal fluid intake group (60 cm H₂O, range 45-86) (p=0.003). No other urodynamic data differed significantly between the two groups. Ambulatory urodynamics in normal young men showed a large inter -individual variation, detrusor contractions during filling were frequently recorded, and premicturition contractions were consistently found. The data found in this study were similar to
previous home flow recordings in the same group [Schmidt 2004].

In a retrospective study of 186 selected investigations the influence of urine production during filling cystometry on total bladder volume was observed. Mean filled volume (external infusion plus urine production) was 346±152 mL, but mean real bladder capacity (VV + residual urine) was 391±170 mL. In all patients, 14% extra urine was produced due to urine production (mean rate, 6.1 mL/min). In 42% of the investigations, the real bladder capacity was more than 110% of the infused volume. In 18% of the patients, the contribution of natural bladder filling was more than 25% of the infused volume [Heesakkers 2003].

Urodynamic tests were, in another study, conducted on 39 asymptomatic male volunteers with a mean age of 25.8 years (range 21 to 31) and mean weight of 75.5 kg (range 63 to 95) to examine the pressure-flow relationship and obtain evidence to support the hypothesis that fluid consumption has a role in detrusor voiding function. Volunteers were divided into 2 groups according to water consumption regimen of 30 mL/kg daily (17 patients, group 1) and 60 mL/kg daily (12, group 2). Bladder pressure was monitored via a suprapubic catheter and abdominal pressure was measured via a rectal balloon using an ambulatory system with an average duration of 20.5 hours. Doubling of water consumption increased urethral opening pressure from 51.2 ± 3.2 to 61.5 ± 5.1 cm. H₂O (p<0.05), maximum detrusor pressure from 58.9 ± 4.5 to 70.0 ± 6.2 cm. H₂O (p<0.01) and contractility from 15.4 ± 1.4 to 17.7 ± 1.4 W/m². There were no significant differences due to water consumption in maximum flow rate (24.4 ± 1.4 to 25.2 ± 1.8 mL/s) or bladder capacity (286 ± 20 to 329 ± 15 mL) but a significant increase in the number of micturitions from 5.8 ± 0.5 to 9.8 ± 0.5 per day (p<0.001) proportional to water consumption [Schmidt 2002; Nager 2007].

2. COMPLIANCE

Compliance is the ratio of a change in volume measured relative to the corresponding change in pressure. Usually compliance is calculated over the change in volume from an empty bladder to that at MCC.

In 17 healthy subjects, using a filling rate of 35 mL/min, [Waalwijk 1992] the range of compliance values was very wide (range = 11-150 mL/cm H₂O; mean ± sd = 46 ± 40 mL/cm H₂O). Such a mean value implies only a small rise in pressure on filling (a few cm H₂O), consistent with having high compliance. Even higher values of compliance were reported by Hosker (range = 31-800 mL/cm H₂O; mean ± sd = 124± 150 mL/cm H₂O) in 72 healthy females (age 25-75 years) and these reproduced the wide range of values already published [Hosker 2004].

The results were comparable in elderly, peri and post menopausal women [Pfister 2007]. In another selected group of healthy middle aged, volunteers compliance was 'high' on average, however with a large variation [Pauwels 2004]. Similarly, Robertson showed that in 17 healthy male and female volunteers, the median detrusor pressure rise on conventional filling cystometry was 5 or 6 cm H₂O at filling rates of 50 and 100 mL/min respectively [Robertson 1999]. On ambulatory monitoring the median pressure rise was 0 cm H₂O however, a significantly smaller value.

Compliance cannot only be quantified in the units of mL/cmH₂O but also as a dimensionless number measured from empty to MCC. Compliance increases with age (because bladder capacity increases with age). This dimensionless value of compliance is to present a value that is independent of age (BUT not into old age). This is presented to be especially relevant in children when intra- and inter- individual test (retest) comparisons are made [Wahl 2004]. Consistently, among 22 healthy female volunteers, conventional cystometry and ambulatory study, performed in random order, showed a larger detrusor pressure rise on conventional filling as compared with ambulatory studies [Harlington 1996].

3. NORMAL SENSATIONS AND BLADDER CAPACITY

Earlier consultations have indicated the striking variability from centre to centre: FSV for example occurs at about 100 mL in one centre but at about 350 mL in another, a value large enough to provoke a strong desire to void in the first.

The bladder capacity is somewhat less variable from centre to centre, its mean varying from 340 to 570 mL. Apart from this inter-centre variability, the inter-subject variability of all the parameters is also substantial, with an sd of about 100 mL. Some of this variation represents genuine differences between subjects, but it should be noted that the within-subject variability is also quite large, in order of magnitude 50 mL.

As a rule of thumb in healthy adult subjects, and omitting some of the more inconsistent values, FSF occurs at about 170-200 mL, FDV or NDV (the ICS makes no distinction [Abrams 1988]) at 250 mL, and strong desire to void at about 400 mL; MCC is about 480 mL. It is interesting that the mean VV on ambulatory monitoring falls between FSV (on cystometry) and FDV/NDV. Thus, in daily life, the bladder is usually emptied long before a strong or even a 'normal' desire to void would be felt on cystometry, although much more can be held if voiding has to be postponed. Correspondingly, there is a discrepancy in bladder capacity between daily life and urodynamic study, also depending on the method of measurement (uroflowmetry, voiding diary or cystometry) [Hertzberg 2003]. There is no evidence after the last
consultation to show that this inter investigator variability has decreased.

4. DETRUSOR (OVER-) ACTIVITY IN NORMAL SUBJECTS

DO is observed during conventional cystometry in up to 17% of asymptomatic subjects with a mean percentage of about 8%. The percentage is much higher, up to 69%, with ambulatory studies, although lower in other observations. DO can be observed during urodynamic testing, in healthy subjects (without the symptoms that are usually associated with OAB) which might also indicate that the observation of ‘detrusor overactivity’ should not always be interpreted as ‘synonymous with pathology that demands treatment’. Nevertheless the false positive percentage remains unknown in those uncontrolled studies.

Conclusions (level 2)

• Various studies have been helpful in giving normal values and test retest variation of urodynamic parameters in healthy volunteers.

• There is some evidence that evaluation of filling sensation may be different between laboratories, (thus: ‘may be observer dependent’), making data exchange as well as generalization and interpretation of published data difficult.

Recommendations (grade B)

• The committee recommends that investigators and clinicians bear in mind the results of urodynamic testing in healthy persons and to recognize ‘normal’ test-retest variation as well as the differences and/or variations between ‘usual lower urinary tract behaviour’, ambulatory monitoring and office urodynamic testing.

• The committee suggests that clinicians should be sufficiently aware of the normal variation, and normal values of lower urinary tract function and urodynamic studies.

• The committee recommends further standardisation and a practical objective means of recognizing and recording the parameters relevant to sensation during bladder filling.

5. INFLUENCE OF CATHETER ON VOIDING

A urodynamic database of 600 consecutive women referred for the evaluation of voiding symptoms was reviewed to examine the effect of a 7F transurethral catheter on flowrate. Before urodynamics, all patients voided privately using a standard toilet and free flow was recorded. Only 100 patients who voided similar volumes, varying by less than 20%, on the free flow, and pressure flow studies were included. In each VV category and urodynamic diagnosis, pressure-flow parameters were significantly different from the equivalent free flow parameters in all but 4 cases. Specifically the maximum flow rate was significantly less and flow time was significantly longer on pressure versus free flow studies (each p<0.01). An intermittent flow pattern was more common on pressure-flow, than in free flow measurements (43% versus 9%) [Groutz 2000].

Women between the ages of 30 and 70 years, without LUT complaints and without a history of surgery for UI, were recruited to prospectively examine the effect of a 6F urethral catheter on the urinary flow rate in healthy women without LUT symptoms. After a free flow rate, cystometry and pressure-flow studies were performed twice using a 6F urethral catheter. With a 6F urethral catheter in place, the women had a mean maximum flow rate of 16 mL/s on the first study and 15 mL/s on the second. A significant difference was demonstrated between the free and intubated maximum flow rates for both the first (p = 0.0006) and the second (p = 0.0001) study. No significant difference was detected between the two intubated maximum flow rates (p = 0.262) [Baseman 2002].

The impact of three different sized (4.5-, 6- and 7F) catheters on pressure-flow studies was studied in 60 women undergoing urodynamic evaluation for LUT symptoms, divided into two groups (A and B) of 30 women each. The patients underwent non-invasive free-flow uroflowmetry with determination of PVR In group A the two consecutive pressure-flow studies were performed using a 4.5F catheter once and a 6F catheter once; in group B the two consecutive pressure-flow studies were performed using a 4.5F catheter once and a 7F catheter once. Free-flow rates were better with lesser residual. There was no significant difference in maximum flow rate, average flow rate and flow time between 4.5- and 6F catheter pressure-flow studies (A). However, there was a statistically significant difference between 4.5- and 7F pressure-flow studies (B) in those uroflowmetry parameters. Detrusor pressure at maximum flow (p_{det Q_{max}}) and maximum detrusor pressure (p_{det max}) in group A did not show statistically significant differences between 4.5- and 6F pressure-flow studies whereas in group B, p_{det Q_{max}} and p_{det max} were significantly different between 4.5- and 7F pressure-flow studies [Scaldazza 2005]. This more or less resembles the results in male patients, when a higher percentage of BOO shows that a ‘mechanical’ catheter effect is probably clinically relevant with catheters of 7F and larger [Zhao 2006; Trumbeckas 2006].

Conclusion (level 3):  
• There is evidence that, in general, flow is reduced when voiding with a urodynamic catheter in the urethra and that this reduction is partially caused by the size of the catheter.

Conclusion (level 4):  
• It is also the opinion of the committee that single catheters 6-8F incorporating both a filling channel
and a pressure-sensing channel should be used for intravesical pressure measurement during cystometry (i.e. double lumen catheters in the case of using fluid filled pressure lines).

**Recommendations (grade B)**

- The committee recommends that investigators interpret pressure-flow voiding parameters and the subsequent post void residual together with the free flow (not catheterised, representative) voiding parameters.
- The committee recommends the ‘standard’ use of, as thin as possible, ‘one-catheter-systems’ (dual lumen if fluid filled) for filling and pressure recording during urodynamic testing.

**III. REPRODUCIBILITY, RELIABILITY AND NORMAL VALUES OF URETHRAL PRESSURE MEASUREMENTS**

### 1. NORMATIVE AND COMPARATIVE DATA FOR MAXIMUM URETHRAL CLOSURE PRESSURE

Tables in the previous consultations show that the between-centre variability in the values reported, with mean MUCP is large and that the between-subject differences, reported in most studies show a wide range. However in spite of this variability, the mean MUCP was consistently lower in patients with signs and symptoms of SUI than in non-SUI women. There is nevertheless so much overlap that MUCP cannot be regarded useful for diagnosis of SUI [Weber 2001].

Eighty primiparous women with self-reported new SUI, 9-12 months postpartum, were compared with 80 primiparous continent controls and 80 nulliparous continent controls to identify impairments specific to SUI. MUCP (± sd) in primiparous incontinent women (62.9 ± 25.2 cm H2O) was lower than in primiparous continent women (83.9±21.0) who were similar to nulliparous women (90.3 ± 25.0). This lower MUCP followed by ultrasound assessment of bladder neck mobility on coughing was the measure most associated with de novo SUI after first vaginal birth [DeLancey 2007].

Studies providing normative data for men are scant, but there are some data on the UPP in normal males, however without any relevance for UI (neither for BOO or storage dysfunction) [Yalla; Abrams 1977].

### 2. RELIABILITY OF URETHRAL PRESSURE VARIABLES

In clinical practice, use of a fluid-perfusion technique to measure resting urethral pressure profile parameters such as MUCP yields an sd that ranges from 3.3 to 8.1 cm H2O. On average, the sd is approximately 5 cm H2O (95% confidence limits ± 10 cm H2O) or ± 5%. With a micro tip transducer technique the sd varies between 3.3 and 16.5 cm of water, which means that the 95% confidence limits may be as large as ± 33 cm H2O. The coefficient of variation when using the micro tip transducer technique has been reported to be 17% (95% confidence limits ± 34%). In one study using fluid perfusion the coefficient of variation of MUCP varied from 3% to 11% (95 % confidence limits 6% - 23%) [Toguri 1980].

Another, comparative study between fluid-filled and micro tip pressure transducers observed that MUCP obtained from the fluid-filled catheter was significantly higher than that obtained from the microtip catheter. However, the authors also concluded that the use of the double-lumen fluid-filled catheter for the measurement of MUCP can be considered a reliable technique since its reproducibility is as good as that of the micro tip catheter [Wang 2002].

A significant difference between MUCP values recorded by micro transducer versus fibre optic catheter systems has also been observed. Significantly lower mean MUCP’s were recorded by the fibre optic system than by the micro transducer system. No significant difference was however observed between these two systems in the measurement of VLPP [Culligan 2001].

As mentioned above, the performance of air-charged catheters in measuring MUCP has been shown to be comparable to micro transducers in the measurement of maximum urethral closures pressure in a non-randomised study [Pollak 2004]. However, there was a difference in functional urethral length which was attributed to the different diameters of the two catheters.

In 2008, Zehnder et al carried out a randomised comparison of these air-charged catheters with micro tip catheters in 64 women and found that the air-charged catheter was as least as reliable as the micro tip for measuring both MUCP and functional urethral length. However, they found that the air-charged catheter gave a higher reading of both parameters compared to the micro tip device [Zehnder 2008].

### 3. AGING

It is well established that in women the UPP changes with age. A recent study of 255 women, ages 20-77 years, without DO, overt neuropathy or pelvic or UI surgery, confirmed that the MUCP is negatively associated with age (r = -0.5, p< 0.0001) [Schick 2003].

### 4. OTHER PARAMETERS AFFECTING THE MEASUREMENT OF URETHRAL CLOSURE PRESSURE

The 2002 ICS standardisation reports, relating to urethral closure pressures, discusses that the value of MUCP is not only dependent on the type of catheter
used but also its orientation within the urethra, the degree of bladder fullness and the position of the patient [Lose 2002]. There is no new evidence, nor evidence regarding newer techniques, that the intrinsic (urethral pressure) measuring quality has improved to a clinically relevant level with regard to sensitivity, specificity and reliability.

**Conclusions (level 2)**

- Various studies have shown considerable test-retest variation of all urethral pressure measurements or parameters.
- Various studies have shown that normal and pathological values of urethral pressure parameters are largely overlapping.
- Various studies have shown that urethral pressure(s) (parameters) are affected by age.
- Studies have shown that urethral pressures depend on patient position, volume of fluid in the bladder and position of the patient.
- Studies have shown that urethral pressures depend on the pressure recording catheter used and its orientation within the urethra.

**Recommendations (grade B)**

- The committee recommends that investigators and clinicians recognize the poor sensitivity and specificity of urethral pressure measurements and their ‘normal’ test retest variation.
- The committee does not recommend urethral pressure measurement as the only urodynamic test in patients with urinary incontinence either to confirm or to refute stress urinary incontinence.
- The committee recommends that the clinical relevance of urethral pressure measurements, if performed, is judged in relation to other urodynamic tests (such as cystometry) and to the clinical examination.

**IV. LEAK POINT PRESSURE**

**1. INTRODUCTION**

The detrusor pressure or the intravesical pressure (\(P_{\text{det}}\) or \(P_{\text{ves}}\)) at which involuntary expulsion of urine from the urethral meatus is observed is the LPP. The rise in bladder pressure causing leakage may originate either from the detrusor (caused for example by the filling of a low-compliance bladder) or from an increase in the abdominal pressure. Thus there are two different leak point pressures – the DLPP (DDLPP) and the abdominal LPP. The abdominal pressure increase during the latter is produced voluntarily by coughing (CLPP) or by Valsalva (VLPP).

LPP is not consistently defined throughout the reports in literature and we have not found any standardisation (report) of the technique. Any comparison of findings between studies is hindered by this.

The elements of CLPP or VLPP which could be standardised include: 1) the basic definition of LPP (baseline value of pressure; route of measurement – urethral, vaginal or rectal), 2) whether Valsalva or cough is used to produce leakage, 3) the technique to confirm urine loss, 4) location of catheter, and shift in location on cough or strain, 5) calibre of catheter (if transurethral) 6) type of pressure sensor 7) the volume in bladder, 8) the rate of prior bladder filling and 9) patient position [Weber 2001].

The same elements are relevant for DLPP except pressure measurement has to be from the bladder but could be through a suprapubic catheter.

**2. RELIABILITY OF LEAK POINT PRESSURE MEASUREMENTS**

**a) Diagnosis**

In a study that recruited 168 patients it was seen that women who demonstrate urodynamic SUI at lower bladder volumes do not report greater bother from the UI than women who leak at higher volumes. The authors concluded that leakage severity ‘quantified’ by this urodynamic method, is not an adequate reflection of UI related quality of life (Qol) and or subjective UI severity [Lowenstein 2007]. Another study confirms these observations [Albo 2007].

A total of 200 women with SUI were clinically evaluated and underwent urodynamic study to determine the correlation between VLPP and the UPP. A progressive correlation of VLPP with MUCP was found when UPP was performed at 50 mL (\(r = 0.305, \ p<0.0001\)), at 250 mL (\(r = 0.483, \ p<0.0001\)) and at maximum bladder filling (\(r = 0.561, \ p<0.0001\)). The authors concluded that there is a significant correlation between MUCP and VLPP [Almeida 2005].

Another prospective study in 109 patients assessed the relationship between CLPP and VLPP with SUI (n=61; 56%), DO (n=21; 19%) or a combination of these (n=27 25%). More women with SUI leaked during CLPP than during the VLPP; fewer women with DO leaked during CLPP and more during the VLPP [Sinha 2006]. LPP’s are reported to be dependent on patient position; being lower in the standing position as compared to supine position [Nguyen 2002]. Another study with the goal of determining the effect of position on UPP seems to have been troubled by ‘poor test retest reproducibility’ in the standing position [Dorflinger 2002].

Two studies have been performed, one with 369 patients, including some without UI, and another study with 65 female patients with UI stratified into groups with various levels of LPP, various grades of urethral (hyper-)mobility, and various grades of UI severity. Both studies were unable to find strong ‘urodynamic’ discriminators for the type or the severity of UI.
and concluded that all values overlapped. Patients with SUI can be characterised by LPP and change in the urethral angle and or mobility, although these variables have never resulted in define discrete classes [Fleischmann 2003; Schick 2004].

The results of these newer studies confirm the earlier conclusion in an expert review: 'It is not apparent that either LPP measurement or UPP can accurately predict which patients will achieve the best outcome of surgical treatment for SUI. Other parameters assessed during urodynamic evaluation might provide prognostic information regarding the risk of voiding dysfunction postoperatively and the possibility of persistent urgency-related leakage following surgery, though not directly predict cure’ [Lemack 2004].

b) Treatment

Can any value of LPP (Valsalva or cough) and/or UPP help in the selection of treatment for patients with SUI? This question has been addressed by various investigators.

In a retrospective cohort analysis of 3-month outcomes in 145 subjects (TOT = 85; tension-free vaginal tape (TVT) = 60) it was observed that relative risk of postoperative urodynamic SUI, 3 months after surgery, in patients with a preoperative MUCP of ≤ 42 cmH₂O, was 5.89 (1.02 to 33.90, 95% confidence interval) when TOT was compared with TVT tape [Lemack 2004].

The value of urethral hypermobility, MUCP in the diagnosis of SUI was evaluated in 369 women with clinical symptoms suggestive of SUI without symptoms of detrusor overactivity. The cohort was divided into 2 groups according to continence or incontinence status. Continent and incontinent patients differed with regards to MUCP and hypermobility (each p<0.0001). Incontinent patients had a greater probability of a higher grade of each factor. MUCP was significantly lower in the incontinent group (p<0.001) [Schick 2004].

A prospective study assessed the difference in measured urethral function before and after TVT procedure. Twenty-three (65.7%) of 35 consecutive women had a preoperative diagnosis of intrinsic sphincter deficiency (ISD) as defined by MUCP < 20 cm H₂O and/or VLPP <60 cm H₂O. Subjective (Impact of Incontinence score and Urodynamic Distress Inventory) and objective success rates were 91% and 83%, respectively. The mean change in MUCP was -1.3 cm H₂O (95% CI -5.9, 3.3), whereas the pressure transmission ratio increased 15.7% (95% CI 5.0%, 26.3%). The mean decrease in straining urethral angle was 16.3 degrees (95% CI -23.9 degrees, -8.7 degrees). Cured subjects, demonstrating hypermobility preoperatively, continued to do so postoperatively. The effectiveness of the TVT did not appear to depend on a clinically significant change in the straining urethral angle. [Mutone 2001]

A total of 221 women 29 to 80 years old (mean age 55.2) were included in a later study to evaluate the outcome of the TVT procedure for SUI with low VLPP. Mean follow-up was 10.5 months (range 6 to 52). Patients were divided into 61 with low (<60 cm H₂O) and 160 with higher (>60 cm H₂O) VLPP. The overall cure rate was significantly lower in patients with low versus higher VLPP (82.0% versus 93.1%, p = 0.013). In women with low VLPP, multivariate analysis indicated that urgency symptoms and low MUCP were independent factors for treatment failure (OR 15.12, 95% CI 1.90 to 120.61, p = 0.010 and OR 0.92, 95% CI 0.86 to 0.99, p = 0.018, respectively). [Paick 2004]

174 consecutive patients who underwent a distal polypropylene sling procedure for the treatment of SUI were prospectively evaluated and reported in a slightly earlier study. The group was divided by VLPP into group 1: 60 patients who did not leak on urodynamics, group 2: 27 patients with VLPP > 80 cm H₂O, group 3: 71 patients with VLPP 30 to 80 cm H₂O and group 4: 16 patients with VLPP < 30 cm H₂O. Mean follow-up was 14.7 months (range 12 to 30) and mean patient age was 62 years (range 32 to 88). The groups were well matched before surgery with respect to age, number of previous surgeries, and severity of SUI symptoms and UUI. The percentage of patients who were cured or improved was similar among groups. After surgery there was no statistical difference among patient mean self-reported symptoms of or bother from SUI or UUI. The distal urethral polypropylene sling provides similar symptom improvement in all patients regardless of preoperative VLPP. LPP is helpful in the diagnosis of SUI but appears to be of minimal benefit in predicting the outcome of the distal urethral polypropylene sling procedure. [Rodriguez 2004]

A later study reported that neither MUCP nor LPP were good predictors of post-operative SUI but, because this was not the primary outcome measure of this study, there may not be adequate power to make this a definitive conclusion. [Paick 2007]

UDS which included CLPP and pressure flow studies that were performed twice at two visits 2 weeks apart were reported in a subsequent study to determine reproducibility in various diagnosis groups. Thirty-one women completed both visits, of those 14 had SUI in both sets of UDS, 11 had mixed UI result at UDS on both visits, six had SUI on one visit and mixed UI result in the other. The UDS variables of MCC and cough LPP have the most repeatability. Analysis in women with SUI alone compared to USI together with DO showed that the repeatability for pressure flow parameters and CLPP was better in women without DO, of which the CLPP was significantly different (p = 0.036). [Rahmanou 2008]

c) Within-patient variability

Sixty consecutive women with ‘genuine’ SUI underwent duplicate VLPP determinations by use of 8F
and 3F vesical and 8F vaginal catheters. Subjects also underwent a standard resting UPP, CLPP determinations, and pressure-flow micturition studies. Leakage was demonstrated on both Valsalva maneuvers in approximately 80% of subjects with both catheters and a high correlation between the test-retest VLPP within both catheters. The inter-catheter correlation between the 8F and 3F VLPP was significant but much weaker than the intra-catheter correlations; 8F VLPP's were significantly higher than 3F VLPP, although there were individual exceptions to this observation. The authors concluded in 1995 that VLPP technique must be precisely described, standardized, and validated before a technique can be advocated for clinical use. A later study to determine the quantitative and qualitative effects of patient position on coughing and VLPP in women with USI was done in 2002. Thirty-seven patients with genuine SUI and 4 with mixed incontinence underwent standardized UDS. LPP were performed using 8 Fr microtip catheters placed in the bladder and vagina at a bladder volume of 250 ml in the supine, semi recumbent and standing positions. UPP was performed in the semi recumbent position at similar bladder volume. The mean (+/- standard deviation) VLPP in the supine, semi recumbent and standing positions were 82 +/- 23, 73 +/- 24 and 63 +/- 22 cmH₂O, respectively (p<0.001). The mean (+/- standard deviation) CLPP also decreased as the patients were moved from the supine (98 +/- 29 cmH₂O) to the semi recumbent (88 +/- 24 cmH₂O) and standing positions (77 +/- 24 cmH₂O) (p<0.001). The correlation between LPP and MUCP was statistically significant and was dependent upon patient position and the provocative maneuver used. [Nguyen 2002]

The committee has found no reports on inter-observer variability.

Conclusions (level 2/3)

- Different definitions and techniques to determine (urine) leak point pressure exist.
- Various studies have demonstrated a weak association between abdominal leak point pressures and the patient experience of, or measured severity of bother, or amount of incontinence. It can be born in mind, in this regard, that one millilitre of fluid is already 20 drops and a 10cm diameter wet spot on a cotton cloth.
- Studies have shown that the 'isolated' parameters from abdominal leak point pressure measurements are not very helpful as predictors of success from surgery with either tension free vaginal tape or transobturator tape in patients with stress urinary incontinence.
- Studies have shown that different techniques and patient positions influence the results of leak point pressures determination.

Recommendations (grade B/C)

- The committee does not recommend abdominal leak point pressure measurement as a single urodynamic test in patients with urinary incontinence either to reject the diagnosis of stress urinary incontinence, or to select treatment.
- The committee recommends that the result of abdominal leak point pressure measurements, when performed on patients with urinary incontinence, should be judged in relation to other urodynamic tests such as cystometry and to the clinical examination.
- The committee considers detrusor leak point pressure in patients with neurogenic lower urinary tract dysfunction a relevant parameter. This is discussed in section III (neurogenic lower urinary tract dysfunction) and in section IV (patient evaluation: children).

V. DIAGNOSTIC PERFORMANCE OF FILLING CYSTOMETRY AND AMBULATORY MONITORING

1. SENSITIVITY AND SPECIFICITY OF FILLING CYSTOMETRY IN OVERACTIVE BLADDER SYNDROME

Earlier consultations [Homma 2002; Rosier 2010; Rosier 2010; Rosier 2010] have summarized scientific evidence for positive sensitivity, specificity and predictive value of symptoms for urodynamic SUI. Specificity, sensitivity and predictive value of symptoms were found to be less for DOI and also the association of ‘mixed symptoms’ of UI with UDS results was very low. We have found some additional studies and summarize the newest results.

a) Detrusor overactivity incontinence

The association of the results from UDS and symptoms assessment was summarized to be around 70% in the previous consultations; three more or less relevant studies are reported here predominantly reporting on patients with mixed symptoms of UI. It was noted in one study that some women with mixed symptoms of SUI and OAB reported worsening of their UI in a prospective trial, of duloxetine, used to improve urethral storage function. In this study, an assessment was made, as to whether pre-treatment pressure flow studies predicted which women with USI, in combination with DO(I) experienced increased leakage after treatment with duloxetine. All women included had mixed symptoms of UI with moderate or severe symptoms (bother) of SUI. Pressure flow studies of women who recorded a worsening of their UI were compared to those women who recorded no change or an improvement of their UI. The maximum or average flow rate, the bladder capacity, the detrusor pressure at maximum flow and volume voided showed no difference when the two
groups were compared. The pre-treatment voiding time was however longer in women who got worse following treatment with duloxetine. [Vella 2010]

The authors of another monocenter study in retrospective concluded that (semi-recumbent) UDS diagnoses of DO, and USI with DO are associated with significantly worse UI related bother and health related quality of life when compared to those with USI without OAB (or DO). [Haessler 2009]

The purpose of another study was to assess clinically relevant relationships between urinary diary and quality of life as well as to evaluate the reproducibility of validated questionnaires and urinary diaries in women with SUI as well as OAB symptoms of UI; a combination that is frequently, but imprecisely defined, named mixed UI. Forty-seven women with mixed symptoms of UI completed 7-day diaries, the Urinary Distress Inventory (UDI-6), Incontinence Impact Questionnaire, and the Medical, Epidemiological, and Social Aspects of Aging -questionnaire 2 weeks apart. The number of UUI(I) episodes predicted UI severity on UDI-6 (R (2) = .38, p<.03). Except for the number of SUI episodes, diary variables and questionnaire responses were reproducible (range from Spearman’s rho = .7 to rho = .96, p<.001). The 6 questions of the UDI-6 were concluded to adequately represent UI severity.

b) Detrusor overactivity alone

The sensitivity, specificity and predictive value of symptoms for the diagnosis of DO, was given in a review of papers quoted in the third ICI [Colli 2003] All authors of the various manuscripts and the reviewers have concluded, more or less strongly that the correlation between symptoms and DO is modest; underlining the necessity of urodynamic testing to obtain an objective diagnosis. Van Brummen et al [Brummen 2004] examined the sensitivity of DO, observed during conventional UDS, for UUI. They examined 95 women, with OAB, symptomatic SUI, and/or POP. Symptoms were assessed by a bladder diary and conventional filling cystometry was performed (sitting, fill rate 60 mL/min). Urinary frequency, urgency and UUI had similar associations with the cystometric observation of DO. Among patients with only one of these symptoms, DO was however not observed in 77-81%. In another study 171 women were recruited. The aim of this study was to develop a scoring system to discriminate between the symptoms of SUI and OAB. Physicians completed a specially developed questionnaire for all women complaining of LUTS. Women then underwent UDS. A scoring system based on the likelihood of each symptom for DO was developed using odds ratios and 95% confidence intervals (CI). This scoring system was subsequently used to discriminate those women with OAB from those with SUI. This scoring system had a sensitivity of 79%, a specificity of 78% and a positive predictive value of 73% to identify DO. Investigators suggested that the scoring system could be applicable in primary care to help discriminate between SUI (USI) and OAB (DO). [Vella 2008]

In a similar study, the accuracy of a UI questionnaire in the diagnosis of various types of UI was classified according to the results of multichannel UDS. Using a UI questionnaire consisting of 12 urinary symptoms questions, 129 women with symptoms of UI were interviewed. Of the 12 questions, only three questions (two SUI symptoms and one OAB symptom) were significantly associated with the diagnoses of (urodynamic) USI or DO. The sensitivity and specificity of the questions was relatively low leading to the author’s conclusion that symptoms of UI were not sufficient to predict types of UI, and the suggestion that UDS is essential in the diagnosis and management of female UI. [Roongruangsilp 2005]

In a study to determine the prevalence and associations of ‘sensory urgency’ in comparison with DO 592 women, attending for an initial urogynaecological /urodynamic assessment, took part. The group was separated into those having ‘sensory urgency’; OAB symptoms, without urodynamic DO, or those with DO. The only difference in the clinical profile between the groups was increased prevalence of the symptom of UI. The authors concluded that sensory urgency and DO appear to be part of the same clinical spectrum of bladder dysfunction. [Haylen 2007]

To determine and compare the urodynamic characteristics in patients with OAB and patients with combined symptoms of OAB plus SUI (OAB+SUI), 120 patients (60 each in OAB and OAB+SUI groups) underwent detailed history, physical examination, complete UDS and 20-minute pad test. FDV, SDV, urgency, and the percentage of urodynamic SUI were greater in the OAB+SUI group; and functional urethral length, maximal urethral pressure and MUCP were significantly lower in the OAB-SUI group, than those in the OAB group (p<0.03). [Lin,L.Y. 2004]

c) Overactive bladder syndrome and detrusor overactivity

Many studies have been done to compare, more or less systematically retrieved, symptoms with the results of UDS. Apart from the fact that symptoms assessment varies between studies, (and UDS-techniques vary), the committee has stated in the introduction that it is highly unlikely that one subjective symptom (or a few symptoms) can be identical to the result of the UDS, which gives a broader view on the individual’s LUT function. Nevertheless we report the recent studies in this regard.

Digesu et al [Digesu 2003] studied whether UDS is useful in the management (Table1) of women with symptoms of an overactive bladder (OAB). Women with LUTS and or UI were fully evaluated, with history,
urinary symptoms questionnaire, frequency-volume chart, vaginal examination, and UDS. Women with symptoms consistent with OAB (urinary frequency, urgency, and/or urge incontinence) were selected. Women with neurological disorders were excluded. A total of 4,500 women 22-73 years of age were studied. Only 843 women (18.7%) could be classified as having an OAB. Of these, 457 women (54.2%) had DO, whereas 386 women (45.8%) had no DO. Sixty-eight (8.1%) of the women studied had PVR greater than 100 mL. Of the 4,500 women studied, 1,641 (36.5%) had DO on UDS. Only 27.5% of these women (457 of 1,641) had OAB symptoms. False positive and false negative symptoms of ‘OAB’ were frequently noted and therefore the study concluded that OAB symptomatic diagnosis did not correlate with DO and that UDS remains mandatory for an exact diagnosis.

Sekido et al [Sekido 2006] retrospectively reviewed the UDS of 50 adult patients (selected from a series of 137, referred with UI) with urinary urgency (12 males and 38 females) and looked into the correlation between bladder storage function (FSF, MCC, compliance and DO) versus OAB. 75% of male patients with OAB symptoms had DO in supine position and only 36.8% female patients.

Hyman et al [Hyman 2001] examined 160 men, mean age 61 ± 15 years, without neuropathy but with symptoms ‘suggestive of DO’. They observed DO in 68; a sensitivity of 43% for OAB symptoms. When there was UUI, then DO was seen more often than with symptoms of frequency, urgency, nocturia alone, suggesting a higher sensitivity for UUI.

In a retrospective study with 1,626 women with mixed (or ‘combined’) symptoms of UI were divided into stress predominant mixed urinary incontinence (MUI); urge predominant MUI; or equal severity of stress and urge MUI on the basis of the symptom scored most severe on the King’s Health Questionnaire. [Digesu 2008] The frequency of different UDS diagnoses for the all women with MUI and in each of the above groups was calculated. Overall 3,338 women were studied. Of these 49% (1,626/3,338) reported MUI symptoms and were included. In this group 29% (464/1,626) had stress predominant MUI, 15% (248/1,626) had urge predominant MUI and 56% (912/1,626) had equal severity of urge and stress MUI. On UDI 42% (665/1,626) had pure USI, 25% (414/1,626) had pure DO, 18% (299/1,626) had both DO and USI and 15% (248/1,626) had UDS without abnormal filling phase. In those with stress predominant MUI, 82% had USI; in those with urge predominant MUI, 64% had DO. The UDS diagnoses were different for the different balance of symptoms (Chi2; p< 0.05). In women with equal severity of UUI and SUI, 46% had DO while 54% had UDS. The relative severity of MUI symptoms from the Questionnaire significantly distinguished between different UDS diagnoses in this evaluation that concluded that women with urge predominant MUI are more likely to have DO while those with stress predominant MUI are more likely to have USI.

In another study, 1457 adult males and females were retrospectively selected, based on OAB syndrome symptoms, to determine how well the symptoms of OAB syndrome correlated with urodynamic DO using ICS definitions. A better correlation in results between OAB symptoms and the urodynamic diagnosis of DO was observed in men than in women. Of men 69% and 44% of women with urgency (OAB dry) had DO, while 90% of men and 58% of women with urgency and UUI (or OAB wet) had DO. SUI seems to have accounted for the decreased rates in women since 87% of women with UUI also had the symptom of SUI. The ICS definition does not specify what constitutes abnormal voiding frequency. Analysis of results showed that increasing voiding frequency did not have any effect on increasing the accuracy of diagnosis of DO except in women with 10 or more daytime micturition episodes. The authors concluded that the bladder is a better and more reliable witness in men than in women. [Hashim 2006]

The association between urinary symptoms and the UDS diagnoses of DO and USI was calculated to describe the relationship between symptoms reported in a self-completed postal questionnaire, and urinary disorders based on UDS. The study population was selected from women aged 40 years or over living in the community, who responded to a postal questionnaire. Four hundred eighty-eight women completed UDS; 29.1% (142/488) were found to have DO (with and without leakage), 33.6% (164/488) USI, 20.7% (101/488) mixed diagnosis of incontinence, and 16.6% (81/488) no abnormality on filling cystometry. SUI and UUI were included in the risk model for USI. SUI reported monthly or more, was associated with more frequent diagnosis of USI, and UUI reported weekly or more, with less frequent diagnosis of USI (sensitivity: 76.9%; specificity: 56.3%; positive predictive value: 67.8%). Strong or overwhelming urgency, UI monthly or more, and nocturia once a night or more, were all significantly associated with an increased diagnosis of DO. Reporting of SUI monthly or more reduced the risk of DO (sensitivity 63.1%; specificity 65.1%; positive predictive value 63.1%). The conclusion was that a postal urinary symptoms questionnaire
was associated with UDS diagnosis with moderate accuracy and applicable. [Matharu 2005]

One hundred and fourteen women attending a tertiary urogynaecology clinic were included in a randomised crossover study to either an initial interview-assisted questionnaire in the clinic, with a follow-up postal questionnaire, or an initial pre-outpatient questionnaire followed by an interview-assisted questionnaire at the clinic visit. Question responses were compared with urodynamic diagnoses. With the interview method, only severity of UI was significantly associated with DO (p = 0.012). With self-completion, severity of nocturia (p< 0.05), urgency (p = 0.003), UUI (p = 0.003), leakage without warning (p = 0.035) and incomplete voiding (p = 0.01) were significantly associated with DO. On interview, the symptom of SUI (p = 0.002) and use of pads (p = 0.011) were significantly associated with a diagnosis of USI. Severity of SUI (p< 0.001), frequency of leakage (p = 0.004), use of protection (p< 0.018), nocturnal incontinence (p = 0.002) and quantity of leakage (p< 0.05) on self-completion were strongly associated with diagnosed USI. There was no association between the symptoms of urgency or UUI, and USI. Concluded in this study was that no symptom had a high enough specificity and sensitivity to replace UDS in this postal questionnaire responses and had a better relationship with DO, for USI and for DO, than interview-assisted questionnaire responses. [Khan 2004]

The pattern of filling sensations was evaluated during standard UDS bladder filling in 75 patients who complained of UU(I) and showed DO, to evaluate whether a compelling desire to void is always perceived suddenly, or whether it can result from the gradual build-up of bladder-filling sensations. A compelling desire to void occurred suddenly, without a preceding sensation in 13% of the patients, at lower intravesical volumes, whereas 66% reported at least two normal preceding filling sensations before a compelling desire to void. The bladder volume at which the FSF was reported was not different regardless of whether it was described as a FSF, a FDV or a compelling desire to void (p = 0.42). The warning volumes were not different between patients with one or no filling sensation landmarks (p = 0.7), but they were significantly smaller than in patients with two or three filling sensations (P = 0.85). Compelling desire to void can occur suddenly if normal filling sensation is disturbed, but also gradually if the usual filling sensations are reported. In cases of disturbed filling sensation, the volume at compelling desire to void and the warning volume are significantly lower. [Wachter 2008]

To evaluate the reliability of spontaneously reported bladder sensations during real and faked cystometry in patients with non-neurogenic LUTD. In another study by the same researchers, fifty-nine patients with non-neurogenic LUTD were submitted to a real and a faked (no water infused) filling cystometry and were asked to describe all bladder-related sensations during the investigations. During the genuine cystometry, the expected pattern of filling sensations was reported by 88%. During the faked cystometry, not one of the patients reported the normal pattern of filling sensations. However, a minority of patients reported some sensation of bladder filling without actual bladder filling from the UDS equipment. The investigators concluded that patients with a non-neurogenic LUTD can reliably report bladder filling sensations during UDS. [Wachter 2008]

Five hundred and ninety-two women attending for an initial urogynaecological/urodynamic assessment were enrolled in a prospective study. Many signs and observations were reported but the reported prevalence of sensory urgency (defined as increased perceived bladder sensation during filling, a low FDV and low MCC in the absence of recorded urinary tract infection or DO) was 13%. The only differences in the clinical and UDS profiles of it and DO were reported as a significantly increased prevalence of the symptom of UUI and (by definition) the detrusor contractions during filling cystometry in women with DO. The authors concluded that ‘sensory urgency’ and DO appeared to be part one spectrum of LUT dysfunction. [Haylen 2007]

Fifty-eight patients with USI, 29 with DO, and 22 with both USI and DO were analysed in another monocenter cohort study. From 3-day hand-written and computer-analysed bladder diaries, average and maximum VV were calculated, and also voiding frequency and 24 hr urine production, as well as number, severity and type (whether accompanied by activity or urge) of UI -episodes, to compare frequency-volume and UI episode patterns in patients with USI and DO. Compared to the USI patients, the DO patients tended to have higher voiding frequency, lower VV, more urgency-related than activity-related leaks, smaller volume and equally frequent leaks and higher severity -scores for UI symptoms. The age- and volume-adjusted percentiles better separated the USI and DO groups’ frequency and volume measurements than did the raw measurements. Almost 60% of the USI patients had low VV measurements, high voiding frequency, and 40% had leaks with urgency sensations. A subgroup of 29 USI patients with ‘low’ (average volume <30th reference population percentile) VV measurements had high incidences of urgency and UUI. Reference population percentiles better separate the frequency /volume patterns of USI and DO than do the raw measurements. The investigators observed a substantial subgroup of patients with USI that had an OAB-like clinical picture, again suggesting that symptom assessment is important but not diagnostic with regard to the underlying LUTD. [Parsons 2007]

The UDS of women with DOI and USI, before
undergoing tension-free vaginal tape (TVT) surgery were retrospectively reviewed to determine if specific pre-operative urodynamic parameters could predict DO following TVT in patients with urodynamic mixed incontinence. Patients underwent clinical evaluation pre-operatively and those with persistent SUI after conservative treatments underwent TVT. Patients were re-assessed after at least 6 months post-operatively. Fifty-one women were reviewed. Forty-six of the 51 attended follow-up and 35/51 agreed to conventional urodynamic studies. Seventeen of the 35 reported OAB symptoms, and 18/35 were asymptomatic. Nineteen of the 35 women had DO and 16/35 had normal UDS. The median pre-operative opening detrusor pressure was higher in women with overactive bladder symptoms post-operatively. The median pre-operative opening detrusor pressure in women with DO post-operatively was 33.0 cmH₂O and the median pre-operative opening detrusor pressure in those with normal UDS post-operatively was 16 cmH₂O (15.0-23.0 cmH₂O p< 0.05 Mann-Whitney U-test). The investigators have concluded, in retrospect, that opening detrusor pressure before treatment is related to post-operative DO after TVT, in their series, but that higher numbers of patients are required to demonstrate the real predictive value of opening detrusor pressure. [Panayi 2009]

Conclusions (level 2)

- Many studies have shown the weak correlation between symptoms and the result of urodynamic investigation, especially filling cystometry, in patients with urinary incontinence.
- The committee concludes that the sensitivity and the specificity of the symptoms, when systematically assessed and voiding diary is included, is at best and in the ‘most typical patients’, around 60-70%, in comparison with the result of the objective results of urodynamic testing.
- The correlation of the symptom ‘stress urinary incontinence’ (expressed, or questioned) with the result of urodynamic investigation is somewhat better than the correlation of urgency or urgency urinary incontinence (expressed, or questioned) with urodynamic investigation.
- The committee concludes that especially when frequent voiding, urgency and/or urgency incontinence is part of the symptom complex of patients with incontinence, urodynamic investigation is of value to obtain an objective diagnosis, prior to invasive therapy.
- Taking into account the variation between various institutes and the test-retest variation, the committee considers it relevant that investigators and clinicians judge also how adequate the results of the performed tests represent the individual patients’ symptoms.

Recommendations (grade B)

- The committee recommends urodynamic testing in patients with incontinence when an objective diagnosis is warranted. This is commonly the case when symptoms do not exclusively direct to stress incontinence, or when (for all types of incontinence) conservative measures have not been successful, or when relevant co morbidity exists or relevant previous surgery has been performed.
- The committee recommends interpretation of the results of the complete urodynamic testing in relation with the symptoms, signs, and the clinical (or other) examinations and with the voiding diary in all patients.

d) Distinguishing or defining characteristics of detrusor overactivity

Several groups have attempted to find characteristics of DO that may distinguish DO incontinence with different aetiologies, or DO incontinence of different severity.

One group [Flisser 2003; Romanzi 2001] examined 132 patients with OAB symptoms (with and without neurological disease) by videourodynamics. Based on the characteristics of their filling phase, patients were divided into 4 categories: type 1- no evidence of DO on videourodynamics; type 2 – DO present, and patient able to abort it; type 3 – DO(I) present, patient aware and able to contract the sphincter (judged from the videourodynamics) but not to abort contractions; and type 4 – DO(I) present and patient unaware but unable to contract the sphincter or abort contractions. There was no significant relationship between the category and severity of symptoms as judged by voiding frequency, functional bladder capacity, or pad test. The authors concluded that the characteristics of the DO were not distinct enough to aid in differential diagnosis, but that the ability to abort DO and stop incontinent flow might have prognostic implications, especially for the response to behaviour modification, biofeedback training, and pelvic floor exercises.

Cucchi et al [Cucchi 2007] looked into detrusor contraction strength, detrusor contraction velocity and contraction sustainabilty. In this retrospective review, the authors separated male patients (without relevant neurological abnormalities) into three groups; Group 1 had DO, with urgency and UUI. Group 2 was similar to group 1 but did not have urgency before DO and Group 3 consists of ‘normal’ men. They found that detrusor contraction velocity was increased (or higher) in the group with urgency versus no urgency or normal, implying that this may be an underlying mechanism for urgency.

Defreitas and co-workers [Defreitas 2003] examined three groups of patients: group 1, men with LUTS and no known neurological condition for DO (n = 22); group 2, men with Parkinson’s disease and
LUTS (n = 39); and group 3, women with Parkinson’s disease and LUTS (n = 18). Patients with Parkinson’s disease had a significantly lower median volume at first detrusor constraction than those with non-neurogenic DO. The percentage of group-1 patients with UUI was significantly lower than that found in the other two groups (9% versus 54% and 56%, p<0.001 and 0.002, respectively). No statistically significant correlation between the duration or severity of Parkinson’s disease and urodynamic parameters was found. The distinction between Parkinson’s disease proper and multiple system atrophy, which appears to be important with regard to bladder dysfunction,[Fowler 2001] was not made in this study.

In the study cited above,[Hyman 2001] 160 older men without neuropathy, but with symptoms ‘suggestive of DO,’ were examined. DO was seen more often when there was UUI, than with symptoms of frequency, urgency and nocturia alone. The bladder volume at which DO was observed tended to be lower in those with UUI, frequency and urgency than in those without UUI (p = 0.07). The prevalence of DO was similar in men with and without BOO.

Ockrim at al [Ockrim 2005] compared the variability of DO in men with LUTS to that in men with SCI by sequentially repeating urodynamic studies three times. They observed a significant decrease in the number and amplitude of DO contractions in the 60 patients with non-neurogenic LUTS, whilst in the 35 SCI patients, the urodynamic variables remained the same over the subsequent studies.

The urodynamic characteristics of DO in women with multiple sclerosis (MS) (n = 54) were compared with the detrusor pressure ‘pattern’ found in women with LUTS and idiopathic DO (n = 42) in a retrospective study. Among other parameters, the amplitude of the first contraction, maximum detrusor contraction, and threshold volume for the first contraction were evaluated. The amplitude of the first contraction was statistically greater in the patients with MS and DO compared with patients with IDO (28.3 versus 20.5 cm H2O, p = 0.003), as was the maximum detrusor contraction (46.4 versus 30.8 cm H2O, p = 0.002). The threshold volume for DO was greater among patients with neurogenic DO (186.8 versus 150.5 mL, p = 0.037), which was likely to be secondary to the elevated PVR volume noted among patients with MS (p = 0.049). The authors concluded that additional investigation is required to determine whether these differences are due to neurogenic influences directly on the detrusor muscle through aberrant innervation or by other mechanisms. [Lemack 2006]

Miller et al [Miller 2002] suggested that functional bladder capacity was smaller in those with more severe incontinence as judged from the voiding diary in a study to evaluate quantification of DO.

Conclusions (level 2)

- Studies have not been able to show relevant differences in patterns or characteristics of detrusor overactivity whether the cause of overactivity is neurogenic or idiopathic.
- Various studies have not been able to reliably quantify the severity of detrusor overactivity, in a clinically or scientifically applicable way.

Recommendation (grade C)

- The committee recommends that neither the cause (neurogenic or idiopathic) nor the severity of detrusor overactivity is diagnosed on the basis of parameters from urodynamic investigation (cystometry).

Topics for research

- The committee recommends further evaluation and development of objective parameters for assessing the treatment outcome of detrusor overactivity.

e) Provocative manoeuvres

Some studies have shown that 50% of DO occurs during supine cystometry without provocation and that the remaining 50% is revealed by posture change, standing cystometry, on provocation by cough, or on catheter removal. [Turner Warwick 1979; Arnold 1974]

Awad and McGinis [Awad 1983] observed DO in 30% of female patients in the supine position versus 61% in the standing position. A systematic review of the literature by Al-Hayek et al [Al-Hayek 2008] concluded that supine cystometry failed to detect a significant percentage of patients with DO.

Webster et al [Webster 1984] concluded that in 52% of women with DO, provocation by fast filling in the standing position, with exercises such as coughing, was required to reveal it. Investigative technique, in particular the inflation of a balloon in the proximal urethra [Colstrup 1982] or the instructions given to the patient [Blavas 2001], is also said to affect the frequency of the observation of DO.

Choe et al [Choe 1999] systematically examined which manoeuvres were most provocative of DO. In 134 women with symptomatic UUI they performed gas (CO2) cystometry. Six provocative manoeuvres were performed consecutively to evoke DO, including lying supine, rising to a seated position, walking toward the bathroom, hand washing, coughing and sitting on the toilet with instructions not to void. By filling to maximum capacity and performing these manoeuvres in 2 different orders, they were able to demonstrate DO in 76/134 subjects (67%). Sitting on a toilet with a full bladder and with the instruction not to void was the most provocative manoeuvre, responsible for revealing DO in 52 of the 76 (68%). Hand washing was a distant second, revealing overactivity in 15 of the 76 (20%). Other manoeuvres revealed very little DO.
An extreme provocative manoeuvre is the bladder cooling (ice water) test advocated by Geirsson et al. [Geirsson 1993]; The empty bladder is filled with water at a temperature of less than 10°C. This stimulates C-fibres that normally carry afferents from receptors sensitive to temperature and pain. In infants, stimulation of these receptors can initiate a detrusor contraction, but this response is normally lost at ages over 5 years. The bladder cooling test stimulated detrusor contraction (neurogenic DO) in 91-97% of patients with traumatic upper motor neuron lesion, but in only 47% of those with presumed idiopathic DO. Detrusor contraction was not observed in any patient with a lower motor neuron lesion or 'pure' (urodynamic) SUI. Thus the conclusion was that the bladder cooling test is highly sensitive for neurogenic DO, and highly specific for DO in general.

The bladder cooling reflex, elicited by the ice water test (IWT) was performed in patients with painful bladder syndrome (PBS, n = 17), idiopathic DO (IDO, n = 22), neurogenic DO, n = 4) and SUI (as controls, n = 21). The IWT was performed by intravesical instillation of cold saline (0 - 4 degrees C). A positive IWT was observed in IDO (27.3%) and neurogenic DO (100%) patients, but was negative in all PBS and all control patients. Thirteen (76.5%) PBS patients reported pain during the IWT, with significantly higher pain scores during ice water instillation compared to the baseline (p = 0.0002), or equivalent amount of bladder filling (100 mL) with saline at room temperature (p = 0.015). [Mukerji 2006]

A total of 114 patients over 50 years, with an International Prostate Symptom Score (IPSS) >8 and QoL >2, were evaluated by UDS and IWT to investigate whether DO and/or the response to the IWT were related to night time urinary frequency. The DO-positive IWT responders had a significantly higher BOO-index than did the DO-positive IWT non-responders and the DO-negative IWT non-responders. The DO-positive IWT responders had significantly more frequent nocturia and smaller night time maximal and lesser VV than did the DO-negative IWT non-responders without any difference in the nocturnal VV. The patients with nocturia, two or more times, had a significantly larger nocturnal VV and smaller night time minimal VV than the patients with nocturia less than two times. The incidence of DO-positive IWT responders was significantly greater among the patients with nocturia three or more times than that among those with nocturia less than three times. The authors concluded that high grade BOO leads to development of C-fibre reflex activity. [Hirayama 2005]

Conclusions (level 2)

- A systematic review concludes that more detrusor overactivity is seen when the patient is in the sitting position during cystometry, when compared to the supine position.

- There is some evidence that moving to a toilet, and also hand washing, is strongly provocative of detrusor overactivity.

- Evidence suggests that ice water cystometry can be applied to elicit detrusor overactivity in patients with NLUTD and that a detrusor contraction during filling with ice water can be interpreted as a sign of pathologic (existing only in patients with relevant neurology) C-fibre reflex activity. It has however also been shown in this regard that false-negative tests do occur.

Recommendations (grade B)

- The committee recommends that the results of provocative cystometry are interpreted in the light of the patients’ symptoms and to bear in mind whether the results obtained are representative.

- The committee recommends the performance of urodynamic investigation in the sitting position whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the better possibility of representative voiding and better patient comfort.

- The committee recommends that the position of the patient during filling cystometry is always taken into account because it can influence the demonstration of detrusor overactivity. Repeating the cystometry in a different position can be helpful when it is deemed clinically necessary.

2. AMBULATORY URODYNAMICS: SENSITIVITY AND SPECIFICITY

Ambulatory urodynamics is performed in an effort to capture more realistic or more physiological observations, especially of UI episodes. Thus, similar to provocative manoeuvres, it is an attempt to increase sensitivity by providing a longer time for DO to manifest itself. Strict protocols for the test (e.g. duration) and standards for systematic analysis are lacking. The authors of a review article [Cassidenti 1999] concluded that ambulatory monitoring detects UI better than conventional cystometry.

Radley et al. [Radley 2001] found that ambulatory monitoring revealed DO in 70/106 women with symptoms suggestive of DO (twice as many as conventional cystometry with provocation by hand washing), and that it detected DOI in 40 of the 70. The observation of DOI was correlated with symptom severity, but it was not clear how many women complaining of UUI showed DOI. Therefore the sensitivity observed in this study has remained unknown. The specificity of this method is at present not evaluated, and it is not very likely that therapy can be improved on the basis of (additional) ambulatory testing.

Conclusions (level 3)

- Studies have shown that ambulatory monitoring
is more sensitive to detrusor overactivity however the predictive value towards the selection (and outcome) of optimal treatment is still unknown.

**Recommendation (grade A)**

- The committee does not recommend ambulatory monitoring in the routine diagnosis of patients with urinary incontinence.

### 3. THE ADJUNCT USE OF IMAGING AND ELECTROMYOGRAPHY

Videourodynamics is an investigation where cystometry is carried out simultaneously with imaging (usually x-rays) of the lower urinary tract. This can be useful in the management of some patients; particularly children and patients with NLUTD and is briefly discussed in the relevant chapters. There is a fuller discussion of videourodynamics in the chapter on Imaging, Neurophysiology and other tests.

Another adjunct to cystometry is the simultaneous measurement of striated muscle activity using EMG. Most frequently this is used in the investigation of patients with NLUTD and often surface electrodes are placed on the perineum to detect (all - unspecific) striated muscle activity from pelvic floor muscles. Amongst other uses, failure of the urethra/pelvic floor to relax and pelvic floor voiding dysfunctions can theoretically be detected during voiding using this technique. Unfortunately, it is technically difficult to ensure a good quality EMG signal from the precise and relevant muscle(s) during this procedure and there have been no publications in at least the last 20 years investigating the benefits of combining EMG with cystometry.

### VI. THERAPEUTIC PERFORMANCE OF FILLING CYTOMETRY AND AMBULATORY MONITORING

#### 1. PREDICTION OF TREATMENT RESPONSE

##### a) Filling cystometry

The authors of a review of papers from 1980-2000 [Colli 2003] concluded that it is not possible to correlate the results of urodynamic tests with the effects of non-invasive therapy. Consistent with the table, Malone-Lee et al [Malone 2003] reported on 356 female patients with OAB symptoms. On urodynamics, 266 showed DO. There was no significant difference (between those with and without DO) in treatment outcome after 6-8 weeks of oxybutynin and bladder retraining.

On the other hand, previous reviews have concluded that women with UI and DO respond less well to surgery for SUI than those without DO. [Homma] Friis et al [Friis 1982] conducted a blinded prospective study to evaluate the usefulness of urodynamic examination compared to clinical diagnosis. The study showed that when urodynamic examination was added to the preoperative planning of treatment for female UI a more beneficial cure rate was found if the patient was treated in accordance with the urodynamic findings. However, the patient material is small and the power of the study is weak.

A retrospective study has shown that a careful minimal evaluation may be adequate to identify ISD, predict postoperative voiding difficulties and maximize surgical outcomes. [Thompson 2000] A Cochrane review concluded that current evidence is insufficient to demonstrate a clear improvement in clinical outcomes as a result of performing urodynamic studies. [Glazener 2002]

In men, fewer studies have been done. Golomb et al [Golomb 1999] examined whether preoperative urodynamic examination allows us to predict the risk of UI after radical prostatectomy. A small group of 20 patients underwent radical retropubic prostatectomy for prostate cancer. Urodynamics showed DO in 12/20 pre-operatively. 5 of these 12 suffered from UUI post-operatively. The positive predictive value of preoperative DO for post-operative UI was thus only 42%.

In a literature overview of the diagnostic and therapeutic value of urodynamic investigations in patients undergoing POP surgery, the reviewers found a large heterogeneity of results. ‘Occult’ SUI showed large variation between studies and de novo DO after TVT as adjunct to POP surgery was observed in inconsistent and unpredictable percentages. It was impossible to estimate the predictive value of urodynamic testing on the basis of this review and prospective studies were demanded. [Roovers 2007] A later clinical study confirmed this view. [Roovers 2007]

A study presented a decision-analytic model that evaluated the cost-effectiveness of basic office evaluation before surgery in women with POP and SUI symptoms and contrasted it with that of urodynamic testing. Costs were obtained from the Federal Register; effectiveness of treatment for UI was based on the published literature. The strategies of basic office evaluation and urodynamic testing had the same cure rate of UI (96%) after initial and secondary treatment. Under baseline assumptions incremental cost-effectiveness (cost for single extra cure of UI) of urodynamic testing was $328,601. According to sensitivity analyses, basic office evaluation was more cost-effective than urodynamic testing when the prevalence of pure DO was <8% or when the cost of urodynamic testing was >$103. The analysis concluded that urodynamic testing before surgery in women with POP and SUI symptoms is not cost-effective relative to basic office evaluation. [Weber 2000]

##### b) Ambulatory monitoring

Brown and Hilton [Brown 1999] used conventional
and ambulatory urodynamic monitoring to study the incidence of DO before and after colposuspension. They showed that preoperative ambulatory monitoring was unable significantly to predict which patients would suffer from urgency postoperatively, or even which women would demonstrate DO post-surgery. Another paper addressed specifically the effect on clinical management of doing ambulatory urodynamics. [Gorton 2000] In this retrospective chart review of 71 women, there were technical difficulties in 30/71 ambulatory studies although only 2 were not interpretable. 32/71 women showed DO and nearly all were treated with medication. Among the remainder without DO fewer received medication. However, fewer than half of those who received medication improved. The authors concluded that ambulatory urodynamics was not very helpful in deciding on management.

Conclusions (level 2/3)

- Various studies have shown that the result of urodynamic investigation does not perfectly predict the outcome of relevant treatment in all patients: either in patients with urodynamic detrusor overactivity or in patients with urodynamic stress incontinence and also not in patients with a ‘double’ urodynamic diagnosis.

- A retrospective study with subsequent health economic modelling has shown that in patients with ‘pure symptoms of stress incontinence’ urodynamic testing might not be cost effective.

Recommendations (grade B/C)

- The committee recommends that the result of urodynamic investigation is applied to ‘optimize’ treatment strategy without attributing perfect specificity to the result of treatment, in an individual patient.

- The committee recommends that the cost effectiveness of urodynamic testing is taken into account when discussing the necessity of urodynamic investigation with the patient.

Topics for research

- The committee suggests that large multicentre (‘national’) prospective studies might be of help to better understand the cost-effectiveness of high quality urodynamic testing in health care quality for patients with incontinence.

C. CLINICAL APPLICATIONS OF URODYNAMIC STUDIES

I. PATIENT EVALUATION: WOMEN

1. INTRODUCTION

The clinical evaluation of an incontinent woman is based on the combination of the medical history, physical examination and, when appropriate, selected urodynamic tests.

The patient’s symptom SUI is clearly defined and the sign often can be objectively demonstrated as ‘the observation of urine leakage from the urethra synchronous with exertion/effort, or sneezing or coughing’. Traditionally, cystometry with cough tests at representative volumes has been the core test for the urodynamic diagnosis of USI. Dynamic urethral closure pressure profilometry, leak point pressure testing and ambulatory urodynamics have been used to sub classify patients with USI.

In the previous report two expert reviews were cited which summarize the likelihood of correctly predicting the result of the UDS from symptoms and signs. [Harvey,M.A. 2001; Homma,Y. 2002] There have been further studies [Agur,W. 2009; Digesu, 2003], reporting that confirmation of USI in the group of patients with the sole symptom of SUI is observed in ±70-80% of the patients. However, patients with that ‘sole symptom’ were only a relatively small proportion of all reported and analysed cohorts. There have been 2 other studies highlighting the unpredictability and large variation of urodynamic diagnosis on the basis of symptoms in women [Mc Nakley, et al; Hameed, et al] An earlier study [van Waalwijk van Doorn,E.S. 1992] showed that, in a group of 154 females with both complaints and urodynamic demonstration of incontinence, the clinical observation of pure USI had a sensitivity and specificity of 90% and 65% respectively for the isolated symptom of SUI which would be challenged by these 2 further (retrospective) studies, both of which use a much larger data bases, one of over 6000 patients.

The objective information about LUT function adds to the diagnosis that is made on the basis of signs and symptoms. This addition can be of value for the professional when selecting a treatment to offer to the patient. However, it should be noted that besides their diagnostic potential, UDS can contribute qualitative and quantitative information about the underlying or coexisting pathophysiology that is valuable for the patient as well. One study did use a patient preference model to assess the utility of UDS in assessment. This study did highlight that whilst on QoL evaluation, UDS, by itself, did not lead to a better outcome, patient compliance with treatment was better in the group having UDS. Secondly far more women opted for UDS than was predicted. [Majumdar,A. 2010]

Malone Lee however, demonstrated that the presence or absence of DO in patients with symptoms OAB did not relate to outcome of anticholinergic treatment in a prospective randomised trial. [Malone-Lee,J.G. 2009] Likewise 2 studies have shown that symptoms reported during UDS vary between groups, and comparison of the results between groups may be difficult. [van Mastrigt,R. 2004; van Mastrigt,R. 2006]
The committee discusses in the following paragraphs the clinical application of UDS in patients with signs or symptoms of UI. Firstly women with SUI, followed by women with OAB with UUI.

2. STRESS URINARY INCONTINENCE

a) Urethral pressures and severity of stress urinary incontinence

There is no consensus on how to measure the severity of SUI clinically or urodynamically. Severity can be expressed on the basis of simple clinical measures such as questionnaires, or on a bladder diary or on pad weighing tests. A review concludes that static UPP parameters such as MUCP or cough profile parameters such as pressure transmission ratio cannot be used to characterize the severity of incontinence and suggested that abdominal LPP measurement might be a useful tool to quantify urethral dysfunction associated with SUI. [Weber, A.M. 2001]

However, other studies have found no correlation between leak point pressures and the severity of UI as measured by bladder diaries and QoL instruments. [Albo, M. 2007; Chen, C.C. 2008; Theofrastous, J.P. 1995; Nager, C.W. 2001] Leak point pressures are also limited as a diagnostic tool by the lack of standardisation of the technique. [Rodrigues, P. 2006]

A total of 221 women, 29 to 80 years old (mean age 55.2), were included in a prospective TVT treatment study, performed mostly using local anaesthesia with a mean follow-up of 10.5 months. Patients were divided into 61 with low (less than 60 cm H2O) and 160 with higher (60 cm H2O or greater) VLPP. The overall (subjective and stress test) cure rate was 10% lower in patients with low versus the patients with higher VLPP and, in women with low VLPP, but multivariate analysis indicated that symptoms of OAB, independent from low MUCP, were independent factors for treatment failure. The authors concluded that women with urgency symptoms and or with low MUCP should be considered to be at higher risk for failure after the TVT procedure. [Paick, J.S. 2004] In another report the role of preoperative VLPP in predicting the outcome of the suburethral sling procedure for the treatment of SUI was prospectively evaluated in 174 consecutive patients with diverse grades of VLPP. The TVT provided similar symptom improvement in all the patients regardless of preoperative VLPP [Rodriguez, L.V. 2004] which was confirmed in a more recent study. [Costantini, E. 2008]

An expert review of the use of LPP testing and urethral pressure profilometry prior to surgical treatment for SUI, concluded that there remains no consistency as to whether this testing enhances surgical outcome of SUI treatments by improving case selection or altering the surgical approach based on study findings. The reviewer found little evidence to suggest that patients with more severe forms of USI on urodynamic testing fare more poorly after the most commonly offered surgical treatment than those with less severe forms. [Lemack, G.E. 2004] Subsequent studies and reviews have tried, without positive results, to identify ways in which UDS may predict voiding difficulties after suburethral tapes. [Mostafa, et al.; Murray, S. 2010]. However, the lack of (multicenter standardised) prospective evaluations has been implicated in the lack of progress on this topic. There is also a lack of knowledge with regard to subclasses of SUI and (types of) pelvic floor muscle exercises. [Herderschee, R. 2011]

Most retrospective monocenter studies show higher failure rates after surgery in women with low MUCP (≤ 20 cm H2O) at MCC. [Weber, A.M. 2001; Miller, J.J. 2006; Guerette, N.L. 2008] However, other investigators have shown that a low MUCP is not an efficient predictor of surgical failure. [Homma, Y. 2002; Weber, A.M. 2001] In a recent prospective, randomised trial of women undergoing either Burch retropubic suspension or bladder neck slings, LPP’s were not found to be predictive of surgical outcome for SUI. [Nager, C.W. 2008]

The value of urethral hypermobility, MUCP and urethral incompetence was analysed in a study with 369 women with symptoms suggestive of SUI, without symptoms of DO. Continent and incontinent patients differed with regards to urethral incompetence and hypermobility. Incontinent patients had a greater probability of a higher grade of each factor. Even after adjusting for the older age of incontinent patients by ANCOVA, MUCP was significantly lower in the incontinent group. The best univariate optimized cut-off point for discriminating continence from incontinence was obtained with urethral incompetence greater than grade I. [Schick, E. 2004]

In an attempt to define the urodynamic contraindications to Burch colposuspension, 79 patient’s, eligible for continuous postoperative follow-up were enrolled in a prospective study. On post-hoc analysis, a VLPP level <60 cm H2O was not found to represent an absolute contraindication to Burch colposuspension, provided that other parameters, such as MUCP and functional urethral length, are within acceptable ranges. [Bai, S.W. 2005]

From a total of 168 women, the 31% that demonstrated SUI at lower bladder volumes (100 mL) did not report greater bother from UI than the 35% women who leak at higher volumes (>400 mL). The Urogenital Distress Inventory, Incontinence Impact Questionnaire, and also the MUCP and VLPP were similar in the groups. Among the 116 patients who had a sling procedure, USI persistence did not differ according to the volume at which USI occurred preoperatively (p=0.72). The authors concluded that ‘bladder volume when leaking’ during a urodynamic study is not an adequate reflection of UI related QoL. [Lowenstein, L. 2007]
A review was done to highlight controversies, concerning the use of UDI prior to surgical treatment for SUI. The review focused on LPP testing and UPP. On the basis of the literature available at that time it was concluded that there remains no clear consensus as to whether UPP or V(A)LPP testing enhances surgical outcome of SUI treatments by improving case selection or altering the surgical approach based on study findings. Furthermore the author concluded that there was little evidence to suggest that patients with more severe symptoms of SUI by UPP or V(A)LPP testing fare more poorly after the most commonly offered surgical treatment than those with less severe forms. The third observation done in this review was that there are certain sub-populations of women who appear to be at higher risk of ‘persistent urgency’ and or of voiding dysfunction following incontinence surgery, and that UDI may aid in identifying this group. Overall was concluded that it is not apparent that either ALPP measurement or UPP can accurately predict which patients will achieve the best outcome of surgical treatment for SUI. The author suggested that other parameters assessed during UDI might provide prognostic information regarding the risk of voiding dysfunction postoperatively and the possibility of persistent urge-related leakage following surgery, though not directly predict cure. [Lemack,G.E. 2004]

Conclusions (level 2/3)

• Various studies have shown a weak association of incontinence severity with urethral function tests (leak point pressures and urethral closure pressures).

• Cohort studies have shown that incontinence volume and intravesical volume at leakages are poorly associated with symptoms severity and or with patients’ quality of life.

• Studies have shown that urethral function tests (leak point pressures and urethral closure pressures) are of very little value in predicting the outcome of treatment with suburethral tapes.

• No studies have shown the relevance of urethral function tests (leak point pressures and urethral closure pressures) in predicting the outcome of non surgical or other treatments for stress urinary incontinence.

Recommendations (grade B/C)

• The committee recommends that urethral function measurements of leak point pressures and urethral closure pressures are not used as a single factor to grade the severity of incontinence.

• The committee does not recommend the use of contemporary urethral function tests to prediction the outcome of any surgical treatment for stress urinary incontinence.

Topics for research

• The committee suggests further studies with the aim of better understanding urethral closure function and dysfunction, in relation to the diverse treatments (especially conservative) of stress urinary incontinence.

b) Aspects of urodynamic studies relevant to therapy for stress urinary incontinence

In a systematic meta analysis (only) 129 (out of 6009) studies were relevant for inclusion using the Quality Assessment of Diagnostic Studies (QUADAS) tool to identify and synthesize studies of diagnostic processes of UI and to construct an economic model to examine the cost-effectiveness of simple, commonly used primary care tests. The diary appears to be the most cost-effective in the diagnosis of USI of the three primary care tests (diary, pad test and validated scales) used in addition to clinical history and clinical stress test. However, the meta-analysis also conceded that if a patient is to undergo an invasive urodynamic procedure, multi-channel urodynamics is likely to give the most accurate result in a secondary care setting. [Martin,J.L. 2006] Two attempts to use artificial intelligence in UDS interpretation have been reported [Serati,M. 2011; Witjes,W I998], one reported neural networking and the second an automated analysis process of uroflow: neither was felt to be robust enough to improve diagnostic accuracy.

In 2006 in the UK, the National Institute of Health and Clinical Excellence (NICE) issued guidelines, on the basis of expert opinion collated by a modified Delphi process, that urodynamics was recommended before surgery for UI only if there is a clinical suspicion of DO or, if there has been previous surgery for SUI, or is anterior compartment POP or, if there are symptoms suggestive of voiding dysfunction [National Institute for Health and Clinical Excellence] and urodynamics was not routinely recommended for women before surgery for a ‘clearly defined clinical diagnosis of SUI’. The evidence base for this recommendation has been disputed and is controversial and challenged and is now subject to several studies [Nager,C.W. 2008; Nager,C.W. 2001] and the reports of these are awaited. A study in 2008 by Agur et al casts doubt on the wisdom of the UK-NICE recommendation. [Agur,W. 2009] In their tertiary centre, patients are referred with lower urinary tract symptoms. A database of systematic analysis before UDS was used retrospectively to identify women aged 18-80 years who had UDS for UI over a 17-year period (1 January 1990 to 31 December 2006). The reliability of the patients’ history in predicting ‘pure’ USI in patients with ‘pure’ SUI on the basis of the NICE criteria, was investigated. Only 324/6276 (5.2%) women had pure SUI; moreover, a quarter of those with pure SUI symptoms ultimately had urodynamic diagnoses other than USI, that could affect the outcome of continence surgery.
They concluded that only a small group of women fulfil the NICE criteria of pure SUI and it seems inevitable that even with these strict criteria, a woman could go forward to a surgical procedure with potentially important urodynamic findings unaddressed.

**Conclusion (level 1)**

- It is concluded in a model study, based on a selected retrospective cohort, that urodynamic testing is not cost effective in the primary health care setting for women with predominant stress incontinence symptoms.

- It shown that in the referred population, urodynamic investigation is the most accurate way to obtain an objective diagnosis in an individual patient with urinary incontinence symptoms.

**Conclusion (level 3)**

- It has been shown in retrospective and prospective cohort studies that symptoms of 'pure stress urinary incontinence' do not exclude other abnormalities of lower urinary tract function.

**Recommendation (grade A)**

- The committee recommends that the cost effectiveness of urodynamic testing is kept in mind when discussing 'cost and gain' of the various methods of diagnosis for urinary incontinence, in relation to the method of treatment.

**Recommendation (grade B)**

- The committee recommends urodynamic studies are carried out in all women prior to surgical intervention for stress urinary incontinence.

**Topic for research**

- The committee suggests that multicentre studies should address the question as to whether women with symptoms of 'pure' stress urinary incontinence are more at risk of failure from surgical treatment of their incontinence without pre-operative urodynamics, or have more adverse events following surgery without pre-operative urodynamics than women who have pre-operative urodynamic studies.

- The committee suggests that the balance of (over-) diagnosis (when urodynamic testing is used) versus (over-)treatment (with surgical interventions and risk of harm) carefully analysed in a prospective series of consecutive (otherwise unselected) referred women with incontinence.

**c) Prediction of failure of surgery**

Based on review of the available evidence it has been concluded that urethral pressure profilometry is not standardised, reproducible, or able to contribute to the differential diagnosis in women with SUI symptoms. [Weber, A.M. 2001] This review was done on studies of treatments done before suburethral tapes were widely used, but has been confirmed in the era of tapes. [Lemack, G.E. 2004]

Urethral retro-resistance pressure has also been studied as a potential predictor of surgical success. However, it has failed to show any predictive value for surgical success with colposuspension, retropubic suburethral slings and transobturator suburethral slings. [Tunn, R. 2007] This was underscored in a later manuscript. [Roderick, T. 2009]

Ward and colleagues carefully examined the impact of urodynamic testing on decision-making and treatment recommendations in incontinent women. They found that the probability that urodynamics would alter recommendations for medical treatments was 27% and 46% for surgical treatment. [Ward. 2002]. Johan [Johan, et al.] looked for similar effects with POP in 72 randomly selected cases. A total of 60% of the patients underwent preoperative UDS and 53% of the 43 women undergoing UDS had an abnormal result with POP reduction; 19% of these had pure SUI, and 30% had DO, either in isolation or in combination with SUI. The surgical management was altered in 7%, who had an additional continence procedure performed as a consequence of the UDS. UDS changed management in 33% patients and in 7% of patients, the surgical procedure was changed.

**Conclusion (level 2)**

- Leak point pressures are reported not to correlate with failure (or success) rates of colposuspensions, transobturator and retropubic suburethral, bone-anchored suburethral slings.

**Conclusion (level 3)**

- There is conflicting evidence that low urethral closure pressures are associated with poorer success rates of sub-urethral slings.

- It is the opinion of the committee that most evidence suggests now that urethral pressures (profile or leakpoint) are not relevant to predict the outcome of treatment in women with uncomplicated stress incontinence.

**Recommendation (grade B/C)**

- The committee recommends that measurements of urethral function (leak point pressures and urethral closure pressures) are not used to predict the likelihood of success after surgical treatment for women with uncomplicated primary stress incontinence.

**d) Voiding difficulties after surgery**

Surgery for SUI may lead to voiding difficulties. [Botros, S.M. 2007; Jarvis, G.J. 1994; Wang, A.C. 2003] One major problem is that many published studies do not use an unambiguous (urodynamic)
The risk of persistent urgency was more closely associated with high-pressure DO (pdet ≥ 25 cm H2O) than low-pressure DO. [Lose, G.1988; Pow-Sang, J.M. 1986; Lockhart, J.L.1984] Consequently, it was suggested that cystometry may allow a more precise selection of patients who respond to surgery despite DO with or without urgency symptoms. The success rate after anti-incontinence surgery in patients with low-pressure contractions are reported to be similar to the success rate in those without DO in a number of studies. [Lose, G. 224; Pow-Sang, J.M. 1986; Lockhart, J.L. 1984; Schrepferman, C.G. 2000] but the success rate in women with high-pressure DO is however reputed to be less than 50%. [561 Lose, G. 1988; Pow-Sang, J.M. 1986; Lockhart, J.L.1984; Schrepferman, C.G. 2000] On the other hand are reports that preoperative urgency symptoms resolve in a proportion of patients. [Nilsson, C.G. 2001; McGuire, E.J. 1980; Ward, K. 2002] Hypothetically, and suggested by some, surgical correction of the bladder outlet prevents ingress of urine into the proximal urethra which it occurs, has been said to induce urgency or DO in some patients. [Jung, S.Y. 1999; Karlson, S.1953; McGuire, E.J. 1976]

De novo UII has however also been reported to occur in 10-20% of patients after surgery. [Jarvis, G.J. 1994; Holmgren, C. 2007]

There is scant information on clinical or urodynamic risk factors; possibly the type of surgery plays a role. A recent retrospective trial suggested that the incidence of de novo UII is higher in bladder neck slings than in retropubic suburethral slings which were also associated with more de novo UII than transobturator suburethral slings. [Alperin, M. 2008; Botros, S.M. 2007] Another study showed that women with preoperative mixed symptoms of incontinence and DO, as well as women that used anticholinergics, had significantly worse outcome at 6 weeks. [Kenton, K. 2009] This observation was confirmed in a larger longer term prospective follow-up study. [Lee, J.K. 2011]

Conclusions (level 2)

- Prospective studies have indicated that overactive bladder syndrome, mixed symptoms of incontinence and or detrusor overactivity during urodynamics at presentation have a negative effect on the outcome of (all available) surgical interventions for stress incontinence.

- Current test methods have been unable to reliably predict which patients will develop de-novo urinary urgency (overactive bladder syndrome) after surgery for stress urinary incontinence.

- Post hoc evidence suggests that procedures for the treatment of stress urinary incontinence which are more ‘obstructing’ produce a higher chance of de novo urinary urgency (OAB-syndrome).
Conventional urodynamic testing, including pessary testing, has been applied to initiate a plausible management strategy for patients with POP. [Smith, P.P. 2005; Ballert, K.N. 2009] Many studies emphasize the importance of urodynamic assessment with POP reduction to assess potential occult SUI and possibly DO. [Romanzi, L.J. 1999; Ghoniem, G.M. 1994; Versi, E. 1998; Weber, A.M. 2000; Marinkovic, S.P. 2004] However, although occult SUI is revealed in a high proportion of cases with severe POP, studies that assess reproducibility are lacking, inconclusive and or conflicting. [Bump, R.C. 1996; Colombo, M. 1997; Gordon, D. 1999; Heesakkers, J.P. 2005] Another study [Gravina 2007] concluded, on the basis of a mathematical model, that included DO, that urodynamic testing before a POP operation was not cost-effective if performed in all patients.

Conclusions (Evidence level 1)

• Various studies have shown that symptoms of stress urinary incontinence can appear after surgery for pelvic organ prolapse.
• There are a variety of methods to uncover ‘occult stress urinary incontinence’ in women with pelvic organ prolapse. In prospective studies, it is demonstrated that all have different sensitivities and specificities. Standardisation of these tests is necessary.

Recommendation (grade B)

• The committee recommends that patients with pelvic organ prolapse are informed about the relatively unpredictable chance of developing stress incontinence after surgery for pelvic organ prolapse.

3. URGENCY URINARY CONTINENCE

a) Pathophysiology and severity of urgency urinary incontinence

Urgency urinary incontinence (UUI) is the symptom, complaint, or sign of involuntary urine loss of urine associated with urgency. DO is the occurrence of involuntary detrusor contractions occurring during filling cystometry. Precise individual relationships between symptom severity and the various variables observed during urodynamic testing have not been established. Individual symptom severity is dependent on other factors besides lower urinary tract function, furthermore, urodynamic testing measures lower urinary tract function, in isolation from those factors. Studies have shown that symptoms and treatment result relate to QoL. [Kubota, Y. 2011; Payne, C.K. 2007]

As already indicated above, treatment and treatment response seem to depend relatively little on urodynamic measures, and also patients with OAB symptoms but without DO improve on antimuscarinergic treatment. [Malone-Lee, J.G. 2009]

Although urodynamic classification of UI type is related to adverse effects on QoL, no studies have
been successful in relating the quantified urodynamic abnormalities, when DO exists, to the symptom severity. [Duggan,P. 2011], although high scores on the urgency severity scale predict the finding of DO. [Chung,S.D. 2011] Urodynamic capacity, volume at first contraction, and or amplitude of the first, or highest contraction, are used as endpoints in treatment studies, and are, in those studies, observed to be altered in the direction of symptom improvement. (We refer to the treatment section for these observations.) A precise association between symptoms, symptom change and urodynamic findings can however not be deduced from this.

b) Prediction of treatment response

The positive predictive value of OAB (urgency usually accompanied by frequency and nocturia with or without UUI) for urodynamically determined DO is reported to be around 50%. [Digesu,G.A. 2003] On the other hand DO is reported in 10-69% of asymptomatic female volunteers, depending on the definition and type of cystometry. [van Waalwijk van Doorn,E.S. 1992; Heslington,K. 1996; Robertson,A.S. 1999; Homma,Y. 2002; Morgan, K.; Turner-Warwick, et al 1979]

There are studies that show that, in patients with OAB, treatment response is not per se dependant on the observation of DO, however this does not make clear whether the urodynamics simply 'missed' the DO. It does also not exclude the necessity of urodynamics in the patients that has failed medical treatment which are the most common patients in referral clinics. [Saleem,A. 2010; Malone-Lee,J.G. 2009] Studies on voiding difficulties or de novo SUI or mixed incontinence (as a consequence of increased capacity because of treatment for UUI) have not been published.

Conclusions (level 2/3)

- Studies have not been able to show a strong association between overactive bladder symptoms and detrusor overactivity during urodynamic investigation.
- Various studies have directly or indirectly concluded that the individual prediction of the response to treatment for overactive bladder symptoms, on the basis of the characterization or quantification of detrusor overactivity during urodynamic investigation, is impossible.

Recommendation (grade B/C)

- The committee recommends that investigators and clinicians discuss with patients, with detrusor overactivity, that neither the quantity nor specific characteristics of detrusor overactivity predicts the response to any of the therapeutic approaches.

Topics for research

- The committee suggests further studies to find predictors of response on treatment for patients with overactive bladder syndrome.
- The committee suggests further studies to find urodynamic predictors of response for patients with overactive bladder without detrusor overactivity.

4. RECOMMENDATIONS FOR URODYNAMIC STUDIES IN WOMEN WITH URINARY INCONTINENCE

Recommendations for clinical practice:

1) The committee recommends non-invasive urodynamics (voiding and incontinence diary, PVR, and possibly uroflowmetry) for all patients with urinary incontinence.

2) The committee suggests that treatment, without invasive urodynamic testing, is offered in situations where the type of UI is clear, if the patient accepts the uncertainty margins of the diagnosis and there are no complicating factors. Furthermore the planned treatment should be not invasive and be simply reversible. The committee provides the following examples:

- Uncomplicated symptoms of stress urinary incontinence with normal bladder diary, normal flowmetry and without relevant post-void residual urine. (Symptomatic pure stress urinary incontinence with no symptoms or signs of voiding difficulties), for treatment with pelvic floor muscle training.

   - Uncomplicated symptoms of urgency urinary incontinence, with a bladder diary in accordance with these symptoms, with normal flowmetry and without relevant post-void residual urine. (Symptomatic pure urge urinary incontinence with no symptoms or signs of voiding difficulties), for treatment by bladder training with or without combined pharmacotherapy.

3) The committee recommends that, whenever surgical intervention is planned, whenever there is doubt about the pathophysiology, or about whether the UI is uncomplicated or not, that invasive urodynamics should be performed in order to provide the knowledge on which rational treatment decisions and prognosis can be based. The committee also recommends urodynamics for patients that have had failed first therapies. The investigation should be tailored to the individual patient; typically this means that it will be a comprehensive examination of multiple aspects of storage and voiding function, and not just of the incontinence itself.

Recommendations for research:

1) The committee recommends research programs:

   - to more clearly establish the technical and physiological basis of the urodynamic observations that are made in women with urinary incontinence
II. PATIENT EVALUATION: MEN

1. INTRODUCTION

The incidence of UI in men is generally regarded as much lower than in women. The incidence of LUTS, in general, including OAB and symptoms suggestive of BOO in men however increase with age, as in women. [Kondo, et al.2002], although the QoL of women is more likely to be affected by OAB than men. Both men and women with bothersome OAB were significantly more likely to seek treatment, and to report the lowest levels of health related QoL. [Coyne,K.S. 2011]

In this section, the characteristic pathologies that lead to UI in men, rather than women, are discussed from the point of view of urodynamic testing. Although UI associated with, BOO (including BPO) or to prostatic surgery is most frequently encountered, other pathological conditions such as nocturnal enuresis and post-micturition dribbling are also clinically relevant (but not specific for) in men. [Kondo, et al.2002; Coyne,K.S. 2011] This section is organized according to the suspected origin or cause of UI or related LUTS, reflecting the diverse aetiologies responsible for incontinence in men.

2. URODYNAMIC TESTING OF DETRUSOR OVERACTIVITY AND OVERACTIVE BLADDER IN MEN

It has been estimated that 29.8 million adults aged >=40 years in the United States have bothersome OAB symptoms. The prevalence of OAB symptoms at least 'sometimes' was 27.2% in men and the prevalence of moderate/severe UI was 4.5%. [Coyne,K.S. 2011] The prevalence increased with age from 0.7% in 20 to 34 years old, to 16.0% in men 75 years old or older. [Markland,A.D. 2010] Storage LUTS was more prevalent than voiding or post-micturition LUTS in men (44.6%, 28.5%, 15.9%, respectively). The most prevalent LUTS was nocturia (36.6%). [Lee,Y.S. 2011] Significant negative correlation exists, between pre-treatment mean ICIQ-SF score and first sensation, and positive correlation between pre-treatment mean ICIQ-SF score and maximum detrusor pressure, were noted in a group of (male and female) patients taking pharmacotherapy for OAB. [Seckiner,I. 2007; Irwin,D.E. 2009] LUTS, OAB, UI, and LUTS/BOO are highly prevalent conditions, in men. [Irwin,D.E. 2009; Irwin,D.E. 2011] Treatment options for UI are rapidly expanding. Initial management of LUTS including UI, include basic diagnostic tests to exclude an underlying disease or conditions such as UTI. In the EAU guideline the advised initial treatment is conservative (lifestyle interventions, physiotherapy, physical therapy, pharmacotherapy) and of empirical nature. [Thuroff,J.W. 2011]

In a systematic review on several longitudinal studies it was shown that OAB and UI symptom severity progresses dynamically over time, and may persist over long time periods for many individuals. [Irwin,D.E. 2010] The overall incidence of DO was 76.1% in male OAB patients, 63% of men with urgency (OAB dry) had DO, while 93% of men with urgency and urgency urinary incontinence (OAB wet) had DO. A better correlation in results between OAB symptoms and the urodynamic diagnosis of DO in men, than in women, was reported, more so in OAB wet than in OAB dry. [Al-Ghazo,M.A. 2011]. A high urgency severity score (USS) recorded in conjunction with a voiding diary, and OAB wet, were strongly associated with urodynamic DO. [Chung,S.D. 2011]

Detrusor contraction velocity is observed to be related to urgency, and urgency may have a role in enhancing and sustaining detrusor contractions in patients with DO. [Cucchi,A. 2007] First sensation ratio and bladder urgency velocity were statistically significantly correlated with the Urgency Perception Score. Urodynamic variables correlated with bladder sensation questionnaire scores and may be an objective method to assess sensory dysfunction. [Rapp,D.E. 2009] However among the 84 ‘BPH-DO’ patients, 52 reported the symptom of urgency while 32 did not. Hypothetically, BPO patients with DO may neglect the symptom of urgency due to abnormal bladder sensation, or negate the symptom by subconscious sphincter contraction to abort the overactivity. [Tong,Y.C. 2007]

Reduced bladder sensation is defined as a bladder volume at first sensation >300 mL. Increased bladder sensation is defined as bladder volume at the first sensation <100 mL. Chronic post void residual and neuropathies are the most common cause of reduced (late) bladder sensation. In contrast, my-
elopathies are the most commonly reported cause of increased (early) bladder sensation and reduced capacity without DO. [Tsunoyama,K. 2011]

Idiopathic detrusor underactivity (DUA) is reported to result from two-stage development. [Cucchi,A. 2007] Patients with idiopathic DUA could be divided into group 1: low maximum possible detrusor contraction velocity, low isovolumetric detrusor pressure and bladder emptying efficiency <67%; group 2: low maximum possible detrusor contraction velocity, low isovolumetric detrusor pressure and bladder emptying efficiency >67%; and group 3: low maximum possible detrusor contraction velocity, normal isovolumetric detrusor pressure and bladder emptying efficiency >67%. [Cucchi,A. 2009]

During filling cystometry, rectal contractions (RC) are frequently detected, the clinical significance of which has not been investigated, however reduced bladder compliance and bladder trabeculations were more common in patients with RC. The occurrence of RC correlated with the incidence of cerebrovascular accidents in males in a large monocenter retrospective cohort. [Cho,S.Y. 2010] Ambulatory urodynamics are complex but sensitive for the detection of DO, are prone to artefacts and time consuming. Therefore, the method is considered of best value when all other diagnostic means have failed. [Pannek,J. 2008]

**Conclusions:**

- Epidemiologic studies show that lower urinary tract symptoms in men >50 years of age are highly prevalent and that storage lower urinary tract symptoms are relatively more reported than voiding or postmicturition symptoms.

- Case series indicate, in male patients, that overactive bladder wet is associated with urodynamic DO. Overactive bladder dry symptoms might involve other lower urinary tract dysfunction or be the result of obstructed and or ineffective voiding.

- Guidelines suggest that the initial treatment for male lower urinary tract symptoms can be based on the predominant symptoms, without urodynamic testing.

- Guidelines recommend, on the basis of expert opinion, urodynamic testing when the initial management fails to resolve the storage lower urinary tract symptoms.

**3. LOWER URINARY TRACT SYMPTOMS RELATED TO MALE LOWER URINARY TRACT DYSFUNCTION: DETRUSOR OVERACTIVITY AND BLADDER OUTLET OBSTRUCTION**

Lower urinary tract dysfunction is as prevalent in elderly men as in women however urinary incontinence is less prevalent in elderly male, (without a history of relevant surgery) However if UI is present in men, urodynamics can be helpful. Coexistence of UI in men with BOO and DO increases with age and with the degree of BOO. [Oelke,M. 2008; Vesely,S. 2003] The prevalence of UI ranges from 11% to 34% among community-dwelling men aged ≥65 years. BPO-related incontinence may be related to progression of BPH, through BPE, or as a post surgical complication. [Han,E. 2007] Significantly more cases (14%) reported reduced sexual activity and decreased enjoyment of sexual activity because of LUTS in a large case control series of elderly men, and significantly fewer cases were satisfied with their sex lives compared with controls. [Irwin,D.E. 2008]

Among 1418 men investigated urodynamically (median age: 63 yr) 864 (60.9%), had DO. In univariate analysis, men with DO were significantly older, had larger prostates, and higher grades of BOO, higher storage IPSS sub scores, a lower VV at free uroflowmetry, and a lower bladder capacity at cystometry. In patients with ‘clinical BPH’, DO was independently associated with age and BOO. [Oelke,M. 2008]

LUTS in elderly men does not equate to BOO due to BPE, and, in particular, young men presenting with LUTS have a different prevalence of underlying aetiologies. Urodynamic studies are useful in the evaluation of this group of patients Abnormal UDS were noted in 36 (72%), including DO in 9 (18%), underactive detrusor / acontractility in 5 (10%) and BOO in 21 (42%). Fourteen (28%) had primary bladder neck dysfunction and five (10%) had BPO in a retrospective monocenter report of 50 men < 50 years. [Toh,K.L. 2006]

LUTS can result from a complex interplay of pathophysiological features that can include bladder dysfunction and BPO or poor relaxation of the urethral sphincter. About one third of men with LUTS who were older than 55 years of age had BPO. Patients younger than 55 years old with LUTS were more likely to have poor relaxation of the urethral sphincter. [Kuo,H.C. 2007] In a group of men with LUTS and small prostates (mean prostate volume was 29.2 +/- 7.2 mL and mean IPSS was 13.5 +/- 4.6) BOO was diagnosed in 42 (50.0%) patients, and underactive detrusor in 41 (48.8%) and DO in 28 (33.3%) were the other diagnoses. The results emphasize the value of urodynamic studies in this population, especially when invasive treatments are being considered. [Gomes,C.M. 2008]

Non-invasive investigations such as uroflowmetry and measurement of PVR are easy to perform, but, even in simple situations, can only give clues to the underlying pathology. Low Q<sub>max</sub> on uroflowmetry cannot distinguish BOO from the poor detrusor contraction. [Chancellor,M.B. 1991] furthermore there is also a significant variation in Q<sub>max</sub> in repeated tests. [Feneley,M.R. 1996] A recent study showed that the time to flow, while performing uroflowmetry, associates with the reported symptom of urinary hesitancy on IPSS. [Park,K.K. 2011] Relatively strong relationships were found between average flow rate and
flow time with scores of intermittency, weak stream and IPSS scores in elderly men with LUTS and a reduced flow rate. [Itoh,H. 2006]

Seki at al reported that DO, at initial evaluation, negatively affected outcome in a retrospective study of 384 patients who had undergone TURP for symptomatic benign prostatic enlargement. [Seki,N. 2006] In another study with patients with prostate carcinoma and symptoms, it was demonstrated that 95% of men who proceeded to TURP on the basis of urodynamic diagnosis, had improved flow rates at 12 months after palliative TURP. [Gnanapragasam,V.J. 2011] Monoski at al found, in 40 men who underwent photoselective laser vaporisation prostatectomy for ‘BPH’ and retention, that the presence of DO in patients on pre-surgery Urodynamics, is associated with significantly more storage symptoms, and are twice as likely to require anticholinergic treatment than the patient without DO. [Monoski,M.A. 2006]

After HoLEP, 29 patients (16.2%) had de novo UI, most of which resolved within 1-6 months; low MUCP at baseline urodynamics was found to be the independent urodynamic predictor of de novo UI after surgery, amongst others in a multivariate analysis. [Cho,M.C. 2011] UDS was used to assess the functional outcome following KTP -laser prostatectomy. All selected patients in this controlled monocenter series (n=45) showed significant improvement in the IPSS in urodynamic pressure and flow. Detrusor contractility was not affected. [Hamann,M.F. 2008]

In an experts group discussion, it was concluded that UDS is indicated for the evaluation of effectiveness of new treatment modalities for elderly male patients. As in the existing guidelines, this expert group supports, on the basis of their expert opinion that UDS are not necessary before pelvic floor muscle training or medical treatment of LUTS/BPO or OAB. [Bosch,J.L. 2011]

Silodosin is evaluated to improve DO and BOO grade in patients with BPH and urodynamic testing showed objective improvement of voiding in a proportion of patients in a small monocenter study. [Yamanishi,T. 2010] In elderly male with OAB symptoms anticholinergics do not seem to influence effectiveness of (urodynamic) voiding. [Ronchi,P. 2009]

The role of urodynamics and the finding of DO, in predicting continence outcome, after radical prostatectomy, still remains controversial. Aboseif et al compared 92 men with and without DO on pre-operative urodynamics before radical prostatectomy. They found, after one year, a significantly higher incidence of UI (39% v/s 3%) in patients with pre-operative DO compared to those without pre-operative DO. [Aboseif,S.R. 1994] On the other hand, Kleinhans et al concluded (44 patients) that preoperative DO did not correlate with post surgical UI eight months after radical prostatectomy. [Kleinhans 1999]

Conclusions:

• Various studies indicate that male lower urinary tract symptoms including incontinence may be due to detrusor dysfunction and or bladder outlet obstruction.

• Monocenter cohort observations demonstrate that detrusor overactivity and urethral sphincter dysfunction should also be considered in young men with lower urinary tract symptoms or men with a small prostate.

• Mono and multicenter cohorts show that although urodynamic studies do not unequivocally predict outcomes of pharmacological or surgical treatment, treatment results are however shown to be better predicted in patients who have had objective urodynamic tests.

Recommendations (grade C)

• Evidence that urodynamics improves outcome is limited, but nevertheless the committee recommends that all elderly male patients with incontinence should receive a complete urodynamic evaluation in order to understand the problem

• The committee recommends that clinical parameters are investigated which correlate with urodynamic results such as BOO or DO, in order to achieve better treatment outcome for LUTS in men, without invasive urodynamics.

4. POST-PROSTATECTOMY INCONTINENCE

a) General

After prostatectomy, a noticeable number of patients suffer from UI. The reported incidence following surgery varies widely and is believed to be related to patient age, pre-surgery lower urinary tract function, benign or malignant prostatic disease and the type of surgery and furthermore depends on the definition of incontinence that is applied. Approximately 10-14% of patients, suffer incontinence 2-5 years after radical prostatectomy. [Penson,D.F. 2005] A prospective survey study on 1201 patients and 625 partners, of outcome after treatment for prostate cancer, showed that UI was at its worst 2 months after surgery and then improved in most patients. Factors that were associated with worse UI were, older age, black race, and a high PSA score at diagnosis. Patients in the brachytherapy group reported significant deterioration in ‘urinary irritation’, symptoms suggestive of BOO and UI, compared with baseline. UI after brachytherapy was reported by 4 to 6% of patients at 1 to 2 years after treatment. [Sanda,M.G. 2008] Comparative studies indicate that UI is the most incident adverse effect of radical prostatectomy. [Wilt,T.J. 2008] Understanding of prostatic-vesical anatomy and the pelvic floor, and meticulous surgical technique, are of importance in preventing UI.
Using accumulated data from 573 patients, reported in 8 articles from 1978 to 1997, which collated urodynamic evidence for UI following surgery for ‘BPH’ or prostatic cancer, it was suggested that the most common aetiology was isolated sphincter weakness, followed by sphincter weakness plus DO, and also DOI and or reduced compliance alone. Thus, a blanket assumption that there is a single cause of the UI would be wrong in two-thirds of men after radical prostatectomy. Furthermore also obstructed voiding is reported in these series. [Kondo, et al 2002; Porena, M. 2007; Ficazzola, M.A. 1998; Huckabay, C. 2005]

UI was more prevalent in men who were obese and physically inactive (59% UI) after prostatectomy. The best outcomes were in men without obesity and physically active (16% UI). Pre-prostatectomy physical activity and weight (BMI) may be important factors in UI after radical prostatectomy and the return of continence. [Wolin, K.Y. 2010]

Preoperative DO was not associated with worse post radical prostatectomy UI outcomes, or increased incidence of UI. Monocenter observations suggest that even if DO is present in men with USI after radical prostatectomy they may be considered for a male sling procedure. [Ballert, K.N. 2010]

Conclusions:

- Many case series show that sphincter weakness is the most common aetiology of male urinary incontinence after prostatectomy. However case series and reviews show that other lower urinary tract dysfunction besides sphincter incompetence plays an incident role in post prostatectomy urinary incontinence.
- Case cohorts indicate that detrusor overactivity before radical prostatectomy is not an important indicator for the postoperative incidence of urinary incontinence, or for the outcome from surgical interventions to treat the urinary incontinence.

b) Transurethral resection of the prostate and Open Prostatectomy for benign disease.

Approximately 1% of patients who have undergone TURP suffer from post-prostatectomy incontinence. [Mebust, et al 1989] Das and his co-investigators [Das, A. 2001] showed that the role of urodynamic investigation in preventing post-operative incontinence before laser resection of the prostate may be marginal. Another large monocenter study showed that the incidence of post laser-prostatectomy incontinence is less than 1%. [Krambeck, A.E. 2010] A systematic review and health technology assessment did not show differences in the incidence of incontinence following various more or less invasive (non medical) interventions for ‘symptomatic BPH’. [Lourenco, T. 2008]

Kuo [Kuo, H.C. 2002] urodynamically evaluated 185 men aged from 55 to 91 with a mean of 75 years who had had variable LUTS after TURP which had been refractory to conventional treatments. He found that UI was present in 74 patients (40%) and that BOO and DO with impaired contractility (DHIC) were the most common findings associated with post-prostatectomy incontinence, followed by DO. Post-transurethral- prostatectomy incontinence is usually due to sphincter damage as a complication of prostatectomy, but may result from other causes, such as DO. Urodynamics showed no significant change in filling or voiding parameters when suburethral ‘male’-slings were implanted. [Wadie, B.S. 2010]

After HoLEP, 29 patients (16.2%) had de novo UI, most of which resolved within 1-6 months; 11 had SUI, 12 had UUI, and the remaining 6 had mixed UI. A lower MUCP, on baseline urodynamics, was found to be the independent predictor of de novo UI after surgery. [Cho, M.C. 2011]

Conclusions:

- Case series have concluded that urinary incontinence after prostatectomy may be attributed to bladder storage dysfunction and can exist in association with (neo-bladder neck) bladder outlet obstruction although the most prevalent cause is a lesion of sphincteric function.
- Retrospective studies have shown that urodynamic tests cannot predict which patient will develop SUI or detrusor overactivity (with or without urgency incontinence) after surgical treatment for benign prostatic obstruction.
- Studies have shown that urodynamic tests can identify the aetiology(ies) of urinary incontinence (or other lower urinary tract dysfunction) after surgical treatment for benign prostatic obstruction, however the predictive value for the outcome of subsequent treatment is unknown.

Recommendation (grade C)

- The committee recommends urodynamic testing when elderly male patients have urinary incontinence after surgical treatment for benign prostatic obstruction if further surgical or invasive treatment is planned.

c) Radical Prostatectomy and Radiotherapy

Is (invasive) urodynamic investigation of incontinence after radical prostatectomy necessary?

Sphincter weakness, neo bladderneck outlet obstruction, DO and mixed incontinence are contributing to post-prostatectomy incontinence. [Kuo, H.C. 2002; McCallum, T.J. 2001] These parameters can be only identified by urodynamics, which is considered by most [Sakamoto, K. 2001; Gomha, M.A. 2002; Yurkanin, J.P. 2001], but not all [Hindley, R.G. 2001], to be one of the main tools for investigating
UI after radical prostatectomy. In brachytherapy for prostate cancer, urodynamics may have some value for predicting which men might develop acute urinary retention or might require CIC after treatment when the prostatic edema has caused temporary retention. [Henderson,A. 2002] Castille et al prospectively assessed 229 men who were scheduled to undergo radical retropubic prostatectomy with preoperative urodynamics in an attempt to help physiotherapists predict postoperative incontinence. [Castille,Y. 2003] They observed that all men diagnosed as having DO or neo bladderneck outlet obstruction were incontinent 6 weeks after operation but had improved 4 months later. DO and neo bladderneck outlet obstruction were considered risk factors for postoperative incontinence.

Groutz et al [Groutz,A. 2000] found that USI was the most common urodynamical abnormality after radical prostatectomy (73 patients, 88%), followed by DO in 6, neo bladderneck outlet obstruction in 1 impaired detrusor contractility in 1, and normal findings in 2. Of 73 men diagnosed as having USI, 27 suffered from pure urodynamic USI, and the remaining 46 had concomitant bladder disorders such as impaired detrusor contractility (22 men), neo bladderneck outlet obstruction (14 men) or DO (10 men). Huckabay et al evaluated 60 men and found that twenty-four (40%) men had DO with 8 (13%) also having DOI. Only one patient had impaired bladder compliance. All men had USI, but 21 (35%) men demonstrated it only after removal of the (7F) urethral catheter. For men leaking with and without the urethral catheter, the respective abdominal LPP was significantly different, 86.3 and 67 cmH2O, respectively. The men who leaked only in the absence of the urethral catheter had significantly higher abdominal LPP measurements. [Huckabay,C. 2005] Although SUI was one of the predominant symptoms of incontinence following radical prostatectomy, half of patients had USI together with UUI or decreased bladder compliance. Co-existing detrusor dysfunction had to be taken into consideration, as well as ISD, in order to properly treat persistent post-prostatectomy incontinence. [McCallum,T.J. 2001; 130 Lai,H.H. 2009] Male SUI is mainly caused by sphincter lesions after retropubic radical prostatectomy (RRP). After RRP, two-thirds were continent after 6 months, whereas one-third still suffered from incontinence. MUCP and FPL in the SUI was significantly lower in comparison with the continent group, accompanied by a characteristic UPP configuration. Postoperative urodynamics after 6 months may be predictive for persistent incontinence at the bladder, sphincter, and both. [Bentzon,D.N. 2009] Based on a study of 29 men with incontinence after radical prostatectomy, it was concluded that abdominal LPP is relatively poorly associated with incontinence severity and, therefore, has limited clinical value in the urodynamic evaluation of post-prostatectomy incontinence. [Twiss,C. 2005] Another study also investigated if abdominal LPP correlates with objective incontinence severity in patients suffering from post-prostatectomy SUI. There was only a weak inverse correlation between abdominal LPP and 24-hr pad weight which was not statistically significant. Age and time from prostatectomy did not significantly correlate with abdominal LPP. The abdominal LPP was considered a relatively poor predictor of incontinence severity and, therefore, has limited clinical value in the urodynamic evaluation of post-prostatectomy incontinence. [Twiss,C. 2005] Several robot-assisted radical prostatectomy (RARP) series have reviewed the impact of the initial learning curve on perioperative outcomes. Outcomes between groups (cases 1-300, 301-500, and 501-700) were compared. Continence rates improved from 75% to 93% for cases 501-700 (p<or=0.05). Furthermore, significant improvement in continence rates between consecutive case groups was observed at all postoperative time points. [Frank,S.J. 2007]

Is (invasive) urodynamic investigation of incontinence after radiotherapy necessary?

There are few manuscripts reporting the effects of radiotherapy in those with prostatic cancer, and even fewer discussing the place of urodynamics. [Choo,R. 2002; Do,V. 2002] Henderson et al. [Henderson,A. 2002] assessed 100 patients with prostate cancer patients for brachytherapy with a minimum dose of 145 Gy. Prior to the treatment an unselected group of 57 of the 100 patients had been evaluated urodynamically. Patients with larger prostate volumes (> 35 mL) and or with (UDS confirmed) BOO were more prone to problems after brachytherapy. The authors concluded that urodynamics might have a role in the selection of treatment for men with prostate cancer. Beekman et al found in 204 patients that high PVR (> 100 mL) is associated with slower resolution of voiding symptoms, prolonged (more than 3 days) catheter dependency, and increased post-brachytherapy surgical intervention for BOO. [Beekman,M. 2005] Also Wehle et al suggested that the combination of urinary flow rate, prostate volume, postvoid residual urinary volume, combined with the American Urological Association symptom score helped to identify patients with underlying voiding dysfunction. Urinary flow rate was a statistically significant predictor of genitourinary tract morbidity after brachytherapy for localised prostate adenocarcinoma. [Wehle,M.J. 2004]

Men after brachytherapy were, in a monocenter retrospective cohort, reported to have a relatively high incidence of DO, prostatic and urethral strictures and prostatic urethral stones. [Blaivas,J.G. 2006] A survey amongst 625 (responding) patients that assed the QoL following radical prostatectomy, high dose external beam radiation therapy and brachytherapy iodine implantation as monotheapies for localized prostate cancer showed that a better rate of urinary continence was maintained in those who underwent radiation based therapies. Better bowel function, lesser sexual function and
less urinary irritation was reported in those who underwent surgery. [Frank,S.J. 2007]

**Conclusions:**

- Case series and reviews show that the main cause of urinary incontinence after RRP is sphincter weakness and that detrusor overactivity contributes in only a small proportion of those patients.
- Case cohorts show that higher maximal urethral closure pressures or abdominal leak point pressures, indicating greater urethral sphincter resistance is not of utmost clinical relevance.
- UI after RRP will improve with time. A study concluded that postoperative urethral pressure profile after 6 months may be predictive for persistent incontinence.

**d) Artificial urinary sphincter and male sling**

Gomha and Boone [Gomha,M.A. 2002] treated 86 patients who were incontinent following prostatectomy with implantation of an artificial urinary sphincter (AUS) and assessed whether or not prior radiation affected surgical outcomes in those who had or had not had radiotherapy. Urodynamic study prior to artificial sphincter implantation revealed that DO was much more prevalent in group with radiation (26%) than in group without radiation (5%). In spite of this, post-operative urgency with or without urgency incontinence was found in similar proportions of the 2 groups, and similar proportions wore to 1 pad a day to protect against their incontinence. They concluded that the pre-operative urodynamic finding of DO did not predict outcome in this group. Similarly, Thiel and co-workers retrospectively re-viewed 86 patients and concluded that patients with post radical prostatectomy USI, plus DO, low compliance, or decreased MCC and FSF have identical outcomes after AUS implantation to those just with USI. [Thiel,D.D. 2007]

The presence of adverse preoperative UDS features as: poor bladder compliance <10 mL/cm, the presence of DO, early sensation of bladder filling at <75 mL, an early FDV at <125 mL, reduced MCC of <200 mL, low abdominal LPP of <30 cm H(2)O, low peak flow of <10 mL/s, low detrusor pressure at peak flow of <10 cm, or a bladder contractility index of <100, did not negatively affect the post-AUS daily pad use or the continent rate after AUS implantation in patients with post (radical) prostatectomy UI. [Lai,H.H. 2009]

Recent publications on the male suburethral sling show good continence cure rates in post prostatectomy cohorts. A monocenter retrospective study reported that, when post-hoc criteria are applied, cure rates were lower in men that used more pads before sling implant. [Bochove-Overgaauw,D.M. 2011] Also, Ullrich & Comiter evaluated 22 patients urodynamically, at a mean of 25 months after a male sling procedure, and found that patients with postoperative retrograde leak point pressure < 50 cm H,O and DO were seen to be associated with failure. [Ullrich,N.F. 2004] The trans obturator -tape (TOT) for treatment of post-radical prostatectomy UI, was shown to be effective and well accepted by patients. The mean MUCP improved, which associated with cure, and a majority of patients in a small (n=20) uncontrolled single centre cohort was satisfied. [Rehder,P. 2007]

At 12-month follow-up of this treatment, with a larger group of patients (n=118), 73.7% of the men were cured and using significantly less pads, 16.9% were improved, and 9.3% were still incontinent. The detrusor voiding pressure, postvoid residual urine volume and maximal flow rates remained unchanged, while the VLPP improved significantly. [Rehder,P. 2010]

A concern of any procedure in treating men with UI after radical prostatectomy is whether the treatment induces obstruction and causes retention. A study to evaluate this with regard to the ‘male sling’ questioned whether this treatment eliminates UI without affecting the voiding. The VLPP improved significantly and the detrusor voiding pressure, PVR volume, and maximal and average flow rates remained relatively unchanged. At 3 and 6 months postoperatively, the Incontinence Quality of Life scores had improved significantly compared with the preoperative scores with a reduction in pad-use (from 5 to 1) and urine loss (780g before and 70g after). [Davies,T.O. 2009]

These studies confirm the earlier observations, that the fixed urethral resistance of the perineal male sling for the treatment of (post RRP) SUI in male patients, did not cause BOO or cause de novo voiding dysfunction. Average maximum flow rate did not change significantly nor was there a significant change in detrusor pressure at maximum flow rate, but the pad use, LPP and UI scores were significantly improved after sling surgery. [Ullrich,N.F. 2004]

**Conclusions:**

- Studies have not consistently concluded that urodynamic variables provide predictive value for treatment in male post prostatectomy incontinence.
- There is weak evidence to support urodynamic evaluation (for patients with a large prostate) before radiotherapy for cancer of the prostate.
- Studies have shown that urodynamic tests are needed to identify the aetiology of urinary tract dysfunction after surgical or radiotherapy treatment of prostatic carcinoma. However the predictive value of urodynamics for the effect of subsequent treatment is unknown.
- Leak point pressures and urethral pressures, measured in their various ways, are consistently reported to be improved after anti-incontinence treatment using different surgical techniques, and
their improvement is associated with cure or reduction of incontinence volume and or pads use.

- Most single centre reports conclude that urodynamic variables, used to evaluate voiding, do not show clinically significant change after suburethral sling procedures or artificial urinary sphincter implantation.

**Recommendations (grade B)**

- The committee recognised that urodynamic testing for incontinence after radical prostatectomy is not particularly important for the diagnosis of sphincter dysfunction (stress urinary incontinence) in patients with post prostatectomy incontinence. However, the committee recommends that urodynamic testing is considered in patients where other dysfunctions of the lower urinary tract (obstructed voiding, significantly reduced bladder compliance and or detrusor overactivity) cannot be excluded on the basis of signs and symptoms.

**Topics for research**

- The committee suggests research to find predictors for lower urinary tract dysfunction after treatment for benign prostatic obstruction or for prostatic carcinoma.
- The committee suggests research to improve the prediction of success (whether or not on the basis of urodynamic testing) of treatment for lower urinary tract problems that may follow treatment of benign prostatic obstruction or prostatic carcinoma.

5. NEUROLOGICAL LESIONS RELATED TO MALE INCONTINENCE

Several ailments or pathological conditions have been reported to be closely associated with incontinence, e.g., neurological diseases, prior radiotherapy, neurogenic DO, diminished bladder compliance, nocturnal enuresis, post-micturition dribble and terminal dribbling. [Kondo, et al.] A history of prostatectomy as well as the existence of BPE in combination with one of the here before mentioned conditions may be a diagnostic challenge. Nocturia has a variety of potential causes and was shown to have high impact on bother score, strong associations with poor health and other LUTS. Nocturnal polyuria (NP) is a predominant cause of nocturia. Principal causes for nocturia were global polyuria in 17%, NP in 33% and small functional capacity <250 mL in 16.2%; 21.2% had mixed forms of NP and reduced bladder capacity and 12.6% suffered from other causes. [Klingler,H.C. 2009]

a) **Nocturnal enuresis**

Nocturnal enuresis in adult males is rather rare. Sakamoto and Blaivas reported, in a tertiary care practice, important interesting observations based on data of over 3000 patients referred for the evaluation of LUTS. [Sakamoto,K. 2001] They found that 8 of 3277 patients (0.02%) had adult onset nocturnal enuresis without daytime enuresis. All these patients were male, with a mean age of 63 years (48 to 80 years) and all suffered from BOO with mean maximum urinary flow rate 8.5 mL/s, mean IPSS 12.6, and mean PVR urine 350 mL (50 to 489 mL). The authors identified hydronephrosis in 5 of the 8 patients, a bladder diverticulum in 3/8, vesico-ureteric reflux in 4/8 and low bladder compliance in 4/8. Five of the 8 underwent TURP resulting in improved symptoms. Thus BOO is one of the distinct pathologies that can provoke nocturnal enuresis with variable LUTS, but it is not the only pathological factor. For example, Hunsballe [Hunsballe,J.M. 2000] found more delta activity in electroencephalography among adult primary enuresics compared to normal controls. Therefore, invasive urodynamics may be justified in such patients, because it is the only way of reliably identifying BOO.

Nocturnal enuresis plagues nearly 28% of patients with a neobladder. Indeed, 25 of 30 patients (83%) who underwent the Stanford pouch ileal bladder had nocturnal enuresis 1 year later. [Uygur,M.C. 2000] Patients older than 65 years are at greater risk because of the physiological increase in LUTD nocturnal diuresis associated with aging. An orthotopic neobladder produces variable LUTD including both failure to empty the bladder and failure to store urine. The urodynamic behaviour depends on the type, length, and configuration of the bowel segment used. [Steers,W.D. 2000] There may be overdistension, elevated PVR, lack of sensation, reduced MUCP, or more frequent and higher-pressure DO. [El Bahnasawy,M.S. 2000] The intestinal overactivity in a neobladder resembles bowel peristalsis. [Sakakibara,R. 2007]

El-Bahnasawy et al studied urodynamically 50 enuretic men at least 1 year after a radical cystoprostatectomy and ileal neobladder and compared them to 17 men with only occasional enuresis and 50 men without enuresis after similar surgery. Both enuretic groups had significantly higher residual urine volumes, higher pressures at mid-capacity and at maximum enterocystometric capacity, higher amplitude of contractions and lower compliance than continent men. Men with occasional enuresis also had a significantly higher frequency and duration of DO contractions and lower maximum urinary flow rates than continent men. [el-Bahnasawy,M.S. 2005]

Urodynamic investigation is important to establish the diagnosis and select treatment, although one group suggested that nocturnal enuresis or nocturia could be simply alleviated by waking up at least twice per night to void. [Uygur,M.C. 2000]

**Conclusions**

- Epidemiology shows that non-urologic causes for nocturia are prevalent and nocturnal polyuria can
b) Stroke

Stroke is a common and well-known cause of enuresis and LUTD in the older population. The predominant symptoms are urinary frequency, urgency and UUI (including night-time incontinence) while DO is the most common finding on urodynamics. [Marinkovic,S.P. 2001] In patients after a stroke, incontinence (or LUTD in general) is a serious threat for Qol. [Edwards,D.F. 2006] Post-stroke UI is a predictor of greater mortality at 1 week, 6 months and 12 months after stroke. However, patients who regain normal bladder control in the first week have a comparable prognosis as the patients who do not have micturition disturbances following stroke. [Rotar,M. 2011]

Because DO in male stroke patients with LUTD is prevalent, conservative or pharmacologic treatment is often instituted without prior urodynamic investigation. An expert summary of the literature suggested that the size and the site of the stroke does have an influence on urological findings. [Badlani,G.et al] Experts agree that simple tests such as uroflowmetry and, especially, PVR urine assessment (by ultrasound) are however useful, since elevated residual urine is to be expected in a significant proportion of these patients, and its evaluation can improve caregiving and Qol. [Chan,H. 1997; Teng,C.H. 2005] Cystometry has limited value: the prevalence of DO in older people is quite high even in the absence of stroke (perhaps 10% in women and 25 to 35% in men). Therefore the observation of DO alone may not be helpful although the finding of other LUTD, such as obstructed voiding, is.

The prevalence for isolated UI, on admission, was 12.4%, for isolated faecal incontinence 7.6% and for double incontinence 33%. At discharge, the prevalence had decreased, to 8.1% for isolated UI, 4.9% for isolated faecal incontinence and 15.1% for double incontinence. Double incontinence was more prevalent than isolated incontinence in patients after stroke during post-acute rehabilitation. [Kovindha,A. 2009]

Evaluation of the stroke type may be helpful in the determination of the type of urinary dysfunction and in deciding the appropriate bladder management: the ischemic group was reported to have DO (70.7%), underactive detrusor (29.3%), and hemorrhagic group has DO in 34.6%, and underactive detrusor in 65.4%. (P = 0.003). [Han,E. 2007]

In patients with stroke and voiding dysfunctions, UDI can be performed to identify the presence of BOO or dysfunctional voiding. Voiding dysfunction is also a significant problem in patients with head injury. NDO is seen in patients with injuries above the pontine micturition centre. The voiding abnormality has good prognosis and resolves spontaneously. [Singhania,P. 2010] Among the 36 patients with stroke and DO, 25 patients (62.5%) had DO without sphincter dyssynergy and 11 (27.5%) had DO with sphincter dyssynergy. UDS is a useful tool to assess and manage the bladder following stroke with UI. No significant correlation was found between UDS findings and site of (stroke) lesion in a retrospective single institute study with 18 women and 22 men. [Gupta,A. 2009] In a urodynamic study of bladder dysfunction in idiopathic normal pressure hydrocephalus (iNPH), LUTS were seen in 93% of the patients, with storage symptoms (93%) being more common than voiding symptoms (71%); and urinary urgency (overactive bladder) (64%) frequency (64%) being more common than UI (57%). Although the majority of patients had normal bladder volume at the first sensation (mean 134 mL), bladder capacity was small (mean 200 mL) and DO was seen in 95% of patients. [Sakakibara,R. 2001]

Conclusion:

• Detrusor overactivity and or underactive detrusor can be present in patients with stroke or other neurological lesion.

• In ambulatory male patients, after stroke, with voiding dysfunctions, careful urodynamic study can be offered to identify the presence of detrusor overactivity, or static (BPO) or dynamic (dyssynergic) bladder outlet obstruction.

c) Parkinson’s disease

Parkinsonian diseases are known to significantly influence bladder function (see section D.V.6). LUTS may be the first sign, especially nocturia in male patients. Large capacity bladder (when discovered during urodynamic testing for LUTS) may also be a sign of Parkinsonism. [Purohit,R.S. 2008; Williams,D.R. 2009; Blackett,H. 2009; Cheon,S.M. 2008] DOI is common in male patients with Parkinsonism [Defreitas,G.A. 2003], but urodynamic findings differ in different diseases of this group. [Sakakibara,R. 2001] Defreitas et al carried out a retrospective review of the urodynamic results in men with DO due to BOO (22 patients) and compared them to men (39 patients) and women (18 patients) with Parkinson’s disease. Patients with Parkinson’s disease had a significantly lower median volume at first detrusor contraction than those with non-neurogenic DO. The percentage of urgency incontinence was significantly lower in patients without Parkinson’s disease than in men and women with it (9.1% versus 53.8% and 55.6%). No statistically significant correlation between the duration or the severity
of Parkinson’s disease and UDS parameters was found. [Defreitas,G.A. 2003] The most prevailing urinary symptom in Idiopathic Parkinson’s Disease was nocturia (77.5%) followed by urgency (36.7%) and frequency (32.6%). Urodynamic tests revealed neurogenic DO in 33 patients (67.3%), underactive detrusor in 6 patients (12.2%), and 10 (20.4%) patients with normal detrusor function. However, no significant correlations between any of the urodynamic parameters and disease severity was found. The urinary (storage) symptoms manifested urodynamically as neurogenic DO are more common in IPD patients than voiding symptoms. [Ragab,M.M. 2011]

Urinary dysfunction, manifested primarily as storage disorders with subclinical voiding disorders and normal anal-sphincter electromyography, occurs in early and untreated PD patients. Urodynamic studies showed abnormal findings in the storage phase in 84%, with DO and increased bladder sensation without DO in 58.0% and 12.0% of patients, respectively. In the voiding phase, underactive detrusor, impaired urethral relaxation such as detrusor sphincter dyssynergia, and BOO were present in 50.0%, 8.0% and 16% of patients, respectively. In patients with both storage and voiding phase abnormalities, DO plus underactive detrusor was the most common finding. [Uchiyama,T. 2011]

One study investigated the LUTS and urodynamic and cystometric findings in PD, dementia with Lewy bodies (DLB), and Alzheimer disease (AD). Urgency and urgency incontinence suggest DO, which was more prevalent in dementia with Lewy bodies than in PD and Alzheimer disease, whereas mean VV, free flow, MCC, and detrusor pressure were similar in the groups; DO was seen in 92% of the patients with DLB, 46% of the patients with PD, and 40% of the patients with AD. [Ransmayr,G.N. 2008]

**Conclusions:**

- Detrusor overactivity and detrusor underactivity, with or without urethral sphincter dyssynergia, are commonly found in male patients with Parkinson’s disease.

- Bladder outlet obstruction is not related to Parkinson’s disease. For male patients with Parkinson’s disease and voiding dysfunction, urodynamic testing is recommended to select appropriate treatment strategy.

d) Diabetes Mellitus (DM)

Men with DM and LUTS can present with varied urodynamic findings, apart from the classic sensory or motor cystopathy. Urodynamic studies showed delayed first sensation (>250 mL), increased capacity (>600 mL) underactive detrusor, DO, high postvoid residual urinary volume (more than one third of capacity), and BOO (Abrams-Griffiths number >40) in 23.1%, 25.0%, 78.8%, 38.5%, 65.4%, and 28.8% of the men, respectively. [Bansal,R. 2011] Kebapci re-evaluated the urodynamic findings of LUTD in type 2 diabetic patients describing patient characteristics and concomitant chronic complications: LUTDD was present in 74.07% of men. The group defined ‘diabetic cystopathy’ as diminished sensation of filling and significant postvoid residual and observed that in 50% of their patients, also BOO, (25%) and DO (25%) were observed. ‘Diabetic cystopathy’ (in this specific definition was the most frequent finding. Ageing, duration of diabetes, worse metabolic control, PVR >100 mL, cardiac, oesophageal and gastric parasympathetic autonomic neuropathies, retinopathy, and microalbuminuria provided a means to predict LUTD, and select patients for urodynamics. [Kebapci,N. 2007]

It was observed in a monocenter retrospective case control study that patients with DM who undergo radical cystoprostatectomy take longer to regain daytime and, even more so, night time continence than non diabetic patients. [Kessler,T.M. 2008]

There is a relatively low prevalence of BOO in diabetic patients with prostate enlargement and LUTS. Of the 50 patients in the study, 23 (46%) had BOO. There was no correlation between the IPSS, uroflowmetry, post-voiding residual urine or prostate volume and the presence of BOO (p > 0.05). Non-invasive tests did not allow the identification of LUTD and only urodynamic evaluation is able to determine symptom aetiology. [Dib,P.T. 2008]

**Conclusions:**

- Clinical cohort studies show that men with diabetes and lower urinary tract symptoms can present with a variety of urodynamic findings, including detrusor overactivity, underactive detrusor and bladder outlet obstruction.

- Uncontrolled cohort studies indicate that non-invasive tests are less sensitive to relevant abnormalities in comparison with urodynamic evaluation and investigators have concluded that urodynamic investigation is necessary when lower urinary tract symptoms arise in patients with diabetes mellitus.

e) Recommendations for urodynamic investigation for men suffering from nocturnal enuresis, stroke, Parkinson’s disease or DM

**Conclusions (level of evidence 2/3)**

- Nocturnal enuresis in adult males is rare but problematic, and it is associated with many possible aetiologies.

- Nocturia, nocturnal enuresis or lower urinary tract symptoms may be the first, or an early sign, of Parkinsonism in elderly male patients.

- Lower urinary tract dysfunction in patients with Parkinsonism can be the result of detrusor overactivity, (benign prostatic) bladder outlet obstruction,
Recommendations (grade B/C)

- The committee recommends that urodynamic evaluation should be conducted in all cases of nocturnal enuresis in adult males.
- The committee recommends that urodynamic evaluation should be performed in patients with Parkinsonism. There should be flowmetry and postvoid residual assessment in all cases and invasive testing when abnormalities are observed in flowmetry and postvoid residual assessment.
- The committee suggests that investigators should be alert for large capacity bladder and/or underactive detrusor (or large residual without significant bladder outlet obstruction) as an early sign of Parkinson's disease.

III. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

1. INTRODUCTION

Neurogenic LUTD is not precisely defined. The International Continence Society has defined 'neurogenic detrusor overactivity' (NDO): 'when there is a relevant neurological condition'. [Abrams,P. 2002] The specificity and sensitivity of signs and symptoms to confirm a relevant neurological condition are unknown, which is more or less acknowledged in the ICS standard above. However, for some of the urodynamic outcomes, also mentioned in this standard, a confirmation of ‘clinically normal neurology’ is required. In a recent EAU guideline the term 'neurogenic LUTD' is referred to as 'secondary to confirmed pathologic of the nervous supply' and a precise description of the advised neuromuological examination is provided. [Stohrer,M. 2009] Neurogenic incontinence may be described by terms such as, ‘Reflex’ or ‘overflow incontinence’. These terms are not currently recommended by the International Continence Society nor used in the EAU guideline but they will also be discussed below, together with other relevant topics for this group of patients which are not covered elsewhere in this chapter.

2. WHAT IS USUALLY EVALUATED?

Because not all patients with neurogenic conditions develop LUTS or have abnormal urodynamic findings, a specific understanding of the dysfunction in each individual is a prerequisite for the correct choice of therapy. The aim of the diagnostic tests is to describe the (dys)function of the bladder, the urethra and the pelvic floor, their coordination during filling and voiding, and their influence on other conditions (e.g. autonomic dysreflexia) or organ systems (e.g. renal function).

Except in a few diseases where empirical, conservative therapy can safely be instituted, or where LUT dysfunction is predictable (e.g. post-stroke), urodynamic investigation is usually deemed to be required on the basis of clinical practice guidelines and expert reviews. Urodynamics is advised to provide the understanding of the situation on which rational treatment must be based. Even when empirical therapy is instituted without urodynamics, experts’ opinion usually agrees on the basis of good clinical practice which is that the patient must be carefully monitored to determine whether and when urodynamics is needed. [Stohrer,M. 2009; McGuire,E.J. 2010]

A large proportion of patients with neurological conditions show anatomical abnormalities that involve the LUT, especially those born with abnormal neurology (MMC-see in children section of this chapter), and do have congenital relevant ‘end organ (LUT)-sequelae' that can be demonstrated by imaging. Videourodynamics is the test of choice usually advised on the basis of expert opinion when relevant anatomical information is needed and relevant to establish treatment. [Stohrer,M. 2009]

3. SPECIAL TESTS

In patients with spinal cord injury (as a result of a trauma in later life) the detrusor and its innervation can be assumed to have developed normally (unless there was a positive history of urologic or other relevant abnormalities), before the injury. [Yoo,P.B. 2011; Kennelly, M.J. 2010]. Also, it has e.g. been shown that urethral sphincter relaxation in persons with dyssynergic activity can be improved or normalized. [Huang,Y.H. 2008]

Ice water (bladder cooling) test is sometimes used in an attempt to identify neurogenic DO (see section C.V.1.e: provocative manoeuvres) or to demonstrate the integrity of the detrusor muscle function and or its innervation. The clinical relevance of the ice water test is however undetermined and in patients with high level spinal cord injury the test can cause autonomic dysreflexia. [Chancellor,M.B. 1998; Huwyler,M. 2007]

One channel cystometry is reported to be feasible and reliable because patients with complete spinal cord injury usually do not generate much (abdominal or other) muscle activity below the lesion level and intravesical pressure adequately represents detrusor (relaxation or) activity. [Wyndaele,J.J. 2009]

4. NEUROGENIC DETRUSOR OVERACTIVITY INCONTINENCE

DO in association with neurological disease, may lead to UI. Observed during urodynamics, this type of incontinence is termed neurogenic DOI. The corresponding clinical sign or symptom is however variable: if the DO is accompanied by sensation (desire to void) it might be termed UUI; frequently however any sensation is absent, and so the term urgency in-
continence is an incorrect description of the situation. For this reason the term ‘reflex incontinence’ was introduced [Abrams 1988], implying uncontrolled emptying of the bladder without sensation. This term is no longer recommended. [Abrams 2002]

When a selection of symptomatic patients with NDO was analysed retrospectively, it was observed that patients with incomplete lesions had similar amplitudes of detrusor contraction and that also leakpoint pressures did not differ from patients with complete lesions. The authors consider it therefore relevant to perform UDS in patients with incontinence who have incomplete SCI. [Moslavac,S. 2008]

5. DETRUSOR-SPHINCTER DYSSYNERGIA

Neurogenic DO is often accompanied by detrusor-sphincter dyssynergia: a neurogenically determined failure of pontine coordination of detrusor and bladder outlet. In DSD the failure of the urethral sphincter and or the pelvic floor to relax completely and sustained, when the detrusor contracts, causes a dynamic type of BOO which may not only prevent complete bladder emptying, but can also lead to chronic and or intermittent high detrusor pressures, during bladder filling and or attempted voiding or incontinence. If high intra -detrusor pressures are present for prolonged periods in daily life, renal function is endangered (see the following subsection on ‘overflow incontinence’).

6. LEAKAGE ASSOCIATED WITH CHRONIC RESIDUAL/ RETENTION OF URINE (‘OVERFLOW INCONTINENCE’)

‘Overflow incontinence’ is another term that is no longer recommended. [Abrams 1988] It meant continuous or intermittent (-stress ‘like’) leakage from a constantly overdistended bladder. [Abrams 1988] However neither what constitutes ‘overdistended’ nor the cause of the leakage are defined by the term ‘overflow incontinence’. The presenting symptom is usually characterized by small amounts of incontinence, exacerbated by increased abdominal pressure, together with an inability to empty the bladder by voiding. Whilst incontinence appears as a problem of lower urinary tract storage function, ‘overflow incontinence’ originates from a dysfunction of voiding. Overflow incontinence can exist in combination with BPE and BOO but also exists in conditions with relevant neurologic pathology. Incontinence due to neurogenic underactive detrusor (or acontractility) or DSD, with incomplete emptying, and neurogenic incomplete voiding with incontinence, are clinical (urodynamic) descriptions and have not been officially defined.

During urodynamics a frequent observation is of a bladder with low compliance and little or no detrusor activity; as the bladder is filled, the detrusor pressure rises because of the poor compliance, until it reaches a value sufficient to overcome urethral resistance and open the urethral sphincter; dribbling leakage then ensues. Clinically, the most important variable is usually reported to be the detrusor pressure at which leakage occurs, the detrusor leak point pressure (DLPP). If this pressure is elevated, and if similar pressures are attained during continual leakage in daily life, then renal function is endangered because the constantly high detrusor pressure hinders outflow of urine from the ureters into the bladder. Conventionally, DLPP’s of 40 cm H₂O or more are believed to be unacceptable. There is evidence (mostly from paediatric studies with children with meningomyelocele) that upper urinary-tract deterioration is more probable when DLPP is elevated above that 40cmH₂O. [McGuire,E.J. 1996; Tanaka,H. 1999; Kurzrock,E.A. 1998] However, the evidence for a cut-off at 40 cm H₂O seems less clear and an expert opinion appears to introduce ‘as low as reasonably achievable’ and a ‘safe’ detrusor pressure of below 20 cmH₂O, over the entire ‘daily’ volume range, when CIC is part of the treatment, is advised. [McGuire,E.J. 2010]

7. REPRODUCIBILITY AND RELIABILITY OF TESTS

Since many patients with NLUTD have severe sub-pontine neuropathy, the influence of the emotional (limbic) nervous system on lower-tract function is reduced or eliminated; thus, urodynamic observations may be less influenced by the test circumstances than those made in individuals with an intact nervous system. Nevertheless, the test conditions (e.g. the rate of filling the bladder) do influence the results, and should be chosen carefully. [Homma et al 2002] Some advocate ambulatory monitoring to reduce the variability of filling cystometry. [Pannek,J. 2009] However, tests of longer duration with natural filling, did not relevantly assist in the diagnosis and selection of treatment in patients with SCI in a monocenter prospective comparison. [Martens,F.M. 2010]

8. DOES URODYNAMIC TESTING HELP TO SELECT (OPTIMAL) TREATMENT?

The aims of therapy for NLUTD are to achieve the most physiological filling and voiding conditions possible, as well as a management situation acceptable to the patient in daily life. Long periods of elevated detrusor pressure during bladder filling or (abnormally prolonged) voiding put the upper urinary tract at risk. [McGuire,E.J. 1996; Tanaka,H. 1999; Kurzrock,E.A. 1998]. The primary aim of therapy in patients with such problems is conversion to a low pressure bladder during filling, [Stohrer,1994; Rivas, D.A. 1995; McGuire,E.J. 2010] achieve continence, and to manage incomplete emptying due to (medically induced) underactive detrusor or detrusor acontractility, with CIC. [Stohrer,M. 2009]

Adequate management depends on whether the detrusor is overactive or has reduced compliance, and only urodynamic testing can answer those questions unequivocally. Timely and adequate diag-
nosis is of paramount importance for the patient's Quol, as well as for safety. [Bomalaski,M.D. 1995; Cardenas,D.D. 1995] There is expert agreement that urodynamic investigation is essential to monitor the effects of any treatment and in the follow up of any sequelae of the disease and its management. Urodynamics is certainly needed to document the effects of new treatments or management strategies for patients with NLUTD. But changes in urodynamics do not always relate to clinically relevant improvements in these patients. [Huwyler,M. 2007; Pannek,J. 2009; Kabay,S.C. 2008] A retrospective study shows with 80 SCI patients and a minimum follow-up of 5 years, that it is possible to manage continence and preserve (100% of) upper tracts with ultrasound monitoring of the kidneys and repeated UDS. [Nosseir,M. 2007] Another retrospective observation indicates, in a series of 200 children with various types of NLUTD, that the intensity (frequency) of urodynamic follow up can be adapted according to the estimation of the risk for upper tract deterioration on the basis of urodynamic parameters achieved at a baseline. [Wang,Q.W. 2006]

**Conclusions (level 3)**

- There is expert agreement on the basis of a large number of case series that urodynamic testing is of great relevance to establish the management and to achieve the best long term clinical outcome in patients with neurogenic lower urinary tract dysfunction.
- On the basis of expert opinion, videourodynamic evaluation is necessary when anatomical information is deemed clinically relevant.
- Case series indicate that it is possible to monitor patients without anatomic abnormalities of the lower urinary tract (especially adult age spinal cord injury) with cystometry and ultrasound of the upper tract.
- No specific reports about the optimal frequency and techniques of follow-up urodynamics in patients with neurogenic lower urinary tract dysfunction exist.
- No conclusive evidence exists about the predictive value towards (the outcome of) treatment with regard to ice water testing, or of ambulatory monitoring of patients with neurogenic lower urinary tract dysfunction.
- Some evidence from centres of excellence indicates that ‘simple, one channel, cystometry’ is feasible and reliable in the monitoring (follow-up) of a selected group of patients with complete spinal cord injury.

**Recommendations (grade B/C)**

- The committee recommends that patients with signs and symptoms of dysfunction of the lower urinary tract and relevant neurological abnormalities should receive urodynamic evaluation (including filling and voiding cystometry), if initial treatment will be affected as a consequence of the urodynamic diagnosis, or if ‘simple’ first line diagnosis and management have been unsuccessful.
- The committee recommends that at least at a baseline, to establish the state and function of the lower tract in patients with neurogenic lower urinary tract dysfunction, videourodynamic evaluation is indicated if relevant anatomical abnormalities are to be expected.
- The committee recommends that the frequency of testing and the techniques applied in the follow-up of patients with neurogenic lower urinary tract dysfunction be critically analysed and optimised, and to develop guideline recommendations on the basis of those analyses.
- The committee recommends that urodynamic testing in patients with neurogenic lower urinary tract dysfunction is done with special attention to the specific needs of the patients. It is highly preferable that all professionals involved are specifically trained for that purpose.

**Recommendations for research:**

- Comprehensive urodynamic testing should remain an integral part of the evaluation of new therapies and management strategies for neurogenic lower urinary tract dysfunction whether conservative, medical or surgical. The first goal of this should be to monitor the safety of the (developed) approach for the patient and the secondary goals of this urodynamic testing should be the efficacy outcomes (preferably on predefined urodynamic criteria).
- Specific urodynamic diagnosis categories and diagnostic techniques need to be developed to quantify detrusor sphincter dyssynergia and neurogenic underactive detrusor.

### IV. PATIENT EVALUATION: CHILDREN

#### 1. INTRODUCTION

The indications for urodynamic evaluation in children are usually neurological, anatomical and or functional abnormalities, with the types of studies to be performed being based on the presumed underlying pathological conditions rather than on the presenting symptoms.

Many of the conditions for which urodynamics is employed in children involve anatomical and or neurological abnormalities, in which LUT dysfunction is variable, and may be multifaceted and unpredictable on the basis of clinical signs and symptoms. UI in children is relatively more frequently seen (compared
to adults), and in combination with other lower urinary tract (or lower bowel or pelvic floor) dysfunctions. On the other hand, urinary continence (and lower urinary tract function) are the result of a normal maturation process that can be delayed in some, and ‘cure’ (or ‘resolve’) without requiring medical intervention. Urodynamic testing is used to establish as clearly as possible the baseline situation where needed, so that changes as a result of treatment and/or growth can be assessed, and some guidance is obtained in the choice of treatment. The result of urodynamic testing will, however, not necessarily be the only deciding factor in this regard. Perhaps more clearly than in any other patient group, the aim of urodynamic studies in children is to provide objective knowledge about LUT function and dysfunction as well as to provide understanding to the care-giver and to the patient (and her or his parents). More extensively than in other ages, non-invasive urodynamic techniques are initially explored, not only because they are easier accepted and better applicable for children, but also to have comparable parameters during follow-up, and to exactly identify those children and clinical conditions that will benefit from further invasive exams. Essential are a meticulous and complete history, physical examination including clinical neurological testing and assessment by voiding diaries. Furthermore, initial ultrasonographic measures of bladder volume and wall thickness have been reported more and more as a useful tool in selecting who will need invasive testing. [Bower,W.F. 2010; Drzewiecki,B.A. 2011]

2. NEUROGENIC BLADDER DYSFUNCTION

a) Myelodysplasia

For the last 20 years, initial urodynamic studies, very early in the neonatal period, have been recommended for children with myelodysplasia, the basis being that they help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture. [Sidi,A.A. 1986] DO on cystometry, underactive detrusor during voiding, detrusor-sphincter dyssynergia (usually established on the basis of surface EMG), DLPP, and PVR are the key elements of a detailed urodynamic study that need to be considered. [McGuire,E.J. 1981; Bauer,S.B. 1984]

In an exhaustive review of the efficacy and reliability of urodynamic studies in newborns with myelodysplasia [McLellan 2003], of 24 studies analysed, 13 focused on EMG activity of the striated urethral sphincter or pelvic floor, 7 on bladder compliance and 2 on cystometric technique. Twenty-one studies had level of evidence 4, 2 had level 3 and one level 1 study was found. Nine of the 24 studies were performed at international sites and the remainder within the United States. The urodynamic patterns of normal detrusor function (66%), acontractile detrusor (33%), DO (57%), and detrusor compliance, as well as detrusor-sphincter dyssynergia (21%), DSD (37%) and sphincter denervation (60%) were similar, with little variability across comparable studies.

Van Meel et al have shown that repeating the IWT will increase its positivity. Combining the IWT and electrical perception threshold (EPT) will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurological cause of the dysfunction in children with idiopathic DO. In those with negative IWT’s, the EPT’s were significantly different between the neurological and not neurological patients, independent of the number of IWT’s done. [Meel 2007]

Bladder capacity was studied in a group of 506 myelodysplastic children [Palmer 1997] and found to conform to the formula: capacity in mL = 24.5 x (age in years) + 62. This formula for the increase in bladder size with age is 20% less steep than published age-related bladder capacities in neurologically unaffected children (e.g. 30 x age + 30). [Starfield 1967; Koff 1983] However, those children who did not have DO had a bladder capacity similar to normals. Because neurological impairment affects detrusor compliance, cystometric filling rate also influenced the measured capacity and compliance as noted in 3 studies that addressed this issue. [Palmer 1997; Kaefer 1997; Landau 1994] The lower the filling rate the greater the compliance and the larger the capacity.

Bladder augmentation alone without simultaneous anti-reflux repair is usually considered sufficient for the resolution of pre-existing vesico-ureteral reflux in children with NLUTD. Cystometry can be used to evaluate the effect of this treatment. A retrospective study by Juhasz et al in 2008 suggested that diverse GI segments used for augmentation had identical effects on the urodynamic results and the resolution of vesico-ureteric reflux. [Juhas 2008]

Several studies that evaluated the urodynamic result of bladder augmentation have been published. Significant increase in bladder capacity and compliance were achieved and maintained in the long term. [Lima 2008] A recent small mono-centre study, showed that preoperative urodynamics has some predictive value on the outcome of augmentation towards the relief of vesico-ureteric reflux in those children. [Soygur 2010] Follow up of affected children after early childhood is relevant, and urodynamic testing forms the basis for (surgical) management. [Almodhen 2007] A 20 years follow-up of 52 children demonstrates also that the early urodynamic diagnosis has been an adequate basis for the management of children with meningomyelocele in a single centre of excellence. [Thor 2011]

Rendeli et al retrospectively assessed the usefulness of urodynamic testing to determine the optimal timing of neurosurgery and to evaluate the evolution of bladder function in children with lipomeningocele. All patients underwent urodynamic testing
preoperatively and during extended follow up (mean 6.5 years, range 3 to 12). At the latest follow up, 65% of patients in the youngest group had improved urodynamic parameters compared to 33% of those 12 to 36 months old and 28% of those older than 36 months. Urodynamic evaluation and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele, and in diagnosing the onset of tethered cord. [Rendeli 2007]

A recent retrospective mono-centre study confirmed that urodynamic testing is relevant towards the outcome of neurosurgical interventions. [Maher 2009]

Six studies evaluated the relationship between level of the neurological lesion (on clinical examination) and LUT function, but none could predict a specific urodynamic pattern based on the level of the lesion. Sacral level lesions can be associated with an upper motor neuron urinary tract 'urodynamic pattern' just as readily as the expected lower motor neuron findings. [Dator 1992] Similar findings have been noted for children with thoracic or high lumbar level lesions where the incidence of sacral reflex sparing is 54%. [Pontari 1995]

Approximately 90% of children born with meningo-myelocele will have a normal upper urinary tract at birth. Over time, many children who have not received proactive urological care develop upper and/ or LUT deterioration. The deterioration is an acquired phenomenon secondary to the development or progression of various LUT hostility factors such as DO, reduced bladder compliance, detrusor-sphincter dyssynergia and/or high LPP. [Sidi 1986; Bauer 1984; Wang 2006] Despite the fact that only one study was at level 1, all urodynamic studies corroborated their reliability by reporting that the prediction of upper urinary tract deterioration on the basis of urodynamic testing is possible with 90% accuracy.

In 2006, Wang et al calculated a urodynamic risk score including a DLPP of >40 cmH\textsubscript{2}O, a bladder compliance of <9 mL/cmH\textsubscript{2}O and evidence of acontractile detrusor. They postulated that the selective use of urodynamic variables might be valuable for predicting the risk of upper urinary tract dilatation in children with neurogenic bladder-sphincter (or LUT) dysfunction. They found that decreased bladder compliance, increased DLPP and acontractile detrusor are the main urodynamic risk factors, and they reciprocally increase the occurrence and grades of upper urinary tract dilatation. The grades of renal dilatation are compatible with increases in relative unsafe cystometric capacity and the calculated urodynamic risk score. [Wang 2006] Severe bladder trabeculation in incontinent children with NLUTD is reported to be associated with BOO. [Khoury 2008]

Monocenter studies suggest that prevention of high bladder filling pressure (before upper tract dilatation is observed) is necessary and feasible even before any urodynamic diagnosis. [Dik 2006; Hopps 2003; Obara 2003; Jong 2008] However not all authors consider that prophylactic (high pressure prevention) treatment is beneficial, but all recommend periodic cystometry when new onset hydronephrosis, vesico-ureteric reflux or UI develops, the latter in children on a continence program already (i.e. CIC and/or drug therapy). [Bauer 1985; Geranio 1988]

When new onset UI, not related to urinary infection, nor easily treated by increasing current treatment regimens occurs, one study has shown that repetition of cystometry, urethral pressure profilometry, and EMG measurements, is helpful in management. [Teichman 1994]

When incontinence develops in spite of strict adherence to bladder and bowel continence programs, or when changes occur in leg function or sensation, or when the child experiences back pain or increasing scoliosis, a change in neurological impairment might be expected. 4 studies, noted that a considerable number of myelodysplastic children (40% to 61%) regardless of their neurological level have progressive neurological deficits as they grow up and reach puberty. [Dator 1992; Spindel 1987; Lais 1993; Tarcan 2001] Two of these studies noted changes particularly early in infancy, while a third study noted changes throughout childhood. Most clinicians agree that myelodysplasia is a dynamic disease process which changes as the child grows and that warrants constant vigilance of both the neurological picture and lower urinary tract function.

In 2006, Schulte-Baukloh et al evaluated prospectively the efficacy and tolerability of propiverine for treating neurogenic DO in children and showed that urodynamic testing has been relevant to evaluate the treatment. [Schulte 2006] This was recently confirmed in a longer follow up with urodynamic evaluation as an outcome. [Schulte 2011]

Renal transplantation in patients with myelodysplasia is a challenging issue. Persistent LUT dysfunction carries increased risks for the grafted kidney. Recent publications suggested that renal transplantation is a safe and effective treatment modality in patient with myelodysplasia when objective analysis of LUT function is done and the results are taken into account properly. Some series show cohorts where videourodynamic tests were performed on all patients preoperatively as well as postoperatively. Augmentation cystoplasty has been reported to be required in a proportion of children to achieve a low-pressure reservoir with adequate capacity [Ali-El-Dein 2004; Bilg 2008; Luke 2003] to optimize the LUT for transplantation.

b) Occult spinal dysraphism

Several series characterising the preoperative urodynamic evaluation of children with occult spinal dysraphisms have documented abnormalities in striated urethral sphincter function (denervation and/or detrusor-sphincter dyssynergia) in 20 - 35%.
of babies under 2 years of age with normal neurological examinations; thus emphasising the need for urodynamic testing in these children. [Keating 1988; Yip 1985; Satar 1997; Torre 2002; Hsie 2006; Kumar 2008] Six reports in older children revealed a greater correlation (70 – 90%) between an abnormal neurological examination and the likelihood of finding an abnormality on urodynamics. [Keating 1988; Hsie 2006; Kumar 2008; Satar 1995; Kondo 1996] A few studies demonstrated that between 10% and 20% of patients experience a loss in function immediately postoperatively (most of whom had abnormal LUT function preoperatively), and a variable number, usually inversely related to age, have improved sacral cord function on postoperative assessment 3 or more months after surgery. [Keating 1988; Satar 1997; Satar 1995; Kondo 1986] Two studies, both retrospective, revealed an efficacious response in EMG activity, with stabilisation or improvement in up to 60%, on postoperative urodynamic assessment when the dysraphic state was corrected before 2 years of age. [Keating 1988; Satar 1995] When children were first operated on after 2 years of age, urodynamic reports documented an additional 25 to 35% with progressive changes in urethral sphincter function with axial growth, very few of whom had a detectable change on physical examination. [Yip 1985; Satar 1995]

In a small prospective study in 2008, it was observed that children with meningomyelocele, as compared to closed dysraphism, tended to have more bladder dysfunction as exemplified on clinical history and urodynamic assessment. The authors concluded that a urodynamic study before neurosurgical intervention helped to identify the severity of bladder dysfunction in clinically overt cases and also identified LUTD in clinically silent cases. Evaluation after operation tended to show better outcome in children with closed dysraphism. The study also identifies deterioration in some patients with seeming clinical improvement. [Kumar 2008]

In 2007, Abrahamsson et al studied the urodynamic findings in a consecutively treated population of children with meningomyelocele after untethering of the spinal cord. Severe bladder dysfunction, moderate dysfunction and mild dysfunction were defined preoperatively. After untethering, 35% of the patients experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward, and 90% of those who were stable preoperatively continued to be stable postoperatively. [Abrahamsson 2007; Snodgrass 2010]

**Conclusions (level 2/3)**

- Retroactive and prospective studies have shown that the urodynamic diagnosis of (neurogenic) detrusor overactivity and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms.

- Many retrospective and prospective studies have shown that regularly repeated urodynamic testing in patients (children) with meningomyelocele or (occult) spinal dysraphism reveals clinical relevant results with regard to management and surgical or medical treatment.

- On the basis of expert opinion, videourodynamic testing is preferable above urodynamic testing without video, however the exact advantage (e.g. in repeated investigation) is not substantiated.

- Various studies have shown that lower urinary tract function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and physical growth)

- No studies have been published that are a help to determine the optimum of timing and frequency of urodynamic follow-up.

**Recommendations (grade B/C)**

- Comprehensive urodynamic testing is advised in all patients with myelodysplasia or (occult) spinal dysraphism throughout the entire life on a regular basis from earliest childhood.

- On indication, unscheduled urodynamic testing should be considered when relevant (lower body half and or urinary tract) clinical (or neurologic) signs or symptoms arise or when significant (surgical or medical) treatment changes have been instigated.

**Recommendations (grade C)**

- The advantages and disadvantages of the addition of video (x-ray) to urodynamic testing should be considered in children with myelodysplasia or (occult) spinal dysraphism on an individual basis.

- Timing and technique of urodynamic testing in patients with myelodysplasia or (occult) spinal dysraphism must be selected on an individual basis.

- To help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture, initial urodynamic studies, very early in the neonatal period, are recommended for children with myelodysplasia or (occult) spinal dysraphism.

- The committee recommends on the basis of expert opinion that anorectal function or dysfunction is simultaneously evaluated with urinary tract function in children with myelodysplasia or (occult) spinal dysraphism (see also the chapter on faecal incontinence).

c) Sacral agenesis

Sacrology agenesis, absence of the lowermost vertebral bony segments, is a lesion that can be missed in infancy because of its sometimes subtle clinical
manifestations, with generally no loss of lower extremity motor and sensory function, and the non-progressive nature of its pathophysiology. [Guzman 1983; Borrelli 1985] Urinary and/or faecal incontinence usually manifests at an older age when the child fails to toilet train on time. A careful physical examination noting flattened buttocks and a short gluteal crease is pathognomonic for the diagnosis. In 8 reports that provided enough data, urodynamic studies had been 90% accurate in delineating the neurological deficit, which cannot be predicted by the level of absent vertebrae. [Jabokson 1985; Gotoh 1991; Saito 1991; Boemers 1996; Boemers 1994; Boemers 1994; Wilmhurst 1999; Mosiello 2003; Taskinen 2002] These studies reveal that between 30 and 40% of these patients have an upper motor neuron type lesion with DO and an intact but dysynergic sphincter, while 25 to 50% have signs of a lower motor neuron deficit with acontractile detrusor and denervation in the sphincter, and 15 to 20% have normal LUT function. [Guzman 1983; Jabokson 1985] Tethered cord occurs in children without sacral anomalies as well as in those with low anorectal malformation (ARM).

Mosiello et al [Mosiello 2003] recommend evaluation of all patients that have sacral agenesis with MRI, and this necessity has been confirmed by others, who found the extension of the sacral defect as a prognostic factor for retethering. [Kim 2010] When MRI shows sacral or spinal cord anomalies, UDS should be considered, preceded by neurological exam and considering neurophysiological testing (evoked potential testing) The authors of this and subsequent studies recommend a non-invasive evaluation for all other children, and urodynamics when NLUTD is suspected. [Borg 2009] It is presumed that the neurological deficit associated with this entity is fixed because no study showed any progression of the neurological disorder with increasing age.

Conclusions (level 3)

- Case series have shown that urodynamic evaluation of lower urinary tract function in children with (partial) sacral agenesis reveals a substantial incidence of clinically hidden dysfunction.

- It is shown that approximately one third of children with anorectal anomalies have spinal dysraphism and/or tethered spinal cord associated with urodynamically demonstrable neurogenic lower urinary tract dysfunction.

Recommendations (grade C)

- Clinicians should consider urodynamic testing in children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma

- Clinicians must consider that in children with lower urinary tract dysfunction, otherwise clinically silent sacral agenesis can exist.

**d) Spinal cord injury**

The scarcity and variability of spinal cord injuries in children makes it difficult to propose any one treatment program unless the specific type of LUT function is known on the basis of urodynamic testing. [Chou 2006; Generao 2004; Silveri 2006] Even if the individual regains the ability to void spontaneously and empty his/her bladder, it is imperative to know the detrusor filling and emptying (detrusor) pressures. Even if the child is continent on CIC, it is important to measure detrusor compliance in order to determine the potential risk for vesico-ureteric reflux and hydroureteronephrosis. [Pannek 1997] Four studies extol the need for urodynamic studies once spinal shock from the initial injury wears off, to determine the presence of low filling and voiding pressures and the ability for complete emptied, for the reasons cited above. [Decter 1993; Kim 1998; Fanciullacci 1988; Iwatsubo 1985] All studies are monocenter, retrospective and use historical controls for comparison.

In the presence of elevated urodynamic filling and voiding pressures, a 30% incidence of upper urinary tract deterioration can be expected. [Kurzrock 1998] Effective voiding with pressures below 40 cm H2O in the absence of detrusor-sphincter dyssynergia ensures a stable upper urinary tract. [Fanciullacci 1988] Urodynamic monitoring has been demonstrated to be relevant in the follow up and prevention of upper tract deterioration in a retrospective cohort study. [Generao 2004] In another study on 17 children aged 6 months-18 years with cervical (4), thoracic (8) and lumbar (5) SCI, all but one showed DO on first evaluation, which was changed to an acontractile and or compliant detrusor pattern by medical treatment; 7 had increased bladder capacity and 8 decreased DLPP at follow-up; only 2/17 developed minor UUT impairment. [Silveri 2006] A cauda equina injury usually leads to a lower motor neuron type of deficit of the striated sphincter that may not require any treatment to prevent upper tract damage because the bladder empties readily at low pressure, but it probably necessitates medical and/or surgical therapy to achieve continence. Urodynamic studies are invaluable to efficaciously manage any spinal cord lesion related LUT dysfunction, in order to maintain a healthy upper urinary tract and long-term survival with minimal morbidity. [Kim 1998; Watanabe 1996]

Urodynamic studies, undertaken no earlier than 6 weeks after injury, allow for the manifestation of the extent of the neurologic injury. [Iwatsubo 1985] Periodic urodynamic reassessment is appropriate up to 2 years after injury, due to the potential for changes during that time. Further urodynamic follow up is ‘standard’ as in adult patients. [Nosseir 2007]

Conclusion (level 2/3)

- Retrospective studies have shown that urody-
The committee recommends that urodynamic testing of all children with spinal cord injury is relevant.

- Retrospective studies have shown that urodynamic testing of children with spinal cord injury results in diagnoses and treatment similar to adults with spinal cord injury.

**Recommendations (grade C)**

- The committee recommends that urodynamic testing in children with spinal cord injury is planned on an individual basis, but no earlier than 6 weeks after injury.

**e) Cerebral palsy**

Only a few published studies describe the urodynamnic findings in children with cerebral palsy. [Decter 1987; Mayo 1992; Reid 1993; Yokoyama 1989] The vast majority of the children with cerebral palsy tend to gain normal lower urinary tract function, but often at an age that is later than expected for normal individuals. [Decter 1987] Any incontinence is usually secondary to urinary urgency from DO. [Reid 1993] A meta-analysis of urodynamic studies performed in children with either persistent incontinence despite frequent toileting, or urinary tract infection, revealed either normal function (15%) or DO (73%; 85 of 117 patients);[Decter 1987; Mayo 1992; Reid 1993] detrusor sphincter dyssynergia is very rarely observed during voiding (5%; 12 of 249 patients). [Dator 1992; Mayo 1992; Yokoyama 1989] In some recent studies, detrusor-sphincter dyssynergia was present in higher prevalence than earlier reports (11% / 5%). [Karaman 2005; Bross 2007] Normal function was less prevalent (only 15%) in the more recent case series. [Bross 2007; Silva 2009]

Therefore, it has been suggested on the basis of expert opinion that cystometry and sphincter EMG are to be considered, but only when frequent toileting or anticholinergic therapy fails to control incontinent episodes, the child develops urinary infection from ineffective voiding, or when ultrasonography reveals hydronephrosis.

However, videourodynamic assessment can be considered in all patients with infantile cerebral palsy. The decision should not be based on clinical symptoms because at least half of the children with spastic cerebral palsy have clinically silent bladder dysfunction. 100% of children had clinical improvement postoperatively (selective dorsal rhizotomy), 71% who were incontinent preoperatively became continent and none had deterioration on urodynamics. [Bross 2007; Houle 1998; Farmer 2007] There is a spectrum of clinical and urodynamic LUT function in children with cerebral palsy; 77% void spontaneously but do have UI. Incontinent children have a lower age-related bladder capacity, as shown both in slow-fill water cystometry study [Richardson 2009] and in a noninvasive evaluation (flowmetry plus PVR), showing a significant difference between observed and expected bladder capacity. [Ersoz 2009]

**Conclusion (level 3)**

- Some studies with historical/literature-control groups have shown that clinically unexpected lower urinary tract dysfunction – predominantly dysfunctional voiding and lower bladder capacity - can occur in children with cerebral palsy.

**Recommendations (grade C)**

- Clinicians should carefully evaluate voiding in children with cerebral palsy and should consider complete urodynamic testing when dysfunction is suspected

- Urodynamic testing is to be considered in all patients with spastic cerebral palsy. Undiagnosed and untreated patient's bladder dysfunction remains pathological and potentially dangerous, and may damage the upper urinary tract.

**f) Tumours**

LUTD exists after sacrococcygeal teratoma resection and recently again it was, on the basis of a monocenter cohort, proposed that urodynamic testing is necessary for those children. [Mosiello 2003; Ozkan 2006; Berger 2011]

A recent study showed that children with central nervous tumours can have urodynamic abnormalities, whether the tumour is in the spinal cord or not. On the basis of this, a monocenter and selected cohort study concluded that a child with a CNS tumour regardless of location needed urological and urodynamnic testing. [Nguyen 2010]

**Conclusion (level 3)**

- It was shown in monocenter cohorts that urodynamnic testing is relevant after resection of a sacrococcygeal teratoma.

- A study showed that all children with central nervous system tumours can have lower urinary tract dysfunction regardless of the location of the tumour.

**3. ANORECTAL MALFORMATION OR IMPERFORATE ANUS**

Imperforate anus is classified as high, intermediate or low depending on whether or not the rectum ends above, at, or below the levator ani muscle. In the past, imperforate anus repair for high lesions frequently resulted in urinary (stress-) incontinence due to a pudendal nerve injury that often occurs from a perineal approach to bringing the rectum down to the anal verge. [Pena 1986] With the advent of the posterior sagittal anoplasty this complication has been eliminated as a cause for subsequent UI, although bladder neck incompetence may be a consequence of extensive mobilisation of the sigmoid colon which helps transfer the rectum to its final location. However,
reports of spinal MRI's reveal a 35% incidence of distal spinal cord abnormalities in children with an imperforate anus. [Barnes 1986; Greenfield 1991; Kakizaki 1994]

Wetting after definitive repair is reported to be the possible result of stress incontinence through ineffective emptying (‘overflow incontinence’) and underactive or contractile detrusor rather than sphincter injury. In 2005, Shimada et al reported on the reconstruction of cloacal anomalies in a consecutive series of 11 girls. The main clinical characteristic of bladder dysfunction was a failure to empty. [Shimada 2005] They could not define the precise aetiology, but iatrogenic injury from extensive dissection can lead to the higher risks of peripheral nerve damage.

In 2004, Warne et al prospectively studied the effect of surgical reconstruction by posterior sagittal approach and total urogenital mobilisation in either causing or worsening bladder dysfunction in new patients with cloacal anomalies. A comparable group of patients with ARM were studied as comparative controls to assess the effect of posterior sagittal approach without urogenital surgery. Natural filling urodynamics via a suprapubic catheter showed that bladder dysfunction was present in 9 of 10 patients with cloacal anomalies and in 12 of 20 patients with ARM. After surgery there was significant deterioration (frequently a change to underactive detrusor) in bladder function in half of the cloacal group and in 1 of 20 patients with ARM. Patients with cloacal malformation have a high incidence of innate LUTD and surgical reconstruction can cause further deterioration particularly in the group that needs extensive intrapelvic mobilization. Urodynamic assessment is required to evaluate LUTD in these patients. [Warne 2004] In 2006, a prospective study reported on children with ARM, prior to and following definitive procedure, using urodynamic evaluation. Among these 19 children, 13 underwent re-evaluation after definitive surgery for ARM. Only 9 of the 19 patients had normal urodynamics pre-operatively and post-operatively, and the LUT function of 3 patients was found to be worsened postoperatively. [Kumar 2006]

Mosiello et al recommends evaluation of all patients with ARM using MRI. When MRI shows sacral or spinal cord anomalies, urodynamics should be performed. They recommend a non-invasive evaluation for all other children and urodynamics when NLUTD is suspected. [Mosiello 2003]

NLUTD occurs in 50% of those with ARM. [Kumar 2006; Boemers 1996] The prevalence of spinal dysraphism and/or tethered cord in patients with ARM is 32-34%, independently from the severity of ARM and a variable proportion (40-60%) of those patients who have tethered cord needed untethering. [Kim 2010; Suppiej 2009]

The reliability and reproducibility of these findings among the various studies analysed confers an important role for videourodynamic studies as an integral part of the evaluation and management of these children: it has diagnostic accuracy; it provides arguments to consider treatment of any intraspinal (neural) abnormality to improve the child’s chances of achieving urinary and faecal continence. Urodynamic testing is also considered useful as a basis for future comparison, if LUTD should subsequently become a problem in children not undergoing early spinal cord exploration.

The VATER or VACTERL association is a group of diverse abnormalities that include Vertebral bony, Anal atresia, Cardiac, Tracheo-Esophageal fistula, Renal and Limb anomalies. [Cardenas 1995] Imperforate anus may occur as an isolated lesion or in conjunction with this association. Spinal cord pathology occurs in 38% of cases producing a picture of upper and/ or lower motor neuron deficits to the LUT. [Boemers 1996; Greenfield 1991; Emir 1998; Capitanucci 1996; De Gennaro, M. 1994] By combining the incidences in 3 studies it was found that the presence of an abnormal sacrum increases the likelihood of LUTD to as high as 76% (38 of 50 children). [Boemers 1996; Emir 1998; Capitanucci 1996] When the rectum ends above the levator ani muscle there is a much greater chance of LUTD than when it ends below the pelvic floor [Mosiello 2003; Emir 1998] and the older the child is at the time of urodynamic assessment the more likely he/she is to have abnormal LUT function. [De Gennaro, M. 1994; Capitanucci, M.L. 1996]

**Conclusions (level 3)**

- Various studies have shown that a significant proportion of children with an anorectal malformation has primary or secondary dysfunction of the lower urinary tract, lower urinary tract innervation abnormalities or pelvic floor dysfunction.

**Recommendations (grade C)**

- Clinicians should consider urodynamic testing in children with imperforate anus when clinical signs of lower urinary tract dysfunction exist.
- Clinicians should consider urodynamic testing in children where, on the basis of an MRI, or on the basis of clinical examination, relevant neurological abnormalities exist, before and or after reconstructive surgery independent of (the existence of) lower urinary tract symptoms.

### 4. ANATOMIC ABNORMALITIES

The use of urodynamics for evaluating anatomic lesions that affect the lower and, consequently, the upper urinary tract in children is still somewhat controversial. Essentially, the evidence consists of uncontrolled case series and expert opinions although many clinicians now feel its usefulness is beyond question.

**a) Posterior urethral valves**

Nowhere is the above controversy more obvious
than in boys with posterior urethral valves. [Bauer 1979; Mitchell 1982; Glassberg 2001] Prior to the ready availability of urodynamics, persistent upper urinary tract dilation was managed with bladder neck resection and/or straited urethral sphincter resection. By demonstrating the presence of DO or secondary underactive detrusor, urodynamic studies have helped explain the findings of hydroureronephrosis that many of the children exhibited over time despite adequate valve ablation. These studies changed the focus from increased bladder outlet resistance to altered bladder function as the aetiology of the longer term sequelae.

There are only a few urodynamic reports prior to valve ablation. In one, DO was seen in 60%, poor compliance in 10% and normal function in 30%. [Kim 1997] In the other, all 46 patients had ‘bladder hypercontractility’ (obsolete term, used in the manuscript) and comparable high maximum voiding detrusor pressures. At the end of follow -up (mean 4.5 years) in this second study, no patient in group 1 (22 patients who underwent simultaneous valve ablation and bladder neck incision at the 6 o’clock position) had ‘bladder hypercontractility’ or DO, and the mean maximum voiding detrusor pressure was 53 ± 15 cm H₂O. In comparison, 9 patients in group 2 (24 patients who underwent simple valve ablation) had ‘bladder hypercontractility’. 6 had DO and the mean maximum voiding detrusor pressure was 87 ± 45 cm H₂O (p<0.01). [Kajbafzadeh 2007] Another study compared urodynamic patterns before and after valve ablation, and within 15 days following ablation and at one year of life. At presentation, median cystometric bladder capacity was 22 mL (5 to 125) and maximum voiding pressure was 112 cm H₂O (40 to 331. No significant differences were found before and after ablation. Voiding pressures had significantly decreased (p=0.01) and bladder capacity had increased (p<0.001) at 1-year follow-up. [Taskinen 2009] Comparing the patterns found in other series of infants, voiding pressures in infants with posterior urethral valves are as high but not higher.

In a series of urodynamic studies after valve ablation, the type of bladder function observed, correlates with the time elapsed from surgery; DO is the predominant pattern initially [Bauer 1979] but changes are noted in both DO and compliance over time. [Holmdahl 1995; Holmdahl 1996; De Gennaro,M. 1996; De Gennaro,M. 2000; Donohoe 2004] In 2005, a series of 30 patients showed DO with single or multiple detrusor contractions in 60 %, and small capacity, reduced bladder compliance in 40%. [Puri 2005]

Myogenic failure, in conjunction with increasing capacity and poor emptying, are primarily a later phenomenon, and are most likely to be secondary to increased urine production and decreased frequency of voiding with advancing age. [Holmdahl 1996] Despite early valve ablation, a large proportion of boys treated for PUV have gradual detrusor ‘decompensation’ and/or secondary bladder neck outlet obstruction leading to obstructive voiding and finally underactive detrusor or acontractility. [Androulakis 2005] Vesico-ureteric reflux was initially, in a small and selected series, most commonly noted in boys with DO, whereas hydronephrosis is most frequently seen with a poorly compliant bladder, [Peters 1990; Ghanem 2004] while in a recent study patient with and without reflux had similar voiding pressures. The persistence of upper urinary tract changes is related to the bladder’s unresponsiveness to medical therapy for the DO and/or for detrusor underactivity (usually clean intermittent (self-) catheterisation). However, it is possible that this condition is secondary to sufficiently infrequent voiding in the face of increased urine production. BOO from a secondary hypertrophied bladder neck can also occur, requiring further intervention. [Kajbafzadeh 2007] Several studies have shown the predictability of the development of renal failure based on specific detrusor patterns seen on urodynamic evaluation; persistent poor compliance, high detrusor pressures, BOO and or chronic failure of the detrusor to adequately contract during voiding with increased PVR are the most likely causes of deterioration. [Bauer 1979; Mitchell 1982; Holmdahl 1995; Holmdahl 1996; Peters 1990; Lopez 2002; Ansari 2010] Most probably, the extended use of antenatal diagnosis could select a ‘new generation’ of valve patients, who undergo proper early ablation of the obstructing valves allowing normal cycling, which helps ‘bladder healing’. Youssif, comparing a group of 16 children who underwent valve ablation as newborns and a group of 16 boys observed after age 1 year, showed that post-void residual urine and vesicoureteral reflux improved in a higher percentage in those early treated. [Youssif 2009]

b) Bladder extrophy and persistent Cloacal anomalies

Once the extrophied bladder is closed it may be difficult to manage persistent UI, upper urinary tract dilation or vesico-ureteric reflux. Whether to further improve continence function and whether to perform augmentation cystoplasty for a small capacity, poorly compliant bladder are challenging questions. In addition, as more children undergo complete primary repair of the exstrophic bladder in the neonatal period, the most accurate assessment of bladder function is by urodynamics. Only a few studies report the change in LUT function following bladder neck reconstruction in patients with persistent incontinence; 20% show DO preoperatively versus 37% postoperatively, and compliance worsens in up to 50% after surgery. [Hollowell 1993; Diamond 1999; Burki 2006; Caione 2005] No studies are extant that have correlated incontinence with bladder capacity, compliance, DO and/or LPP. [Gargollo,P.C. 2008; Kajbafzadeh 2008; Camanni 2009]
c) Ectopic ureterocele

Urodynamic studies in babies with an ectopic ureterocele have shown that LUT function may be altered in as many as half the affected patients; 2 reports revealed that between 55 and 70% had a larger than normal capacity bladder for age with high compliance, and poor bladder emptying due to underactive detrusor. [Abrahamsson 1998; Sherman 2003] In another multicentre analysis of 616 children with a variety of ureterocele types, investigators found only a 6% incidence of bladder dysfunction (all in children with an ectopic ureterocele) consisting of primarily DO; less than 1% had poor bladder emptying whereas the remainder had normal bladder storage function and complete emptying. [Holmes 2002] In a recent study in 2007, voiding dysfunction was suspected in 23% of patients. [Shimada 2007] UI and/or infection following surgical incision or excision of a ureterocele is likely to be secondary to the obstructive effects of the ureterocele directly on the bladder outlet and not to any surgical complication. [Holmes 2002; Sherman 2003; Abrahamsson 1998] Patients undergoing bilateral ectopic ureterocele repair are at increased risk for postoperative voiding dysfunction. Whether this risk is present preoperatively or is a result of a trigonal lesion is unclear. Recently, there is an increasing agreement in favour of conservative management of paediatric duplex system ureteroceles, by mean of simple endoscopic puncture followed by close surveillance: reflux can resolve spontaneously in a significant number of patients, and bladder function should be conserved. [Matsui, F. 2009; Jesus 2011]

d) Vesico-ureteral reflux

It had been shown that vesico-ureteral reflux may be a secondary phenomenon resulting from DO and not a primary anatomical abnormality at the ureterovesical junction in a significant proportion of children. [Koff 1979; Griffiths 1987; Sillen 1996; Greenfield 2000; Capitanucci 2000; Podesta 2004] There is growing evidence that DO may lead to vesico-ureteral reflux in a marginally competent ureterovesical junction mechanism. [Khoury 2008; Chandra 1996; Chandra 2000] This DO may be a natural phenomenon in the infant bladder, especially in boys, due to the presence of higher voiding pressures [Podesta 2004; Webster 1984; Sillen 1992; Sillen 1996; Yeung 1997; Bachelard 1999] and/or a learned dysfunction in older children who try to withhold voiding throughout the day. [Greenfield 2000] Several investigators have shown that DO tends to resolve with increasing age [Chandra 1996; Sillen 1996; Nielsen 1989; Sjoström 2009], also showing, in a longitudinal study, that changes occur between the first and second year of life in children with dilating reflux, going from an immature pattern, with high pressure levels, to a high capacity bladder with incomplete voiding. [Sjoström 2009]

The bladder pressure at the onset of vesico-ureteric reflux, as determined by nuclear cystometrography, is a significant independent predictor of vesico-ureteric reflux resolution in children. The pressure at the onset of vesico-ureteric reflux was also highly predictive of spontaneous resolution (p = 0.0005). Vesico-ureteric reflux occurring at greater pressures was more likely to resolve spontaneously, independent of the vesico-ureteric reflux grade or bladder volume at the onset of vesico-ureteric reflux. [Arendonk 2007] The degree of renal scarring (p=0.018) and the degree of reflux (p=0.038) were found associated with the detrusor pressure with highest detrusor pressure in the group with ‘urge syndrome’. [Acar 2009] In addition to grade of reflux, bladder volume relative to predicted bladder capacity, at the onset of vesico-ureteric reflux, appears to provide additional prognostic information regarding the likelihood of spontaneous resolution of primary vesico-ureteric reflux. [McMillan, Z.M. 2006] Large bladder capacity and high compliance correlated with ‘passive’ reflux, while reflux during micturition correlated with low bladder capacity: the first pattern showed a lower resolution rate within the third year of life, in a longitudinal study by videocystometry. [Wahl, L. 2009]

Despite this finding, there is ample evidence in 4 studies to show that treating the DO and/or voiding dysfunction with anticholinergic agents leads to a faster rate of resolution of vesico-ureteric reflux (63 - 92% within 1 year) [Homsey 1985; Scholtmeijer 1994; Batista 1997] than it might when the child is treated only with antibiotics to prevent recurrent infection (resolution rate 25 - 54%). [Seruca 1989; Ural 2008]

In this setting, history-taking about voiding habits [Gool 1992], and urodynamics with cystometry and uroflowmetry to confirm the abnormal bladder and possibly sphincter function, become paramount, rather than just treating the child with antibiotics and getting yearly voiding or nuclear cystograms. Urodynamic studies have confirmed the presence of DO and/or high voiding pressures in at least half the babies studied with high grades of vesico-ureteric reflux, whereas only 38% had totally normal function. [Webster 1984; Bachelard 1999; Yeung 1998; Bachelard 1998; Sillen 1999; Ural 2008] Upper urinary tract damage is more apt to occur in children with abnormal bladder function as reported in 4 retrospective reviews. [Nielsen 1989; Scholtmeijer 1994; Sillen 1999; Leonardo 2007]

In 2006, videourodynamic studies were performed in 40 patients. LUTD was present in 76% of the children, with DO in 73% of the children with vesico-ureteric reflux, in 63% of the children with UI, in 77% of the children with episodic urinary tract infection, and in all of the children with diurnal enuresis. Compared to children without LUTD, the voiding pressure was significantly higher in children with dysfunctional voiding (with vesico-ureteric reflux, 61 ± 30 vs. 25 ± 16 cm H₂O, p = 0.004; without VUR, 53 ± 24 vs. 25 ± 16 cm H₂O, p = 0.010). [Kuo 2006] In the 5 patients
who had post-treatment urodynamic studies, biofeedback pelvic floor muscle training and treatment with antimuscarinics effectively decreased detrusor pressure, increased bladder capacity and maximum flow rate, and reduced the grade of VUR. In children with recurrent or persistent urinary tract infection, meticulous assessment of signs and symptoms is reported to have a ± 70-80% association with the result of invasive UDS. [Ramamurthy 2010]

Special attention should be given to secondary causes of vesicoureteral reflux such as primary bladder neck dysfunction (reported to be an underdiagnosed entity in those children), since conventional treatment will most likely fail if these conditions are not addressed in those children, since conventional treatment will most likely fail if these conditions are not addressed which was shown to be relevant in a randomized trial. [Kajbafzadeh 2010; Glassberg 2010]

Many clinicians treating patients with vesico-ureteric reflex, advocate urodynamics to assess the LUT in children with high grade vesico-ureteric reflux, especially for those patients that have incontinence, renal damage, or who are about to undergo surgery for vesico-ureteric reflux. [Scholtmeijer 1994; Moran 2004; Musquera 2004; Fotter 2005; Kajbafzadeh 2010] Precise urodynamic (pressure flow) criteria for outlet conditions in children are however still undefined.

e) Urethral stricture

Urethral stricture disease in boys is rare, usually arising from a previously unsuspected straddle injury. Uroflowmetry can accurately predict the presence of a urethral stricture in 88% of affected males. [Martin 1995] The significantly decreased quotient of Q max at greater and at smaller VV’s was suggested to be useful to demonstrate a mild BOO. [Szabol 1996] An occult urethral obstruction develops in some asymptomatic children after hypospadias repair and uroflowmetry can be helpful [Orkiszewski 2004; Kaya 2007], as showed by significantly different pre- and post-meatotomy findings of Q max (p=0.001), voiding times (p=0.03) and curve morphology. [VanderBrink 2008]

Periodic urinary flow rates, analysing the maximum flow rate in relation to volume voided, may alert the clinician to early signs of renarriuation but efficacy of periodic flow rates has not been corroborated. [Bukurov 1992] Uroflowmetry should be integral in the management of urethral stricture and complete urodynamic investigation is repeatedly required after treating traumatic rupture of the posterior urethra. [Otgun 2006]

Conclusions (level 3)

• Many case series have demonstrated frequent urodynamic abnormalities, predominantly detrusor overactivity and reduced bladder compliance or large capacity bladder with impaired filling sensation, in children with posterior urethral valves, urethral stricture, ectopic ureterocele, vesico-ureteric reflux or bladder exstrophy.

• Proper urodynamic assessment has shown to be of help to determine when further medical or surgical management is indicated in children with these abnormalities.

• The use of urodynamic studies has aided in an objective measurement of success or failure of treatments for these abnormalities.

Recommendations (grade C)

• Clinicians should consider complete urodynamic testing of the filling and voiding function, at least once, in children with posterior urethral valves, urethral stricture, ectopic ureterocele, vesico-ureteric reflux or bladder exstrophy.

• Clinicians should consider regular uroflowmetry and postvoid residual urine assessment in the follow-up and further management of children with posterior urethral valves, urethral stricture ectopic ureterocele, vesico-ureteric reflux or bladder exstrophy.

5. FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT

When assessing functional disorders involving the LUT in children, one must take into account the dynamics of the maturing nervous system, learned habits of elimination for bladder and bowel function and social influences that might modulate the child’s behaviour in a negative or in a positive manner. [Yeats 1976; MacKeith 1973]

a) Diurnal incontinence

Urodynamics has a limited place in diurnal (day and night) incontinence. This condition is not considered worrisome before age 5 or 6. When older, most children without an (until then unsuspected) anatomic or neurological lesion should be dry. [Bellman 1966; Neveus 2006] UI in children can have many causes and history and clinical investigation are very important in this regard. UI can also coincide with dysfunctional voiding and or bowel elimination problems. [O’Regan 1985; Koff 1998] Treating these elimination dysfunctions with behavioural modification, biofeedback training, drug therapy or CIC [Pohl 2002] and/or antibiotics to prevent further urinary infection is necessary before considering urodynamics. [McKenna 1999] Uroflowmetry with a PVR urine determination and cystometry are however indicated; especially if the incontinence persists despite medical therapy. A monocenter study reports that children with chronic constipation as the predominant symptom can also have unrecognized LUT problems. [Kasirga 2006]

In one study of girls with recurrent infection without vesico-ureteric reflux two distinct patterns of dysfunction emerged in 80% of those studied, either DO with a normal urinary flow pattern and complete emptying, or a normal detrusor with an intermittent flow pattern and incomplete emptying. [Borer 1999] In boys
with persistent day and night time incontinence, UDS is warranted to determine the presence of different forms of LUTD that may be contributing to the symptoms. [Ramakrishnan 2008; Yeung 2004]

Faecal incontinence in the absence of any anatomical or neurological deficit often affects LUT function and contributes to UI in a number of ways. Constipation and faecal impaction have been shown to cause DO and a reduced functional bladder capacity. [Kasirga 2006] Understanding and eliminating this possible aetiology can normalise LUT function. There is no need for urodynamic testing, before starting treatment for faecal impaction, in these cases. [O'Regan 1985]

Persistent daytime and night-time incontinence in the absence of urinary infection and a normal bladder and bowel emptying regimen warrants cystometry, pressure-flow studies and a urinary flow rate. A meta-analysis, over 20 years, of 460 children with daytime incontinence evaluated with urodynamic studies reveals DO in 57% (261 of 460), dysfunctional voiding (failure to relax the sphincter mechanism) in 22% (34 of 152) and normal findings in only 14% (64 of 460). [Webster 1984; Hanna 1981; Borzsikowski 1987; Rodriguez 1989] Many of these studies use terms that are outdated now and those should be replaced ("transformed" where possible) with the new. [Neveus 2006] In recent studies, dysfunctional voiding was present in 76% of 40 children with DO. [Kuo 2006; Zajaczkowska 2004] These findings are not gender-specific but are age-dependent, with most children outgrowing the abnormal findings by puberty. [Borzyskowski 1987] It is presumed that normal children, without day or nighttime wetting, do not have a pronounced degree of DO or dyssynergia but the evidence for this is lacking due to the paucity of studies in normal children.

Urodynamic testing has clearly improved our understanding of the aetiology of diurnal incontinence but no study has shown that urodynamic characterisation of any abnormality has improved the efficiency of treatment for these children.

b) Enuresis (nocturnal)

Night-time wetting (enuresis) is a condition that is common in children aged 5 years but which improves with time, so that less than 15% of pubertal boys and 5% of pubertal girls continue to be affected. [Fergusson 1986] Multiple causes for the persistent wetting, ranging from genetic factors, to maturational delays, to sleep disturbances, to social causes, to attention deficit disorders, to bladder and urethral dysfunction, to excess fluid intake, to abnormal vasopressin secretion and/or to constipation, have been implicated. [O’Regan 1985; Hoebeke 1995; Hjalmas 1997; Chandra 1998; Neveus 2006] Although in various cultures there may be social and familial pressures to resolve the condition before puberty, in western societies it is generally not necessary to conduct urodynamics until adolescence, to determine why the wetting has not abated. Urodynamic testing in 615 enuretic children, with and without daytime symptoms, has identified DO in 61%. [Mayo 1990; Medel 1998; Hellerstein 2003] In a prospective study, bladder volume and wall thickness index was calculated based on ultrasound studies. The index was measured by dividing maximum bladder volume by mean bladder thickness. Bladder volume was expressed (normalized) as percentage by dividing the patients measured bladder capacity by expected bladder capacity and subsequently the detrusor was classified as thick (index:< 70), normal (70 to 130) or thin (>130). Of the patients with an index of less than 70: 96% exhibited DO on cystometry. [Yeung 2004; Sreedhar 2008] In another prospective study, 116 children with primary enuresis were evaluated and urodynamic abnormalities were seen in 80/116 (69%) patients namely DO 50/116 (43%), small bladder capacity 20/116 (17%), large bladder capacity 4/116 (3%), decreased bladder compliance 3/116 (3%) and detrusor sphincter dysynergia 3/116 (3%). The combination of abnormal micturition history with daytime urinary urgency or frequency, or dysfunctional voiding symptoms like squatting and/or abnormal voiding charts, predicted abnormal results of urodynamics correctly, with a sensitivity of 81% and specificity of 86%. [Sehgal 2007] However, other studies state that urodynamic diagnoses are more distinctive than symptom complexes for LUTD in children. [Glassberg 2010]

When the children are divided into those with day and night-time incontinence (non monosymptomatic) versus those with just nocturnal wetting (monosymptomatic), the incidence of DO decreases from 64% to 35% in the latter group. [Medel 1998] In another prospective study comparing enuretics to age-matched non-enuretics, bladder capacity at night (enuretic capacity) was significantly less in those who wet versus those who did not. [Kawachi 2003] Although the authors did not speculate on aetiology they felt that enuretics were less able to hold their urination than non-enuretics. Management should be directed at improving the child’s ability to withhold urination. Treating the non monosymptomatic child using antimuscarinic agents can be very effective (as high as 77% cure) with low recidivism rates when based on the findings of urodynamic testing. [Porter 1995; Kosar 1999; Neveus 2010; Hoebeke 2010; Abidari 2002]

Conclusions (level 2/3)

- Various studies show that treatment for children with functional incontinence (and of the, frequently associated, bowel elimination problems) can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and uroflowmetry with postvoid urine assessment.
- Various studies, reviews and guidelines agree on the relevance of urodynamic testing in children
Recommendations (grade B/C)

- The committee recommends uroflowmetry and postvoid residual urine assessment (until -for the individual child- representative values are obtained) as ‘urodynamic-screening and evaluation in all children with lower urinary tract symptoms, urinary incontinence and or with nocturnal enuresis resistant to first line therapy.

- The committee suggests urologic signs and symptoms assessment in children with chronic constipation.

- The committee recommends complete urodynam ic testing in children with urinary incontinence and or with nocturnal enuresis resistant to conservative treatment, if invasive or clinical (dry-bed training) treatments are contemplated.

Suggestion for research

- The committee suggests that further integrated approaches to the diagnosis (and management) of children with anorectal (elimination) dysfunction, in combination with lower urinary tract dysfunction are undertaken.

6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS

Often, differences in urodynamic parameters exist from one study to another, or one year to the next. Chou et al provided reference ranges for ‘normal’ variability in urodynamic parameters that can be considered as ‘no real change’ from one study to the next. It was a retrospective chart review. Fifty consecutive individuals with spinal cord injury had 2 trials of urodynamic studies done 5 minutes apart. They established percentile ranges. Knowing these ranges of variability can be helpful in determining whether differences between filling trial 1 and filling trial 2 in a single study, or year-to-year changes in urodynamic studies, are significant or simply the normal variability of the urodynamic study. [Chou 2006]

‘Functional’ bladder capacity (as derived from the voiding diary, without the first voiding in the morning) is presented as a relevant parameter for the clinician in the International Children’s Continence Society definitions. [Neveus 2010] To assess the voiding phase, pressure flow studies are performed immediately after filling cystometry. Available reports on detrusor pressure during voiding in symptom free children is reported to give a wide range; between $\pm 50-60$ cmH$_2$O in one study [Wen 2007] and $\pm 100$cmH$_2$O in another [Yeung 1995]

A rate of filling resulting in 10% increment of the expected bladder volume per minute, has been recommended in children to determine detrusor compliance and functional bladder volume accurately and standardised. [Hoebekne 1998] Some investigators advocate that infants should be assessed with much lower rates of filling or with natural filling cystometry. [Yeung 1998; Sillen 1999] Several studies do show lower detrusor pressure increases under natural filling versus even slow filling rates during cystometry. [Norgaard 1995; Landau 1994; Kaefer 1997] Even though the practicality of time management plays a role in a busy urodynamic laboratory, it is essential to perform urodynamic testing in a way that reveals what one considers clinically important information. One study in particular [Kaefer 1997; Landau 1994] demonstrated that the intravesical pressure was lower when it was measured initially by catheterisation (before emptying the bladder) and then compared to the pressure at the same volume during the subsequent cystometrogram. Except for determining bladder volumes at specific pressures, [Landau 1994] no study has shown that these differences are crucial in the management of children with LUTD. One study looked at the effect of the temperature of the instillate (25°C versus 37.5°C) on measured detrusor pressures and found no significant differences in compliance. [Chin 2003] Van Meel et al have shown that repeating the IWT will increase its positivity. [Meel 2007]

The smallest dual-channel urethral catheter available should be used in children for the same reasons as specified for adults, although the measuring lumen must be large enough to measure pressures in a technically adequate manner. Although urethral catheters of moderate size (8F) do not always obstruct the urethra in girls [Griffiths 1982] or produce higher than the normal voiding pressures, as measured with suprapubic tubes, it is prudent to employ the smallest calibre catheters that are practical when doing a cystometrogram that measures filling as well as voiding pressures. For very young infants it may be better to insert a suprapubic catheter placed under anaesthesia the day before the test to make the subsequent investigations more accurate [Yeung 1999; Yeung 1999] but this has not been assessed with any precision. Furthermore, precise standards for pressure-flow analysis in boys or girls, or for grading of BOO ‘resistance’, have not been published. The precise association and or prevalence of obstructed voiding with incontinence is therefore also unknown.

Most children can undergo urodynamic studies without pre-medications; only the most agitated may require some degree of sedation [Bozkurt 1996] and it does not appear to have a significant effect on the outcome of the testing. Even then, children should not be so heavily sedated that they cannot void around the catheter. However, there are no studies that show a difference in bladder filling pressure (whether related to compliance or to DO) in awake versus anaesthetised children.
In the previous consultation the recommendation was made that children should receive comprehensive urodynamic testing in a laboratory that is specialised in paediatric urodynamic testing with appropriately trained personnel. [Ramamurthy 2010; Bael 2009; Uluocak 2009]

Conclusions (level 3/4)

- The committee concludes (on the basis of various studies to determine normal and test retest values for urodynamic testing in children) that within the limits also provided for adults, urodynamic testing in children is reliable and reproducible.
- Although it is plausible and considered useful to reduce filling speed and catheter size in relation to patient size, the exact values cannot be given and the influence of the transurethral catheter size on voiding is unknown.
- The committee concludes that standards for pressure flow analysis in children are lacking.

Recommendations (grade C)

- The committee recommends that the specific demands of children, physically as well as psychologically are taken into account, before urodynamic testing is carried out as well as during the testing. The committee advises specialised workers, units and equipment to ensure this.
- The committee recommends that invasive diagnostic tests should be done if indicated by the results of non-invasive procedures and should be done only when the outcome will or can alter management.
- The committee recommends that clinicians take into account the variability and test retest differences of urodynamic testing in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child’s behaviour, and the implications for the results of the tests.

Suggestion for research

- The committee suggests to elaborate on standardisation of evaluations to judge how the ‘laboratory’ circumstances have influenced the child’s behaviour, with the aim to better include how well the urodynamic tests have represented the actual dysfunction, in the evaluation of the test.

V. PATIENT EVALUATION: FRAIL ELDERLY

1. INTRODUCTION

Frail older patients are poorly represented in all studies, but especially in those involving invasive inter-

ventions or medications. By definition, they suffer from multiple impairments (e.g. poor mobility, cognitive impairment, renal failure) or disease conditions (heart failure, multiple medications). [Fairhall, N. 2011; Fried, L.P. 2001; Inouye, S.K. 2007] Such individuals are at risk of admission to hospital or a care home. [Hrisanfow, E. 2011] Older people age at different rates, with some developing a clinically recognised pattern of frailty characterised by impairments in a number of functions including a greater risk of developing incontinence. [Ferrucci, L. 2004; Baltes, P.B. 2003; Hirayama, F. 2008] However usually the multimorbidity excludes them from research trials, which limits appropriate continence care. [Narayan, S. 2007; Ferrucci, L. 2004] Elderly patients should however not be considered differently from younger subjects simply because of their chronological age. LUTS, especially storage ones, showed age-related alterations in the two sexes in the absence of any overt underlying disease, and bladder function in both sexes may be subject to a gender-independent aging process. [Araki, I. 2003] UDI findings in the (frail) elderly tend to demonstrate DO [Jones, K.W. 1985; Resnick, N.M. 1989], even in individuals that do not spontaneously report symptoms or bother. There may also be a reduction in bladder capacity, urinary flow rate and detrusor contractility. [Homma, Y. 1994] Because of these age dependent changes, the utility of UDI has to be judged against this specific background in the elderly where diagnosis and treatment of specific conditions is strongly dependent on and related to frailty by itself. [Homma, Y. 1994] These features need to be born in mind when considering the contributors to, and investigation of, incontinence. Limitations to care may also be appropriate in a frail older person who is nearing the end of their life. [Gillick, M. 2001] The invasive nature of conventional UDI becomes a relatively more important factor in the old or frail elderly, who may be more vulnerable to any intervention than younger people. For example, one study [Okorocha, I. 2002] showed that there was a significant association between age and the presence of asymptomatic bacteriuria before cystometry and between the bacteriuria and urgency (without DO) on cystometry. Asymptomatic bacteriuria did not influence the UDI outcome except in patients with urgency (without DO); and the authors recommended that screening and treatment be considered individually in older women who are being investigated for storage symptoms.

Given the multifactorial nature of incontinence in the elderly [Miller, K.L. 2002] and the fact that there may exist easily reversible causes or contributory factors relatively more frequently in these patients, it is suggested repeatedly that screening for contributing factors in the ‘vulnerable elderly’ is very relevant. [Resnick, 1984; Bing, M.H. 2007; Gibbs, C.F. 2007; Fonda, 522] UDI is reserved for patients in whom conservative management and medical management, direct or
indirectly aimed at lower urinary tract improvement, has failed or has proved inadequate, and in whom more intensive or invasive therapy is being considered. Also in the elderly, there is a given group of patients who desire further attempts to correct or manage the incontinence, and who therefore need a detailed and objective diagnosis. [Sims, J. 2011] Improvements in the structure and process of ‘continence care’ for the elderly has resulted in improved patient reported (Quol) outcomes, and the structure presented by a geriatrics (ambulatory) clinic may serve as an example of care quality improvement. [Min, L. C. 2011] Certainly assessment of persistent LUTD and UI is of relevance in the elderly after urological interventions, however UDI diagnosis is rarely mentioned in the follow-up of persons with ‘failed’ interventions. [Shikanov, S. 2010; Namiki, S. 2009; Poulakis, V. 2007]

The place of UDI in the frail elderly with incontinence is not precisely established, given that the number of studies seeking to establish its clinical utility is even smaller than in younger adults: there is very little objective evidence for or against clinical UDI in this population group. However, the same principles apply as those in younger age groups, namely that UDI should only be done if it is going to affect the management of the patient and that conservative and medical therapy has failed with the patient desiring further treatment. [Abrams, P. 2009] A recent review, on the basis of a RAND procedure, to search for health care quality indicators underpins that UDI ‘should be performed’ in the workup of vulnerably elders when surgical intervention is considered. [Fung, C.H. 2007]

The changes in function that occur with age, not only in the LUT, but also in the neural system that controls it (or fails to control it), may all have impact on urological problems. UDI research studies, to establish what these changes are, how they are related to other aging associated changes, and how the changes might be reversed, are needed. [Inouye, S. K. 2007]

Overactive bladder syndrome is frequently diagnosed in the elderly and in the frail elderly and medical (pharmacological) treatment seems plausible for elderly, with extrapolated evidence from younger patients. In non-systematic reviews on pharmacotherapy UDS do not play an important role to initiate treatment for overactive bladder syndrome in the frail elderly. [Kraus, S. R. 2010; Staskin, D. R. 2005; Wagg, A. S. 2007]

2. ROUTINE EVALUATION

Among the frail elderly, incontinence is the paramount troublesome symptom, in both men and women, with a steeply rising incidence after age 80. [Hunskaar, S 2002] The type of incontinence appears to be predominantly urgency. [Hunskaar, S. 2002] Mixed symptoms of incontinence are the commonest in women [Valentini, F.A. 2010] SUI is relatively uncommon in men of any age (except post radical prostatectomy) and it seems to become gradually less common in women after the age of about 50, [604 Hunskaar 2002] or is reported with a range of incidences. [Wennberg, A. L. 2009] for reasons that are incompletely understood.

a) Urinary urgency incontinence

The symptoms of UUI are frequently the result of DO. Thus one possible reason to perform UDI might be to identify DO. The relevant test is filling cystometry. There are reasons to question whether this is the best approach because in straightforward symptoms of urinary urgency incontinence in the elderly, DO is highly probable, and it is considered possible to initiate pharmacological or behavioural therapy without a very significant possibility of harm. [Kraus, S. R. 2010; Staskin, D. R. 2005] On the other hand: DO is only one of the contributors to the symptoms of urinary urgency incontinence [Miller 2002; Griffiths 1996], and non voiding detrusor overactivity is believed to exist in (older) people who are apparently free of (bothersome) bladder symptoms. However, if making the diagnosis of DOI is essential, it is necessary to demonstrate leakage caused by an involuntary detrusor contraction.

Reduced bladder sensation or ‘awareness’ may lead to very little warning of impending leakage, and it is believed to have a neurological (cerebral) in the elderly with LUT symptoms. [Griffiths, D. 1998; Griffiths, D. J. 2002]

In symptomatic elderly people, UUI frequently coexists with incomplete bladder emptying. Among men who have not had prostate surgery, BPO is a frequent contributor to incomplete emptying. However, if there is no BOO, particularly in women, in whom the incidence of BOO is very low, incomplete emptying is usually a sign of impaired bladder contractility, termed by the ICS as underactive detrusor. The UDI abnormality underlying UUI with incomplete emptying (assuming no BOO) has also been named ‘DHIC’. [Resnick, N. M. 1987] Its significance is that the standard pharmacological treatment of UUI – with antimuscarinics – may worsen bladder emptying and possibly lead to urinary tract infection, or even make the incontinence worse. However, on the other hand, if the patient has large residuals, then treatment with CIC may be considered indicated and therefore combining that with antimuscarinic therapy is an option, although such a combination can be problematic in frail elderly patients.

In frail elderly women, DO is reported to be the commonest UDI diagnosis in a large retrospective series of referred elderly women. Intrinsic sphincter deficiency, underactive detrusor and reduced bladder compliance [Valentini, F.A. 2010] were also prevalent in this series. Population surveys with symptoms questionnaires (without UDI’s) confirm this pattern in various countries and care-
Simple cystometry:

Some report that UDI’s in the elderly can be done by ‘simple cystometry’, as cystometry is indicated and no equipment or referral is available. [Wall, L.L. 1994] The procedure applies a large open syringe attached to a single-lumen catheter, sterile water or saline and a tape measure. Fluid is infused by gravity and LUT function can be semi quantified at the bedside and may be applicable for disabled patients. [Sutherland, J.R. 1984; Sand, P.K. 1991; Ouslander, J. 1988; Dennis, P.J. 1991; Fonda, D. 1993; Galarneau, L. 2003] Simple cystometry, as compared with multichannel cystometry, has a specificity of 75-79% and a sensitivity of 75-88% for the observation of DO in those studies [Fonda, D 1993; Ouslander, J. 1988], and is improved by combining it with simpler tests [Sutherland, J.R. 1984; Ouslander, J. 1988] such as a clinical stress test. [Resnick, N.M. 1996] However, the clinical significance of these findings is limited because DO is found in up to 50% of symptom-free elderly while DOI is the most likely finding incontinent frail elderly in any case. [Resnick, N.M. 1987; Resnick, N.M. 1989; Griffiths, D.J. 1992] Furthermore ‘detrusor hyperactivity (2010: ‘DO’) with impaired contractility’ (DHIC) [Resnick, N.M. 1989] is reported to be a common abnormality observed in the frail elderly population with incontinence and cannot be diagnosed with simple cystometry. [Resnick, N.M. 1987; Resnick, N.M. 1989] A total of 185 patients who had persistent LUTS after TURP were enrolled in one study, and the results revealed that a normal videourodynamic tracing was found in 9%, pure DO in 10%, ‘low detrusor contractility’ in 19%, DHIC in 14%, poor relaxation of the urethral sphincter in 19%, and recurrent or remaining BOO in 28%. [Kuo 2002] Single-channel cystometry is less sensitive for detecting low-pressure detrusor contractions than multichannel recording [Resnick, N.M. 1996] and if a detrusor contraction coincides with a cough, the leakage might be wrongly regarded as the sign of a positive stress test.

b) Stress urinary incontinence

Among older men, SUI is almost entirely confined to post radical prostatectomy patients (see section D.II, Patient evaluation: Men). Among elderly women, pure SUI seems to be rare. UDI testing usually follows the methods used in younger women. Frequently, it is difficult to perform a ‘typical’ examination because the patient is not able to produce a strong cough or valsala in the upright position. On the other hand, it may be just such factors that make SUI less common in this population or of lesser relevance in this group.

3. EVIDENCE FOR REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC TEST IN THE GERIATRIC OR FRAIL ELDERLY POPULATION

There is little published evidence about reproducibility and reliability in this patient population. Two groups have recently examined specific aspects of geriatric urodynamics which have some bearing on this topic. There is a little earlier evidence on the reproducibility of some parameters.

a) Filling cystometry

One group[Goode, P.S. 2002] sought UDI changes associated with behavioural and drug treatment of UUI in 105 ambulatory, non-demented, community-dwelling women, of mean age 67 years (range 55-91). Although oxybutynin and behavioural treatment were both effective, the authors were unable to demonstrate that the improvement in incontinence was related to the UDI changes observed, probably because of diverse UDI diagnoses at inclusion, as well as the variability of the UDI outcome. (See sections C.I and C.II).

b) Post-void residual urine

Residual urine is believed to depend on the presence of BOO (in men) as well as underactive detrusor. [Abrams, P 2001] Thus, in a man, the presence of substantial residual urine (> 100 mL), in the absence of a large prostate, and or severe BOO, suggests that the increased residual urine is mainly due to a reduction in detrusor contractility. [Rosier, P.F. 1996] There may be a clinically relevant age-dependent decrease in contractility in both sexes. [Abarbanel, J. 2007; Abdul-Rahman, A. 2010]

Post void residual urine varies in a given individual and can wax and wane over time. Significant daily variations have been observed in elderly patients of both sexes, with larger residuals (up to 40% greater) being measured in the early morning. Similar changes have been described in patients with BOO or underactive detrusor. [Bristow, S.E. 1996; Thind, P. 1995] Residual urine is an unspecified sign of dysfunction and also no clear predictor of deterioration of residual urine volume or of complete urinary retention has been identified in general, however prostatic obstruction is an undisputed prevalent cause of urinary retention in elderly male.

c) Pressure-flow studies

Another group retrospectively analysed UDI data on 84 females 53 years old or older, with UUI, who received either a titrated dose of antimuscarinic medication or placebo in a controlled trial. [Tan, T.L. 2003] The detrusor muscle is believed to deteriorate in function as a result of aging, by diverse investigators and since antimuscarinic treatment might affect detrusor voiding function urodynamics is applied to
monitor this. Driving a contraction to its maximum load (and zero contraction velocity) is a manner to evaluate muscle force, and stop-flow test is the practical way to do this. Three different variations of the stop test were therefore compared to analyse detrusor voiding contraction before and on treatment in this study. The voluntary stop test yielded isovolumetric detrusor pressure values inconsistent with the other 2 tests. The mechanical and continuous occlusion tests gave very similar results that were highly correlated with one another. Treatment with oxybutynin decreased isovolumetric contraction pressure only statistically significant for the continuous occlusion test. The authors concluded that voluntary stop test should not be used to evaluate detrusor contraction power, but that occlusion stop test can be of relevance to evaluate the effect of treatments that affect detrusor voiding contraction in the elderly.

4. EVIDENCE THAT PERFORMING URODYNAMIC TESTING IMPROVES CLINICAL OUTCOMES IN THE GERIATRIC POPULATION

Few relevant studies have been published in this population. One publication assessed the results of TVT for the treatment of SUI in 76 consecutive women more than 70 years old (median age 76 years). 31% (24/76) of the patients had OAB symptoms and 4 (3%) had proven DO. [Sevestre 2003]. All patients had preoperative multichannel UDI evaluation however the technique applied was very imprecisely described. At a mean follow up of 25 months, 67% of the patients were cured. Pre-operative urgency symptoms were cured in 46% of the group. Among the failures, 14 (18%) had UUI, while 'de novo' urgency without incontinence was noted in 21%. Pre-operative UDI was not able to predict the outcome of a popular SUI procedure in older women in this monocenter uncontrolled cohort. It does show that post-operative difficulties may be due to urgency and UUI, however, symptoms are not a good 'predictor' of UDI diagnosis, and therefore pre-operative urodynamics in women undergoing SUI surgery is valuable in helping to counsel patients especially if they have signs or symptoms of OAB.

5. THE PRACTICAL INDICATIONS FOR URODYNAMIC STUDIES AND WHICH TESTS ARE NEEDED

a) Post-void residual urine

Based on the above, there is general agreement that, certainly in the elderly, PVR urine measurement is indicated before treatment of incontinence either with anticholinergic medication or by SUI surgery. A consistently large residual urine certainly is a reason for caution, and careful monitoring of bladder emptying, and may be a relative contra-indication to such treatment. [Thuroff, J.W. 2011]

b) Uroflowmetry

Uroflowmetry is a simple and non-invasive test. A normal uroflow without much residual urine probably rules out significant BOO or underactive detrusor, but this finding is unusual in the elderly. Conversely, a poor uroflow is common in the elderly irrespective of sex, and although it cannot distinguish between BOO and underactive detrusor, in either case there is a relative contraindication to anticholinergic therapy. Consequently, uroflowmetry (with residual urine measurement) may be a useful screening tool prior to instituting therapy. However, interestingly, in a retrospective study of hundred women tested, the first free flow was not interpretable in 44% but interpretable in 91% on the second free flow. [Valentini, F.A. 2010] This confirms the usefulness of performing at least two free flows on patients. [Reynard 1996]

c) Pressure-flow studies

In male patients with cognitive impairments or Parkinson’s disease or multiple system atrophy (MSA), is sometimes unclear whether the incontinence is due to BPO or to the cerebral changes. There is weak evidence to suggest that prostatectomy may improve the continence if UDS shows 'severe' BOO. [Gormley, E.A. 1993] If BOO is equivocal or absent, then there is little point in performing surgery in an attempt to alleviate the signs and symptoms. After screening with uroflowmetry and residual urine measurement, pressure-flow studies may be indicated in older men in whom BOO cannot be ruled out and surgery is at least contemplated.

6. THE URODYNAMIC PARAMETERS IMPORTANT IN VARIOUS GERIATRIC CONDITIONS

Various papers have examined the urodynamics of Parkinson’s and related diseases. Parkinson’s and related diseases as well as dementia’s are prevalently associated with aging as are prostatic obstruction, detrusor and pelvic floor muscle degeneration and deterioration sensomotoric functions. UDS can be of relevance to determine the most important cause of the LUTS in the elderly, where central nervous system disease is a frequently occurring comorbidity and clinical signs and symptoms are regularly more difficult to obtain.

a) Parkinson’s Disease

One group [Defreitas 2003] found that men with presumed BOO related LUTS were less likely to have DOI on UDI’s than men or women with Parkinson’s disease. DO associated with Parkinson’s disease occurred at smaller bladder volumes than DO in BOO-related DO, although this finding was more pronounced in women than in men. The duration and severity of Parkinson’s disease were reported not be related to the UDI abnormalities in this study.
Another group [Sakakibara 2001] found that the majority of patients with Parkinson’s disease (72%) or MSA (100%) had symptoms of LUTD. DO was more common in Parkinson’s disease. DSD was seen only in MSA. BOO (> 40) was more common in Parkinson’s disease than in MSA. A detrusor underactivity was less common in Parkinson’s disease than in MSA and PVR (> 100 mL) was only present in (47% of ) patients with MSA.

Conclusions (Level 3-4)

• There is direct and indirect evidence that urinary incontinence in the (frail) elderly often has diverse and or multiple coexisting factors.

• Apart from general health, mobility, neurological diseases and medications, the lower urinary tract is directly affected by aging of the detrusor, and can be both overactive during storage as well as underactive during voiding,) and aging of the outlet; prostate, and pelvic floor muscle function.

• In common with all patients, but maybe even more relevant; symptoms are not synonymous to the abnormalities that can be measured with urodynamic studies

• Every test or procedure can cause harm in the (vulnerable) elderly but there is no published evidence that invasive urodynamic studies causes significantly more harm in the elderly.

• Simple bedside urodynamic testing has an inherent unreliability, and it is unclear whether the risk of misdiagnosis outweighs the ‘simplicity’ over conventional urodynamic studies.

• Especially, but not exclusively, male patients, with central neurological disease, can have urologic disease (e.g. prostatic obstruction) as a cause for incontinence or other lower urinary tract dysfunction.

Recommendations (grade C)

• As urinary incontinence in frail elderly people may be the result of a number of contributory factors, many of which are reversible by simple measures, such patients should be first evaluated by a clinician skilled in the care of older people before any invasive investigations or more potentially harmful medications are given.

• Post-void residual urine measurement by a non-invasive method is recommended before institution of pharmacological or surgical treatment of incontinence. It should be repeated to monitor the effect of such treatment

• Uroflowmetry should used to screen for voiding abnormalities prior to invasive treatment in the elderly.

• Filling cystometry, as a single investigation, has limited value in this patient population. ‘Simple cystometry’ is not recommended

• Simple cystometry can be used as a ‘screening test’ for non-invasive, or other low risk treatments, when a urethral or suprapubic catheter is already present for management. However, the low specificity and sensitivity towards complete urodynamic studies diagnosis must be taken into account.

• The committee recommends offering comprehensive urodynamic testing to all elderly, with due consideration of any co morbidity, that have not responded to management of relevant contributing factors, and or behavioural or pharmacological therapy, and in whom further invasive therapy is considered.

• The committee recommends that comprehensive urodynamic testing be performed in centres with a special interest in incontinence in the frail elderly, by trained and certified staff who frequently perform urodynamic testing of patients referred with suspected lower urinary tract dysfunction.

• To maintain adequate urodynamic expertise in this difficult-to-examine patient population, and to provide a background of ‘regular’ patients against whom specific patients can be judged, it is essential that such centres examine substantial numbers of frail elderly patients.

Topics for research

• Study of biological mechanisms of continence and incontinence in the frail elderly, especially those related to supraspinal control or lack thereof.

• Development and testing of treatments specific to the frail elderly with incontinence.

• Establishment of the reproducibility and reliability of urodynamic measurements in the frail elderly.

• Investigation of the associations of defecation and faecal loading or impaction of the bowel on detrusor contraction, incontinence and other lower urinary tract problems (e.g. UTI), as well as investigation of the management of combined faecal and urinary incontinence.

• Further investigation of the (cause of, and optimal management of) clinically observed association of DO and underactive detrusor during voiding (and post void residuals) in the (frail) elderly.

A. INTRODUCTION

The Committee was given the task of updating the evidence on imaging, neurophysiological testing and other tests in the field of urinary and anal incontinence. The Medline, Embase and Cochrane databases were searched for the relative subjects from January 2008 and February 2012. All references obtained from the database search were screened for relevance, full text papers were obtained and reference list were used as additional source of evidence when appropriate.

The chapter covers different issues including: imaging, neurophysiological testing, and other investigations (laboratory tests, tissue analysis and Pad test) in the paediatric and adult population, male and female subjects, neurogenic and non-neurogenic patients.

The following keywords were used for the difference subjects:

- Imaging: the Medline database was searched using the following keywords: imaging, urinary incontinence, continence, anal incontinence and faecal incontinence; the search has been limited to period from 2004 to 2008.
- Neurophysiology: clinical neurophysiology, conventional urodynamics, neurourology, urinary dysfunction.
- Other investigations: keywords including urinary incontinence, continence, pad test, urinalysis, urine culture, tissue analysis were used.

Members of the committee were allocated the different topics of the chapter based on their specific expertise in the field. The first draft of the chapter was reviewed by all committee members, the final draft was then edited first by the Committee Chair and then by the book Editors.

Diagnostic techniques were evaluated with reference to the technique and its standardisation, intraobserver and interobserver variability, diagnostic accuracy, cost/benefit ratio and clinical benefit. The level of evidence was graded taking into consideration that imaging, neurophysiological testing and the other tests pertain to the area of “diagnosis” and the quality of the published papers is graded according to the criteria specific for this area. Areas of future research were identified.

Notwithstanding the large body of evidence research on imaging in anal and urinary incontinence, its clinical benefit remains questionable. Test-retest, intraobserver and interobserver accuracy are often provided for diagnostic tests although diagnostic accuracy is sometimes difficult to calculate. When ultrasound is used to measure bladder volume, catheterisation can be used as a reference standard and accuracy can be easily calculated but when sphincter volume is calculated with ultrasonography, there is no solid reference standard except another imaging technique (e.g.: MRI) and the validity of the measurement is tested against another weak test such as Valsalva Leak Point pressure of maximum urethral pressure profile. Imaging can either be performed to better understand the pathophysiology of incontinence and pelvic organ prolapse and it may be of importance although no immediate clinical benefit is evident (e.g.: calculation of sphincter volume with ultrasound). It can be performed as a diagnostic test in patients undergoing surgery so that quantification of the clinical benefit requires complex clinical trials (e.g.: MR imaging of pelvic organ prolapse in patient undergoing prolapse repair) in which different reference standards can be used (e.g.: physical examination or anatomic finding during surgery). Although imaging can sometimes offer a better understanding of the anatomy underlying the condition (e.g.: presence of an enterocele) the clinical benefit of this additional information may not be observed in all patients.

Although imaging is clearly a difficult area for research, the consensus regarding introduction of a
diagnostic test into our daily practice must rely on the evidence of clinical benefit in terms of safety, outcome or cost-benefit ratio.

Imaging studies belong to the area of diagnostic studies, they should follow the suggestions of the STARD initiative and they differ substantially from other types of clinical trials (Bossuyt 2003). The aim of clinical studies of diagnostic tests should be to provide information regarding the diagnostic accuracy of the proposed test although, this is not always possible.

A few considerations regarding the levels of evidence in imaging studies may be instrumental in reading this chapter and are summarised herewith.

Imaging of parameters with known prognostic value (e.g. PVR)

- The first issue is to prove that imaging studies image what they are supposed to image. Although the issue may be trivial in case of PVR imaging or anal sphincter imaging, the issue is relevant in other areas (eg: enterocoe imaging) and should be solved using imaging in cadavers or other approaches such as intraoperative confirmation of the observed condition.

- When the imaging is quantitative, accuracy versus the gold standard technique should be provided. When the imaging is qualitative (e.g. presence or absence of vaginal vault prolapse) the diagnostic value should be provided (sensitivity, specificity, positive and negative predictive value, accuracy, inter-rater and intrarater variability).

- Once validity has been proven, one can assume that the predictive value of the imaging study is equal to that observed for the parameter measured with the gold standard. The same applies to its value for patient management.

Imaging of parameters with unknown prognostic value (e.g. MRI of the pelvic floor)

- When the imaging is qualitative (eg: intact versus damaged levator ani), once validity is proven, the diagnostic value should be investigated providing sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability in cadavers or patients undergoing surgery.

- Once validity is proved, the prognostic value for patient management should be investigated.

- Confirmation of the proposed imaging study by independent groups is required ideally for both validity and prognostic value or at least for the latter parameter (we can assume that confirmation of the prognostic value is obtained, validity of the imaging technique can be inferred).

This is a very wide area that often requires a multiprofessional and multidisciplinary approach. The patient population is quite heterogeneous including children, female and male subjects suffering congenital malformation of the genital and urinary tract, neurogenic disorders, iatrogenic conditions and traumatic lesions. Clinical guidelines always refer to the so called “standard patient” but the majority of subjects referred to secondary and tertiary referral centres cannot be defined as such and their management sometimes requires deviation from guidelines recommendations. The large variability and the uniqueness of the observed cases may justify the adoption of a knowledge-based management in the absence of proven clinical benefit. Research on imaging of urinary incontinence and genital prolapse remains very active. Although all guidelines recommend not to use imaging in the evaluation of the standard patient, many clinicians believe this is an ideal adjunct to physical examination in evaluating the anatomical condition of the individual subject.

Urinary incontinence is defined as the complaint of any involuntary leakage of urine, it can be urethral or extraurethral [1]. This latter condition either results from congenital anomalies such as ectopic ureters (inserting in the female distal urethra or vagina), iatrogenic or traumatic conditions such as fistula. In some patients, LUTD causing UI, might compromise the transport of urine from the kidneys to the bladder resulting in hydronephrosis and renal failure. The relationship between high bladder storage pressure and renal deterioration was first identified in myelodysplatic children and then considered to apply in all neurogenic patients [2] and automatically transferred to male and female patients with or without neurogenic problems; the value of 40 cmH2O of bladder pressure as threshold value at which the UUT is at risk should therefore used with caution. In male patients, chronic retention of urine can be associated with UI and lead to chronic renal failure. In women, severe urogenital prolapse may cause angulation of the pelvic ureter by the uterine arteries leading to hydronephrosis [3] (Figure B 1 a,b).

### I. IMAGING OF THE UPPER URINARY TRACT

#### 1. INDICATIONS

Generally speaking, there is no need for upper tract imaging in patients with UI unless any of the
previously described conditions is suspected or diagnosed. In children with extraurethral incontinence imaging of the UUT helps to identify the underlying cause.

The objectives of UUT in the incontinent patient are as follows:

1. Evaluation of the upper urinary tract when the presence of an ectopic ureter or ureterovaginal fistula are suspected.
2. Evaluation of the kidneys whenever UI is related to bladder dysfunction with high storage pressures (e.g. in neurogenic voiding dysfunction, chronic retention with overflow or low compliance bladders)
3. Exclusion of hydronephrosis in cases of UI associated with severe uterine prolapse (Figure B 2 a,b,c,d).

2. TECHNIQUES

Upper tract imaging modalities include intra-venous urogram (IVU), ultrasound sonography (USS), computerised tomography (CT scan), magnetic resonance imaging (MRI), and isotope scanning. No data regarding reproducibility, specificity, sensitivity, positive and negative predictive value in relation with the diagnosis and management of UI are available. The choice of the imaging modality also depends on availability, expertise, and local management policies. Generally speaking, low cost and low risk techniques such as USS are preferred. Unless otherwise described, the following considerations regarding the different imaging modalities are based on expert opinion.

a) Ultrasonography

USS is the gold standard technique for primary imaging of the upper urinary tract because of the relatively low cost of the equipment and the examination, its wide availability, the lack of any exposure to ionising radiation. Renal USS is independent on kidney function and provides a good evaluation of kidney morphology. Concomitant renal disorders such as urinary lithiasis and neoplasms can also be diagnosed. In patients with LUTD, the detection of hydronephrosis is of importance and it can be related to either vesico-ureteral reflux or obstruction. Although, no strict correlation exists between the degree of dilatation and the severity of obstruction, the grade of hydronephrosis is correlated with the extent of cortical damage [4]. In children, kidneys with a pelvic diameter >20 mm are considered to be at risk for deterioration and require intervention [5]. Measurement of the resistive index in the interlobar and arciform arteries of the kidney has been proposed for the diagnosis of urinary obstruction but this is rarely used in the evaluation of the incontinent patient [6]. Whenever hydronephrosis is diagnosed on USS, other imaging modalities are often used to evaluate renal function, the degree of obstruction or vesico-ureteral reflux. USS is an ideal technique to follow the degree of hydronephrosis over time or the response to treatment.

b) Intravenous Urography

IVU is the original radiographic examination of the upper urinary tract which allows evaluation of upper urinary tract anatomy and function. Successful examination is dependent upon adequate renal capacity to concentrate urine and the examination is currently contraindicate when creatinine levels exceed 2.0 mg/dL [7] because of the possible increased toxicity of the contrast medium and the lack of concentration of the contrast agent by the impaired kidneys. While the former can be taken care of by adequate hydration of the patient, the poor concentration
capacity of an impaired kidney limits the possibility to delineate the collecting system. A number of different conditions such as renal dysfunction, obstruction, congenital anomalies, fistula, stones and tumours may be detected. IVU is the appropriate first study in cases of extraurethral incontinence. When ectopic ureter is suspected (although this condition can also be responsible for urethral incontinence), delayed films and tomography are important because the renal unit or moiety associated with an ectopic ureter is often poorly functioning. In fact, IVU is sometimes unable to detect a small, malfunctioning moiety associated with a duplication and ectopic ureter or a poorly functioning or abnormally located kidney with a single ectopic system [8-10]. In such cases where the diagnosis of ectopia is still suspected after IVU, another imaging modality such as CT, MRI (Figure B 3 a, b) or isotope scanning should be considered [11-13]. IVU is the appropriate first imaging study when uretero-vaginal fistula is suspected, usually after pelvic surgery. Typically, one sees ureteropyelocaliectasis proximal to the level of the fistula. This finding has been reported in 84-92% of cases [14, 15]. Sometimes extravasation can be seen. Confirmation of the presence of the fistula, its size and exact location is often obtained with retrograde ureteropyelography.

c) Computerised tomography

High quality information of the upper urinary tract anatomy can be obtained using multidetector helical CT scans and 3D reconstruction software. Differently from IVU which only acquires images in the antero-posterior or oblique CT acquires images in the axial plane. Pictures can then be reconstructed in 2D along any plane or in 3D whenever required. CT scan can be used irrespective of renal function when no iodinated contrast medium is used. Whenever hydronephrosis is present, urine can be used to delineate the collecting system reducing the need for contrast agents. In general, intravenous contrast medium is required to highlight specific anatomic characteristics. CT scan is often used after a first line evaluation with USS and it has replaced IVU almost entirely. Sev-
eral authors have reported the use of CT scan to detect ectopic ureter, in cases where the diagnosis is suspected, despite a normal IVU and ultrasound [16]. In these cases the small size and poor function of the ectopic moiety make diagnosis difficult by IVU.

d) Magnetic resonance imaging

MRI shares some of the advantages of CT over IVU in the evaluation of the upper urinary tracts. Furthermore acquisition can be performed along any plane and pictures can then be presented in a 2D or 3D fashion. The paramagnetic contrast medium is free of allergic reaction risk although its use in the upper urinary tract remains dependent upon renal function and concerns about its nephrotoxicity have been recently raised [17]. The development of the uro-MRI technique has gained an increasing role for the technology in the evaluation of hydroureter and urinary tract anomalies as an alternative to IVU. The use of MRI in the diagnosis of ectopic ureters has recently been described [18-20].

e) Isotopes

Isotopes are used primarily to examine morphological and functional characteristics of the upper urinary tract. Isotope scanning can be used to identify the location of a small kidney which is otherwise difficult to image with radiological techniques.

Renography is used to examine the differential function of the two kidneys, to identify disorders of urine transit and to quantify obstruction of the upper urinary tract. There are many physiological factors and technical pitfalls that can influence the outcome including the choice of radiolabel, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function and compliance of the collecting system [21, 22]. Diuresis renography with bladder drainage is recommended when obstructive uropathy is suspected [23]. Renal scintigraphy may be useful in the evaluation of ectopic ureters associated with hypoplastic kidneys [24].

f) Conclusions

Imaging of the UUT is rarely required in LUTD unless the condition originates from a malformation, a traumatic or a iatrogenic problem of the UUT. More rarely a condition of the LUT may endanger renal function, the preservation of which is required to guarantee a normal life expectancy in patients with LUTD.

g) Consensus Statement

- Imaging of the UUT is NOT indicated in the evaluation of non-neurogenic stress, urgency or mixed UI. [Level of Evidence 3, Grade of Recommendation C]

- Imaging of the UUT is indicated in cases of:
  a) neurogenic UI with high risk of renal damage (due to high detrusor pressure, e.g. myelodysplasia, spinal cord injury, and low compliance bladders) [Level of Evidence 3, Grade of Recommendation C]
b) chronic retention with UI [Level of Evidence 3, Grade of Recommendation C]

c) untreated severe POP [Level of Evidence 3, Grade of Recommendation C]

d) suspicion of extra-urethral UI by upper tract anomaly [Level of Evidence 3, Grade of Recommendation C]

The choice of the imaging techniques and their sequence depend on the clinical question and their availability. The least invasive techniques should be preferred and should precede the more invasive, also taking into consideration cost effectiveness. [Level of Evidence 3, Grade of Recommendation C]

h) Suggested Research Areas

- Prevalence of upper tract deterioration in various UI populations
- Natural history of upper tract damage
- Relation between upper tract dilation, renal damage and bladder function

II. IMAGING OF THE LOWER URINARY TRACT

The use of imaging of the LUT in patients with UI dates back 40 years, particularly in female patients. The techniques have changed, over the decades from static to dynamic imaging, from qualitative to quantitative information. Although some of the techniques are now more than 50 years old their clinical value remains at best, unclear.

1. X-RAY IMAGING

Voiding cystourethrogram (VUCG) was the mainstay of x-ray imaging of the LUT but it has been replaced almost entirely by USS because of its ease of use, low cost and availability. While CT has not gained acceptance because of the exposure of ionising radiations, MRI took the lead as the most promising imaging modality because it offered a comprehensive view of the pelvis and enabled visualisation of the position of visceral organ in relation to bony reference points. 3- and 4D USS recently offered volume acquisition with limitations in terms of the volume that can be acquired. Continuous technical development in imaging technology and techniques made this research area particularly interesting.

In males the purpose of voiding cystourethrogram has been mainly to locate infravesical obstruction separating the bladder neck from benign prostatic obstruction although it may play a role in the management of post-prostatectomy incontinence. In children the diagnosis and classification of reflux and diagnosis of posterior urethral valves have been the primary goals. The severity of the vesicoureteric reflux on one side determines the development of contralateral reflux and indicates a poorer resolution rate for reflux.

Positive-pressure urethrography has been used for the diagnosis of female urethral diverticula, it was shown to be more sensitive than voiding cystourethrography [4-6] although MRI is the gold standard for the diagnosis of diverticula and planning surgical repair [7, 8].

The rationale for imaging studies of the lower urinary tract in this field derives from the hypothesis that stress UI is caused by urethral hypermobility. This was the theoretical base of the classification of UI published by Green in 1968 and then modified by Blaivas and Olsson in 1998 [9, 10]. Investigation into cohorts of continent and incontinent patients failed to provide evidence to support the hypothesis and imaging techniques aiming at measuring bladder neck displacement during straining have been abandoned. The same applies to outcome research in urinary incontinence where surgery that limits bladder neck displacement does not necessarily lead to cure of the condition. A renewed interest derived from the availability of USS which took imaging out of the radiology suites and moved it into the urological and gynaecological outpatient clinics opening new opportunities for clinical research in this field. The possibility of imaging what was usually perceived during physical examination such as bladder neck mobility or POP increased the usefulness of USS. Research in the field of MRI first looked into the possibility of fast dynamic acquisition to image the displacement of visceral organs during effort to better qualify POP and then moved into morphological imaging of the pelvic organs muscular support to investigate the physiopathology of genital prolapse.

a) Female Cystourethrography

X-ray imaging of the urinary bladder and urethra has been used to assess the female urinary tract in women suffering UI to evaluate urethral/bladder neck hypermobility and to assess associated conditions such as urethral obstruction, vesico-urethral reflux, diverticula, fistula, stones and tumours. In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction [1, 11].

The diagnosis and classification of reflux and diagnosis of posterior urethral valves in children have been the primary goals [2]. In a study comparing cystourethrogram with direct radionuclide voiding cystography and voiding urosonography with contrast medium, voiding sonography and direct radionuclide voiding cystography were shown to be the most sensitive [12].

1. BACKGROUND

History and methodology of cystourethrography in females had been reviewed by Olesen [6]. The technique is now over 70 years old. Voiding cys-
touretrography with lateral projection was first done by Mikulicz-Radecki in 1931 [13]. The use of a metallic bead chain to identify the urethra was introduced by Stevens and Smith in 1937, and in 1956 Ardran, Simmons and Stewart reported on a cinematographic technique with contrast media also in the vagina and rectum [14, 15]. In an attempt to combine qualitative and quantitative information regarding the function of the lower urinary tract, the combined used of fluoroscopy and pressure-flow recordings was proposed during the nineteen sixties and seventies [16-20].

2. METHODOLOGY (PROJECTION, POSITIONING AND EXPOSURES)

Bladder neck displacement is best viewed and quantified in true lateral projection although image quality is sometimes poor because of the increased body mass and the overlap of bony structures with the bladder neck area. Consequently, oblique projections are sometimes used notwithstanding the lack of quantitative information. Achieving a quasi-physiological voiding in a radiology suite is difficult because of the inevitable impact of the environment. The use of a sitting position is recommended for micturition studies as voiding while standing or lying will increase the embarrassment and therefore many impair the quality of the examination [13]. Especially in patients with large body mass index, imaging of female urethra in a true lateral projection is difficult, it necessitates high radiation doses as the central x-ray beam must penetrate the trocanteric regions and further because the urethrovesical junction is sometimes overshadowed by the lateral parts of the bladder. A significant improvement in this area has been brought about by digital imaging which allows the subtraction of the bony structures [Figure B 4]. The position and mobility of the urethrovesical junction as well as urine leakage are supposed to be influenced by the filling volume as has been demonstrated on ultrasonography and leak point pressure measurements [21, 22]. However, in VCUG the bladder is filled to capacity. Addition of a urethral bead chain or catheter and vaginal contrast to improve the visualisation of the urethra, bladder neck and trigone has been abandoned. Contrast in the rectum is not necessary for urinary incontinence purposes. Exposures at rest should be supplemented with provocative manoeuvres to test bladder neck mobility by contracting and relaxing the pelvic floor (e.g.: coughing, straining, and squeezing). Whenever possible, pictures while the patient is voiding should be obtained. It is important to consider that coughing and straining result in a different effect on the pelvic floor. Straining might be associated with relaxation or contraction of the pelvic floor, and the imaging can change accordingly.

During coughing there is a reflex contraction of the pelvic floor, but coughs are of short duration and difficult to catch on spot films. Bladder suspension defects were diagnosed at rest in 49% of 420 examinations, while coughing and micturition disclosed a further number of 20% and 4% respectively [13]. Squeezing can demonstrate pelvic floor awareness and contraction [23].

3. COMBINED IMAGING AND URODYNAMICS

Videourodynamics has been by some regarded as the “gold standard” in the evaluation of LUTD [23]. Reproducibility of the combined examination has not been assessed and further the radiation dose has to be considered [15, 20, 24-26]. One study has attempted to compare videourodynamics with saline cystometry [23]. Independent observers carried out the two procedures with 75 women having the saline cystometry first and a further 75 women had videourodynamics first. The degree of bladder descent noted on screening was greater than on clinical ex-
amination. Nineteen women had trabeculation and a further 11 women had bladder or urethral diverticula, urethral stenosis and vesicoureteric reflux [1, 11, 14]. Only seven of the eleven women could have been predicted by a selective imaging policy based on history alone which would image 43% of the 150 women. This suggests that a selective policy of screening will unnecessarily expose patients to radiation while not using the optimal technique for investigation for all patients who need the test. Nevertheless simultaneous videomonitoring along with tracings of pressure and urine flow rate are important to ensure that the exposures are made at appropriate moments so that the radiographs can be representative of the various functional states [13, 18, 27, 28].

Patients with Parkinson’s disease and multiple system atrophy are best evaluated by videourodynamics and sphincter motor unit potential analyses to identify characteristic features of these conditions including: external sphincter denervation, neurogenic sphincter motor unit potentials, open bladder neck at rest and detrusor-external sphincter dyssnergia [29]. Neurogenic patients show severe bladder trabeculation with diverticula and pseudodiverticula, pelviureteric reflux, widening bladder neck and proximal urethra. Narrowing at the level of the membranous urethra can suggest, the presence of neurogenic dysfunction of the lower urinary tract (occult spinal dysraphism, non-neurogenic neurogenic bladder [also known as the Hinman syndrome]) even in the absence of neurogenic symptoms and signs [30-32]. Urodynamic parameters in children do not discriminate between those with or without vesicoureteral reflux thus videourodynamics have been considered essential. Additionally, children with non-neurogenic voiding dysfunction are found to have a number of abnormalities with videourodynamics [33, 34]. Indications for videourodynamics include previous continence and vaginal surgery, neurological disorders and suspicion of urethral diverticula.

4. NORMAL AND DEFECTIVE BLADDER SUPPORT

The whole issue about the clinical value of VCUG is about the role of defective bladder support in the pathophysiology of SUI in female patients and the relation between the surgical correction of such a defect and cure. The concept of urethral hypermobility was inherent to the classification of SUI and the concept that impaired transmission of abdominal pressure to female urethra could be responsible for the observed leakage. Little remains regarding the concept of urethral hypermobility in a modern view of female SUI and this contributed to the decreasing use of VCUG in the evaluation of a standard female patient.

The normal resting bladder has a smooth surface although bladder trabeculation is often seen in elderly women and not necessarily related to any pathological condition. The internal urethral orifice is located just above a horizontal line through the lowermost part of the symphysis in a coronal projection. The urethra is straight and runs anteriorly and caudally toward the external meatus.

On coughing and straining, relaxation of the pelvic floor results in downward movement of the bladder neck, which can be associated with a backward movement of the bladder neck resulting in a change in urethral axis. Squeezing (and sometimes also straining) results in contraction of the pelvic floor muscle with a cranial movement of the bladder neck Figure B 5a. During voiding (Figure B 5b) the bladder base is usually lowered about 1 cm, the angle between the urethra and the trigone is straightened, making a funnelled appearance of the proximal urethra and the bladder base, the bladder contour is rounded and a fine sawtooth irregularity of the mucosa becomes visible above the trigone. Angles and distances between the urethra, bladder base and symphysis pubis have been assessed radiologically. The following parameters have been assessed for reliability:

1. The posterior urethrovesical angle (PUV) is defined by lines along the posterior urethra and the trigone [35]. Cut off values were usually 115° or more [36, 37];

2. The urethral inclination is between the proximal urethral axis and the vertical plane, which is a plane outside the patient and, therefore, the angle

Figure B5: Female Cysto-urethrography 1a: normal appearance on couching, straining and squeezing b: normal appearance on voiding
also varies with pelvic inclination. In Green type I and type II descent the angle is less or more than 45° respectively [37];

3. The urethropelvic (UP) angle is measured during voiding as the anterior angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis through the lowermost part of the obturator foramen closest to the film. In normal subjects the mean UP is about 95° and the cut off point for bladder descent are values below 70° [13];

4. Symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice. Normal values are 31 ± 6 mm (mean ± SD) and values less than 20 mm are the cut off points for descent [13];

5. The urethral axis at rest (UAR) and during straining (UAS) (Figure B 6) Funnelling of the proximal urethra and flatness of the bladder base (both anterior and posterior to the internal urethral orifice) and the most dependent portion of the bladder base (the urethrovaginal junction or a point posterior to that) are important qualitative parameters estimated on straining films [36].

Anterior bladder suspension defects or bladder base insufficiency (BBI) (Figure B 7) is defined as SO < 20 mm with a normally positioned vagina.
at rest, during coughing or micturition and/or funnelling of the bladder base at rest or with coughing. BBI can be graded 1-3, which corresponds to Green's type I descent [13, 38]. The supportive defect is supposed to be in the fascial and ligamentous system and their abnormal detachments (eg., paravaginal defects).

Posterior bladder suspension defects (Figure B 8) are defined as a posterior-inferior bladder displacement and a UP of less than 70° [13]. It corresponds to Gruen's type II [39]. Sometimes (Figure B 9) only the trigone and posterior part of the bladder is involved. The supportive defect is supposed to be in the muscular pelvic floor, that is, the pubo-vesical part of the pubococcygeus muscle or in paravaginal detachment.

Interestingly, when UAR and UAS were examined in a group of 76 continent women and correlated with age, a perfect linear regression was noted between UAR and age (R²= 0.28). Patients with stress urinary incontinence were found to have an average UAR value of 25° with a mean UAS of 43° leading to a threshold value of hypermobility of about 20°. When standing cystourethrograms were repeated 3 to 6 months after surgery for SUI, UAR and UAS values were found to be close to normal suggesting a relation between the correction of the defective bladder support and cure [39]. A more structured definition of cystocele (ranked by height in centimetres) was also obtained, adding to the emerging data that the reliability of the pelvic organ prolapse quantification (POP-Q) system increases when measurements are performed in a more upright position [39].

5. Reproducibility

The observer variation has been evaluated in four university uro-gynecological units (Table 1) [23, 36, 40, 41]. The inter-observer agreement was 43-79% and the intra-observer agreement was 53-99%. These figures are in the same range as has been found for other diagnostic tests [42].

6. Accuracy for the diagnosis of SUI and post-operative results

Evaluation of accuracy is the mainstay in the evaluation of a diagnostic technique. One has to consider that sensitivity and specificity depend on intrinsic factors such as reproducibility (as measured by
intraobserver and interobserver variation) and extrinsic ones such as the characteristic of the patient cohort used to assess accuracy.

The accuracy of the previously mentioned radiological criteria have been measured by comparing imaging data with the ‘so called’ index-test which in this case was a clinical diagnosis of urodynamic stress incontinence and expressed as specificity and sensitivity or as predictive values. Unfortunately the diagnosis of SUI is controversial and might be based on subjective criteria, urodynamic tests, or measurement of leakage. Even radiological criteria have been included in the diagnosis.

Reproducibility (e.g. test-re-test agreement) has not been measured, but intra- and inter-observer variation has been calculated and also adjusted for expected chance agreement (kappa coefficient). The predictive values and the kappa coefficient are supposed to depend on the prevalence, and therefore, comparison between different materials are difficult [42].

No consensus has been reached in the peer-review literature as to the lack of discriminant value of VCUG between SUI and continence, the majority of published papers are consistently negative although new promising data have been published [37, 39, 43-45]. The specificity of 5 radiological parameters on static bead chain VCUG was 44-76% and the sensitivity 53-100% [45, 46]. Neither was the degree of SUI correlated with the type or degree of suspension defects [23, 40, 47]. The positive and negative predictive values for a bladder suspension defect were 0.70 (95% C.I.: 0.62-0.78) and 0.52 (95% C.I. 0.41-0.63) respectively on voiding colpo-cystourethrography [38, 48]. In a later publication on 159 women, positive and negative predictive values of 0.56 and 0.74 were obtained [45]. Evaluation of the urethral angle at rest and during stress in controls and in patients with SUI and various grades of anterior vaginal prolapse show a significant relationship between UAR and aging (from 2.4° ± 14.9° in the third decade to 29° ± 9.2° in the 9th decade; r2= 0.28). In patients with SUI, UAR and UAS decreased from 25.7° ± 13.6° and 42.6° ± 15.9° to 16.6° ± 14.7° and 23.8° ± 17.5°, respectively; the observed changes were found to be statistically significant. A similarly significant difference was found in patients with moderate to grade 3 cystocele and urethral hypermobility (at least 5 cm descent of the bladder base below the inferior ramus of the pubic symphysis on the lateral view of a standing VUCG): UAR and UAS decreased from 48.1° ± 16.5° and 64.4° ± 16.8° to 22.3° ± 26.9° and 29.8° ± 22.8°, respectively.

Comparison of a randomly selected control cohort (aged-matched) with patients suffering SUI showed a significant difference of UAR and UAS at diagnosis.
while similar values were found after surgery (Figure B 10). This was similar to patients with grade 3 cystocele in whom both UAR and UAS were significantly different from controls at baseline while showed similar values in the postoperative follow-up.

Measurement of the cystocele height (LATH), obtained as the distance between the inferior border of the pubic symphysis and the inferior edge of the cystocele in controls and patients with mild and severe cystocele showed a significant difference between the two cohorts (16.63 ± 10.9 versus 27.4 ± 12.3 mm versus 73.4 ± 15.6 mm, respectively). Following formal cystocele repair, a significant change of LATH values was found in patient with mild and severe cystocele (from 27.4 ± 12.3 mm to 13.9 ± 18.0 mm and from 73.4 ± 15.6 mm to 25.4 ± 24.6 mm, respectively [p<0.001]).

These are the first data supporting the used of standing VCUG as an outcome measured, previous peer-review papers suggested the inability of its technique to distinguish postoperative failures from success [13, 23, 42, 44, 46, 49-52].

7. COMPARISON OF CYSTOURETHROGRAPHY AND ULTRASOUND

The development of USS techniques for the evaluation of the lower urinary tract raised the question of the relationship between X-ray and USS imaging. Static bead chain cystourethrography has been compared with transrectal and perineal USS and voiding colpo-cystourethrography has been compared with perineal USS [46, 47, 53, 54]. The findings correlated well regarding bladder neck position and mobility, PUV, urethral inclination, SO distance and rotation angle.

Specificity, sensitivity and interobserver agreement were also comparable for the two methods. All the authors seem to prefer the sonographic modality because imaging can be performed at the same time as the physical examination. This has also been the case in men with neuromuscular dysfunction [11]. Simple and extensive funnelling is more easily imaged in upright patients during cystourethrography than in the supine position frequently used for ultrasound studies [30].

8. COMPARISON OF CYSTOURETHROGRAPHY AND MRI

The introduction of MRI in the assessment of the LUT required adequate comparison of this technique with standard X-ray imaging. The comparison of cystourethrography and colpo-cystourethrography with dynamic MRI showed comparable data on bladder neck position and cystocele extension [55, 56]. Although there is an obvious concern about the fact that dynamic MRI
imaging is usually performed with the patient lying in a dorsal lithotomy position, comparison of standing and lying colposcystourethrography did not show any significant difference [56].

9. CONCLUSIONS

VUCG does not have a major role in the evaluation of the standard female patient with UI confirmatory results on the clinical utility of measuring urethral angle and cystocele height in patients with UI and POP who are scheduled for surgery still missing. Defective bladder support can be diagnosed on VCUG with a reliability comparable with other diagnostic tests.

Dependent on local facilities the method might be considered if the choice of a surgical procedure is based on type and degree of supporting tissue deficiencies and possibly if new procedures are evaluated for the ability to restore this deficiency.

10. CONSENSUS STATEMENT

- Cystourethrography is NOT indicated in primary uncomplicated stress, urge or mixed female urinary incontinence [Level of Evidence 3, Grade of Recommendation C].
- Cystourethrography may be a reasonable option in the preoperative evaluation of complicated or recurrent female urinary incontinence [Level of Evidence 3, Grade of Recommendation C].

11. SUGGESTED RESEARCH AREAS

- Variation of VCUG parameters in patients with SUI +/- ISD and prognostic value for surgical repair.
- VCUG in re-do surgery for SUI

2. ULTRASONOGRAPHY

Ultrasoundography has been used in the evaluation of urinary incontinence as early as 1980 [1]. Over the past three decades the quality of the ultrasound image and its processing has improved beyond what could have been imagined during the 70’s. Various new developments, such as the use of contrast medium, colour Doppler, 360 degree transducers and three- and four-dimensional imaging have been introduced and have led to more widespread use of ultrasonography in the evaluation of the lower urinary tract and pelvic floor disorders.

A number of studies have reported good correlations between ultrasonography and x-ray in the evaluation of urinary incontinence [2-9] Schenck et al 2011. In particular, the position of the bladder neck at rest and during Valsalva [10] manoeuvre has frequently been compared, and all authors agree on a good correlation. Some authors even found better accuracy for ultrasound [5], especially in obese women [2]. Ultrasonography is cheaper than X-ray imaging, it is often preferred by physicians because the imaging studies can be performed in their own office as part of the physical examination and it is also more acceptable to patients because of the lack of for radiation exposure. However ultrasound itself produces problems by needing to be in direct contact with the patient even during dynamic manoeuvres and the resolution is dependent on the frequency of the probe used. The higher the ultrasound frequency, the better the resolution but there is reduced penetration into the tissues.

a) Types Of Ultrasonography

Different imaging approaches have been used, such as abdominal, transvaginal, transrectal, perineal and transurethral. Synonyms for the perineal approach are transperineal, introital, labial or translabial access, all use a similar method and there does not appear to be a substantive difference between these terms, a common agreed term needs to be decided upon.

Abdominal ultrasonography is generally not considered to be helpful in pelvic floor and urethral imaging because of the acoustic shadow caused by the pubic bones particularly in the obese patient [1]. All approaches in ultrasound have a problem of distorting the tissue being imaged due to compression. With vaginal ultrasonography this risk is probably highest [11], although this has also been denied [12]. Most recent studies report on perineal ultrasonography that allows the visualisation of all three compartments in one image but again compression of the urethra may occur and imaging is impaired with vaginal prolapse or gas in the rectum. The development of three-dimensional ultrasonographic systems has brought increased accuracy to measuring volumes of irregular structures as well as reconstructed images from novel directions and allowing pelvic floor imaging. Three-dimensional ultrasonography was first described for the female urethra in 1999 [13]; the three-dimensional image can either be evaluated as a separate entity on the screen, or in combination with each of the two-dimensional planes from which it is derived (Figure B 10) (see figure in this document). These three two dimensional planes are at orthogonal to each other being the sagittal, coronal and axial planes. Three-dimensional images are built up as a rendered image of a self defined region of interest, major advantages over 2D imaging include the possibility of reviewing the acquired images from any investigator and the ability to analyse the acquired volume through any plane (similar to CT scans or MRI) (Figure B11). This means that the levator ani muscle can be easily visualised. However interest has focused on the absence of the pelvic floor being imaged and a defect being implied. Ultrasound produces images by being reflected by a tissue. These reflective surfaces produce images of great clarity and resolution which are independent
of the ultrasonic frequency. However once the tissue is perpendicular to the direction of travel of the ultrasound waves then axial resolution is effective, this limits the accuracy and the ability for tissues to be imaged. This highlights the importance of testing all ultrasound imaging modalities against a gold standard such as cadaveric dissection or comparing with another medium such as MRI or CT. Four-dimensional imaging involves a volume of tissue being continuously scanned, this inevitably involves a time delay and cannot be “real-time” but incorporates the enormous improvement in speed of three-dimensional systems over the last few years and it makes three-dimensional assessment of the dynamic relation of the pelvic organs on Valsalva manoeuvre and pelvic floor contraction possible.

b) Standardisation

No consensus has been reached as to the standardisation of image orientation. Some prefer orientation with cranial structures below (Figure B 12a) [14] whereas others prefer presentation of the cranial parts above (Figure B 12b) [15]. All authors agree that the symphysis pubis, and its inferior border in particular, is a well recognisable and fixed reference point. This point can be used in the evaluation of the various aspects of relevant structures at rest and during dynamic imaging. In general, ultrasonographic studies are performed in the supine position (Figure B 13). Small differences between the supine and standing position of the patient have been documented, although these differences disappeared during a Valsalva manoeuvre [16]. Only a few studies have been performed in the standing position [17]. There is no clear consensus on the amount of bladder filling, some authors prefer significant bladder filling, others prefer a nearly empty bladder because an empty bladder seems to descend more on Valsalva manoeuvre compared with a full bladder [18, 19]. Attempts to standardise Valsalva manoeuvre, ideally with intra-abdominal pressure measurements, has not been widely accepted [12, 20]. In one study [17], a peak flow meter has been used, where women were asked to “huff” maximally and to reach the same force during a number of “huffs”. It has been shown that the mobility of the bladder neck differs between coughing and Valsalva manoeuvre [21]. Co-activation of the pelvic floor muscles during Valsalva manoeuvre has been documented and is one of the reasons for the lack of standardisation [21].

c) The Urethra And Bladder Neck

When collagen fibres and muscle fibres are located parallel to the ultrasound beam, the structure
Ultrasound may result in variable images of the urethra, since the echogeneity of the structures depends on the position of the transducer in relation to the urethra. This may produce confusing images, especially in the dynamic process of pelvic floor contraction and Valsalva manoeuvre. In the midsagittal plane on perineal ultrasonography, and with normal anatomical position of the urethra at rest, the internal sphincter and inner mucosal layer of the urethra will appear hypoechogenic (Figure B10), these structures cannot be distinguished from each other on ultrasonography. In the midsagittal plane and with normal anatomical position of the urethra at rest, the striated external sphincter or rhabdosphincter will appear hyperechogenic, and can hardly be distinguished from the surrounding structures. It will, however, be easily visible as a hyperechogenic circular structure in the axial plane as seen on three-dimensional ultrasonography [22,23]. The rhabdosphincter has been found to be thinner dorsally [13], and both ventrally and dorsally [24] by various authors and more difficult to distinguish from the internal sphincter ventrally and dorsally compared with laterally [25]. These differences may be due to the approach used to image the structures as well as types of probes applied but this has not been addressed in any study to date.

With the use of ultrasonography, thickness and length of the urethral sphincter muscle can be measured and urethral volume calculated [15, 25, 26]. Intra-urethral ultrasonography has been used for this purpose although complete imaging of the lateral parts of the sphincter are difficult due to the higher frequencies emitted by these probes [27], others have used two- or three-dimensional ultrasonography of the urethra [13, 22, 24, 28].

Comparison of transvaginal and transrectal approach showed a lower degree of urethral compression with the latter approach [24, 29]. Ultrasound measurement of the female urethra has been found to be reproducible [13, 22]. Sphincter volume may differ significantly when 2D or 3D imaging is used [22]. Urethral volumes, measured by 3D ultrasonography, were positively correlated with the actual volumes in cadavers [28]. A significant and positive correlation between rhabdosphincter volumes and symptoms and signs of urinary incontinence has been reported [13]; correlations with the urethral pressure profile...
(UPP) have been found [23, 25, 26, 28] but these data could not be reproduced [30]. Ultrasonography imaging during micturition has been explored with the aid of a remote control systems [31]. The use of intra-urethral ultrasonography with rotating probes (360°) has been proposed by various authors although no particular advantages over perineal US could be identified and incomplete imaging appears to be a problem due to the high ultrasound frequency emitted [27, 32-35].

The advantage of preoperative and intraoperative three-dimensional ultrasound scanning in women with urethral diverticula has been outlined by Yang et al. [36, 37].

d) Bladder Neck

The bladder neck and proximal urethra are easily visible on all types of ultrasonography without the need for catheterisation (Figure B 10). Measurements are usually taken at rest, during straining (Valsalva manoeuvre), and sometimes during a cough and squeeze. The position and movements are measured in relation to the lower margin of the symphysis pubis. The difference between rest and strain is referred to as the bladder neck descent (the distance between the bladder neck and a horizontal line through the lower end of the symphysis pubis) (Figure B 14). On Valsalva manoeuvre the bladder neck rotates in a posterior and inferior direction away from the symphysis pubis. The axis of the urethra in relation to a vertical or horizontal line can be measured in degrees and provide the degrees of urethral rotation or bladder neck mobility. Other parameters are the posterior urethrovesical angle and the anterior urethrovesical angle. A number of studies have validated the use of ultrasonography in the assessment of the position and mobility of the bladder neck and proximal urethra. Good results for this validity testing have been reported although the clinical value of such measurements is still elusive [4, 12, 38-40]. Normal values of bladder neck mobility have not been defined, since there is a great range in mobility even in young nulliparous women. In one study amongst nulliparous continent women of approximately 20 years of age, the bladder neck descent varied between 1mm and 40mm [41].

Others [38] found an average descent of 15 mm on Valsalva manoeuvre and 8 mm on a cough. Brandt et al. have found an average bladder neck descent of only 5 mm in 16 year old girls [42]. Racial differences have been demonstrated, with white women having greater bladder neck mobility compared with black women [43]. Genetic determination of bladder neck mobility has been suggested [44]. Numerous studies have found greater bladder neck mobility in parous compared with nulliparous women [12, 30, 45-47]. Bladder neck hypermobility, however defined, is considered to be related to stress urinary incontinence [15, 30]. A large number of studies have correlated ultrasonographic findings with urodynamic parameters [47-56]). Specificity and

Figure B 14: Perineal midsagittal two-dimensional view at rest and on Valsalva manoeuvre. Bladder neck descent. (S= symphysis pubis; U= urethra; B= bladder; A= anal canal.)
sensitivity of ultrasonography for the diagnosis of stress incontinence were 83 and 68% in one study [50] and 92 and 96% in another study [57]. There is one study which has used ultrasound of the bladder neck movement on coughing and Valsalva as a marker with patients undergoing pelvic floor exercises. In this study the response to treatment was not associated with changes to the bladder neck mobility [58] underlining this is probably an associated phenomenon and not the cause for stress urinary incontinence.

One research group has specifically investigated simultaneous perineal ultrasonography and urethrometry. They were able to demonstrate that the variations in urethral pressure were caused by the activity of the urethral sphincter as well the pelvic floor muscles [59]. The contractions from the urethral sphincter during acute stress events such as coughing are thought to be due to fast contractions. Some studies have used ultrasonography in an attempt to optimise patient management, but despite the abundant literature on the use of ultrasonography in the investigation of women with urinary incontinence, disappointingly, a clinical advantage in terms of patient outcome has not been reported until now [60, 61].

Urethral funnelling can be observed on ultrasonography (Figure B 15) particularly with the use of contrast agents. It is a typical finding in women with stress urinary incontinence but can be seen in asymptomatic women as well [62-64]. In a study on stress incontinent women, funnelling was found to be present in nearly all women [63, 65]. Urinary incontinence can be demonstrated by the use of colour Doppler of the urethra [66, 67]. Colour Doppler has, furthermore, been used to visualise the periurethral vasculature in nulliparous women [68] and differences have been described between continent and incontinent women [69, 70] and before and after oestrogen supplementation in postmenopausal women. Doppler velocimetry has recently been used in a study on the vascularisation of the levator ani musculature and a correlation has been found between the absence of an end-diastolic flow and the presence of stress urinary incontinence [71].

The blood flow around the urethra and bladder has been studied with Doppler before and after insertion of tension free vaginal tape and the transobturator tape. The blood flow decreases only after insertion of the tensional free vaginal tape whereas the blood flow was unchanged after insertion of the transobturator tape which may relate to the direction of urethral compression [72].

e) Determination of the Post Void Residual Urine and Bladder Wall Thickness

Ultrasonography is the gold standard technique for measuring bladder volume and post-void residual urine [73-77]. Ultrasonographic data have been compared with residual volumes obtained by in and out catheterisation under ultrasound control and were found satisfactory. However, Khan et al. have

Figure B 15: Perineal midsagittal two-dimensional view.
Urethral funnelling.
challenged the methodology of these studies and have found deficiencies in all reports on the topic [78]. A simple formula often used is [Height * Width* Depth](cm) * 0.7 = Volume (ml) in which the factor 0.7 is the correction for the non circular shape of the bladder. Automated ultrasound systems for measuring bladder volume and post-void residual have been developed and have been found to be more accurate than standard ultrasound measurements, furthermore they can be used by health care providers with no training in ultrasound imaging[79]. These machines are widely used and are, in general, experienced as reliable enough for clinical use, however, in the case of ascites [80] or an ovarian cyst [81] for example, the estimated urinary volumes can be incorrect, and in post partum women.

Recently the normal values for the post void residual urinary volumes in asymptomatic women have been presented; in 60 year old women, the median residual volume was 19 ml, and 95% of women had a post void residual volume of less than 100 ml [74]. Ultrasound measurement of bladder wall thickness (BWT) and ultrasound estimated bladder weight (UEBW). Ultrasound measurement of BWT was first proposed as a non-invasive method for diagnosing infravesical obstruction in children [82]. More recently, BWT has been used to predict the outcome of children with primary nocturnal enuresis [82-84]. BWT has also been proposed as a risk factor for upper urinary tract deterioration in children with myelodysplasia [85]. Measurement of BWT was also proposed to diagnose bladder dysfunction (detrusor over activity and detrusor hypocontractility versus normal detrusor function) in children with urinary tract infection [86, 87]. Additional parameters such as the bladder wall thickness index (length x width x depth of the bladder at full bladder/average BWT) were proposed and a nomogram for the paediatric population provided [88].

In the adult population, higher BWT values have been measured in men than in women. Thickness may certainly differ depending the measurement technique; values of 3.3 +/- 1.1 mm and 3.0 +/- 1.0 mm, respectively were reported by Hackenberg and co-workers [89]. Oelke confirmed a significant difference between male and female detrusor thickness (1.4 versus 1.2 mm, respectively) [90]. A small increase of detrusor hypertrophy with age has been reported in both genders [89]. In men, measurement of bladder wall thickness proved to be the most sensitive parameter (outperforming uroflowmetry) to diagnose BOO in patients suffering LUTS [91, 92].

Transvaginal ultrasound was first proposed in 1994 for the measurement of BWT in women with bladder volume of less than 20 ml. A significant difference was shown in patients with DO and USI (6.7 +/- 0.6 versus 3.5 +/- 0.6 mm, respectively). Low intraobserver and interobserver variability were measured: 0.02 mm in both with a 95% confidence interval of -0.22 to 0.18 and -0.32 to 0.35 mm, respectively [93]. In 1996, Khullar and co-workers showed how ultrasound measurement of BWT is a sensitive method for diagnosing DO in symptomatic women without bladder outlet obstruction with 94% of women with BWT greater than 5 mm having involuntary detrusor contractions on videocystourethrography or ambulatory urodynamics [94]. In 2002, the same group showed no overlap in the 95% confidence intervals of BWT was shown in patients with DO and USI in women with storage symptoms, confirming the potential of this parameter for diagnosing DO [95]. In 2003, a study on ultrasound cystourethrography in women confirmed a significant association between age and intravesical pressure at maximum flow with BWT [96]. Methodological and technical issues in the ultrasound measurement of bladder wall thickness and weight remain open and constitute a major limitation for a more widespread use of these parameters. In 2005 Chalana and co-workers published an early report on automatic measurement of the ultrasound estimated bladder weight from three-dimensional ultrasound. An average value of 42 +/- 6 g was measured in healthy male subjects. A standard deviation of 4 g was seen among measurements performed in the same subject at different bladder volumes (200 to 400 ml) [97].

Further research in this area is certainly needed and further improvement in the accuracy of automated systems is eagerly awaited. Although data published in the peer review literature on this subject are quite consistent, two discordant papers were recently published from Australia. Blatt and co-worker showed uniform values of BWT measured using an abdominal approach among men and women with non-neuromgenic voiding dysfunction suggesting this parameter cannot be used to diagnose storage or voiding dysfunction, this may reflect the thinning of the bladder wall with increasing bladder volume [98, 99, 100]. A retrospective study on women undergoing translabial ultrasonography suggests a significant association between BWT and DO although a low diagnostic accuracy was shown for the diagnosis of DO [101] which could be due to the fact that translabial ultrasound is unreliable [102].

The association between detrusor hypertrophy and bladder dysfunction (DO and BOO) is a well established fact in Urology. Ultrasound measurement of BWT and UEBW is an interesting alternative approach that may avoid invasive urodynamics in some patients. [103]. The reduction in bladder wall thickness has been found after the relief of bladder outlet obstruction [104]. The development of automated ultrasound systems for measuring UEBW is instrumental to foster further research in this area, particularly in the management of patients with LUTS [105] and in the evaluation of bladder response to pharmacological treatment [106].
**f) Pelvic Floor Muscles**

Ultrasonography can be used to assess pelvic floor muscles and their function. Contraction of the pelvic floor results in displacement of pelvic structures that can easily be imaged on ultrasound (Figure B 16) such as the cranial lift of the urethra in relation to the symphysis pubis during a maximal squeeze [16, 107] but also the dimensions of the genital hiatus or the posterior anorectal angle can serve this purpose [108]. Comparison with traditional measurements of pelvic floor muscle strength has been performed [107], and good correlations with palpation and perineometry have been found [109, 110]. Ultrasonography has been used to evaluate the effects of pelvic floor muscle training. A higher resting position of the bladder neck and a reduction in the rotational excursion of the urethra during Valsalva manoeuvre have been found with training [111]. Another research group has reported that the thickness of pelvic floor muscles increased after training [112]. A number of studies have assessed healthy female volunteers to establish normal values [41, 112], and one study has specifically compared elite athletes with normal volunteers [113].

Measurements of the levator ani muscle, with the use of two-dimensional imaging, has been recently described, and although direct comparisons to three dimensional ultrasonography are lacking, the acquired data were comparable [114]. However one study has compared three-dimensional ultrason of the levator ani hiatus at rest and during contraction in a number of different groups of women with prolapse, urodynamic stress incontinence and asymptomatic women suggesting that these measurements are not sensitive enough to discriminate between different groups [115].

Almost half of women are unable to perform an optimal contraction of the pelvic floor muscles. Ultrasonography can be used in pelvic floor training to provide women with a visual feedback of their exercise [16, 116]. In one study, 57% of the women who were not able to perform a proper pelvic floor contraction, were able to do so with the help of visual biofeedback of ultrasonography to observe bladder neck movement [16]. This does not appear to produce better outcomes of changes with pelvic floor physiotherapy [117]. The contraction of the pelvic floor muscle just before and

**Figure B 16:** Perineal midsagittal two-dimensional view at rest and on contraction. Levator contraction with ventro-cranial displacement of the urethra. Measurement of minimal dimension of genital hiatus (from symphysis pubis to levator ani muscle)
during a cough, “the knack”, can also be visualized [118]. It has been demonstrated that the knack can significantly reduce urethral mobility during a cough.

Direct measurement of the pelvic floor muscles is possible with the use of two and three-dimensional perineal ultrasonography. An alternative technique makes use of a 360 degree rectal probe intravaginally (Figure 17) [114]. Most studies, however, have used three-dimensional perineal ultrasonography for this purpose [17, 108, 113, 119, 120]. The thickness of the muscles as well as the hiatal area can be measured. Hiatal dimensions and pelvic floor muscle thickness have been extensively validated and have good test retest and inter observer characteristics [17]. There is a learning curve to measurement of the levator ani hiatus needing over ten sets of scans to perform the measurement. However measurements of the pubic arch were not accurate suggesting that measurements of levator avulsion may require more training [121].

The pelvic floor muscles were found thinner in women with pelvic organ prolapse [15, 114, 122] and with urinary incontinence [123], whereas their genital hiatus was found larger [124] interestingly this finding does not produce a significantly reduced maximal voluntary contraction even with pubovisceral muscle defects [125]. Well trained women have thicker pelvic floor muscles compared with controls [113], and Chinese women had thinner muscles compared with Caucasian women [120]. In nulliparous Chinese women, the anterior/posterior hiatal diameter was significantly increased in women with a higher body mass index [120]. Pelvic floor biomechanics were investigated with ultrasound using the position of the bladder neck in combination with continuous vaginal pressures measurements [126, 127]. A novel biosensor was used to measure the force as well as the displacement of the pelvic floor during contraction [128]. Another research group has inserted a water filled plastic bag to study the shape of the vagina during contraction [129]). Others [130] have assessed elasticity by means of the correlation of the dynamic dimensions of the hiatal circumferences and direct palpation of the muscles.

1. LEVATOR TRAUMA

Using three dimensional transperineal ultrasound avulsion of the levator ani muscle from the symphysis pubis has been described in up to 36% of parous women [131]. The integrity of the attachment of the pelvic floor muscle to the symphysis pubis can be visualised (Figure B 11 and B 18a).

A systematic review of diagnosing pubovisceral avulsions on ultrasound and MRI has been published which showed an association with pelvic organ prolapse and recurrence after surgery. However there was no association between pubovisceral avulsions and urinary symptoms or ano-rectal dysfunction [132]. This is similar to results from MRI studies, where it has been shown that the risk of pelvic organ prolapse further increases when the levator injury goes together with vaginal architectural distortion [133, 134].

Although these defects have recently been identified during labour, it is not known whether there is any reasonable (preventive) treatment for these women [135, 136]. There is an increase of the occurrence of levator muscle trauma with maternal age at first delivery [137]. There was a strong correlation between the presence of levator muscle avulsion and poorer muscle strength [138]. It has, however, been shown that the correlation between the clinical assessment (palpation of the muscle) and three-dimensional ultrasonographic assessment of muscular defects was only poor [139], as well as the inter-observer repeatability of the palpation of defects [140]. A quantification method for levator muscle defects on ultrasonography (tomographic ultrasound imaging) (Figure B 18a and b) has been described [119]. Another parameter, which has been found to be related to the severity of pelvic organ prolapse, was the size of the inner circumference at minimal hiatal

![Figure B 17: Intravaginal 360 degree ultrasound imaging. Levator ani muscle, urethra and anal sphincter complex.](image-url)
Figure B 18-a: Tomographic ultrasound imaging in oblique axial plane. Normal attachment of the levator ani muscle.

Figure B 18-b: Tomographic ultrasound imaging in oblique axial plane. Bilateral avulsion of the levator ani muscle from the symphysis pubis.
The area of the levator hiatus on Valsalva manoeuvre ranges from 6 to 36 cm² in nulliparous women, with an outlier of almost 50 cm² in a young nulliparous athlete [113, 124]. An area of more than 30 cm², 35 cm² and 40 cm² on Valsalva manoeuvre has been described as mild, moderate and severe ballooning of the genital hiatus respectively (Figure B 19) [141]. The assessment of the levator hiatus has been shown to be a reproducible measurement [17, 131], whereas the reproducibility was less for muscle diameter measurements [17, 108, 124].

Comparisons of the hiatal diameters and hiatal area as measured by three-dimensional ultrasonography and MRI revealed good correlations, especially for the measurements at rest. The correlation for hiatal diameter at Valsalva manoeuvre was lower, which is most likely due to the difficulty to reach the correct plane of the levator ani muscle on MRI [142]. However at rest using MRI to alter the angle of acquisition plane has been shown to change the area of the levator hiatus by 10% [143]. This has been supported by subsequent papers showing a good inter and intra-observer relationship when measuring the levator hiatus with ultrasound and MRI [144] and even with interdisciplinary readers [145] though the later group did find only fair agreement when measuring the anorectal angle with ultrasound. The width of the levator ani hiatus on 3D transperineal ultrasound has been found to wider in black women than white women and the urethral sphincter volumes were significantly larger in black women than white women [146].

The presence and clinical relevance of paravaginal defects represent a controversial issue amongst urogynaecologists, and there is a lack of scientific proof for the concept. In a study by Reisinger et al., an echogenic layer in the lower anterior vagina, which was thought to be a part of the endopelvic fascia, could be identified reproducibly in nulliparous and parous women by transrectal three-dimensional ultrasonography [147]. According to more recent insights, however, previously described paravaginal defects with loss of the H-shape of the vagina in the axial plane on three-dimensional ultrasonography [138, 148, 149] are likely to represent the detachment of the levator ani muscle from the symphysis pubis [150]. However in a study comparing ultrasound and MRI to assess levator avulsion there was only a moderate correlation with ultrasound showing a higher

Figure B 19: Perineal three-dimensional rendered image. Ballooning of the genital hiatus
number of complete avulsions and MRI showing a higher number of partial avulsions [151]. In an attempt to increase validity of the levator avulsion diagnosis minimum criteria have been set [152], but even with these more stringent rules two out of three normal women were considered false positives where they were thought to have full avulsions. It is important to note that MRI studies tend to find thinning or aplasia rather than avulsion perhaps indicating that transperineal ultrasound may not have the resolution to visualise very thin levator ani muscles [153].

**g) Pelvic Organ Prolapse**

In cases of mild and moderate pelvic organ prolapse, perineal ultrasonography can be used, for the investigation of the prolapse. Ultrasonography should, however, only be used in addition to the patients history and clinical examination. In cases of severe pelvic organ prolapse, ultrasonographic assessment is not possible due to transducer dislocation by the prolapse. The ultrasonographic imaging of the anterior compartment (i.e. bladder, bladder neck and urethra) is the easiest to perform, and the majority of scientific studies deal with this compartment (Figure B20).

Correlations with clinical examination [154, 155] are also highest for this compartment. Reproducibility of ultrasonographic imaging of prolapse in the anterior compartment were shown to be good [155]. This reproducibility has not been studied for the other two compartments until now.

In studies amongst 83 and 117 women with the uterus in situ, the uterus could be visualized on perineal ultrasonography in 82% and 97% of cases, respectively (Figure B21) [155, 156].

A number of studies have focused on the posterior compartment [157-165]). The distinction between enterocele (Figure B22) and rectocele (Figure B23) is known to be difficult on clinical assessment. In these cases, two-dimensional ultrasonographic imaging in the midsagittal plane can be helpful. The ultrasonographic visualisation of an enterocele has been confirmed with defaecography as well as intraoperative findings [157]. It has not been shown, until now, however, whether this extra ultrasonographic investigation indeed leads to superior clinical outcomes of prolapse surgery. Interestingly anterior compartment prolapse is related to levator ani area whereas posterior compartment prolapse is not as well as prolapse symptoms not being associated with levator ani hiatus area [166].

In a study on ultrasonography of the posterior compartment a differentiation between true rectocele, enterocele and perineal hypermobility has been made [160]. Intussusception can also be visual-

---

ised on ultrasonography [167]. Perineal hypermobility and an enterocele was seen as a descent of the rectovaginal septum or abdominal contents on Valsalva manoeuvre respectively, below a horizontal line through the inferior margin of the symphysis pubis (see below for more information on these measurements). Ultrasonographic staging was significantly correlated with clinical staging and the presence of symptoms of obstructed defaecation [15, 161]. In one third of the patients with clinically diagnosed rectocele, however, no ultrasonographic abnormality could be found. As far as interrater reliability was concerned, two expert ultrasonographists have reached moderate to good interrater reliability for the detection of a rectovaginal septum defect, descent of rectal ampulla, and the depth and width of a rectocele [160]. In one study, rectocele and perineal hypermobility were present in nulliparous women in 12 and 13% respectively the significance of these findings has not yet been determined [162]. The posterior anorectal angle, which is the angle between the anal canal and the posterior rectal wall, can be measured at rest and under dynamic circumstances such as straining and squeezing. A number of studies have compared these findings with defaecography and found in general a good correlation [164, 165, 168] but one study found poor inter-rater reliability [146].

1. Quantitative Assessment of Pelvic Organ Prolapse

In the quantitative assessment of prolapse in the various compartments, a reference line, such as the hymen in POPQ, is needed. For ultrasonography, a horizontal line drawn from the inferior margin of the symphysis pubis is the most widely used reference line for this purpose. A disadvantage of this line is that there is only one fixed point through which the reference line can be drawn and the horizontal line may change with the rotation of a handheld transducer.

The effect of rotation is obviously increased with increasing distance from the fixed point, and consequently there is greatest error in the posterior compartment [155]. Although this problem has been overcome in research settings with the use of motion tracking systems, at the moment this is not a realistic option for routine use in clinical practice [169]. For quantitative assessment of rectoceles, the depths of the rectocele as measured in relation to a line through the anterior anal canal, may be more useful as compared with the descent in relation to the horizontal reference line [170].

Figure B 23: Perineal midsagittal two-dimensional view. Measurement of the depth of the rectocele, perpendicular to a straight line through the anterior border of the anal sphincter complex, i.e. 14 mm.
Since pelvic organ prolapse can be visualised well with the use of ultrasonography, it raises the question whether this assessment modality is superior to others, such as clinical examination. In a recent study on the relationship between prolapse symptoms and the most dependent point of the prolapse on POPQ and on ultrasonographic assessment, POPQ performed better in the prediction of prolapse symptoms with increasing stages of prolapse [170]. This finding has been replicated in all compartment underlining the superiority of clinical assessment over ultrasound [171]. In a previous study, where only women with a single compartment prolapse were studied, the area under the receiver operating curve was, however, as good as 0.86 and 0.82 for the anterior and posterior compartment respectively [172]. In both studies the cut-off value for symptomatic prolapse averaged 15 mm below the horizontal reference line through the symphysis pubis. Larger anterior vaginal wall prolapses do have larger levator ani hiatuses and are more likely to have avulsions (69% compared with 35%) [173].

As far as dynamic MRI and X-ray defaecography are concerned, there are only a few studies available as yet, on comparisons with ultrasonography. For enterocele detection in women with obstructed defaecation, perineal ultrasonography has been compared with X-ray defaecography, but not with the clinical findings [164]. In the women in whom enterocele had been detected by either method, the enterocele was detected by both ultrasonography and X-ray in 71% of women. In this study, perineal ultrasonography showed more severe stages of enterocele compared with X-ray defaecography. In another recent study from a different research group, X-ray defaecography has been compared with perineal ultrasonography using a vaginal probe in women with impairment of the posterior pelvic floor. Good to excellent concordance has been found for the assessment of the anorectal angle, rectocele and intussusception. The authors claimed, however, that rectoceles with a depth less then 20 mm could not be detected on ultrasonography [159], which is discordant with most other publications on the topic and as well as the authors' experience.

h) Ultrasonography In Relation To Pregnancy And Delivery

Vaginal delivery is commonly accepted as the major risk factor for the development of pelvic organ prolapse later in life. In nulligravid women, there is a wide variation in pelvic organ descent for all three compartments [128, 156, 174-176]. In a study of 169 women who underwent ultrasonography during and after pregnancy, a significant increase in pelvic organ mobility (downwards displacement) was found in all three compartments [177]. The increase in mobility was significantly correlated with the length of second stage of labour and the mode of delivery. The greatest mobility was found in women who underwent an operative vaginal delivery, but no association was found with the gestation at delivery, length of the first stage of labour and birth weight, although birth weight reached borderline significance. In a similar study, focussing on the posterior compartment in 52 nulliparous pregnant women, 8 women developed de novo true rectoceles, and the descent of the rectovaginal septum increased with 22 mm for the entire group, which was statistically significant [178]. On the other hand, in a study amongst 207 women, of whom half of the women had a clinically diagnosed rectocele, no relation has been found with (vaginal) parity, and only a weak correlation has been found with age for a posterior vaginal wall prolapse as assessed with ultrasonography [160]. This suggests that the effect of vaginal parity on pelvic organ descent, is most evident in the anterior and central compartments, and may have another pathophysiology compared with the posterior compartment [177]).

Concerning bladder neck descent, it has been shown that the first delivery caused the most marked changes compared with the subsequent deliveries, with the most marked changes with forceps delivery [179]. This is supported by two different research groups, who have reported that an increased antenatal ultrasonographic bladder neck descent was associated with normal vaginal delivery [180, 181]. Furthermore, vaginal delivery was strongly associated with a larger, and more distensible antenatal levator hiatus [180]. The underlying reason remains hypothetical, but more antenatal laxity of the structures may allow for a smoother delivery. Women with increased bladder neck mobility, however, also have an increased risk of de novo urinary incontinence post partum [20] but this outcome can be halved by antenatal pelvic floor exercises [182]. Avulsion of the levator ani muscle from the symphysis pubis, as outline above, is typically found in vaginally parous women only (Figure B 18b) [131, 183, 184]. It has, furthermore, been shown that a higher maternal age at first vaginal delivery is strongly related to an increased risk of these avulsions [131, 184]. Mode of delivery has a strong association with the incidence of levator ani injury such that vaginal delivery 15.4% are affected, 33.3% after ventouse delivery and 71.4% after a forceps delivery but there were no levator injuries detected in the Caesarean section group [185], similar findings have been reported by other groups [186-189]. The timing of the levator ani damage appears to be as the head crowns [190]. The levator ani hiatus has been reported as enlarging after vaginal delivery [191, 192] and this enlargement being maintained for up to three years later [193] but other groups have not found it enlarged nine months after delivery compared with antenatal measurements. However forceps delivery did lead to long term enlargement of the levator ani hiatus [194]. The risk of levator ani avulsions increased with enlarged head circumference and prolonged second stage in labour [195].
Pelvic Floor Surgery

Ultrasonography has been used during anti incontinence surgery with the aim of obtaining optimal results from surgery, for example during Burch colposuspension [196, 197]. On an individual basis, the bladder neck was lifted between 1 mm and 10 mm. The authors have obtained excellent results with a 94% continence rate after 1 year, but unfortunately no control group was incorporated in the study. Levator ani avulsions have been found to be associated with persistent vaginal prolapse even after attempted surgical repair [198].

1. SLINGS AND MESHES

Monofilament meshes, for example polypropylene meshes, are easier to visualise on ultrasonography compared with multifilament meshes, such as IVS [199]. Ultrasonography has been widely used to localise the exact position of tension free midurethral tapes (Figure B 24) [180, 200-203]. The tape is generally easily visible as an hyperechogenic structure under the urethra and is easy to recognise, which contrasts with the poor images of polypropylene on MRI [204]. Exact midurethral position of the tape is not essential for proper function [205]. Despite the fact that the tape was located in the midurethra in only two-third of cases, this had no relation to post-operative continence status [206].

During Valsalva manoeuvre, the tape moves in a semicircle movement around the inferior margin of the symphysis pubis [207]. This results in a position closer to the symphysis, which consequently leads to a certain degree of mechanical compression during Valsalva manoeuvre. Another mechanism of action is kinking of the urethra around the tape [208]. A number of studies have looked at transobturator tape and compared these with retropubic tapes [199, 209-212]. Two studies could not detect any differences between the two types of tape [199, 212], whereas in the other two studies [209, 211], subtle differences with no apparent clinical consequences were found.

Imaging both tension-free and transobturator tape procedures during straining show a reduction in the diameter of the hypoechoic urethral core and the diameter became significantly smaller only in the successful procedures [213] and a reduction in the symphysis pubis to tape distance led to continence [214]. Other authors have suggested optimal positions of the tape being between the distal third and middle of the urethra with a tape-urethral distance of 2mm, greater than 3.9mm distance led to failure of the procedure. The tape to urethral distance can be reliably assessed using 4D ultrasound [215]. Midurethral tapes impinging on the urethra has been reported as being associated with voiding difficulty and the “V” shape of

Figure B 24: Perineal three-dimensional rendered image. Polypropylene mesh (TVT-O) after one-sided incision of the tape.
the tape was the same regardless of the insertion method (ie TOT compared to TVT) [216]. Tapes sited around the midurethra resulted in a reduction in flow rate compared with a distal tape position under the urethra which did not change flow rates [217] and this positional information has been used to determine the management of de novo symptoms after surgery [218].

The bladder neck is displaced during insertion of a midurethral by using a rigid guide during insertion of a tension-free vaginal tape. Ultrasound has been used to determine that the bladder neck is moved by 1.4 cm by this technique [219]. Recently, ultrasonographic localization of polypropylene mesh as used in prolapse surgery has been described (Figures B 25 and B 26) [220]. These meshes are usually easily visible on ultrasonography. It appears that the ultrasonographic appearance of the mesh is significantly shorter and narrower than the size at implantation within six weeks of the procedure [221]. It is unclear whether this is due to shrinkage of the mesh or represents difficulties in visualising the full extent of the implanted mesh. The failure of mesh to support vaginal prolapse was associated with mesh shrinkage [222, 223].

The differentiation between recurrent herniation and the detachment of the mesh arms from the pelvic sidewall for example, will aid in the better understanding of the mode of action of these meshes [224].

2. **BULKING AGENTS / INJECTABLES**

Periurethral bulking agents/injectables, such as microparticulate silicone (Macroplastique), various gels (e.g. Durasphere), and collagen, can be visualised by imaging techniques. For MRI, an overview of appearances of periurethral bulking agents is already available [225]. On ultrasonography, the injectables appear hypoechoic after injection, and become more hyperechoic over time due to dehydrogenation. Good intra-observer variability of repeated measurements of periurethral collagen volumes have been found [226].

The location in relation to the bladder neck and a circumferential distribution of collagen injectables around the urethra, as well as the height and volumes of the injected periurethral collagen bumps, were associated with the treatment success of periurethral bulking agents [226-228]. Although the volume range was wide, a collagen volume of 2.8 cc on three dimensional ultrasonography has been assessed as optimum volume from a continence point of view. Poon et al. have published a decision tree, in which a combination of the patients’ symptoms after collagen injection and the configuration and volume of the periurethral collagen on three-

---

dimensional ultrasonography, assist in the decision for further treatment of women with intrinsic sphincter deficiency [226]. In this algorithm, women with asymmetric deposition and/or low collagen volumes were offered further treatment with injectables as this is associated with failure [229].

Ultrasonography has not only been used for follow-up, but also during placement of periurethral injections. Transurethral ultrasonography-guided injection of autologous stem cells has been used in women and men with stress urinary incontinence. The technique allowed precise injection of the myoblasts directly into the rhabdosphincter, and was more effective in the resolution of incontinence compared with urethroscopic guided collagen injectables in the submucosa in a randomized controlled trial [230, 231]. The use of stem cells in the management of urinary incontinence is of great interest although the subject remains controversial and confirmatory studies are eagerly awaited.

k) Consensus Statement

- Ultrasound is not recommended in the primary evaluation of patients with urinary incontinence and/or pelvic organ prolapse (rectal prolapse is dealt with in a different section). [Level of evidence 3, Grade of recommendation C]
- Ultrasound is an optional test in the evaluation of patients with complex or recurrent urinary incontinence and/or pelvic organ prolapse. [Level of evidence 3, Grade of recommendation C]

l) Future Research Areas

- Standardisation of terminology of pelvic floor US imaging
- Internal and external validity of techniques of pelvic floor imaging
- Confirmatory studies to validate previously published evidence on imaging of UI and POP

Figure B 26: Perineal midsagittal two-dimensional view. Polypropylene mesh of the anterior and posterior vaginal wall (Prolift).

The role of magnetic resonance imaging (MRI) in evaluating pelvic floor disorders has been established in recent years and continues to evolve. This technique provides unparalleled images of pelvic floor muscles, connective tissue, and organs. In addition to the detailed static picture of the pelvic organ support system anatomy, MR can also reveal the downward movement of each pelvic compartment during increases in abdominal pressure. Advances in MR imaging, equipment and software have significantly improved image quality and now MRI provides ever more detailed pictures of anatomy and function. At present active investigation is ongoing to see how this imaging might result in a better understanding of these diseases and improve their diagnosis and management.

Although women might present with symptoms isolated to one of the pelvic compartments, they often have concomitant defects in other compartments or pelvic structures. In these women, imaging can provide information to extend what can be determined on physical examination [1]. Furthermore, surgical failures could result from lack of a thorough preoperative evaluation of the female pelvis and inadequate diagnosis and staging of pelvic floor deformation and dysfunction [2]. Accurate diagnosis of coexisting abnormalities is therefore essential in planning reconstructive and anti-incontinence procedures. Although most diagnoses of pelvic floor prolapse are made on detailed physical examination, the sensitivity and specificity of the pelvic examination in diagnosing various forms of pelvic floor prolapse is low [3] [4] [5]. Ultrasound and fluoroscopy have been used to improve diagnosis [6] [7] and the role of MRI in pelvic floor dysfunction is rapidly developing. A recent systematic review suggests that prolapse assessment on dynamic MR imaging may be useful in the posterior compartment, although clinical assessment and dynamic MR imaging seem interchangeable in the anterior and central compartment [8].

There is now a robust literature indicating that MRI provides detailed images of bladder neck and urethral mobility, rectoceles, cystoceles, enteroceles and uterine prolapse, in a single non-invasive study without exposing the patient to ionizing radiation [9] [10] [11] [12] [13] [14] [15] [16] [17] [18]. MRI can also identify ureteral obstruction, hydronephrosis, and ureter and ovarian pathology. In addition, MRI remains the study of choice for the evaluation of urethral diverticuli.

The following measurements using MRI in urogynecology and female urology have been highlighted in the recent IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction [21]:

(a) Bladder neck and cervical descent/mobility:
- Position of bladder neck and cervix at rest and on Valsalva.
- Pubo-coccygeal line: A line extending from the inferior border of the pubic symphysis to the last joint of the coccyx. Bladder neck or cervical descent >2 cm below this line with straining indicates weakness of the pelvic floor. If alternative landmarks are used in scientific papers they should be clearly described.

(b) Intercurrent pelvic pathology: For example, fibroids, ovarian pathology.

(c) Uterine version: Anteverted or retroverted; flexion at the isthmus.

(d) Bladder abnormalities: For example, tumor; foreign body.

(e) Urethral abnormality: For example, diverticulum.

(f) Postoperative findings: For example, bladder neck mobility.

(g) Pelvic floor measurements/levator defects: Assessment of the configuration of pelvic floor muscles, in particular, the levator ani.

(h) Descent of pelvic organs.

This article is an update to the ICI article on the role of MRI in assessing the female pelvic floor [2009] and provides a current review of where we are in evaluating the role of MRI in understanding the causes and treatment of pelvic organ prolapse.

a) Technique

The evolution of MRI is partly due to new hardware implementation (3Tesla magnets, large magnet sections and opne magnets) but largely to software development in the sense on new sequences that open novel possibilities in the field of functional and dynamic imaging.

1. CONVENTIONAL MRI

Standard MRI consists of two dimensional image acquisitions. Usually conventional T1 images and spin echo T2 weighted images are obtained. Proton density T2 weighted scans provide excellent soft tissue definition [Figure B 27]. However, the long imaging time of conventional MRI hampers its ability to evaluate the movement of organs that are characteristic of POP.
2. Ultra Fast Image Acquisition And MR Sequences

Pelvic organ movement duringValsalva is identifiable using very fast single-shot MR sequences and the technical aspects have been summarised in our prior report [Figure B 28] (ICI 2009). [15] [16] [22] [23]. These sequential images are obtained approximately once per second, either as a series of images covering the entire pelvis (static imaging) or repetitively in one plane while the patient is straining (dynamic imaging). The patients are placed in the supine position with legs slightly spread apart, and knees bent and supported by a pillow. Most pelvic floor details can be seen without the need for bowel preparation, premedication, instrumentation or contrast medium but often, especially with MR defaecography, ultrasound gel or other suitable agents are used to enhance visibility of the rectum and vagina. The MRI torso coil is centered at the symphysis pubis. Images are acquired in the sagittal plane using single-shot fast spin echo (SSFSE) or half Fourier acquisition, single shot turbo spin echo (HASTE) sequences. Single, mid sagittal views are obtained during 3 seconds of apnoea with the patient relaxed and during various degrees of progressive abdominal straining.

Since the time of the last report, continued development of techniques have occurred to allow visualisation of the dynamics of pelvic organ during increases in abdominal pressure. Steady-state free precession gradient-echo imaging provides an alternative T2-like imaging contrast (T2- and T1-weighted imaging) with robust signal and a rapid acquisition time of less than 1 second, thereby permitting near real-time continuous imaging. This is an improvement on the HASTE approach that requires 1–2 seconds between acquisitions to allow T1 recovery; therefore, real-time imaging is not possible. Comparisons of the degree of POP shown on dynamic true fast imaging with steady-state precession (FISP) versus HASTE sequences in symptomatic patients reveal a greater degree of prolapse in all three compartments with a dynamic true FISP sequence. Near real-time continuous imaging with a dynamic true FISP sequence may therefore be useful to evaluate pelvic floor dysfunction in addition to dynamic multiplanar HASTE sequences [24].

During a typical study of pelvic organ movement two sets of images are obtained. The first set consists of static sagittal and para-sagittal images covering the pelvis from left to right sidewall. These images are used to select the mid-sagittal plane for the dynamic second set of images. This static sequence also allows for anatomic delineation of the pelvic sidewalls and muscular and fascial components of the pelvic floor [15] [16] [22] [23]. The perineal membrane and the levator ani musculature, as well as the anal sphincter anatomy, are also clearly demonstrated [25] [26]. The static set consists of 17-20 sequential images independently acquired in a total of about 18 seconds.

Figure B 27: Sagittal mid pelvic section showing anatomical detail visible in static images made with Proton Density sequence.

Figure B 28: The rest and strain image taken from a mid-sagittal dynamic MR sequence revealing cystocele and uterine descent using SSFSE sequence.
The second set of images consists of relaxed and straining mid-sagittal images used to assess the degree of pelvic floor relaxation and organ prolapse. Images can then be looped for viewing on a digital station as a cine stack.

Dynamic MRI allows detection of POP that may not be evident on conventional static sequences, as it permits both structural and functional evaluation. For example, in women with lower urinary tract symptoms evaluation of the urethra may be of added value. [27] There has been further clarification of how the conduct of the examination can affect what is seen. For example, the first time a woman performs a Valsalva maneuver, she may not get the prolapse to protrude to its maximal extent. Tumbarello et al [28] found that 40% of women have a greater than 2cm increase in prolapse size from their first to third Valsalva attempt and 95% of women extend their prolapse further with a third Valsalva. They concluded that, as with clinical examination, several attempts may be required to have maximal anterior compartment prolapse present during dynamic MRI of the pelvic floor. Delancey et al evaluated whether the use of a speculum blade modifies the evaluation of pelvic organ prolapse (POP) as assessed by dynamic MRI. Twenty-seven women with POP Quantification (POPQ) stage II or greater, scheduled for POP surgery, were evaluated using MRI. The procedure was repeated using the posterior blade of a standard plastic Grave’s speculum to successively retract the anterior and posterior vaginal walls. Standard POPQ was 15% stage II (n =4), 59% stage III (n =16) and 26% stage IV (n =7). The use of a blade evidenced hidden pelvic prolapsed compartments in 59% (n =16) of cases. For 48% of patients (n =13), the variation of the leading edge of at least one additional prolapsed compartment was diagnosed as more than 20 mm. In this series, the use of a speculum blade during dynamic MRI modified the POP evaluation in a large proportion of patients with POP stage > or =II [29].

3. THREE DIMENSIONAL MRI

The nature of MRI technique where a series of parallel images are made allows them to represent a 3D block of tissue. Three dimensional (3-D) MRI provides precise detail of the bony and muscular pelvic structures (Figure B 29) so that 3D models can be constructed based on these detailed images. In this technique, static or dynamic images are reconstructed using consecutive planes in the axial, sagittal and coronal dimensions. Anatomic variations of the insertion and path of the pubococcygeus and iliococcygeus muscles can be seen. Fielding et al. made 3D models of the pelvic viscera and supporting muscles and bones with the marching-cubes algorithm and a surface-rendering method in nulliparous continent female volunteers and found that the muscle morphology, signal intensity and volume are relatively uniform [25]. They described an average volume of the levator ani of 46.6 cc, width of the levator hiatus of 41.7 mm and an average posterior urethrovessical angle of 143.5°. In addition, these 3D models made from multi-slice scans during a maximal Valsalva have allowed direct measurements of changes in the relationship between the vagina and pelvic walls.

3D MRI enables evaluation of paravaginal defects, apical descent and vaginal widening. Larson et al [30] studied the relative contributions of “midline defects” (widening of the vagina) and “paravaginal defects” (separation of the lateral vagina from the pelvic sidewall) in women with anterior prolapse using 3D MRI models of the anterior vaginal wall and found that changes in lateral anterior vaginal wall were considerably greater than changes in vaginal width in cases vs controls. These “paravaginal defects” were also highly correlated with apical descent.

The geometry of the arcus tendineus fascia pelvis (ATFP) and arcus tendineus levator ani (ATLA) in women with unilateral levator ani muscle defects and associated “architectural distortion” has been studied using 3D MRI. In those women, the ventral arcus anatomy is significantly altered in the presence of levator defects as well as architectural distortion, resulting in change of the supportive force direction along the lateral anterior vaginal wall, thus increasing the risk for anterior vaginal wall prolapse. [31]

a) Normal Pelvic Floor Functional Anatomy

Understanding how the pelvic floor works: one of the great challenges for every surgeon and physician involved in the management of disorders involving muscle, fascias and viscera on this complex area of the human body. Anatomical description of pelvic floor muscles at autopsy does not always reveal their function and the reasons of their dysfunction that not necessarily derive from anatomical changes but also from derangement of their networking. The variable weight of these two components may explain the variable outcome of conservative and invasive management in the individual subject. MRI offers a unique opportunity to investigate the pelvis

Figure B 29: Pelvic Organs as seen from caudal on a three-dimensional reconstruction from Magnetic resonance images. Copyright Mosby Inc.
a single functional unit and to investigate the relative contribute of its different parts and sections.

1. **MR Imaging of Normal Pelvic Support Structures**

MRI studies of normal subjects have improved our understanding of normal pelvic anatomy, its variations [25] [26] [32] as well as anatomic changes in pelvic floor dysfunction [20] [33] [34].

In the supine position the female pelvic floor is dome shaped at rest [34] [35]. During voluntary pelvic floor contractions the levator musculature straightens and becomes more horizontal. With bearing down the muscle descends, the pelvic floor becomes basin-shaped, and the width of the genital hiatus widens.

---

**Figure B 30**: Axial images according, in 22-year-old (1a-4a), 24-year-old (1b-4b), and 34-year-old (1c-4c) nulliparous women without urogynecologic problems. 1a-c, Level of cervix (Cx) and ischial spine (IS); uterus (Ut) with bright endometrium is also seen. Paracolpium and parametrium suspend (open tips) vagina and cervix from lateral and posterior pelvic sidewall. Smooth muscle of uterosacral ligament (open tips) is best seen in 1c. GM, Gluteus maximus muscle. 2a-c, Level of bladder (B) base. Upper vagina between bladder and rectum (R) and its attachment to pelvic sidewall by vascular and connective tissue mesentery (small arrow) are seen. Levator ani muscle (iliococcygeal part, filled arrowhead) arises from arcus tendineus of levator ani muscle (filled arrow). OI, Obturator internus muscle. 3a-c, At level of proximal urethra, levator ani muscle (pubovisceralis part, filled arrowhead) arises from pubic bone (open arrow). Pubovesicalis muscle (open arrowhead) is clearly seen in 3b. Vessels (white gap) are visualized between smooth muscle layer of lateral vaginal wall and levator ani muscle at this level. 4a-c, At level of middle urethra, pubovesicalis muscle is seen as shown in 4a (open arrowhead). Vessel layer (white gap) between lateral vaginal wall and levator ani muscle (filled arrowhead) has disappeared; direct connection between vagina and levator ani muscle is seen at this level. Small white gap in levator ani suggests fascia between puborectalis and pubococcygeal muscles (especially in 4a and 4c). [123]
With MRI the specific structures are identified and their normal variations described [Figure B 30]. Tan [33] demonstrated the anatomy of the female pelvic floor with MRI. The pelvic and the urogenital diaphragm were well depicted as were urethral supporting structures—the peri-urethral and paraurethral ligaments, and the zonal anatomy of the urethra. The MRI findings in volunteers correlated with the endovaginal MR findings and gross anatomy in cadavers. Chou [36] studied the urethral support structures relative to the arcuate pubic ligament including the arcus tendineus fasciae pelvis, the perineal membrane, the pubococcygeal levator ani muscle and its vaginal and bony attachments, and the pubovesical muscle. Tunn et al [37] showed that 2- to 3-fold differences occur in distance, area, or volume measures of continence system morphologic features in continent nulliparous women with normal pelvic organ support and urodynamics. The uterosacral ligaments also exhibit greater anatomic variation than their name would imply [38].

More recently, characteristic anatomic features of the posterior compartment and perineal body have been studied with MR cross-sectional anatomy and can be further elucidated and integrated with 3-D anatomy. In nulliparous asymptomatic women the posterior compartment’s upper, mid, and lower segments are best visualised in MRI in the axial plane. It is bounded inferiorly by the perineal body, ventrally by the posterior vaginal wall, and dorsally by the levator ani muscles and coccyx. In the upper portion, the compartment is bordered laterally by the uterosacral ligaments, whereas in the middle portion, there is more direct contact with the lateral levator ani muscles. In the lower portion, the contact becomes obliterated because the vagina and levator ani muscles become fused to each another and to the perineal body [39]. (Figure B 31). The perineal body anatomy has been possible to study using 2mm MR images. Visualisation of perineal body anatomy in living women and development of 3-D models enhanced our understanding of its 3 different regions: superficial, mid, and deep [40]. The three distinct perineal body regions are [1] a superficial region at the level of the vestibular bulb, [2] a midregion at the proximal end of the superficial transverse perineal muscle, and [3] a deep region at the level of the midurethra and puborectalis muscle. Structures are best visualised on axial scans, whereas craniocaudal relationships are appreciated on sagittal scans. In the superficial portion at the level of the vestibular bulb (VB), the bulbospongiosus (BS) inserts into the lateral margins of the perineal body, whereas the superficial transverse perineal muscle (STP) and external anal sphincter (EAS) traverse the region. In the perineal body’s midregion at the proximal end of the superficial transverse perineal muscle, the puboperinealis muscle inserts into the lateral margins of the perineal body and in some individuals can be seen to cross the midline. This region also contains the distal internal anal sphincter. The puboanalis muscle is also visible as it inserts in the intersphincteric groove between internal and external anal sphincters. The puboanalis muscle and internal anal sphincter extend into the perineal body’s most deep region at the level of the midurethra. Here the pubovaginalis muscle also becomes visible as it fuses with the vaginal side wall, sending fibers posteriorly to the perineal body. In this location, the longitudinal muscle of the rectum may be visible in the midline. The puborectalis muscle forms a loop behind the rectum at this level but

Figure B 31: The outline of the midsagittal pubic bone (P) is shown. The bladder (B) is yellow; the uterus (U) and vagina (V) are pink; the uterosacral ligament (USL) and perineal membrane (PM) are turquoise blue; the levator ani muscle (LA) is red; the perineal body (PB) is royal blue; the external anal sphincter (EAS) is dark red; and the posterior compartment (PC) is gray. Image A, All organs are shown. B, Levator ani muscles have been faded to show the underlying structures. C, Levator ani muscles have been removed. The locations of the upper, mid, and lower axial cross-sections are shown (39). Reprinted with permission from John O. L. DeLancey.
does not contribute fibres to the perineal body. (Figures B 32-33)

One of the key anatomical contributions MRI has made to the understanding of normal pelvic floor structure, regards the ability to make images of a wide variety of normal living women. The pelvic floor is greatly distorted in cadavers due to loss of muscle tone and pressures during embalming. Otcenasek et al have used MR images of a normal nulliparous woman to establish geometry and then added details from dissection to produce an anatomically based topographically normal 3-D model that displays the features of pelvic floor anatomy (Figure B 34) [41].

2) LLEVATOR ANI MUSCLE FUNCTIONAL ANATOMY

Evidence from MR and CT images in volunteers and cadavers shows that the anterior transverse portion of the levator muscle is basin-shaped; the middle transverse portion funnel-shaped, while the posterior transverse portion dome-shaped. The puborectalis appears u-shaped outside the vertical portion [42]. On MR images of the five Terminologia Anatomica-listed levator ani components: pubovisceral (pubovaginal, puboperineal, and puboanal), puborectal and iliococcygeal portions of the levator ani muscle muscles in women with normal pelvic support, the puborectal muscle can be seen lateral to the pubovisceral muscle and decussating dorsal to the rectum in the axial plane. The course of the puboperineal muscle near the perineal body is also seen best in the axial plane. The coronal view is
perpendicular to the fiber direction of the puborectal and pubovisceral muscles and shows them as “clusters” of muscle on either side of the vagina. The sagittal plane consistently demonstrates the puborectal muscle passing dorsal to the rectum to form a sling that can be seen as a “bump”. This plane is also parallel to the pubovisceral muscle fiber direction and shows the puboperineal muscle [43]. (Figure B 35).

b) Pathophysiology of pelvic floor disorders

1. Levator ani defects

One of the major contributions of MRI to understanding the cause of pelvic floor dysfunction came from its documentation. LA injury seen after vaginal birth is highly associated with POP. In [44] a case-control study with group matching for age, race, and hysterectomy status, women with prolapse (cases) were compared to those with normal support (controls). Major defects were those that lost more than 50% of the muscle bulk. Cases were more likely to have major levator ani defects than controls (55% compared with 16%), but equally likely to have minor defects (16% compared with 22%) (Figure B 36-37). Women with defects generated less vaginal closure force during a pelvic muscle contraction than women without defects (2.0 Newtons compared with 3.1 Newtons) and women with prolapse also generated less vaginal closure force during pelvic muscle contraction than controls (2.0 Newtons compared with 3.2 Newtons). This confirmed earlier uncontrolled observations with ultrasound [45].

It is important to distinguish between muscle thickness and muscle damage. A woman with a normally thin but intact muscle may have less muscle substance than a woman with naturally bulky muscles who has a defect that has involved 25% of her muscle bulk. The issue of muscle damage is relevant to seeing who is injured, while that of muscle bulk, with the capability of the muscle...
Figure B 35: Three-dimensional model of levator ani subdivisions including the pubic bone and pelvic viscera. This model was created by using the magnetic resonance images shown in Figures 2, 3, and 4. Figure B 37: Percentages of cases and controls with no defects, minor defects, and major defects; p ≤ 0.001. © DeLancey 2006 [44].
to close the hiatus. Hoyte et al [46] examined 10 women with prolapse, 10 with urodynamic stress incontinence, and 10 asymptomatic volunteers. Mean 3-dimensional parameters in the 3 groups showed levator volumes of 32.2, 23.3, and 18.4 cm³ (P < 0.005); hiatus widths of 25.7, 34.7, and 40.3 mm (P < 0.005); left levator sling muscle gaps of 15.6, 20.3, and 23.8 mm (P = 0.03), right levator sling muscle gaps of 15.6, 22.5, and 30.8 mm, (P = 0.003), and levator shape (90%, 40%, and 20% dome shaped; P < 0.005). Subsequently, using a novel thickness mapping [47], they found thicker, bulkier anterior portions of the levators in asymptomatic women, compared with women with prolapse or urodynamic stress incontinence while the more posterior portions of the muscle were not affected.

Hsu and colleagues quantified levator ani muscle cross-sectional area as a function of prolapse and muscle defect status [48]. Using muscle cross-sections from 3-D reconstructions they found that women with visible levator ani defects on MR have less muscle ventrally compared with women with intact muscles. Women with major levator ani defects had larger cross-sectional areas in the dorsal component than women with minor or no defects indicating a compensatory hypertrophy in this area. Furthermore, after controlling for prolapse, women with levator defects appear to have a more caudal location of their perineal structures and larger hiatuses at rest, maximum contraction, and maximum Valsalva manoeuvre [49].

Among women with POP, those with major LAD appear less likely to experience stress incontinence when “coughing, laughing, or sneezing” (odds ratio (OR) 0.27) and when “twisting, reaching, lifting, or bending over” (OR 0.26) than women with normal muscles. They are less likely to have obstructive symptoms characterized by assuming an “unusual toileting position” or “changing positions...to start or complete urination” (OR 0.27). Women with minor LAD appear more likely to experience stress incontinence with exercise (OR 3.1) and urge incontinence (OR 4.0) than those with normal muscles. Lower urinary tract symptoms are therefore less common among women with prolapse and major levator ani defects and more common among those with minor defects [50]. This may be explained by the fact that the women with major LA defects have larger prolapses than those who do not have major LA defects. It is a clinical observation that prolapse often reduces the occurrence of stress incontinence (urethral kinking?) and this hypothesis is consistent with the observations mentioned above.

2. Identifying the Injury Zone within the Levator Ani Muscle Most Often Involved by Injury

MRI based 3D models show that in women with bilateral puborectal muscle avulsion after vaginal delivery, the damage affects the pubic origin of the muscle. This structural change alters the support to the whole endopelvic fascia and destabilizes both the anterior and the posterior vaginal walls [51]. In women with significant muscle on one side and damaged muscle in the same individual [52] the injury involves the muscle’s origin from the posterior pubic bone. (Figure B 38) Distortion of the surrounding connective tissue with lateral spilling of the vagina towards the obturator internus muscle is observed in 50% of women. The defect is right sided in 71% of patients. The average difference of the amount of muscle lost in these types of injury between the normal side and the defective side is up to 81% at locations nearest the pubic origin [53]. Almost all of the volume difference (13.7%, P = 0.0004) is attributable to a reduction in the pubic portion (24.6%), not the iliococcygeal portion of the muscle.

3. Changes in the Hiatus Size and Levator Plate Angle with Prolapse

The levator ani muscle’s constant activity closes the genital hiatus. In addition to evaluating defect status and muscle bulk, MRI has revealed changes to the levator hiatus and angle of the levator plate (that midline portion of the muscle between the anus and the coccyx) which is presumed to be influenced by muscle action. Hsu and colleagues [54] studied 68 women with pelvic organ prolapse and 74 normal controls. During Valsalva, controls had a mean levator plate angle of 44.3 degrees. Cases had 9.1 degrees (21%) more caudally directed levator plate angle compared to controls (53.4 degrees vs. 44.3 degrees), 15% larger levator hiatus length (7.8 cm vs 6.8 cm), and 24% more caudal perineal body location (6.8 cm vs 5.5 cm).

Increases in levator plate angle were correlated with increased levator hiatus length (r = 0.42) and perineal body location (r = 0.51). The bladder neck descent at straining is also correlated with the levator plate angle at rest, hiatus length at rest and at straining [55]. Uterine cervix descent at straining is correlated with increased hiatus length and width at straining, and greater levator plate angle (p = 0.007) at straining. Paradoxically anterior rectal bulging at straining is inversely correlated with the hiatus width at rest (p = 0.04).

Perineal descent and localised outward bulging of the levator ani during Valsalva was evaluated by Gearhart and colleagues [56]. In this study, dynamic MRI of symptomatic patients with pelvic floor prolapse demonstrated unsuspected levator ani hernia. Patients with POP, fecal and/or urinary incontinence, or chronic constipation were evaluated. Fifteen percent of patients (12/80) had unilateral (n = 8) or bilateral (n = 4) levator ani hernias on MRI. Perineal descent on physical examination was associated with a levator ani hernia in nine patients.

4. MRI and the Bony Pelvis

Studies of the bony pelvis dimensions and their associations with POP, levator ani defects and stress in-
continence have recently been undertaken. Stein et al showed that bony pelvis dimensions are similar at the level of the muscular pelvic floor in white women with and without POP [57]. Further evaluation of the bony pelvis using MRI scans has also improved our understanding of the natural history of stress urinary incontinence as well as the associations of the bony pelvis dimensions with the prevalence of levator defects (Berger et al unpublished data). Other studies investigating the role that different pelvis shapes play for specific diseases will be described in subsequent sections of this review.

5. MRI OF PELVIC FLOOR AFTER VAGINAL DELIVERY

There are changes observed in the levator ani and pelvic floor musculature immediately after delivery, which change over time. Boreham [58] evaluated the normal visibility of the levator in post term nulliparas using 3-dimensional (3-D) MRI. LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in 92% of 84 nulliparas. Mean LA volume was 13.5 (3.7) cm3. Interestingly there was a positive association between LA volume and higher fetal station with increasing BMI. The muscle signal intensity appears increased at 1 day postpartum on T2 weighted images, but normal by 6 months. The urogenital and levator hiatus decreases significantly by 2 weeks postpartum [59]. More recently, Lienemann [60] found thinning of the puborectal muscle in primiparous women after vaginal delivery (0.6 cm vs. 0.8 cm) and increased descent of the bladder, vaginal fornix, and anorectal junction during straining compared to healthy asymptomatic nulliparous volunteers.

The descent of the bladder and cervix on straining appears greater in women who delivered vaginally compared to those who had cesarean delivery and to nulliparous women. There is a positive correlation between the duration of labour and the area of the levator sling and also between birthweight and the descent of the cervix on straining [61].

The role of levator ani muscle damage and stress soon after birth has also been studied. An investigation of 80 nulliparous asymptomatic women and 160 vaginally primiparous women half of whom had new stress incontinence after their first birth was conducted 9 months after delivery. A visible defect in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the pubovisceral portion of the levator and three were in the iliococcygeal portion. None of the nulliparous women showed these abnormalities [62]. In a further study of this cohort [63] evaluation of obstetric factors associated with levator ani injury after first vaginal birth showed increased odds ratios for levator defect: forceps use 14.7, anal sphincter rupture 8.1 and episiotomy 3.1 but not vacuum de-
livery (0.9) epidural use (0.9) or oxytocin use (0.8). Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labour. Differences in gestational age, birth weight, and head circumference were not statistically significant.

Dannecker [64] compared women after spontaneous vaginal delivery to those delivered by vacuum extraction and a control group of healthy nulliparous volunteers. Significant differences for individual POPQ component measurements were noted for points Aa and Ba, TVL, and GH (spontaneous delivery versus control) and in addition for Ap, Bp, and D (vacuum extraction versus control). Significant differences were observed for the position of bladder base, bladder neck, posterior vaginal fornix, anorectal junction, hiatus perimeter and depth of rectocele. Looking into comparisons with the spontaneous vaginal delivery group, on clinical examination, there was more evidence of anterior vaginal wall descent after vaginal delivery, and TVL and GH. Differences between the groups with regard to points Ap and Bp reached only marginal significance. With MRI measurements primiparous women who underwent spontaneous vaginal delivery as compared to nulliparous women showed considerable and statistically significant descent of almost all assessed structures at rest and on straining. Bladder base, bladder neck and the anorectal junction descended even below the respective reference lines. The bladder neck showed considerably increased mobility, and the genital hiatus showed an increased change on straining. The depth of rectocele increased more than three times. One of 26 women (4%) had a rectocele >3 cm. POPQ measurements that differed significantly between primiparous women after vacuum extraction and nulliparous women of the control group indicated more evidence of anterior and posterior vaginal wall descent after vacuum extraction. In addition TVL and GH was increased and PB was decreased after vacuum extraction. MRI measurements after vacuum extraction, showed considerably increased descent and mobility of the bladder base and bladder neck on straining, and descent of the anorectal junction was prominent. The mean depth of rectocele was four times bigger than in the nulliparous group. Four of 49 women (9%) had a rectocele >3 cm.

Branham and colleagues [65] evaluated postpartum changes in the levator ani muscle in relation to obstetric events. In those subjects recovering to normal MR by 6 months an average of nearly 60% increase in right puborectalis muscle thickness compared with that seen at 6 weeks indicated the extent of the injury. Younger white primiparous women had a better recovery at 6 months than older white women. Subjects experiencing more global injury, in particular to the iliococcygeous, tended not to recover muscle bulk.

Heilbrun and colleagues investigated the correlation between the presence of major LAM injuries on MRI with faecal incontinence (FI), POP, and urinary incontinence (UI) in primiparous women 6-12 months postpartum using a scoring system to characterise LAM injuries on MRI. Major LAM injuries were observed in 19.1% women who delivered vaginally with external anal sphincter (EAS) injuries, 3.5% who delivered vaginally without EAS injury, and 0% who delivered by cesarean section before labor (p=0.0005). Among women with EAS injuries, those with major LAM injuries trended toward more FI, 35.3% vs. 16.7% (p=0.10) and POP, 35.3% vs 15.5% (p=0.09), but not UI (p=1.0). These data confirm that both EAS and LAM are important for fecal continence and that multiple injuries contribute to pelvic floor dysfunction [66].

Handa and colleagues used MRI to measure bony and soft tissue pelvic dimensions in 246 primiparas, 6-12-months postpartum. A deeper sacral hollow was significantly associated with fecal incontinence (p = 0.005). Urinary incontinence was marginally associated with a wider intertuberous diameter (p = 0.017) and pelvic arch (p = 0.017). There were no significant differences in pelvimetry measures between women with and without prolapse in this study[67].

6. MRI AND BIOMECHANICAL INVESTIGATION OF THE PELVIC FLOOR

MRI has allowed anatomically based biomechanical models to be constructed. Simulations have demonstrated important interactions between muscle and connective tissue in providing anterior vaginal wall support [68]. MRI has enabled construction of finite element analysis [69] [70]. It has also allowed for capture of 3D shape variation of the levator ani during straining where complete volumetric imaging is prohibited by the inherent temporal resolution of the scanning technique [71].

Chen developed and validated recently a 3D finite element computer model of the anterior vaginal wall and its supports based on spatial data from MR scans of normal women. They determined the combinations of muscle and connective tissue impairments that result in cystocele formation, as observed on dynamic MRI geometry from a healthy nulliparous woman. It included simplified representations of the anterior vaginal wall, levator muscle, cardinal and uterosacral ligaments, arcus tendineus fascia pelvis and levator ani, paravaginal attachments, and the posterior compartment. The authors found that development of a cystocele requires a levator muscle impairment, an increase in abdominal pressure, and weakening of apical and paravaginal support [72]. These simulations provide a way to see what specific changes in structural components do to pelvic organ support in ways that would be impossible to study in living women.

7. RACIAL DIFFERENCES IN PELVIC DIMENSIONS

There are differences that exist in the occurrence of
prolapse in women from different racial backgrounds. Several groups have evaluated racial differences in the bony pelvis and the levator ani muscles [73] [74] [75]. In a study by Handa et al [73], a wider transverse diameter (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.2) were associated with pelvic floor dysfunction after controlling for age, race, and parity. Hoyle and colleagues found that levator ani volume was significantly greater in African-American (AA) asymptomatic nulliparous women without pelvic floor dysfunction compared to white American (WA) ones (mean = 26.8 vs. 19.8 cm³, P = .002). The levator-symphysis gap was smaller in the AA (left-18.2, right-18.8 mm) versus the WA group (22.4, 22.6 mm, p = 0.003, 0.048) on the left and right. Significant differences were also seen in bladder neck position, urethral angle, and the pubic arch angle [74]. In another study with 3D MRI, levator thickness was significantly greater bilaterally in black nulliparas compared to white ones, yet obturator internus muscle thicknesses were similar [75].

Handa found that the pelvic inlet was wider among white women than African-American women (10.7+/−0.7 cm compared with 10.0+0.7 cm, P<.001). The outlet was also wider (mean intertuberous diameter 12.3+/−1.0 cm compared with 11.8+/−0.9 cm, P<.001). There were no significant differences between racial groups in interspinous diameter, angle of the subpubic arch, anteroposterior conjugate, levator thickness, or levator hiatus. [76].

A broader group of races was studied by Rizk et al with MR in asymptomatic multiethnic nulliparous young volunteers from 5 ethnic groups (Emirati, other Arab, Filipino, Indian/Pakistani, and European/white volunteers), with the white volunteers as the reference group [77]. The white volunteers were taller (p<0.0001) than the other women. Their levator hiatus was longer than the Emirati women (p=0.03) and wider than the Filipino women (p=0.04). The bladder neck descent on straining was also greater than the other groups (p<0.00001). The white women also had the longest transverse diameter of the pelvic inlet (p=0.002). Their sagittal outlet diameter was longer than the Emirati and Arab women (p=0.02), and their interspinous diameter was longer than the Arab women (p=0.002).

c) Pelvic Organ Prolapse

MRI has proven to be a key assessment for understanding pelvic organ prolapse; a problem that arises from damage to connective tissue, muscles, and nerves that are invisible on standard radiography. With the advent of 3D ultrasound and MRI, the actual structures involved in the cause of prolapse can be seen and examined. This is possible not only in static scans that reveal morphological details of the pelvic structure, but also in dynamic scans where the movements of the various organs can be studied.

Evaluation of the degree of anterior compart-
80%, and positive predictive value of 91% [16]. (Figure B 39). Similarly, MRI had a much higher sensitivity for detection of enteroceles when compared to physical exam and dynamic cystoproctography [85]. Whether or not this technique alters clinical outcome remains to be seen.

2. **Cystocele**

MRI has a sensitivity of 100%, specificity of 83%, and positive predictive value of 97% when evaluating for cystocele compared to intraoperative findings. In addition, urethral hypermobility and post-void urine residual can be documented, as well as evaluation of ureteral obstruction, hydronephrosis and other pelvic abnormalities. **Figures B 40 a, b**

MRI can also be helpful in documenting the status of pelvic organ support as part of a program to assess operative efficacy [86] [87] and differentiating such problems as Müllerian remnant cysts from cystocele [88].

Larson et al showed that in women with anterior wall prolapse, Valsalva causes downward translation of the vagina along its length. A transition point separates a proximal region supported by levator muscles and a distal, unsupported region no longer in contact with the perineal body. In this latter region, sagittal and frontal plane “cupping” occurs. The distal vagina rotates inferiorly along an arc centered on the inferior pubis. Downward translation, cupping, and distal rotation are therefore novel characteristics of cystocele demonstrated by 3-D MR imaging [89]. (Figure B 41-42)

3. **Rectocele**

The reported sensitivity of pelvic examination for diagnosis of rectocele ranges from 31% to 80% [3] [4] [6] [90] [91]. This is usually secondary to organ competition for space in the vagina with other significant prolapse [7]. In addition, it is often difficult to reliably distinguish an enterocele from a high rectocele. **Figure B 43** shows a rectocele diagnosed by dynamic MRI. A rectocele is easily seen when filled with gas, fluid, or gel. Although highly specific, when no rectal or vaginal opacification is used, MRI can miss up to 24% or rectoceles [16]. When rectal opacification is used, a correct diagnosis of rectocele can be made in 100% of patients studied when compared to intraoperative findings [19]. Rectal opacification by introducing sonographic transmission gel or gadolinium into

Figure B 42: Midsagittal view of pelvis with normal support (a) and with prolapse (b). Green represents area where levators (blue arrow) provide cranial reaction forces to counteract the action of intraabdominal pressure and caudal movement of the anterior wall. The red arrow delineates the transition to unsupported region lacking this opposing set of reaction forces (blue line), thereby creating a pressure differential acting caudally on that region. c Red arrow illustrates this point on midsagittal MRI with modeled anterior vaginal wall. U uterus, B bladder, Ur urethra. © DeLancey 2009 [89].

Figure B 43: Resting (a) and straining (b) midline sagittal section showing a rectocele that traps intestinal contents.
the rectum is therefore necessary to increase MRI’s ability to diagnose rectocele. In complex situations such as rectal intussusception [92] MR can provide important information by distinguishing mucosal from full-thickness descent. MR defecography also shows movements of the whole pelvic floor. In this study, 30% of the patients studied were found to have associated abnormal anterior and/or middle pelvic organ descent that would not necessarily be seen in traditional evacuation proctography (unless opacification of vaginal, bladder and intestine are carried out).

At maximal Valsalva on MRI, structures are more caudal and the hiatus longer in women with posterior prolapse. The posterior vaginal wall is longer; this length and point Bp strongly correlate with MRI prolapse size (r=0.5; p=0.002; r=0.7; p<0.001, respectively). [93]

What remains unclear is the relationship between anatomical findings and functional problems. The diagnosis of an anatomical abnormality does not mandate surgery. Simply identifying a rectocele on an imaging study based on the location of the intestinal lumen to a reference line does not mean that correction of the rectocele will cure defecation problems. Rectocele surgery is not without complications and the risk of dyspareunia after posterior colporrhaphy is real. Attention should be paid to make sure that symptoms are truly depending on stool trapping and the condition must be shown on imaging.

4. Uterine Prolapse

Although uterine prolapse is easily diagnosed on physical examination MRI is an excellent modality to record the structural relationships with the bladder and rectum in patients with uterine prolapse (Figure B 44). In addition to depicting the position of the uterus and adjacent organs, it has the ancillary benefits of evaluating uterine size, position, orientation (retroversion) and pathology (fibroids, tumors, Nabothian cysts, etc.), but also ovarian pathology (cyst or mass) which may sometimes prove useful if these problems have not been picked up on physical examination. This is helpful information in determining the route of hysterectomy. Furthermore, MR imaging provides information on the presence or absence of cystocoele, rectocele, urethral hypermobility and urethral diverticula, and evaluates for ureteral obstruction [10] [11] [14] [15] [16] [94]. Gousse et al. report a sensitivity of 83%, a specificity of 100% and a positive predictive value of 100% when comparing dynamic MR imaging to intraoperative findings. These numbers were similar when compared to physical examination alone [16]. More importantly, MRI was able to clearly define the other compartments of the pelvic floor and diagnose uterine and/or ovarian disorders in 30 of 100 patients evaluated [16].

5. Grading of Pelvic Floor Relaxation

A number of studies have described reference values for grading POP [15] [16] [18]. In order to evaluate pelvic organ descent, certain anatomic landmarks are used. The pubococcygeal line (PCL) marks the distance from the pubis to the coccyx and serves as a fixed anatomical reference. In the nomenclature used by Comiter et al. [15], Gousse et

![Figure B 44: Pelvic Floor MRI: Uterine Prolapse](image-url)
al. [16], and Barbaric [23], the width of the levator hiatus is measured as the distance from the pubis to the pubococcygeus muscle (H-line). The hiatus is formed by the puborectalis muscle and encompasses urethra, vagina, and rectum. The M-line depicts the relaxation of the muscular pelvic floor by measuring the descent of the levator plate from the PCL. Using these three simple measurements, an MRI classification for degree of POP has been described [15] [23]. In the normal population, during straining, the hiatus (H-line) is less than 6 cm long and does not descend (M-line) more than 2 cm below the PCL. The upper urethra, urethrovaginal junction, bladder, upper vagina, uterus, small bowel, sigmoid colon, mesenteric fat and rectum are all above the H-line. A combination of hiatal enlargement and pelvic floor descent constitutes relaxation. As the pelvic floor descends, so do the organs above it. The grading system for prolapse of any pelvic organ is based on 2 cm increments below the H-line. By determining the degree of visceral prolapse beyond the H-line, the degree of rectocele, enterocele, cystocele, and uterine descent can be graded in a 0 to 3 scale as follows: 0 = none, 1 = minimal, 2 = moderate, and 3 = severe (Table 2). Other similar systems have been described [18] highlighting the need for standardization of nomenclature and grading of organ prolapse using MRI. In a small study, Ginath et al showed that MRI measurements of pelvic landmark angles can differentiate between women with and without uterine prolapse and correlate best with POPQ point C [95].

Novellas and colleagues evaluated two classification systems (using the PCL and the midpubic line, MPL) in 30 patients with symptoms of POP. For prolapse detection, the correlation between clinical examination and MRI ranged between 74 and 89%. For prolapse staging, the correlation was poor to moderate. Inter-observer agreement was good to very good (kappa between 0.67 and 0.95). It was slightly better at the mid stage, with both systems (kappa between 0.83 and 0.97). Comparison of the inter-observer agreement between both MRI classification systems showed better results for the system using the pubococcygeal line (p<0.005). The classification system based on the pubococcygeal line appeared more reliable and simple for the evaluation of pelvic prolapse on MRI [96]. In another study, agreement between clinical and PCL staging was fair in the anterior (kappa = 0.29) and poor in the apical (kappa = 0.03) and posterior (kappa = 0.08) compartments. Agreement between clinical and MPL staging was fair in the anterior (kappa = 0.37), apical (kappa = 0.31), and posterior (kappa = 0.25) compartments. The MPL had higher agreement with clinical staging than the PCL in this study. However, neither reference line had good agreement with clinical staging [97]. The intra- and interobserver reliability of dynamic MR staging in POP patients has also been evaluated using various anatomical landmarks in relation to the PCL, H-line, and MPL. Clinical measurement points were assessed in relation to the mid-pubic line. Overall, the intra- and interobserver reliability of MR imaging measurements was excellent to good. The PCL showed superior reliability (intraclass correlation coefficients-ICC range 0.70-0.99). The reliability of clinical measurement points, however, was only moderate (ICC range 0.20-0.96). The intra- and interobserver reliability of quantitative prolapse staging on dynamic MR imaging were good to excellent. The PCL appeared the most reliable to use [98].

Singh et al [99] compared a new technique of grading POP by using dynamic MRI with the clinical staging proposed by the POP-Q system [100]. A new reference line, the mid-pubic line, was drawn on the MR image to correspond to the hymenal ring marker used in the clinical staging. The proposed staging by MRI showed good correlation with the clinical staging (kappa = 0.61). Torricelli [101] also used MRI to evaluate functional disorders of female pelvic floor. In symptomatic women MRI confirmed the pelvic examination findings in all cases; MRI also detected additional alterations (4 cases of uterine prolapse and 3 of enterocele) that had been missed at clinical evaluation. Deval [102] compared dynamic MR imaging with physical examination as an alternative to dynamic cystoproctography for the evaluation of POP. PCL and pubourethral muscle were the reference points. The grading system is based on degree of organ prolapse through the hiatus and the degree of puborectalis descent and hiatal enlargement. They also used, the mid pubic line, which was drawn on the MR image to correspond to the hymenal ring marker used in clinical staging. Intra-operative findings were considered the gold standard against which physical examination, dynamic colpocystodofaecography and MRI were compared. The sensitivity, specificity and positive predictive value of MRI were 70%, 100%,
100% for cystocele; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enterocele; 87%, 72% and 66% for rectocele. More recently Etlik [103] found physical examination and MR findings to be very concordant in the diagnosis of pelvic prolapse. Statistical correlations in the stages of prolapse between both of the methods were significant for anterior and middle compartment (p< 0.01), as well as for posterior compartment (p< 0.05).

d) Assessing Treatment Outcome

1. Pelvic Organ Prolapse Operations:

Several studies have evaluated the anatomic changes seen after surgical procedures using MRI to better understand how surgical therapies affect pelvic support and structures. Lienemann et al. [104] evaluated women after abdominal sacrocolpopexy and found that functional MRI identified the exact sacral fixation points after the procedure and easily identified the axis of the vagina and the exact position of the synthetic material used for the repairs. Sze [105] used MRI to study vaginal configuration on MR after abdominal sacrocolpopexy and sacrospinous ligament suspension. This study demonstrated the differences in the geometry of these two operations and should prove helpful in establishing outcome variables for different surgical procedures. Similarly Rane [106] used MRI to compare the vaginal configuration following transvaginal sacrospinous fixation (SSF), posterior intravaginal slingspasty (PIVS) (infracoccygeal sacropexy) and sacrocolpopexy (SCP) and demonstrated improvements in the restoration of vaginal configuration and differences between the procedures in final anatomy. Boukerrou [107] compared outcomes of 1) abdominal sacral cervicopexy, 2) vaginal hysterectomy with paravaginal repair, sacrospinous suspension and posterior colporrhaphy and 3) sacrospinous suspension and posterior repair without paravaginal suspension with MRI. The correction provided by vaginal route was found to result in a return of the bladder and the vaginal apex to their normal positions. In addition, vaginal shortening and postoperative change in vaginal orientation were not present postoperatively.

Relationship between assessment of surgical correction studied with MR imaging and symptoms have been studied. Gufler [108] compared preoperative evaluations with those two to four months after surgery. Of the seven patients who had symptoms postoperatively, only two had abnormal findings on physical examination but MRI showed pathologic findings in five of the seven patients. Huebner et al assessed symptomatic changes after anterior levatoroplasty with morphologic changes visualized by MR defaecography [109]. Anterior levatorplasty improved quality of life in patients with symptomatic rectocele and correction of rectocele is accurately documented by MR defecography, however only moderate correlation between morphologic and clinical improvements was observed.

MRI has also been used for the evaluation of the effectiveness of POP surgical mesh procedures.

Dynamic MRI may evaluate the support of anterior and posterior pelvic floor structures by anterior and posterior polypropylene implant respectively. But dynamic MRI evaluations in a small series by Siegmann and colleagues suggest that if one compartment of the pelvic floor is repaired another compartment frequently (73.3%) develops dysfunction. These results did not correspond to clinical symptoms on short-term follow-up (3 months) indicating the need for long-term follow-up studies to prove if dynamic MRI can reliably identify significant POP after surgery and before the onset of symptoms [110]. In another small series of ten women by Kas-turi et al [111] undergoing intravaginal probe with Prolift, postoperative MRIs supported the inert nature of polypropylene mesh.

Recently Larson et al examined structural relationships between anterior mesh kit suspension points and the upper vagina in women with normal support. Using MRI generated 3D models, they found that the anterior vagina extended above superior attachment points in 100% of women at rest and in 73% during Valsalva. It extended posterior to them in 62% and 100% (rest and Valsalva, respectively). The mean percentage of anterior vaginal length above superior anchoring sites was 40 ± 14% at rest and 29 ± 12% during Valsalva. The upper vagina was therefore found to lie above and posterior to superior suspension points in the majority of women with normal support [112].

2. Pelvic Muscle Exercises

Studies on the effects of pelvic muscle training on the pelvic floor [113] demonstrate reduced levator ani surface area and volume encircled by the levator ani muscle during contraction. When elite athletes are compared to normal women significant differences appear in the cross-sectional area and width of the pelvic floor muscles, [114]. These types of studies are being facilitated by improved techniques of aligning contracted and non-contracted muscle [115].

3. Comparison of MRI With Other Examinations and Assessment of Reliability

Dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography (CCP) have previously been considered the best radiological studies for detecting POP. These studies rely on the opacification with contrast material of the bladder, vagina, small bowel, and rectum with all organs opacified together or in phases with each organ opacified individually prior to each straining phase [4] [106] [109][113]. These studies fail to detect up to 20 percent of all enteroceles [94] [116] [117] [118]. Therefore, MRI has proven to be a much simpler and less invasive technique for the evaluation of
enteroceles. In addition, MRI is able to differentiate the enteroceles according to their contents (small bowel, large bowel, rectosigmoidoceles or mesenteric fat). MRI is also an excellent study to differentiate high rectoceles from enteroceles, thus allowing adequate surgical planning and safer planes of dissection [15] [16] [19] [85]. Although multiphasic MRI with opacification of organs and multiphasic fluoroscopic CCP have similar detection rates for enterocele [116], excellent images can be obtained from dynamic MRI without contrast for opacification of the small bowel or rectal contrast. Thus the minimal added information obtained by contrast administration does not seem to warrant the invasiveness of organ opacification at this time [16] [84] [117]. However, recent data suggest that MRI without rectal contrast shows statistically fewer pelvic floor abnormalities than CCP. Except for enteroceles, MRI with rectal contrast shows statistically similar frequency of POP as CCP [119].

Evacuation proctography has been used to diagnose enterocoele, rectoceles, perineal descent and rectal intussusception. Dynamic contrast roentgenography or fluoroscopic CCP have also been used [4] [90] [91] [116] [120] to diagnose rectoceles. The disadvantages of these techniques are the inability to visualise the soft tissue planes comprising the pelvic floor, their invasiveness, and their use of significant levels of ionizing radiation. Without the use of rectal opacification, MRI appears to be a poor choice for the evaluation of rectoceles missing up to 25% of such defects. With rectal opacification a correct diagnosis of rectocoele can be made in 100% of patients in comparison to intraoperative findings [19]. Triphasic dynamic MRI and triphasic fluoroscopic CCP have similar detection rates for rectocoele [116]. Upright dynamic MR defaecating proctography has been reported [121]. Although these studies might prove to be more sensitive in detecting anorectal anomalies, their utility seems to be more pronounced in patients with disorders of defecation include anismus, intussusception, and others, and may be too invasive to justify their routine use in the evaluation of rectoceles.

Kaufman [122] evaluated dynamic pelvic MRI and dynamic CCP in the surgical management of females with complex pelvic floor disorders. Physical examination, dynamic MRI, and dynamic CCP were concordant for rectocoele, enterocoele, cystocoele, and perineal descent in only 41% of patients. Dynamic imaging lead to changes in the initial operative plan for 41% of patients. Dynamic MR was the only modality that identified levator ani hernias. Dynamic CCP identified sigmoidoceles and internal rectal prolapse more often than physical examination or dynamic MR. Whether this type of imaging creates measurably better outcomes remains to be seen. Singh et al [99] showed a reasonably good correlation between clinical staging and MRI staging (Kappa = 0.61) with the mid pubic line being used as a surrogate for the hymenal ring. In addition, specific features such as the levator-vaginal angle the area of the genital hiatus could be assessed quantitatively on MRI.

Torriceelli [101] studied ten healthy volunteers and 30 patients with suspected pelvic floor deficiency with and without POP. They found good concordance between physical examination and MRI with four cases of uterine prolapse and three cases of enterocele seen on MRI that had not been suspected on pelvic examination. Whether these would have been detected at the time of surgery was not discussed. Devall [102] compared intraoperative findings as a gold standard for MRI based diagnosis. The sensitivity, specificity, and positive predictive value of MRI were 70%, 100%, 100% for cystoceles; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enteroceles; 87%, 72%, 66% for rectocoele. Although all of these measurements are somewhat subjective, these figures show that it is possible to quantify the individual elements of pelvic floor dysfunction in reasonable parameters.

e) Conclusions

Proof that MR imaging has value will eventually need to come from increased operative success rates. Better documentation of preoperative and postoperative anatomy could allow us to seek reasons of operative failure. Because MR provides a detailed picture of a woman’s pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure.

f) Consensus Statement

- MRI is not yet indicated in the routine evaluation of patients with [uncomplicated primary] pelvic organ prolapse; however data concerning the causes of prolapse are rapidly accumulating and this may change soon. It can provide useful information concerning complex prolapses and can be used in difficult cases. [Level of evidence 3, Grade of Recommendation C]

- Studies that identify specific defects in the connective tissue and the muscles of the pelvic floor that correlate these findings with the clinical presentation in prolapse are needed.

- Additional studies comparing MRI of healthy volunteers and patients with pelvic organ prolapse are needed to better evaluate the anatomic changes involved in pelvic floor prolapse.

- Standardization of measurement strategies and quality control in MRI, including issues related to consistency of measurement axes, maneuvers required to produce a maximal prolapse during MRI, bowel condition, bladder filling, pushing instructions, etc.)
III. SPECIAL ISSUES

1. POST-VOID RESIDUAL

Post-void residual urine (PVR) is defined as “the volume of urine left in the bladder at the end of micturition” [1]. Evaluation of PVR prevalence in women with symptomatic pelvic floor dysfunction suggests that 81% have a post-void residual of 30 ml or less [2]. This is not significantly different from asymptomatic perimenopausal and postmenopausal women in whom 15% of subjects had a PVR greater than 50 ml [3]. If symptoms cannot predict elevated PVR, a urogenital prolapse beyond the hymen seems to be associated with incomplete bladder emptying [4]. Among patients older than 55 years with symptoms of overactive bladder, previous incontinence surgery, history of multiple sclerosis and vaginal prolapse stage 2 or greater, were found to be independent predictors of elevated PVR [5]. Similar data were obtained by Fitzgerald in patients with urgency incontinence, the presence of pelvic organ prolapse ≥stage 2, symptoms of voiding difficulty and absence of stress incontinence symptoms predicted 82% of patients with elevated PVR [6]. Higher prevalence of post-void residual was found in patients with stress urinary incontinence with 35.5% of women having a PVR >50 ml suggesting they have some degree of voiding dysfunction [7]. Although elevated PVR and bacteriuria are common among elderly residents in nursing homes, no association between the two was observed in a Swedish study [8]. Analysis of elderly patients with urinary incontinence failed to identify any significant association between PVR and any other clinical or urodynamic parameter [9]. Sanders and co-workers addressed the issue of the real need for measuring flow rates and post-void residual urine in women with urinary incontinence. Analysis of 408 women suggested a 4% incidence of PVR 200 ml or greater and a 6% rate of PVR 149 ml or greater. The authors calculated that only 1.5% of patients [6 of 408] had their management modified because of the results of free uroflowmetry and PVR measurement. In their opinion, these data do not justify the inclusion of these tests in the “minimal care” programme for assessing primary, uncomplicated, urinary incontinence in female patients [10].

PVR is often considered a safety parameter, which needs to be monitored in the follow-up of medical or surgical management of urinary incontinence. A number of studies have addressed the effect of antimuscarinic treatment in men with symptoms of overactive bladder to rule out the old dogma that banned the use of these drugs in elderly men. Actually, all published data suggest that antimuscarinic treatment is safe for men with benign prostatic enlargement and no significant change in PVR values was found in active treatment groups compared to placebo [11, 12]. In male patients with bladder outlet obstruction, antimuscarinic treatment may result in a significantly larger PVR (25 vs. 0 ml) that seems to be of no clinical relevance and with higher incidence of adverse events [13].

Measuring PVR is of importance in patients receiving intravesical injections of Botulinum toxin A for UUI. Significant increase of post void residual urine is observed following injection of onabolutinumtoxinA in patients with neurogenic urinary incontinence due to detrusor overactivity with 30 to 42% of patients needing to start clean intermittent catheterisation compared to 12 % in the placebo group [14]. In patients with idiopathic UUI, increase of PVR was observed in those receiving onabolutinumtoxinA compared to placebo although only 8 of 70 patients required CIC and only 3 patients had a PVR >200 ml at day 8 and only one at 6 months [15].

Although the prevalence of incomplete bladder emptying among male and female patients with urinary incontinence and pelvic floor dysfunction is low, there is a general consensus that PVR should be measured in continent patients [16] although the evidence suggests that only patients with UI and symptoms of voiding dysfunction are at risk [17].

a) Measuring PVR

The measurement of PVR can be performed by invasive and noninvasive means. Invasive methods include: in-and-out catheterisation and endoscopy. Noninvasive means are transabdominal ultrasonography with real-time ultrasound or fully automated systems, and radioisotope studies. In-and-out catheterisation has been considered for some time, the gold standard for the measurement of PVR. Nevertheless the method is subject to inaccuracies, if the person performing the catheterisation is not fully instructed as to the procedures and techniques to assure complete emptying (moving the catheter in and out slowly, twisting it, suctioning with syringe, suprapubic pressure), especially in cases of bladder diverticula and vesicoureteric reflux [18]. Stoller and Millard showed inaccuracies in 26% of 515 male patients evaluated by full-time urology nurses with a mean difference between the initial and the actual residual volume of 76 ml in those measurements that were found to be inaccurate [19]. After further education of the nurses, inaccurate assessments were reduced to 14% with a mean difference of 85 ml. PVR can be measured at the time of endoscopy, provided there is a blinded insertion of the instrument to avoid irrigation fluid inflow. Both invasive means are usually performed with some kind of local anaesthesia and carry a small risk of urethral damage and urinary infection.

Before the era of ultrasonography, PVR was measured non-invasively by the phenolsulfonphthaleine excretion test or with isotopes [20, 21].

In 1967, Holmes described the use of ultrasonography in the evaluation of bladder volume and this
technique rapidly gained widespread acceptance as a satisfactory level of accuracy was demonstrated [22, 23]. Using either three diameters (length, height, width) or the surface area in the transverse image and the length obtained in the longitudinal image, various volume formulae for a spherical or an ellipsoid body are utilised to estimate the bladder volume (Table 3). Twenty-one different formulae have been proposed over the years making assumptions about bladder shape which have often been questioned [24]. Comparison of values of bladder volumes obtained using different formulae did not result in any significant difference amongst the various calculations [25]. At present, no single formula can be regarded as the one best volume calculation formula. Several studies report sufficient accuracy with ultrasound estimation of PVR [23, 24, 26-29]. False negative results are rare with PVR less than 20 ml [30]. Recently portable scanners have been introduced, with automatic measurement of bladder volume. In a prospective comparison of one hundred measurements of PVR by portable ultrasound with measurements by catheterisation, the mean absolute error of the scanner was 52 ml [31]. For volumes below 200 ml and 100 ml, the error was 36 ml and 24 ml respectively. More recent studies suggest a good level of accuracy in both female and paediatric populations [32, 33]. Residual urine is usually referred to as an absolute value, but it can be measured as a percentage of bladder capacity.

The intra-individual variability of PVR is high from day to day and even within a 24 hours period. This was reported in men with BPH by Birch et al. and by Bruskevitz et al. [34, 35]. Griffiths et al. examined the variability of PVR among 14 geriatric patients (mean age 77 years), measured by ultrasound at three different times of day on each of two visits separated by 2-4 weeks [36]. Within-patient variability was large (SD 128 ml) because of a large systematic variation with time of day, with greatest volumes in the early morning. The inherent random variability of the measurement was much smaller (SD 44 ml). Several factors can influence PVR variability: voiding in unfamiliar surroundings, voiding on command with a partially filled or overfilled bladder, the interval between voiding and the estimation of residual (it should be as short as possible), the presence of vesico-ureteric reflux or bladder diverticula. Several studies reported the questionable value of PVR as an important outcome prognosticator in male patients with benign prostatic enlargement and benign prostatic obstruction [37-42]. The cause of PVR is probably multifactorial, and no consensus exists on the relation of PVR, bladder outlet obstruction and detrusor contractility.

b) Conclusions

Knowledge regarding pathophysiology of PVR remains unclear. In patients with urinary incontinence there is no consensus as to its value as a safety parameter and particularly its relationship with upper tract dilatation, bacteriuria and urinary infection. The intra-individual variability of PVR has been investigated mainly in male patients with bladder outlet obstruction but little information is available as to its variability in patients with urinary incontinence. Ultrasound is the recommended method for assessing PVR because it is the least invasive and it is sufficiently accurate for clinical purposes yet it is the most expensive. In-and-out catheterisation is invasive and can be inaccurate even if carefully performed. The general opinion is that PVR measurement forms an integral part of the study of urinary incontinence, as a safety parameter to exclude voiding dysfunction associated with incontinence.

Table 3. Comparison of different formulae to assess PVR by transabdominal ultrasound in 30 men with BPH scanned three times (35).

c) Consensus Statements

1. Residual urine measurement is recommended in the initial assessment of urinary incontinence as a safety parameter and in the evaluation of treatment outcome (Level of Evidence 3- Grade of Recommendation C)

2. Measurements should be performed using real-time sonography or a portable scanner or in and-out catheterisation (Level of Evidence 3- Grade of Recommendation C).

3. Due to intra-individual variability, in cases where significant PVR is detected by the first measurement, several measurements should be performed (Level of Evidence 3- Grade of Recommendation C).

4. The method of measurement should be recorded (Level of Evidence 3- Grade of Recommendation C).

d) Future Research Areas

1. Pathophysiology of PVR in male and female populations with UI;

2. Circadian variation of residual urine in patients with UI;

3. Determination of the cut off value of significant residual urine in different patient populations with UI;

4. Residual urine as a prognostic indicator of outcome in the treatment of incontinence (Level of Evidence 3- Grade of Recommendation C).

c) References (see at the end of the chapter)

2. OPEN BLADDER NECK AND PROXIMAL URETHRA AT REST

The significance of open bladder neck and proximal urethra at rest observed during a voiding cystourethrogram or pelvic floor ultrasound scan remains doubtful [1] and the peer-reviewed literature is equally divided into papers associating such a condition with storage disorders and those suggesting this is a chance finding with no negative implications.

A 21% prevalence in nulliparous asymptomatic women has been reported [2]. In the non-neurogenic population there is no pathophysiological correlation between this and urinary incontinence, Digesu and co-workers reported a prevalence of 1:3 amongst females suffering LUTS. An open bladder neck at rest is not pathognomonic of sphincter incompetence although it is associated with USI [3]. In patients with stress incontinence, but also in asymptomatic women [4], funnelling of the internal urethral meatus may be observed on Valsalva and sometimes even at rest; funneling is often associated with leakage. However, funnelling may also be observed in urgency incontinence and cannot be used to prove SUI. Marked funnelling has been shown to be associated with poor urethral closure pressures [5, 6].

Reports in the peer reviewed literature suggest that an open bladder neck and proximal urethra at rest, during the storage phase, may be observed during cystography, videourodynamic or bladder ultrasound, both in patients with and without neurological disease and is interpreted as a sign of internal sphincter denervation as occurs in 53% of patients with Multiple System Atrophy [7]. Distal spinal cord injury has been associated with an open smooth sphincter area, but whether this is due to sympathetic or parasympathetic decentralisation or defunctionalisation remains uncertain [8]. Relative incompetence of the smooth sphincter area may also result from interruption of the peripheral reflex arc very similar to the dysfunction observed in the distal spinal cord injury. Twenty-one out of 54 patients with spinal stenosis were found to have an open bladder neck at rest [9]. In a review of 550 patients [10], 29 out of 33 patients with an open bladder neck had neurological disease. Although the association was more commonly seen in patients with thoracic, lumbar and sacral lesions, the difference when compared to cervical and supraspinal lesions was not significant. Damage to the sympathetic innervation to the bladder was also frequently observed in patients undergoing major pelvic surgery, such as, abdominal perineal resection of the rectum. Patients with myelodysplasia had an inordinately high incidence of open bladder neck (10 out of 18 patients versus 19 out of 290 having different neurological disorders).

Patients with sacral agenesis are included in the larger category of myelodysplastic patients and suffer from an open bladder neck with an underactive bladder. Shy-Drager syndrome is a Parkinson-like disorder with peripheral autonomic dysfunction. Neurogenic detrusor overactivity is usually found in association with an open bladder neck at rest and a denervated external sphincter [11]. Peripheral sympathetic injury results in an open bladder neck and proximal urethra from a compromised alpha-adrenergic innervation to the smooth muscle fibres of the bladder neck and proximal urethra [12]. Although it can occur as an isolated injury it is usually associated with partial detrusor denervation and preservation of sphincter EMG activity. The loss of bladder neck closure suggests an autonomic neural deficit. The site and nature of the requisite deficit is unclear.

Most authors agree on the importance of the sympathetic system in maintaining the integrity of the bladder neck [13-16] although the possible role of parasympathetic innervation has been proposed by others [17, 18]. An open bladder neck at rest in children or in women without neurological disease can represent a different disorder, either related to a congenital anomaly or secondary to an anatomical pelvic floor defect. Stanton and Williams [19] described an abnormality in girls with both diurnal incontinence and bed-wetting, based primarily on
voiding cystourethrography, in which the bladder neck was wide open at rest. Murray et al [20] reported the "wide bladder neck anomaly" in 24.5% of the girls [35] and 9.3% of the boys [10] out of 251 children (143 girls and 108 boys) undergoing videourodynamics for the assessment of non-neurogenic bladder dysfunction (mainly diurnal incontinence). The authors considered the anomaly congenital and made the hypothesis that wide bladder neck anomaly in girls may provide a basis for the development of USI in later life.

The presence of an open bladder neck has been proposed to explain the pathophysiology of urinary incontinence but such hypothesis did not stand the test of time. An open bladder neck was a key point in defining type III stress incontinence according to the classification of Blaivas and Olsson [21]. This classification, no longer used in our daily practice, was based on history, imaging, and urodynamics, and distinguished five diagnostic categories of stress incontinence. Incontinence type III was diagnosed by the presence of an open bladder neck and proximal urethra at rest in the absence of any detrusor contraction suggesting an intrinsic sphincter deficiency.

In pelvic fracture with membranous urethral distraction defects, when cystography (and/or cystoscopy) reveals an open bladder neck before urethroplasty, the probability of postoperative urinary incontinence may be significant, although the necessity of a simultaneous (or sequential) bladder neck reconstruction is controversial [22-24]. Skala and co-workers suggest that an open bladder neck at rest is associated with an increased risk of postoperative complications and failure after open colposuspension [25].

**a) Conclusions**

In conclusion, the diagnosis of open bladder neck at rest does not seem to be helpful to diagnose the underlying cause of urinary incontinence.

**b) Consensus Statements**

When observing an open bladder neck and proximal urethra at rest in male patients, during the storage phase, whatever imaging technique is used, it may be worthwhile to evaluate the possibility of an underlying autonomic neural deficit. (Level of Evidence 3, Grade of Recommendation C)

**c) Future Research Areas**

1. The relation of open bladder neck and proximal urethra at rest to the different neurogenic disorder
2. Longitudinal study of wide bladder neck and proximal urethra at rest in asymptomatic women
3. Evaluate the prognostic value of the open bladder neck and proximal urethra at rest

3. **FEMALE URETHRAL DIVERTICULA**

The prevalence of urethral diverticulum ranges between 1 and 6% with rates up to 10% in among asymptomatic women from tertiary referral centres [1, 2]. The suspicion of a urethral diverticulum stems from LUTS or urethral masses on physical examination. Urethral masses include leiomyoma, vaginal cysts, malignancy, ectopic ureter, granuloma and urethral diverticula. The first case of female urethral diverticulum was reported in 1805 [3]. Since the report from Davis and Cian in 1956 [4] using positive-pressure urethrography (PPU), the diagnosis has become much more common even though, despite increased clinical awareness, this pathology continues to be frequently overlooked. Urinary incontinence is often associated with a urethral diverticulum. Incontinence may be a sequel to urine loss from the diverticulum itself with stress manoeuvres, SUI or urgency incontinence [5]. Aldridge et al. [6] reported urethral diverticula in 1.4% of patients with stress urinary incontinence.

The presenting symptoms of a urethral diverticulum have classically been described as the three Ds (Dysuria, postvoid Dribbling, and Dyspareunia). Since most patients present with nonspecific lower urinary tract symptoms, and the pathognomonic presentation (postvoid dribbling, urethral pain, tender periurethral mass and expression of pus from the urethra) is very uncommon, these patients undergo extensive evaluation and treatment before a correct diagnosis is established [7, 8]. The diagnosis of a urethral diverticulum may be achieved by physical examination, voiding cystourethrography, positive-pressure (double-balloon) urethrography, urethroscope, endocavitary (transurethral or transvaginal) or transperineal ultrasound sonography, urethral pressure profile or MRI. Positive pressure urethrography is usually accomplished using a double balloon catheter according to the method described by Davis and Cian [4]. Two different models exist: the Davis-TeLinde and the Tratner catheter. Positive-pressure urethrography (and voiding urethrography) may result in a false negative study when the inflammation of the diverticulum neck prevents contrast medium from flowing into the diverticulum cavity.

The accuracy of a diagnostic test may depend upon the characteristics of the study population and conflicting data are often reported in the peer-review literature. Blaivas et al reported a diagnostic accuracy of VCUG of 97% in a series of 66 patients and similar results (95%) were obtained by Ganabathi et al. [7, 9]. Less favourable results have been reported by others. Comparison of VCUG versus PPU in the diagnosis of urethral diverticula showed a clear superiority of the latter with good consistency among different studies [10, 11]. In some patients, VCUG only delineated the lower part of the diverticulum [12]. Ultrasound scanning and MRI should theoretically be free of such false negative imaging. Chancellor et al. [13] described the use of intraoperative intraluminal echographic evaluation which may be of help in dissecting the diverticulum and achieving
complete excision without damaging the bladder neck and urethra. A number of studies have shown that MRI is superior to voiding cystourethrography and positive-pressure urethrography and can be considered, if available, the imaging of choice when the diagnosis of urethral diverticulum is suspected [14-19] (Figure B 28 a,b). MRI is superior to VCUG or double-balloon urethrography, particularly in diagnosing diverticula with narrow, noncommunicating necks [15, 16]. MRI proved to be superior to radiological studies because diverticula can go undiagnosed on voiding cystourethrogram, furthermore size and complexity of the diverticulum is better defined on MRI [17]. Endoluminal MRI is considered to be of particular importance in the diagnosis of a circumferential urethral diverticulum, a condition that is relatively rare but the diagnosis may increase with the increased use of this imaging technique. Proper evaluation of the anatomy of the diverticulum is essential in planning reconstructive surgery [1, 20]. MRI also proved to be useful in diagnosing inflammation or tumour in the diverticulum [21, 22]. Endoluminal MRI with either a vaginal or rectal coil, may provide even better image quality than simple MRI [18]. A comparison of MRI versus urethrography and urethroscopy, in a group of 20 women with urethral diverticulum, reported a 69 and 77 per cent accuracy of the two latter imaging studies versus MRI [14]. When surgical findings were compared to MRI, urethrography and urethroscopy, the diagnostic ability of the three methods was 70, 55 and 55 per cent, respectively. Diverticula ostia could not be identified by MRI not withstanding the use of contrast material. Neitlich et al. [15] reported in a series of 19 patients that MRI (using a fast spin echo T2-weighted pulse sequence and a dedicated pelvic multicoil) had a higher sensitivity for detecting urethral diverticula and a higher negative predictive rate in comparison to double balloon urethrography. Blander et al. [17], compared MRI and VUG in 27 patients with urethral diverticula and found that endoluminal (endorectal or endovaginal) MRI was extremely accurate in determining the size and extent of urethral diverticula compared to VCUG; the related information can be critical when planning surgical approach, dissection and reconstruction. In conclusion, review of the peer reviewed literature suggests that positive pressure urethrography is still a valuable tool to diagnose female urethra diverticula notwithstanding both ultrasound sonography and particularly MRI represent better alternatives with a significantly higher diagnostic accuracy.

In males, both VCG and ultrasonography can be successfully used to diagnose syringocele (cystic dilatation of the Cowper’s gland), congenital and acquired diverticula [23].

**a) Conclusions**

Proper imaging of female diverticula is essential to diagnose the condition and, in planning and conducting proper surgical repair. Ultrasonography may suffice to identify size and location of the diverticulum although MRI imaging in preferable whenever available.

**b) Consensus Statements**

- In cases of female urinary incontinence if a urethral diverticulum is suspected, appropriate imaging (positive pressure urethrography, voiding cystourethrography, urethroscopy, ultrasound, MRI) is recommended. (The choice of the type of imaging depends on their availability. Data show a higher accuracy of MRI.) (Level of Evidence 3 – Grade of Recommendation C)

**c) Future Research Areas**

- Properly conducted prospective studies are needed to compare the accuracy of ultrasonography and MRI in the diagnosis and staging of female and male diverticula.

**d) References (see at the end of the chapter)**

4. IMAGING OF THE NERVOUS SYSTEM

**a) Lumbosacral Spine x-rays**

In children with lower urinary tract dysfunction and urinary incontinence, the presence of a spinal dysraphism must be ruled out. Although in most of the cases abnormalities of the gluteosacral region and/or legs and foot are clearly visible, antero-posterior and lateral films of the lumbosacral spine have to be evaluated in order to identify vertebral anomalies. Sacral agenesis involves the congenital absence of part or all of two or more sacral vertebrae. In the absence of two or more sacral vertebrae a neurogenic bladder is usually found. Spina bifida occulta has a variable significance. Simple failure to fuse the laminae of the fourth and fifth lumbar vertebrae is unlikely to be important, but if the spinal canal is noticeably widened, there may be cord involvement (diastematomyelia, tethered cord syndrome).

**b) CT, MRI, SPECT and PET**

Numerous papers refer to rare neurological conditions presenting with different symptoms including urinary incontinence in which CT scan, MRI, SPECT, and PET imaging were carried out to identifying the underlying CNS disease. These references have little impact on daily practice although they can be helpful in occasional difficult cases.

With regards to the clinical diagnostic use of CT or MRI, a few papers evaluated the role of fetal MRI imaging. Fetal MRI has higher contrast resolution than prenatal sonography and allows better identification of normal and abnormal tissue. Moreover, MRI can
diagnose some abnormalities such as cerebral malformations and destructive lesions which can be occult on prenatal sonography, where the more anterior cerebral hemisphere cannot be properly evaluated due to reverberations by the overlying structures [2]. Common indications for fetal MRI include the evaluation of all the sonographically diagnosed abnormalities of ventriculi, corpus callosum, or posterior fossa, as well as all those fetuses at increased risk for brain abnormalities, such as in families with a history of a prior child or fetus with anomalies, genetic disorders, complications of monochorionic twinning, and maternal illness (such as maternal infection or major cardiac event). Moreover, with recent advances in fetal surgical techniques, fetal MRI is being increasingly used before surgical intervention [3]. The results of fetal MRI, whether verifying absence of abnormality, confirming sonographically detected abnormalities, or discovering additional abnormalities that were not apparent by sonography, have been shown to affect clinical decision-making during pregnancy, both by physicians and parents, resulting in changes in pregnancy management in nearly half of cases [2]. With regard to myelomeningocele, prenatal ultrasound can easily identify the absence of posterior elements of the vertebral bodies at affected levels and extension of the subarachnoid space posteriorly through the bony spina bifida, as well as the frequently associated presence of small posterior fossa alteration and herniation of cerebellar tissue into the cervical subarachnoid, which define the Chiari II malformation. However, fetal MRI can be a helpful adjunct when sonography analysis is limited, such as in cases of large maternal body habitus, oligohydramnios, low position of the fetal head, or when the fetal spine is positioned posteriorly with respect to the mother. Moreover, fetal MRI can be very useful to detect additional associated anomalies, such as callosal agenesis or hypogenesis, periventricular nodular heterotopia, cerebellar dysplasia, syringohydromyelia, and diastematomyelia [3]. If fetal surgery will be shown to improve long-term outcome, fetal MRI will surely become a routine examination for affected fetuses.

MRI is also recommended in children with anorectal abnormalities as abnormalities of the spine and of the spinal cord are diagnosed in 42 to 46% of cases and in about 50% of cases the spinal cord is involved [1]. Wraige et Borzyskowski suggested that spinal cord imaging should be considered in children in whom day-time wetting is associated with impaired bladder sensation or poor bladder emptying even in the absence of clinical or radiological suspicion of lumbosacral spine abnormalities. Four out of 10 children with these symptoms had a spinal cord defect diagnosed on MRI [4].

MRI of the lumbar spine is now the gold standard for evaluating children with spina bifida and adults in which an occult form of spina bifida is suspected. A potential technical update might be the use of intrathecal contrast medium to perform cisternography and ventriculography contrast-enhanced MRI. Munoz et al., evaluated a series of 10 patients with complex cerebrospinal fluid diseases, where other imaging techniques had been unclear or inconclusive, performing MRI with intrathecal administration of gadopentate dimeglumine. In 8 out of the 10 patients, imaging findings influenced or changed the clinical decision-making program and the surgical planning [5].

Sharma et al. recently evaluated with MRI the surgical outcome in patients with spinal dysraphism. Specifically, MRI spectroscopy was used to evaluated the composition of cerebrospinal fluid before and after surgery. Before surgery, high levels of lactate, alanine, acetate, glycerophosphorylcholine, and choline were observed in the cerebrospinal fluid of patients with spinal dysraphism, while these levels normalised postoperatively to those observed in control subjects. However, in those patients where cord tethering occurred, increased concentrations of lactate and alanine were found, suggesting that MRI spectroscopy might be a promising tool in the assessment of surgical outcomes in patients with spinal dysraphism [6].
Several papers refer to the use of CNS imaging in clinical research of voiding dysfunction and pathophysiology. Positron emission tomography (PET) and functional MRI studies provided information on specific brain structures involved in micturition in humans. During micturition an increase in regional blood flow was shown in the dorsomedial part of the pons close to the fourth ventricle, in the pontine micturition centre (PMC), in the mesencephalic periaqueductal grey (PAG) area, as well as in the hypothalamus including the preoptical area [1]. A good review on CNS imaging and lower urinary tract function was recently published by Drake and co-workers [7].

A couple of significant original studies have been published recently on the role of functional MRI in stress and urgency urinary incontinence. Specifically, previous brain imaging studies showed that during pelvic floor muscle contraction there was activity in the superior precentral gyrus, anterior cingulate cortex (ACC), cerebellum, supplementary motor cortex (SMA) and the thalamus [8, 9]. Similarly, during anal sphincter contractions multifocal cerebral activity was shown in the primary and secondary sensory/motor cortices, the insula as well as the cingulate gyrus, prefrontal cortex, and the parietooccipital region [10]. Di Gangi Herms et al. evaluated the neuroplastic changes of cortical representation of pelvic floor motor function induced with pelvic floor muscle training (PFMT) by biofeedback in patients with SUI [11]. Specifically, the authors used functional MRI to evaluate 10 patients with SUI before and after a 12-week PFMT with EMG-biofeedback program. In the MRI performed before the beginning of PFMT, the authors identified significant brain activation in superior lateral and medial precentral gyrus and the superior lateral postcentral gyrus, in the SMA, the left premotor area, and in the left and middle cerebellum, as well as in the insula and in the ACC. In the MRI film after PFMT, less brain areas were activated, mainly the superior lateral and medial precentral gyrus, superior lateral postcentral gyrus and the insula. In other words, after PFMT there was more focused activation in the primary motor (superior lateral and superior medial precentral gyrus) and somatosensory areas, which is consistent with automation of the relearned skillful behavior [11]. PFMT with feedback may improve muscular strength therefore enhancing support of the urethra and also optimise central muscular control of the pelvic floor, modulate bladder sensation, and reflect the emotional neutralisation related to symptom reduction.

With regards to urgency urinary incontinence, Tadic et al. reported a small study, which used functional MRI to investigate 11 patients with urge urinary incontinence and 10 healthy controls. Specifically, the connections of the right insula (RI) and anterior cingulate gyrus (ACG) to other cortical area were evaluated, based on the assumption that the two areas were among the most important regions of the supraspinal neuronal network controlling the bladder. In normal subjects, there were significant positive effective connections with many of the regions involved in supraspinal bladder control, including left insula and frontotemporal and parietal regions, thalamus, putamen and claustrum, posterior cortex, cerebellum, pontine micturition centre and mesencephalic periaqueductal grey. Vice versa, in the patients with urgency incontinence, significant negative connections to left parieto-temporal lobes, hippocampus, para-hippocampal gyrus and cerebellum were found, with few positive connections [12]. In subjects with normal bladder function, RI and/or ACG have been confirmed to have effective connections with many of the brain regions involved in bladder control such as the frontotemporal and sensorimotor regions, thalamus, putamen, cerebellum and midbrain, as well as to the posterior cortex, a region which may have a role in the control of bladder function. Vice versa, in the patients with urgency incontinence, the connections were shifted to an alternative complex of brain regions, such as left parieto-temporal lobes, para-hippocampal gyrus and parts of cerebellum, which might represent expression of the recruitment of accessory pathways in order to control urgency and the voiding reflex as well as the emotional charge due to the abnormal sensation of urgency [12]. On the whole the data from these recently published studies have improved our knowledge of nervous functional anatomy related to vesicourethral function and dysfunction but, to date, have no clear clinical relevance.

In conclusion, central nervous system imaging is rarely indicated in urinary incontinence. Spinal cord imaging is recommended in cases of children with anorectal malformation and whenever spina bifida occulta is suspected. In the case of clinical neurological signs and/or symptoms suggestive of central nervous lesions, imaging may be indicated along with more specific neurophysiological tests (e.g., signal latency, testing, evoked potential, etc.). Further improvements in the knowledge of the correlation between morphological and functional evaluation of the CNS is foreseeable using present CNS functional imaging technology.

c) Consensus Statements

- In patients with suspected congenital neurogenic incontinence, with or without abnormalities of neurourological physical examination, lumbar-sacral spine anteroposterior and lateral radiological evaluation (or MRI) is indicated. (Level Evidence 3, Grade of Recommendation C)
- Neuroimaging should be considered when a nervous system disorder is suspected on the basis of clinical and/or neurophysiologic test findings (Level of Evidence 3 - Grade of Recommendation C)

d) Future Research Areas

- To investigate the effect of antimuscarinics and neuromodulation on brain activity;
- To standardise bladder filling parameters to investigate brain activity during different types and levels of bladder sensations;
• To investigate the effect of environmental and behavioural factors on brain activity in patients with urgency incontinence;
• To define the sequence of brain activation during bladder filling.

e) References (see at the end of the chapter)

5. ENDOSCOPI C OF THE LOWER URINARY TRACT

Since the introduction of the cystoscope by Bozinni in 1805, endoscopy has played a critical role in the evaluation of lower urinary tract disorders [1]. Many investigators have proposed the routine use of urethroscop y in the evaluation of urinary incontinence. These recommendations have rarely been based on evidence. There are five specific areas pertaining to urinary incontinence in which urethrocystoscopy has been advocated.

1. Observation of the female urethral sphincter to assess its ability to close and coapt. Urethrocystoscopy has been advocated in the static state to assess intrinsic sphincter deficiency (ISD) as well as in the dynamic state, when the patient is straining, to evaluate hypermobility and urethral closure while the patient is straining. It has been reported that sluggish closure of the bladder neck during periods of a rise in intra-abdominal pressure is associated with anatomical stress urinary incontinence. Intrinsic sphincter deficiency has classically been described as a fibrotic or pipe-stem urethra. It has been suggested that endoscopy can even help to differentiate between the hypermobile urethra and the intrinsically damaged urethra.

2. Assessment of the bladder, to rule out concomitant bladder conditions which may be the cause of detrusor overactivity and urinary incontinence or may simply require treatment.

3. Search of extraurethral causes of urinary incontinence, such as vesico-vaginal fistula and ectopic ureter.

4. Intraoperative cystourethroscopy during correction of USI to assess for bladder damage and ureteral patency.

5. Evaluation of the membranous and prostatic urethra in male patients with post-prostatectomy stress incontinence to evaluate possible iatrogenic damage of the external sphincter region. Assessment of bladder outlet in males with urgency incontinence considered to be secondary to bladder outlet obstruction to appraise prostate morphology.

a) Evaluation of the Female Bladder Outlet

Robertson described the procedure of dynamic urethroscopy to evaluate the bladder neck [2]. In this procedure a gas urethroscope is used to observe the urethra, bladder neck, and portions of the bladder. During visualisation manometric recording can be performed. Robertson described the appearance of SUI as a sluggish closure of the bladder neck and the appearance of the overactive bladder as a bladder neck that closes and then opens like the shutter of a camera. This procedure was reported to be extremely useful in patients with urinary incontinence as the bladder neck can then be observed at rest, with straining, and Valsalva manoeuvres. Unfortunately, in Robertson’s original description of this procedure, it was never compared to other standard methods of measuring outlet resistance. Others who advocate the technique of Robertson reported that only 43% of patients with SUI actually had loss of bladder neck support on urethroscopy [3]. Scotti, et al performed a retrospective review of 204 patients who underwent dynamic urethroscopy for the evaluation of SUI [4]. Of the 204 patients, 99 had SUI. Urethroscopy was found to be an imprecise predictor of SUI with a 62% sensitivity, a 74.6% positive predictive value and a specificity of 79.1%. Moreover, there were many equivocal studies. The authors concluded that urodynamic evaluation rather than urethroscopy was a more accurate predictor of stress incontinence. Sand, and associates compared supine urethrocystographic cystometry (dynamic urethroscopy) to the gold standard of multichannel urethrocystometry [5]. They found a sensitivity of only 24.6% and a positive predictive value of only 65.2% in predicting detrusor overactivity.

Horbach and Ostergard tried to predict urethral sphincter insufficiency in women with SUI using urethroscopy [6]. They retrospectively reviewed the records of 263 women who had a diagnosis of SUI. They defined ISD as a maximal urethra closure pressure of 20 cm H2O or less with the patient upright with a symptomatically full bladder. They then divided patients into two groups, those with ISD and those with maximal urethral closure pressures of more than 20 cm H2O. Based on this classification, 132 women, or 50.2%, had evidence of ISD. However, when urethral function was assessed by endoscopy, only six of 132 patients with ISD were found to have an open or partially open proximal urethra and urethrovaginal junction at rest during urethroscopy. Clinically, these patients had very low urethral pressures and reported difficulty with continuous leakage of urine. Endoscopy appeared to have little predictive value for ISD as defined by urethral pressure profilometry. Govier et al compared cystoscopic appearance of the female urethral sphincter mechanism to videourodynamics in 100 consecutive women with complex types of urinary incontinence [7]. Sphincter dysfunction was classified as minimal, moderate, and severe based on the radiographic appearance of the bladder neck with straining. Urethrocystoscopy underestimated the degree of sphincter deficiency 74% of the time in patients with moderate sphincter dysfunction and 44% of the time in patients with severe sphincter dysfunction. The authors concluded that cystoscopy is inadequate to judge the functional integrity of the bladder outlet. Furthermore, cystoscopy
alone will underestimate intrinsic sphincter deficiency in a large number of patients.

b) Evaluation of the Bladder

Is cystoscopy necessary to rule out concomitant bladder pathology in patients with urinary incontinence? Langmade and Oliver reported on 253 patients who were operated on for SUI [8]. They used a simple evaluation that consisted of history, stress tests, and urinalysis alone. They did, however, recommend cystoscopic evaluation if the patient also complained of symptoms of urgency. Although this dogmatic approach was recommended, it was never clearly stated if it made a difference to the treatment or outcome in these patients. Fischer-Rasmussen, et al performed extensive evaluation of women with urinary incontinence [9]. This included cystoscopy in 190 patients. They found cystoscopy to be abnormal in only 12 patients, 8 who had stress incontinence and 4 who had other types of incontinence. Abnormal findings were trabeculated bladder in five patients, benign bladder papillomas in four, and metaplasia of the trigone in two. None of these was considered to be a significant finding. The authors concluded that cystoscopic examination did not contribute to the classification of incontinence in any case. Cardozo and Stanton evaluated 200 patients with SUI and detrusor overactivity [10]. Cystoscopy revealed no abnormalities amongst the 100 patients with USI. Fourteen of the 100 patients with detrusor overactivity had cystoscopic abnormalities, eg trabeculation-11, injected mucosa-1, sacculation -1, a bladder capacity of less than 100 cc-1. However, in none of these patients was the treatment affected by the results of cystoscopy. In support of these findings, Mundy has stated that there is no direct diagnostic value of endoscopy in a patient with an overactive bladder. It may sometimes be helpful to look for and exclude a cause of hypersensitivity when this is in the differential diagnosis [11]. Duldulao and colleagues found this necessary only in patients with haematuria [12]. They performed urinalysis, urine cytology, and cystoscopy on 128 women who presented with urgency incontinence and/or storage voiding symptoms. Of these, 68 patients had urgency incontinence, 35 of whom also had microscopic haematuria. One patient with urgency incontinence and haematuria was found to have a transitional cell carcinoma of the bladder. None of the patients with urgency incontinence (or storage symptoms only) and no haematuria were found to have significant cystoscopic findings. This would support the routine use of cystoscopy for patients with urgency incontinence only if haematuria is present.

c) Extra-Urethral Urinary Incontinence

Endoscopy can be an invaluable tool in the diagnosis and treatment of extravesical incontinence due to vesico-vaginal fistula and ectopic ureter. With respect to vesico-vaginal fistula, cystoscopy can precisely localise the fistula site in the bladder and help plan surgical correction. Occasionally, a small fistula that is not seen on physical examination or radiograph-
ic studies, can only be diagnosed by cystoscopy. Incontinence due to ectopic ureter in the female is usually diagnosed by radiographic studies. However, the exact location of the ureteral orifice in urethra or vagina can be identified by cystourethroscopy and/or vaginoscopy. This can be extremely helpful in the planning corrective surgery.

d) Intraoperative Lower Urinary Tract Evaluation

Several authors have studied the value of routine cystoscopy during operative procedures for incontinence and prolapse. The approach may be transurethral [13] or transvesical [14]. The American College of OB/GYN has published a Bulletin on Operative Lower Urinary Tract Injuries [15] in which is stated “at the conclusion of the procedure, when hemostasis has been ensured, both ureters and the bladder should be inspected to confirm their integrity.” Harris and co-workers [13] reported 9 unsuspected ureteral or bladder injuries during urogynaecological surgery, which included 6 ureteral ligations, with four of these occurring after Burch cystourethropexy. Burch sutures were also found in the bladder as well as fascial lata from a sling procedure.

e) Evaluation of the Male Bladder Outlet

Urgency incontinence is one of the lower urinary tract symptoms associated with benign prostatic hyperplasia, bladder outlet obstruction, and aging in the male population. Based on the available evidence and world literature, The World Health Organization Fourth International Consultation on BPH made the following recommendation: “Diagnostic endoscopy of the lower urinary tract is an optional test in the standard patient with LUTS (lower urinary tract symptoms) because: 1) the outcomes of intervention are unknown, 2) the benefits do not outweigh the harms of the invasive study, 3) the patients’ preferences are expected to be divided. However, endoscopy is recommended as a guideline at the time of surgical treatment to rule out other pathology and to assess the shape and size of the prostate, which may have an impact on the treatment modality chosen [16]. Several contemporary series have described the value of urodynamics in the diagnosis of post-prostatectomy urinary incontinence [17-21]. However, only one describes the routine use of urethrocystoscopy. In that series 67% of patients had urethral fibrosis confirmed by endoscopy [18]. However, how this finding affected treatment was not discussed. In the study by Leach and Yun treatment of incontinence was based solely on urodynamic findings and was successful in 87% of patients [22]. Anastomotic strictures may be suspected based on uroflow and urodynamic (pressure-flow) studies and can be confirmed by voiding cystourethrogram or videourodynamic analysis as well as by endoscopy. However, if intervention for the stricture is deemed necessary, endoscopy would be a more critical part of the evaluation. Furthermore if surgical treatment of incontinence, such as, an artificial urinary sphincter, is planned it would seem to make good clinical sense to evaluate the urethro-vesical anastomosis with endoscopy prior to surgery.
Iatrogenic UI in males usually occurs after prostate surgery for benign and malignant conditions. The pathophysiology of UI following transurethral surgery for BPH includes sphincter damage from extending the resection too distal, particularly in the dorsal aspect of the sphincter where muscle fibres are more abundant. Endoscopy in post-TURP incontinence reveals insufficient closure at rest with tissue loss in the ventral aspect of the sphincter area, voluntary muscle recruitment is often good. The pathophysiology of UI in post-radical prostatectomy patients is unclear. Numerous studies have investigated the relationship between parameters of urethral pressure profile, morphology of the prostate apex and length of the external sphincter area to post-prostatectomy incontinence. Although the results of these studies suggest a relationship between sphincter competence and UI, no consensus has been reached regarding the gold standard test to be performed prior to surgery to assess the individual patient risk of incontinence. Recently, Gozzi and Rehder suggested that post-radical prostatectomy incontinence may be related to prolapse of the sphincter complex and that repositioning of it by a transobturator sling may be successful. Pre-operative selection of surgical candidates for such intervention include endoscopy of membranous urethra testing whether manual push-up of the centrus tendineus perinei results in recruitment of the sphincter fibres comparable to a voluntary contraction. Contraction of the sphincter muscle upon repositioning in a more cranial position is used as an indication for a transobturator sling with the Gozzi and Rehder technique [23-25]. Further research is required to confirm such an interesting pathophysiological explanation of post-radical prostatectomy incontinence and to support the role of endoscopy in the evaluation of these patients.

g) Consensus Statements

- Routine urethro-cystoscopy is NOT indicated in primary female urinary incontinence, when other pathologies are not suspected (Level of Evidence 3, Grade of Recommendation C)
- Endoscopy can be considered (Level of Evidence 3, Grade of Recommendation C):
  - a) in urgency incontinence to rule out other pathologies, especially in case of microscopic haematuria (e.g., bladder tumour, interstitial cystitis, etc)
  - b) in the evaluation of recurrent or iatrogenic cases when surgery is indicated and planned
- Endoscopy is indicated in the evaluation of vesicovaginal fistula and extra-urethral urinary incontinence (Level of Evidence 3, Grade of Recommendation C).
- Endoscopy is indicated intraoperatively in incontinence surgery to look for ureteral or vesical injury (Level of Evidence 3, Grade of Recommendation C).

h) Future Research Areas

- The relationship between of bladder endoscopy and idiopathic detrusor overactivity
- The relationship between of bladder endoscopy and aging
- The relationship between bladder endoscopy and symptoms of voiding dysfunction in female patients with UI

i) References (see at the end of the chapter)

C. Imaging in Anal Incontinence

Anal incontinence may result from anatomical and/or neurological disruption of the anal sphincter complex. Prior to the development of anorectal imagining techniques, anal sphincter disruption was detected by digital palpation supported by EMG needle mapping and ano-rectal manometry. Use of endoanal ultrasonography (EAUS) for anal sphincter imaging was first described by Wild in 1956 [1] but remained neglected for many decades because of the limitation of technology then available [2]. In 1989 Law and Bartum defined the technique of EAUS and endo-anatomic anatomy of the anal sphincter complex [3]. Since then EAUS has become the gold standard for imaging the anal sphincter complex.

Development of 3-D rendering technique over the last decade has enabled better quality imaging of the anal sphincter complex using the EAUS. Recently other imaging modalities such as transvaginal, transperineal and translabial ultrasonography, MRI, Defaecography and Sonoeleastography have been described to assess the anal sphincter complex in patients with anal incontinence.

I. INDICATIONS

Anal sphincter imaging has become an integral part of the assessment of anal incontinence. Following detailed history and examination, the patient should be offered anal sphincter imaging (either 2D or 3D EAUS) depending on the availability of imaging modalities and the expertise. Even though ano-rectal physiological studies indicate dysfunction of the anal sphincter complex, they do not identify the anatomical site and the degree of anal sphincter disruption. EAUS has been the gold standard for detecting anal sphincter disruption or atrophy. EAUS is also used in the follow up of women after obstetric anal sphincter injuries to assess the success of the primary repair and to advise on subsequent delivery [4]. EAUS has been used intra-operatively to identify the damaged EAS prior to secondary repair and also to identify the IAS defects prior to injecting bulking agents.

II. IMAGING MODALITIES

1. ULTRASONOGRAPHY

The increased availability of ultrasound scanners to urologists and urogynaecologists and its high resolution...
in the near field makes this the perfect tool to investigate patients with anal incontinence as a part of their physical examination.

**a) ENDOANAL ULTRASOUND (EAUS)**

EAUS is performed using a 360° rotating rectal probe with a 7-10 MHz transducer (focal range 2-4.5cm) with minimum beam width of 1.1mm. Several systems are currently available, and recently integrated 3D systems are also available (B&K Medical, Sandoften 9, 2820 Gentofte, Denmark). Women should be examined prone with an endoanal system to minimise anatomical distortion. **Figure C1** shows a schematic diagram of the anal sphincter complex in relation to the endoanal probe [4].

The standard EAUS image of the anal canal is of 4 layers (**Figure C 2**):

1. The subepithelial layer is moderately reflective.
2. The internal sphincter is the most obvious landmark and is a well-defined low reflective ring. The internal sphincter varies in thickness with age, being <1mm in neonate, 1-2mm in young adults, 2-3 in middle age and >3mm in the elderly.
3. The longitudinal layer is a complex structure with a large fibroelastic and muscle component, the latter formed from the puboanalis as well as the longitudinal muscle of the rectum (**Figure C 2**).
4. The external sphincter is better defined in men than women, where it tends to be less hypochoic. It is distinguished mainly by interface reflections between muscle/fat planes either side (**Figure C 2**). In women the external sphincter is shorter anteriorly than posteriorly, which must not be misinterpreted as a tear. The transverse perineal muscles fuse anterior with the sphincter, whereas in men they remain separate.

With experience the examination can be performed in about 5 minutes and provides an ideal method for a rapid assessment of sphincter integrity and thickness.

**b) 3 Dimensional Endoanal Ultrasonography (3-D EAUS)**

With 3D-EAUS, the anal canal is scanned in a conventional manner, and dedicated software provides a final 3D appearance (3D rendering). The data obtained from a series of closely spaced EAUS images (0.25 mm) are combined to create a 3D volume displayed as a cube. The image can then be freely rotated and it is possible to visualise defects at different angles and to obtain the most information from the data [5]. The advent of 3D ultrasonographic multiplanar reconstruction of the anal canal has further improved the detection of anal sphincter injuries with nearly 95-100% sensitivity and specificity [6]. With 3D-EAUS, the aspect, localisation (circumference involved, height), size (in degrees or percentage of circumference) and number of sphincter defects can be described in detail, together with a calculation of the volume of such defects [7] (**Figures C3-C4-C5**).

Defects of the puborectalis fibres of the levator ani are less common and these can be seen as heterogeneous remodelling or shortening of the two bands is visible after episiotomy or pelvic floor injury during vaginal delivery. Its role in the development of AI is probably underestimated and characterisation, particularly in terms of volume, would be of interest to assess the functional impact [6]. Two scoring systems has been introduced to objectively evaluate the anal sphincter defects detected in 3D EAUS [8, 9] and both these scoring system have shown acceptable intra observer and inter observer agreement [9]. Although EAUS has been accepted as the gold standard of imaging anal sphincter complex, the equipment and the expertise may not be readily available in some centres. Some patients may find EAUS

---

**Figure C1**: A schematic diagram of the anal sphincter complex in relation to endoanal probe.

**Figure C 2**: Axial endosonography in the mid canal in a normal 38yr old female. Subepith: subepithelial layer; IAS: internal anal sphincter; LL: longitudinal layer; EAS: external anal sphincter. The outer border of the external sphincter is defined by an interface reflection at the fat/muscle boundary (arrow).
technique embarrassing and unacceptable. Hard endoanal cone of EAUS may cause the disruption of normal anal canal anatomy. Because of these drawbacks, other imaging modalities such as Endovaginal, Transperineal and translabial ultrasonography have been evaluated to assess the anal sphincter complex.

c) Transvaginal Ultrasonography

Sultan et al. first described the vaginal use of 360° rotating probe used for the EAUS and obtained clear images of anal sphincter complex [11]. Since then different types of probes including side-fire transrectal probe, a standard transvaginal probe and modified vaginal probe has been used to evaluate the anal sphincter complex with variable sensitivity and specificity for detecting anal sphincter injury [12].

d) Transperineal Ultrasonography

Transperineal ultrasonography (TPU) to image the anal sphincter complex was first described by Peschers et al. [13] and found to have a good inter observer reliability in detecting IAS and EAS defects compared with EAUS [14]. A recent study by Roos et al. [12] comparing endovaginal and transperineal ultrasonography to detect obstetric anal sphincter have concluded that neither of these modalities is sensitive enough to detect anal sphincter defects.

e) Translabial Ultrasonography

Translabial ultrasound (TLU) offers an alternative imaging modality of the anal sphincter complex and has proven to be well-tolerated by patients. It has been used to describe anal sphincter complex integrity [13, 15]. Hall et al. evaluated 60 women with TLU and reported that mean sphincter measurements are given for symptomatic and asymptomatic intact women and are comparable to previously reported endoanal MRI and endoanal ultrasound measurements [16]. The advantages of TLU are that the equipment needed is readily available to all gynaecology and radiology imaging laboratories.

f) Integrated Multicompartmental Pelvic Floor Ultrasonography

Pelvic organ dysfunction includes multiple conditions such as pelvic organ prolapse, urinary incontinence, anal incontinence, defaecatory disorders and sexual dysfunction. Based on this concept integrated multicompartmental Pelvic Floor imaging including two-dimensional (2D), three-dimensional (3D) and 4D pelvic floor ultrasonography as well as transvaginal, endoanal and transperineal techniques, has been described from a global and multicompartmental perspective [17]. The value of this approach in routine assessment of pelvic floor dysfunction is yet to be evaluated.
**g) Dynamic Anorectal Endosonography (DAE).**

DAE uses a rigid biplane transrectal probe with a frequency of 7 MHz with the tip of the probe covered with a water-filled balloon to maintain the acoustic window for the ultrasound waves. By slowly and manually rotating the linear probe through 360°, various layers constituting the anal wall (mucosa, internal anal sphincter, and external anal sphincter), the layer forming the rectal wall, and the perirectal tissues (puborectalis muscle, bladder, and vagina, or prostate) has been demonstrated. After the initial examination, the patient simulates defaecation with the probe left in the same position [18]. In a study of 56 women using DAE and Dynamic MRI Defaecography significantly more internal anal sphincter defects were found with DAE than with dynamic MRI defaecography. But there was no significant difference for the diagnosis of external anal sphincter defects [18].

**h) Sonoelastography**

Sonoelastography is a new imaging technique based on differences in radiofrequency signals following endogenous/exogenous compression due to different elastic properties of the targeted tissues or organs [19]. This technique has been evaluated in pathological conditions of breast, thyroid, pancreas and prostate. The elastographic pictures registered simultaneously with conventional grayscale B-mode images during sonography or endosonography are assumed to distinguish malignant from inflamed areas and thus facilitate diagnosis. Based on this concept it is assumed that Sonoelastography is able to diagnose different conditions causing anal incontinence. However there is only one published study comparing the conventional endoanal ultrasonography and elastography [20]. This prospective study included 50 patients with faecal incontinence following ano-rectal surgery and Crohn’s disease. Elastogram colour distribution within the sphincter representing elastic properties was quantified using a visual analogue scale and an off-line computerised area calculation program. The IAS, a smooth muscle, and the EAS, a striated muscle, have different elastogram colour distributions, probably reflecting their different elastic properties. The absence of significant correlations with the major clinical and functional parameters suggests that in routine clinical practice ultrasound real-time elastography may not yield additional information in patients with faecal incontinence except in patients who have had radiation.

**2. MRI**

Anatomy of the anal sphincter complex has been redefined over the past 20 years by the use of body coil, endoanal coil and phased-array coil magnetic resonance imaging (MRI). However these different MRI techniques have led to conflicting anatomical descriptions of the anal sphincter complex [21]. Endoanal coil MRI studies by Rociu et al. [22, 23] have suggested that the levator ani muscle has only a transverse portion and that the EAS muscle is composed of only a subcutaneous and a superficial portion describing five image layers. (Figure C6)

However, body coil MRI studies by Guo and Li [24] suggested that the levator ani muscle also has a vertical portion (vertical levator), and separate body coil MRI studies by Hsu et al. [25] suggested that the EAS muscle has 3 separate components which has been identified in EAUS as well.

More recent study by Guo et al. [26] using multiplanar body-coil MRI studies demonstrated that the anal region actually has 7 image layers: the mucosa, submucosa, anal smooth muscle, inner space, vertical levator, outer space, and the EAS muscle (Figure C7). The authors reported that endoanal MRI does not reliably outline the superficial layers of the anal region because a blind zone is created in the anal canal near the coil. This blind zone led investigators to effectively ignore the mucosa, submucosa, anal smooth muscle, intersphincteric groove, and subcutaneous sphincter and this accounts for the early endoanal MRI description of the anal region as comprising only 5 image layers.

*Figure C 6: Weighted turbo spin-echo endoanal coil MRI studies by Rociu et al.[22,23]*

A: “5-layer” anal region and blind zone of the endoanal coil MRI.

B: Drawing of anal midcoronal section.

C: Inner intersphincteric space with high signal intensity is mislabeled as the internal sphincter.

Es - external sphincter; Is - internal sphincter; Lam - levator ani muscle; Lm - longitudinal rectal muscle; Pr - puborectalis; Sm - submucosa
Images of the anal sphincter complex obtained using endoanal MRI are thought to be superior to MRI performed with a body coil because of increased signal to noise ratio resulting in high spatial resolution images. Although the endoanal MRI allows comprehensive assessment of atrophy and focal defects of the external canal, the internal sphincter has been less well defined [27]. A meta analysis of nine studies, comparing endoanal MRI with endoanal ultrasound or surgical diagnosis in 157 patients by Tan et al. [28] has shown that Endoanal MRI was sensitive and specific for the detection of external sphincter injury and especially sphincter atrophy. It may be useful as an alternative to endoanal ultrasound in patients presenting with faecal incontinence. However, the limited availability of dedicated endoanal coils outside specialist units has resulted in less widespread familiarity with this technique and further clinical studies are needed to identify its best application in clinical practice.

In addition to the damage to the anal sphincter complex, levator ani muscle (LAM) injury has also been postulated as a cause for anal incontinence especially after childbirth. A recent MRI study by Hellburn et al. [29] reported major LAM injuries in 19% of women who delivered vaginally with external anal sphincter (EAS) injuries compared to 3% delivered vaginally without EAS injury, and 0% delivered by cesarean section before labour. Among women with EAS injuries, those with major LAM injuries tend to have more anal incontinence symptoms than those who did not have LAM injury. These data suggest that both EAS and LAM are important to maintain faecal continence.

3. EVACUATION DEFAECOGRAPHY (PROCTOGRAPHY)

Evacuation defaecography is indicated in patients with constipation, and in those with obstructive defaecation associated with anal incontinence caused by overflow incontinence or post defaecation leakage. In these patients, defaecography is useful to visualise outlet obstruction due to an anatomical (e.g. enterocele, rectocele, intussusception) or a functional (e.g. anismus) cause. Evacuation defaecography is also useful to demonstrate bladder and uterovaginal prolapse as well as pelvic floor descent (Figure C 8 a-b) but gives limited information as to rectal function. Evacuation defaecography has shown good reproducibility in the diagnoses of enterocele, anterior rectocele and their grading in patients with faecal incontinence [30].

The rectum is opacified with 120 mls of a barium paste and the small bowel with a dilute barium suspension given orally about 30mins before defaecography starts. The patient is seated sideways within the fluoroscopic unit on a radiolucent commode. Evacuation of the barium paste is recorded either on video or on cut film at 1 frame/sec using a low dose protocol. At rest the anorectal junction is at the level of the ischial tuberosities and the anal canal closed. Evacuation is rapid (<30sec) and the rectum below the main fold should be emptied completely. During evacuation the anorectal angle widens as the anorectal junction descends and the anal canal opens. At the end of evacuation pelvic floor tone returns and the puborectalis pulls the anorectal junction upwards and forwards back to the resting position. Intra-anal intussusception creates a thick double fold of rectum, which impacts into the anal canal on straining at the end of rectal evacuation. Rectal prolapse represents an extension of this process, with passage of the intussusception through the anal canal and inversion of the rectum (Figure C 9 a-c)

Compared to conventional evacuation defaecography, dynamic MR defaecography at a vertical open magnet unit has become popular recently as it produces multiplanar images with increased soft tissue contrast and avoids radiation exposure. However the comparative results between conventional

![Figure C 7: Midcoronal T1-weighted turbo spin-echo body coil MRI images.](image)

[26]
defaecography and dynamic MR defaecography in patients with prolapse and anal incontinence are variable [31, 32]. Some of these variations have been attributed to the difference in technique. The main drawback of MR defaecography is the supine position required which causes sub optimal assessment of prolapse and evacuation [31]. Since vertical open-magnet MR imaging units are not widely available, the role of MR defaecography in the diagnostic work-up of faecal incontinence is still limited.

III. SPHINCTERIC DISORDERS

1. THE INTERNAL ANAL SPHINCTER (IAS)
IAS is responsible for the maintenance of resting anal pressure and plays a vital role in maintaining anal continence. Isolated IAS defects are associated with surgery for ano-rectal malignancies, anal fissure and undetected obstetric anal sphincter injuries. These patients may present with passive faecal soiling and seepage rather than frank faecal incontinence.

Abnormalities of thickness are usually related to the patient’s age. A sphincter less than 2mm thick in a patient more than 50 years of age is indicative of internal sphincter degeneration (Figure C 10) and is associated with passive faecal incontinence.

Obstetric trauma to the internal sphincter parallels that of the external sphincter in extent, but should always be in the anterior half, so that any defect between 3 and 9 is due to some other cause.

Sphincterotomy may be more extensive than was planned, particularly in women, and 3D studies are especially helpful to assess the longitudinal extent of the defect. The length of the sphincter divided relates directly to the risk of incontinence [33]. Dilatation procedures are hazardous and may completely fragment (Figure C 11) the internal sphincter.

Figure C 8: Sagittal views from a dynamic MRI examination. The dotted line indicates the position of the pubococcygeal line. At rest (a) there is some descent as the anorectal junction (ARJ) is more than 1 cm below this. During pelvic stress (b) there is marked pelvic floor descent, with descent of the cervix (Cx) and bladder base (Bl).

Figure C 9: Evacuation proctogram showing the development of rectal prolapse. Intussusception starts at the end of rectal emptying (a) and rapidly passes through the anal canal (b) to form the external prolapse (c).
2. THE EXTERNAL ANAL SPHINCTER

When striated muscle is stretched beyond the limits of its elasticity fibres rupture and heal with granulation tissue and eventually fibrosis. Most chronic tears are seen with scar formation, and present as a uniform area of low reflectivity distorting and obliterating normal anatomical planes (Figure C 12). A key to the diagnosis is lack of symmetry with the anterior part of the external sphincter not fusing at 12 o’clock as the probe is moved slowly down the canal. This may also be seen on 3D studies in the coronal plane (Figure C 13). Other perineal structures, such as the puboanalis and transverse perinei are frequently torn and distinguishing these tears from external sphincter trauma requires experience, and again may be helped by 3D multiplanar imaging. The distinction is important as tears of the puboanalis or transverse perinei are not associated with a significant fall in squeeze pressure [34], and it is only damage to the external sphincter that results in a significant change. Childbirth damage to the puborectalis part of the levator ani muscle with intact EAS and IAS has been reported as a distinct cause of anal incontinence. 3-D EAUS is reported to be superior in detecting this type of injury [35].

In healthy young adults a good correlation has been found between measurements of layers thicknesses on endosonography and endocoil MRI, with an Ri of 0.96 for the external sphincter [36]. The outer border of the external sphincter is easier to see on MRI, but fibrosis is not so markedly different in signal from normal muscle, so that the conspicuity of tears may not be as obvious as with endosonography.

Atrophy of EAS is a more difficult problem. Determining the thickness of the external sphincter on EAUS depends on visualising its borders from interface

Figure C 10: Endosonography with an axial image in the mid canal of an elderly patient, aged 73yrs with passive faecal incontinence. The internal sphincter measures only 1.1mm (markers) indicative of internal sphincter degeneration

Figure C 11: Endosonography in the mid canal showing gross internal sphincter irregularity, typical of the “fragmented” appearance from trauma after an anal stretch procedure.

Figure C 12: Tears of internal and external sphincters (arrows) between 10 and 1o’clock following a traumatic vaginal delivery

Figure C 13: 3D EAUS of a small tear to the external sphincter (arrow).
effects on the outside and subadventitial fat on the outer border. Atrophy involves a reduction of muscle fibres and an increase in fat, the outer interface reflection is lost and the thickness of the external sphincter cannot be measured (Figure C 14). Such loss of definition of the outer border of the external sphincter on endosonography has a positive predictive value of 71% for atrophy [37]. Using 3D EAUS and a grading system based on definition and echogenicity of the external sphincter showed a comparable accuracy to endocoil MRI in detecting atrophy [38].

Figure C 14 : EAUS showing a normal internal sphincter, but the external sphincter is not visible as it is echogenic and the interface reflections due to advanced atrophy

IV. CONCLUSIONS

Claims for superiority of one or other modality for the detection of sphincter tears probably depend largely on individual experience, but the relative low cost and speed of EAUS makes this an ideal screening procedure to assess sphincter integrity. A leading issue is the significance of occult sphincter tears (diagnosed on endosonography but not apparent clinically) following vaginal delivery. Although these may be detected by careful examination immediately post partum [39], retrospective detection will still require EAUS. A meta-analysis of 717 vaginal deliveries revealed a 26.9% incidence of anal sphincter tears in primiparous, with 8.5% new tears in multiparous women. Overall 29.7% of women with tears were symptomatic, compared to only 3.4% without tears. The probability of faecal incontinence being due to a sphincter tear was 76.8-82.8% [40]. Recent studies confirm the strong relationship between obstetric sphincter damage and faecal incontinence [41], and its late onset [42,43]. Subsequent deliveries increase the risk of incontinence particularly if there has been a tear at the first delivery [44]. Tears that involve the internal sphincter increase the severity of incontinence [45]. A sphincter tear at EAUS is therefore an important finding, but how this is used to decide management is a little more controversial. Secondary anal sphincter repair has fallen out of fashion following the finding that results deteriorate over a few years [46, although a more recent study [47] suggests a better response.

Fluoroscopic studies have little role in faecal incontinence, unless there is an underlying rectal abnormality such as obstructive defaecatory symptoms and prolapse. Dynamic MRI studies have the added value of demonstrating prolapse in the rest of the pelvis, but apart from the lack of ionising radiation, has no real advantage for studying rectal function. EAUS therefore remains the first line imaging investigation for anal incontinence, giving accurate information regarding the external and/or internal sphincter tears and the likelihood of atrophy. Dynamic studies of rectal evacuation are required only if there is some other problem suspected, such as prolapse. The advantages of using MRI are the lack of ionising radiation and a global view of the pelvic floor. Although imaging gives hard evidence of sphincter damage, this is really only part of a much more complex functional problem, and colorectal abnormalities may be just as important [48] with tears accounting for perhaps only 45% of incontinence [49].

V. CONSENSUS STATEMENTS

• EAUS is the first line imaging investigation for faecal incontinence providing accurate information regarding external and/or internal sphincter tears and the likelihood of atrophy. [Level of Evidence 3, Grade of Recommendation C]
• 3-D EAUS offer better quality images and diagnosis of the depth of anal sphincter injury. [Level of Evidence 3, Grade of Recommendation C]
• Routine use of 3-D EAUS is not recommended because of the cost. [Level of Evidence 3, Grade of Recommendation C]
• Routine use of transperineal, transvaginal and translabial ultrasonography to image the anal sphincter complex are not recommended. [Level of Evidence 3, Grade of Recommendation C]
• Dynamic imaging of rectal function is required when rectal abnormalities such as prolapse are suspected [Level of Evidence 3, Grade of Recommendation C]
• MRI offers no advantage over other imaging modalities except for the lack of ionising radiation and global view of the pelvis [Level of Evidence 3, Grade of Recommendation C]

VI. FUTURE RESEARCH AREAS

Better image quality with 3D EAUS and MRI have improved our understanding of pelvic floor anatomy, and this in turn has enabled sonographic anatomy to be re-evaluated, however, conflicting views of anal sphincter anatomy remain.
• Are clinical symptoms related to the size and the site of anal sphincter defect [50] or not [51]?

• Significance of imaging in detecting anal sphincter injury especially immediately after childbirth in preventing future anal incontinence [39, 52].

• The value of ano-rectal physiological studies combined with imaging in assessing the success of surgical repair of the anal sphincter complex [53].

• Identify (and modify) the risk factors leading to anal sphincter injury especially during childbirth and develop preventive strategies [54].

The most valuable aspect of 3-D ultrasonography and MRI imaging is that they give a global view of the pelvis, capable of investigating urological, gynaecological and coloproctological problems at the same time [17]. Many patients do not have faecal incontinence as an isolated symptom, but also have urinary, prolapse or defecatory problems. The overview provided by imaging sets the way for a combined approach to the pelvic floor and should be the prime area of future investigation [17].

D. PAD TESTING

The use of a perineal electronic nappy using electrical conductivity to estimate the amount of urine leakage was first proposed by James et al. [1, 2]. Accuracy of this technique was, however, questioned by others and the technique was improved [3-8]. Walsh & Mills and Sutherst et al. introduced a more simple approach by estimating leakage by perineal pad weight gain [9, 10]. These tests were not standardised until Bates et al. described a “structured” one hour pad test which was endorsed by the International Continence Society in 1988 [11]. This test, however, was shown to have poor interdepartmental correlation and to be highly dependent on bladder volume [12, 13]. In an attempt to make pad tests more reliable 24 hour and 48 hour pad tests were developed. A more precise estimation of urine loss was shown, but they were more cumbersome. The Pyridium pad test was also proposed for diagnosing urinary incontinence [14].

I. DEFINITION

The pad test is a diagnostic method to detect and quantify urine loss based on weight gain of absorbent pads during a test period under standardized conditions.

II. INDICATION AND METHODOLOGY

A pad test allows the detection and quantification of urine loss, but it is not diagnostic of the cause of the incontinence. Several different standards have been developed. Tests can be divided into four groups according to the length of the test: <1h, 1h, 24h and 48 h. (Table 4)

III. OFFICE-BASED PAD TESTING

Pad tests up to 2 hours were developed to be performed in outpatient clinics or hospital wards under supervised conditions. Bladder volume is predefined to reduce variability and a structured set of exercises is usually implemented to elicit the occurrence of urine loss.

1. SHORT PAD TEST

a) Quantification:

These tests are based on a fixed bladder volume and a standard set of activities to facilitate the occurrence of urine loss, if any, over a short period of time. Jakobsen et al. found that the 40 minute test with a bladder volume of 75% maximum cystometric capacity and similar activities as a 1-hour ward test produced consistently larger amounts of urine loss than a standard 1-hour ward test [17]. The difference was attributed to significantly larger bladder volumes during performance of physical activity in a 40 minute pad test.

Kinn & Larsson reported no correlation between a short 10 minute test with fixed bladder volume and the degree of incontinence as judged from the symptoms [18].

Hahn & Fall in a 20 minute test with half cystometric capacity showed no false negative results in 50 women with stress urinary incontinence although there was a discrepancy in 12% of patients between

</tr>
</tbody>
</table>

*Maximum Cystometric Capacity
the perception of incontinence severity and pad test results [15].

These data suggest that short pad tests are more provocative than activities of daily living.

b) Reproducibility:

The correlation factor (Pitman’s nonparametric permutation test) between two separate 20 minute tests was 0.94 (p<0.001) [15]. Kinn and Kinn & Larsson showed that the 10 minute test with a fixed pre-test bladder volume of 75% of maximal capacity was moderately reproducible (r=0.74) [18]. Using a 1 hour pad test, a standardised bladder volume of 300ml and standardised physical activity mean differences of leakage was 8.5 ml and coefficient of repeatability was 33.6 ml [19].

2. ONE-HOUR PAD TEST

The use of a one-hour pad test has been investigated thoroughly for validity, reproducibility and sensitivity to change.

a) Quantification

Jakobsen et al. reported that a one hour test detected less leakage at 3 g compared to a 40 minute (7 g) and a 48 hour pad test (37 g) [17]. In the elderly, one-hour ward test showed incontinence in 66% of those complaining of incontinence compared to 90% with a 24 in-patient monitoring of urine leakage [20]. A one hour pad test was found to reflect everyday incontinence in only 48% of patients in comparison to 81% with a 48 hour test and 77% with a 40 minute test. Jorgensen et al. noted that 90% completed the test and 69% had test results which correlated with daily leakage [16]. Lose et al. found a poor to moderate correlation of the modified one-hour test (200-300 ml in the bladder) with a history of stress urinary incontinence (n=31) [21]. Mouritsen et al. showed that a 1-hour ward pad test did not detect grade I stress incontinence in 46%, grade II in 27% and grade III in 66% [22]. Thind & Gerstenberg compared a 1-hour ward pad test to a 24-hour home pad test and found that a 1-hour pad test had a 36% false-negative rate as compared to a 24-hour home pad test [23].

b) Reproducibility

Klarskov & Hald demonstrated in 3 consecutive 1-hour pad tests, a correlation coefficient of 0.75 and 0.97 depending on the activity regimen [24]. The test, however, was quite demanding and a lot of patients did not complete the full testing. Christensen et al. compared a one-hour pad test in two different urological and one obstetrics & gynaecological departments (20 women) [13]. The test results in two urological departments did not differ with an average pad gain of 24g and 21 g (p>0.1). However, pad test results between the departments of urology and gynaecology differed significantly, with average pad weight gain 9 g and 24 g respectively (p<0.05).

Lose and co-workers showed a significant variation between 1-hour ward test and retest in 18 patients (correlation coefficient 0.68) [12]. In 50% of patients the leakage volume was variable due to differing bladder volume. When the results of the 1-hour pad test were corrected for urine volume, the correlation coefficient value increased to 0.96. Simons et al found the reproducibility of the standard 1 hour pad test to be poor [25].

c) Validity

Walsh & Mills in the elderly and Holm-Bentzen et al. in patients with an AMS artificial sphincter showed that the one hour pad test did not correlate with subjective patient satisfaction but this may due to other lower urinary tract symptoms [9, 26].

d) Bladder volume

Jorgensen et al showed test-retest correlation was improved when the bladder volume was taken into account and the correlation value (r) raised from 0.68 to 0.93 [16]. Fanti et al used a one hour test with the bladder filled to capacity and had a test-retest correlation of 0.97 which was improved if the fluid loss was expressed as a percentage of bladder volume [27]. Lose et al. using a 1-hour pad test with standardised bladder volume of 50% of maximal cystometric capacity (MCC) showed in 25 women a test retest correlation of 0.97 but the intertest variation was up to 24g [28]. Jakobsen et al. compared a 1-hour pad test with a bladder filled to 50% and 75% of maximal cystometric capacity and found that the final bladder volume was equal in both groups showing the importance of diuresis even with equal starting bladder capacities [29]. The amount of leakage in both groups was the same. Simons et al. found the volume in the bladder after a standard 1 hour pad test varies by –44 to +66g in a test-retest situation [25]. The fluid volume in the bladder appears to be critical in making the pad test reproducible and increasing the sensitivity of the test for detecting leakage.

Aslan et al compared a 1 hour pad test loss with the symptom impact index (SII) and the symptom severity index (SSI) [30]. Only the SSI showed a relationship between the severity of the score and the pad test loss. The 1 hour pad test has also been used in assessing the validity of the Incontinence Impact Questionnaire and the Urogenital Distress Inventory unfortunately both had poor correlations with the pad test [31]. This is to be expected as the questionnaires assess other urinary symptoms rather than just leakage.

e) Diagnosis

Fluid loss was significantly greater in patients with detrusor overactivity in comparison to urodynamic stress incontinence [27, 32]. The reverse finding was reported by Matharu and co-workers [33].
There is high variability in patients with detrusor overactivity making the test impractical as a diagnostic tool.

f) Sensitivity to change

The 1 hour pad test has been shown to be useful in detecting significant improvements after pelvic floor exercises for men suffering urinary incontinence after radical prostatectomy [34]. Ward et al. found the standard 1 hour pad test to show significant reductions in loss after tension free vaginal tape procedures from 18g (IQR 6-37) and Burch colposuspension from 16g (IQR 6-38) both decreasing to 0g (IQR 0) [35]. The 1 hour pad test has also been tested for the reduction in loss after conservative and surgical therapy [36]. The changes were significant but there was moderate correlation (r = 0.53) with the changes in the St. George Urinary Incontinence Score.

3. TWO-HOUR PAD TEST

A test period of 60-120 minutes after a 1 litre fluid load was proposed as the optimal duration for the pad test because of a consistently high bladder volume [37]. Han et al. showed, however, that a 1-hour pad test is more practical [38]. In children a 2-hour ward pad test yielded 70% positive results for incontinence [39]. Richmond et al. compared two exercise regimens with a 2-hour pad test and showed no significant differences regarding which order the exercises were performed [40]. Walters et al. performed a 2-hour pad test with standard exercise in 40 women with SUI showing 78% positive tests (>1g pad gain) after 1 hour and 98% after the second hour [41]. Overall, the two-hour pad test was found to be superior to the one-hour one. There was no correlation between pad test results and the severity of a symptoms score.

IV. HOME BASED PAD TESTING

These tests were developed to diagnose and measure urine loss in a situation as close as possible to standard daily life of the patient. The longer observation period usually requires a less structured procedure.

1. 12-HOUR PAD TEST

a) Quantification:

Hellstrom et al. demonstrated in 30 children with incontinence a positive 12-hour home pad test in 68%. When a standard fluid load (13 ml/kg) was instituted in 20 children, the frequency of the positive test increased to 80% [39].

2. 24-HOUR PAD TEST

a) Quantification

Lose et al. found a 90% correlation of a 24-hour pad test with a history of stress incontinence in 31 women [21]. This was better than the results of a 1-hour test. Thirteen of 31 patients were found to be continent after a 1-hour ward test in comparison to only 3 with a 24-hour home pad test. Mourtsem et al. showed that the 24-h home test was well tolerated and as good at detecting incontinence as a 48-h test [22]. Griffiths et al. found only a 10% false negative rate of a 24-hour pad test in an elderly population [20]. Using non-parametric coefficient of correlation, they found a significant difference between the 1-hour test and the 24 hour test. Lose et al. found that a 24h home test performed during daily activities was more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml [21]. High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% [42]. Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence [43].

b) Reproducibility

Lose et al showed poor correlation in a test-retest study with a variation of more than 100% [21] although Groutz et al. using Lin’s concordance correlation coefficient (CCC), found the 24-h test to be very reliable instrument [44]. Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance. (Table 5)

The values for the pad test increase in asymptomatic men and women were reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women [45].

c) Diagnosis

Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities [33]. Pad test loss is unaffected by the degree of hypermobility however there is increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH2O [46].

d) Validity

Karantanis et al found the 24-hour pad test was poorly correlated in women with urodynamic stress incontinence with incontinence episodes on a 3 day urinary diary (Kendall’s corr coeff $b = 0.4$) and the ICIQ-SF ($r = 0.4$) [47]. Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up [48].

3. 48-HOUR PAD TEST

a) Quantification

Jakobseny et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients [17]. No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) [49].

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exer-
cise sessions of 3.19 + 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients [53] (Table 6). Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test [14]. In his study (n=18) the Pyridium test was 100% positive in patients with SUI but had false positive results in normal women (52%).

Mean pad weight loss due to evaporation or leakage (was calculated to be 1.003 g, and ranged from -6.5 to +3.85 g (SD 1.85 g) [9]. Lose et al. showed no evidence of evaporation over 7 days if the pad was stored in a plastic bag [21]. Versi et al. showed pads wetted with saline showed no difference in weight after 1 week and less than 10% weight loss after 8 weeks [51]. Twelve pads were weighed by the patient and a healthcare worker with a coefficient of variance =1.55% with a mean deviation of 49%.

### 4. COMMENTS

Pad tests can either be used as a qualitative diagnostic tool to diagnose urinary incontinence and as a quantitative test to grade its severity. Pad test is unable to distinguish among different types of incontinence such as stress, urgency or mixed urinary incontinence. The ICS definition of urinary incontinence (the complaint of any involuntary leakage of urine) does not describe how the diagnosis is made but clearly refers to a patient’s complaint that excludes urodynamics and rather points at the patient perception of the condition. Following this line of thought, research in this area has moved away from the evaluation of diagnostic accuracy of pad test versus a urodynamic diagnosis of UI and entered the more interesting field of the relationship between the patient perception of UI and pad test. Franco and co-workers in London, UK tested the correlation between different questionnaires for UI
and 1-hour pad test showing that only the ICIQ-SF reached statistical significance with a Kendall’s τb of 0.177 and a P value of 0.037 while no significant correlation was found for a 0 to 10 VAS score, a patient-based 3-point symptom severity scale, Stamey grade, Urogenital Distress Inventory and the Incontinence Impact Questionnaire (IIQ-7) [56]. In another study from Wijma and co-workers, the diagnostic accuracy of pad test for self-reported symptoms of UI was evaluated during pregnancy and after childbirth and the authors conclude that the diagnostic value of pad testing has no clinical relevance in this setting [57]. A similar analysis, performed in a male population undergoing sling surgery for post-radical prostatectomy incontinence suggested a good correlation between ICIQ-SF and the Patient Global Perception of Improvement (PGPI) with a 24-hour pad test [58].

Studies from the Urinary Incontinence Treatment Network in US investigated the relation between different measures of incontinence severity and showed how pad weight from a 24-hour test had a good correlation with the incontinence episode frequency derived from a 3-day bladder diary (Spearman correlation coefficient 0.61 but a much lower degree of correlation was found with questionnaires such as the Medical, Epidemiological, and Social Aspect of Aging (r=0.33), the Urogenital Distress Inventory (r=0.17) and the Incontinence Impact Questionnaire (r=0.34) [59]. In the same study, the use of pad testing as a prognostic parameter for treatment outcome was investigated but 24-hour pad testing showed no prognostic value for treatment failure in a study of Burch colposuspension versus autologous rectus fascia sling [60]. An interesting result was obtained in a predominantly female population of patients receiving neuromodulation for refractory urgency incontinence in which a 24-hour pad test performed after the initial test stimulation was able to predict long term satisfaction in this difficult patient population [61]. In this, as in other studies, the number of pads used per day proved to be an unreliable measure of urinary incontinence [62].

A couple of important methodological issues have been raised concerning the use of pad testing. Khan & Chien eloquently pointed out that test-retest comparison should include methods of blinding and use of an appropriate index of degree of agreement which is the intra-class correlation coefficient. In most of the literature this was not implemented [63]. Kromann-Andersen et al. argued that with considerable inter- and intra-individual variation of urine loss, the correlation of test/retest results may be overestimated and suggested different trials for small, modest and large leakage in large numbers of patients [64]. This trial has not been carried out.

A recent Health Technology Assessment of pad testing concluded that although high sensitivity and specificity for the diagnosis of UI was reported in some studies, it was difficult to draw any conclusions about the diagnostic accuracy for SUI because of the differences existing in pad test methodology. The number of studies comparing the same pad tests with adequate reporting is insufficient and no formal pooling of published data could be performed [65].

5. ROLE OF THE INVESTIGATION

The test has been standardised by ICS in 1988 for quantification of urine loss and suggested uses for assessment and comparison of treatment results for different types of urinary incontinence in different centres. Also, the AUA report on Surgical Management of Female Stress Urinary Incontinence includes a pad test (pretreatment evaluation) as a standard of efficiency for clinical trials [66]. The Urodynamic Society included a pad test in a Standards of Efficacy for Evaluation of Treatment Outcomes in Urinary Incontinence [67]. No suggestion was made in the last two reports of which test to use.

V. CONCLUSIONS

- The 1-hour pad test is not very accurate unless a fixed bladder volume is applied.
- Set exercises during the test improve test-retest reliability.
- The sequence of exercises has little effect on test results.
- A pad weight gain >1 g suggests a positive 1h test.
- A 24 hour test correlates well with symptoms of incontinence.
- A 24-hour test has good reproducibility but poorer compliance.
- A pad weight gain >1.3g = positive 24 h test.
- A test lasting longer than 24 h has little advantage.
- A pad test cannot distinguish between urodynamic stress incontinence and detrusor overactivity.

VI. CONSENSUS STATEMENTS

- The pad test is an optional investigative tool in the routine evaluation of urinary incontinence (Level of Evidence 3, Grade of Recommendation C)
- Pad test is a useful outcome measure in clinical trials and research studies. (Level of Evidence 3, Grade of Recommendation C)

The following standards are suggested:

- 20 min - 1 h ward/office test with fixed bladder volume (pad weight gain ≥ 1g = positive test) (Level of Evidence 3, Grade of Recommendation C)
- 24 h home pad test during daily activity (pad weight gain ≥ 1.3g/24h = positive test) (Level of Evidence 3, Grade of Recommendation C)
VII. FUTURE RESEARCH AREAS

- Proper validation analysis using the coefficient of variability
- Evaluation of the ability to detect all the spectrum of urinary incontinence (from mild to severe)
- Sensitivity to change in time of incontinence status for 24 hour pad tests
- Validity of pad tests with other measures of incontinence such as urinary diaries and symptom questionnaires.

E. NEUROPHYSIOLOGY

I. INTRODUCTION

Neurophysiological investigations of muscles and nerves in the perineum and pelvis originated over 60 years ago, and have evolved with developments in general clinical neurophysiology. The data from these investigations can assist clinicians in diagnosing neurological disease or injury, and are applicable in research. Compared to neurophysiological testing of the limbs and trunk, pelvic neurophysiological testing is relatively limited because of the restrictions imposed by pelvic neuroanatomy.

This text details the investigations, their applications and limitations, enabling investigator and clinicians to make a well informed decision regarding the use of these tests.

The present text is based on the previous chapter on clinical neurophysiology prepared for the International Consultations on Incontinence [1], which has been updated by a literature search in Medline using key words incontinence, clinical neurophysiology, electromyography, reflex, evoked potentials.

1. CLASSIFICATION OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Although different types of tests may be included under the term “neurophysiological”, it is particularly the electrophysiological tests that shall be discussed in the present text.

Electrophysiological tests are an extension of the clinical examination, and a functional anatomical approach to classification makes most sense. For the purpose of this categorisation, the nervous system is divided into the somatic and the autonomic nervous systems. The somatic nervous system provides motor innervation to the skeletal muscles and joints, and sensory innervation from skin and muscle spindles. The autonomic nervous system provides motor innervation to the viscera and other end-organs not under voluntary control (e.g., sweat glands). Its sensory fibres are referred to as visceral afferents. Both systems have central pathways (neurons participating in spinal cord and supraspinal control) and peripheral nerves (those going to and from end-organs).

Thus, electrophysiological tests can be divided into: a) somatic motor system tests (EMG, terminal motor latency measurements/ motor nerve conduction studies, and motor evoked potentials (MEP)); b) somatosensory system tests (sensory neurography, somatosensory evoked potentials (SEP)); c) reflexes; and d) the autonomic nervous system tests (for sympathetic or parasympathetic fibres).

Electrophysiological tests may also be categorised “technically” into those which “just” record some bio-electrical activity (for instance: electromyography), and those which record some biological response to stimulation (these may be subsumed under the term “conduction tests”).

2. BIOLOGICAL CORRELATES OF ELECTROPHYSIOLOGICAL TESTS

a) Conduction Tests: Nerve Conduction, Evoked Potential and Reflex Studies

The electrophysiological responses obtained on stimulation are compound action potentials and relate to populations of biological units (neurons, axons, motor units, muscle fibres, etc.). Latency and amplitude are commonly measured parameters of responses during neurophysiological testing. If the onset of the potential is measured, the latency of a compound potential represents the fastest conduction through a particular neural channel. As a general rule, latency measurements are not markedly affected by technical factors, but provide little information about the loss of biological units (e.g., motor neurons or axons). The amplitude of the compound potential correlates with the number of activated biological units. In theory, the amplitudes are the more relevant physiological parameter, as they reflect the functional or structural loss of biological units. Unfortunately, amplitudes are also strongly influenced by many poorly controllable technical factors. Measurements of latencies and amplitudes of evoked potentials and reflex responses, including sympathetic skin responses, relate not only to conduction in peripheral and central neural pathways, but also to trans-synaptic transmission.

b) Electromyography (EMG)

Knowledge of the structure and function of the motor unit (Figure E 1) is fundamental to
understanding the application of EMG. Motor neurons, which innervate striated muscle, lie in the anterior horn of the spinal cord and are called "lower motor neurons". (Neurons that innervate the sphincters lie in Onuf's nucleus in the sacral spinal cord; they are somewhat smaller than those innervating skeletal limb and trunk muscles). Within the muscle, the motor axon branches to innervate a certain number of muscle fibres, which are scattered throughout the muscle. All muscle fibres innervated by one lower motor neuron are activated simultaneously; all these constituents together are called "motor unit". The innervation of muscle fibres is such that it is unlikely that muscle fibres that are part of the same motor unit will be adjacent to one another.

It is difficult to estimate the number of muscle fibres innervated by a single axon (i.e., the "innervation ratio") or the number of motor units supplying a muscle, by clinically available neurophysiological techniques.

3. GENERAL METHODOLOGICAL CONSIDERATIONS

To date, there are no universally accepted standards for conducting individual uro-genital-anal neurophysiological tests, but the variations of testing in different laboratories are minor.

There are technical standards on equipment safety; standardisation of concentric needle EMG and penile/clitoro-cavernosal testing has been proposed.

a) Equipment

Clinical neurophysiological tests are conducted with complex electronic instruments and various devices that come into contact with the patient. Although this equipment is mostly standard, some specially constructed electrodes or stimulating devices have been devised to conform to uro-genito-anal anatomy. As long as the standards of electrical safety are adhered to, the risk to patients is negligible.

The common form of neurophysiological testing is electrophysiological. Surface electrodes, which are applied to skin or mucosal surfaces, or needle electrodes are used for electrical stimulation and to record bioelectrical activity. The important neurophysiological difference between surface and needle electrodes is their selectivity, and the practical difference is their invasiveness. The choice and application of electrodes is guided by the need for selective recording or stimulation. Less commonly, special devices are used for magnetic and mechanical stimulation.

Stimulation Parameters. The electrical stimulus should be specified and characterised both in technical (e.g., rectangular pulse, 0.2 ms, 15 mA) and physiological terms (e.g., 3-times sensory threshold). A stimulus with defined technical parameters may have variable biological effects because of the variable influences of electrode condition, contact, tissue conductivity etc. Supramaximal stimulation is preferred to elicit a compound muscle action potential (CMAP) or sensory nerve action potential. Supramaximal stimuli yield responses with the largest amplitude and shortest latency, and are the least variable and most reproducible. The sites at which stimulation electrodes are applied should be described using anatomical terms.

b) Recording

1. APPARATUS SETTINGS

For recording, the apparatus settings (gain, sweep speed) have to be adapted to the known range of amplitudes, latencies, and duration of the response and it has to be appropriately displayed for analysis. Particularly important is the frequency setting.

Figure E 1: Schematic representation of a motor unit. The alpha motor neuron with its cell body, its myelinated axon and the peripheral nerve endings is shown. The muscle fibres innervated by this alpha motor neuron are shown in white. (Note that the muscle fibres from one motor unit are intermingled with motor fibres from other motor units).
of filters: for surface electrode recordings it is typically 2 Hz – 1 kHz; for concentric needle EMG recordings, it is 5 Hz – 10 kHz.

Placement of electrodes on the scalp for evoked potential recordings is defined according to the 10-20 International EEG System.

2. Reproducibility and Reliability

Any potential elicited by stimulation should be reproducible; therefore, as a rule, at least two consecutive recording procedures need to be performed. To improve the signal-to-noise ratio some small amplitude responses need to be averaged. Therefore, many repetitions of stimulation/recording need to be done (typically 100-200). Even such an averaged recording needs to be repeated at least twice. CMAPs (i.e., M-waves), MEP, sacral reflexes and sympathetic skin responses (SSR) are recognisable after single stimuli. However, as a rule, several responses are recorded to demonstrate reproducibility. In contrast, other responses (e.g., SSR) show marked fatigability with stimulus repetition.

3. Waveform Analysis

For a particular stimulation procedure, the shape, latency, and amplitude of the recorded potentials are analysed. Morphologically, a particular response (or part of it) needs to be recognised as present or absent. The shape of potentials is important to accurately determine the latency and amplitude of the response. The onset of the response (for M-waves, MEP and sacral reflex testing) or the individual peaks of the potentials (for SEP) are used to determine the latency. The amplitudes are analysed relative to the baseline or “peak to peak”.

II. CLINICAL NEUROPHYSIOLOGICAL TESTS

1. SOMATIC MOTOR SYSTEM TESTS

a) Electromyography (EMG)

The term “EMG” is often used for several different procedures, the common denominator of which is the recording of bioelectrical activity from muscle. The term applies particularly to recordings from striated muscles.

EMG is used a) “just” to record muscle activity (as for instance in combined sphincter EMG and pressure-flow study) and b) to differentiate between normal, denervated, reinnervated, and myopathic muscle. For a) see below – “Kinesiological EMG”.

Although EMG abnormalities are detected as a result of a host of different lesions and diseases, there are in principle only two standard manifestations which can occur: a) disease of the muscle fibres themselves (“myogenic” changes), and b) changes in their innervation (“neuropathic” changes). Myogenic changes may result from muscle disease, probably also from direct trauma (e.g., the anal sphincter tear during vaginal delivery). Neurogenic changes may be attributable to injury at any level along the lower motor neuron supplying the external anal sphincter, extending from the motor neuron body, sacral nerve roots to the small branches within the external sphincter. In the pelvic floor muscles, only neurogenic changes are well recognised and routinely evaluated.

The EMG signal may be further used to indicate that muscle has been activated through its motor nerve, either by stimulation applied to motor pathways (M-wave, MEP) or to sensory pathways (reflex response).

1. General Technique for Needle EMG in Pelvic Floor Striated Muscles

All tests requiring needle electrodes are invasive and some pain is inevitable, even with the use of local anaesthetics. Local anaesthesia is infrequently used for needle EMG examination. Intramuscular electrodes need to be appropriately placed in the target muscle.

The pelvic floor and perineal muscles can be examined, including the levator ani, the bulbocavernous muscle and the striated anal and urethral sphincter muscle. Proper placement of needle examination requires some practice. As a rule, several sites from one or more skin penetrations are sampled, which is difficult in small muscles.

The audio output from the loudspeaker of the EMG apparatus helps in assessment of the quality of recording as well as in recognition of electrophysiological phenomena.

2. Concentric Needle EMG (CNEMG)

The examination is conducted with a single use, disposable electrode. The commonly used amplifier filter settings for CNEMG are 5 Hz – 10 kHz, and need to be defined if MUP parameters are to be measured, as are filter settings employed during data acquisition.

The concentric needle electrode consists of a central insulated platinum wire inserted through a steel cannula and the tip ground to give an elliptical area which can record spike or near activity from about 20 muscle fibres [2]. The number of motor units recorded therefore depends both upon the local arrangement of motor units within the muscle fascicle and the level of contraction of the muscle.

CNEMG can provide information on a) insertion activity, b) abnormal spontaneous activity (Figure E 2), c) MUPs, and d) interference pattern (IP).
In normal muscle, needle movement elicits a short burst of “insertion activity,” which is due to mechanical stimulation of excitable muscle cell membranes. This is recorded at a gain setting of 50 µV per division (sweep speed 5 – 10 ms/division), which is also used to record spontaneous activity. Absence of insertion activity with an appropriately placed needle electrode usually means a complete denervation atrophy of the examined muscle.

The amount of recruitable motor units during voluntary and reflex activation can also be estimated. Normally, MUPs should intermingle to produce an “interference” pattern on the oscilloscope during muscle contraction, and during a strong cough. In addition, the number of continuously active MUPs during relaxation [3], MUP variability as well as MUP recruitment on reflex and voluntary activation can be observed [4].

MUPs (and occasionally encountered end-plate activity) are recordable in normal resting sphincter muscles in a relaxed subject. This is in contrast to limb muscles where relaxation is associated with “electrical silence” by EMG. In addition to continuously firing motor units, new MUPs are recruited voluntarily and reflexly in the sphincters. It has been shown that the two MUP populations differ in their characteristics: reflexly or voluntarily activated “high-threshold MUPs” being larger than continuously active “low-threshold MUPs”. As a consequence, standardised level of activity at which a template based multi-MUP analysis obtains 3-5 MUPs on a single muscle site was suggested [5]. In partially denervated sphincter muscle there is – by definition – a loss of motor units (MUs). This can be estimated during relaxation by counting the number of continuously firing low-threshold MUPs. In patients with cauda equina or conus medullaris lesions, fewer MUPs fire continuously during relaxation [6], probably due to partial axonal loss. The main obstacle to qualified assessment of reduced number of activated MUs and activation of MUs at increased firing rates (as occurs in limb muscles) is a lack of concomitant measurement of level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

There are two approaches to analysing the bioelectrical activity of motor units: either analysis of individual motor unit potentials (MUPs), or analysis of the overall activity of intermingled MUPs. (This is the so called “interference pattern” – IP. Exploring different sites of the activated muscle with a needle electrode provides “samples” of intermingled motor unit potentials (IP epochs), which can be analysed).

Generally three different techniques of MUP analysis (manual-MUP, single-MUP and multi-MUP) and 1 technique of IP analysis (turn/amplitude – T/A) are available on advanced EMG systems [6].

It is easy to grasp the “motor unit potential analysis”, as it is simply a measurement (by different methods) of the “parameters” of single individual MUPs (ie. its amplitude, duration, number of phases…). The changes in MUP parameters furthermore are “direct” results of understandable physiological changes, and are thus “meaningful” to the interpreter.

The changes in IP parameters are, however, less readily grasped. These are: numbers of turns per second (any peak or trough of the signal where the activity changes by more than 100 µV);
turn (change in volts between two turns); number of short segments (parts of signal that has “sharp” activity) percent activity (percent of epoch with sharp activity); envelope (peak to trough amplitude exceeded by 1% of peaks/troughs). These parameters relate both to MUP parameters and to the activation level of the muscle. Recorded data are log transformed and linear regression lines are created. Amplitude/turn, and number of turns/second data from normal subjects can be used to create upper and lower boundaries (95% confidence intervals) for assembly of future data from individual patients. Individual data create a scatter plot (“cloud”) that compares to the normative boundaries. (Figure E 3). It has been asserted that this approach does not require a standardised muscle contraction, but the shape of the “cloud” is dependent on the strength of muscle contraction. Therefore it has been suggested to standardise the method by measuring pressure exerted by the contracting sphincter [7].

Both the template based multi-MUP analysis of MUP and T/A analysis of IP are fast (5-10 and 2-3 minutes per muscle, respectively), easy to apply, and, technically, represent clinically useful techniques.

• CNEMG Findings Due to Denervation and Reinnervation

After complete denervation, all motor unit activity ceases. In a denervated muscle, complete “electrical silence” is noted in the first days after such an event. The diagnosis of complete denervation

![Figure E 3: Comparison of normal (above) and pathological (below) motor unit potentials (MUPs) sampled by multi-MUP analysis from the right halves of the subcutaneous parts of the external anal sphincter (EAS) muscles. To the right logarithm (amplitude) vs. duration plots of the MUPs are shown; the inner rectangle presents normative range for mean values, and the outer rectangle for “outliers”. Below the MUP samples values are tabulated. Three plots on the bottom were obtained by turn/amplitude analysis in the cauda equina patient. Delineated areas (“clouds”) present the normative range, and dots individual IP samples.](image-url)
is confirmed by the absence of muscle response during electrical stimulation. Because motor axons take days to degenerate after injury, this proof is not available for up to 5-7 days after a denervation injury. However, it is rarely necessary to demonstrate complete denervation in the acute stage because the clinical condition is usually obvious. Denervated muscle fibres become hyperexcitable and start to fire spontaneously giving rise to abnormal spontaneous activity, but these may take up to three weeks to appear. The “insertion activity” becomes prolonged and short biphasic spikes (fibrillation potentials) and biphasic potentials with prominent positive deflections (positive sharp waves) appear (Figure E2). Thus, concentric needle EMG (CNEMG) correlates of denervation are pathologically prolonged insertion activity and pathological spontaneous activity. Completely denervated muscle may be reinnervated by axonal regrowth from the proximal nerve stump with few muscle fibres constituting “nascent” motor units. These are short, bi- and triphasic, soon becoming polyphasic, serrated and with prolonged duration. In partially denervated muscle, collateral reinnervation takes place. Surviving motor axons will sprout and grow out to reinnervate those muscle fibres that have lost their nerve supply. This results in a change in the arrangement of muscle fibres within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibres to be part of the same motor unit, following reinnervation, several muscle fibres belonging to the same motor unit come to be adjacent to one another. CNEMG correlates are changes in MUPs (duration, amplitude, number of phases, turns, etc).

Early in the process of reinnervation, the newly outgrown motor sprouts are thin. Therefore, they conduct slowly such that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. Moreover, the neuromuscular transmission is unstable due to immaturity of the motor end-plates. The CNEMG correlate is instability of long-duration complex potentials.

In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. Changes due to collateral reinnervation are reflected by: prolongation of the waveform of the MUP (Figure E3) which may have small, late components (“satellite potentials”). MUPs show instability due to insecure transmission in newly formed axon sprouts and end-plates. This “instability of potentials” (meaning both “jitter” and “blocking” of individual components in a complex potential) is not routinely assessed during sphincter EMG. Nonetheless, it can be a helpful parameter, and may be evaluated not only by SFEMG, as originally described (8), but also by CNEMG, if a low frequency cut-off filter of 0.5 (up to 2) kHz is used along with a trigger — delay unit. In skeletal muscle, the diameter of reinnervating axonal sprouts and conduction velocity increase with time, thereby improving synchrony of activation in the reinnervated motor unit. Thus MUP amplitude increases while MUP duration reverts towards normal. However, in degenerative neurological diseases (such as multiple system atrophy), long duration motor units are a prominent feature of anal sphincter reinnervation [9]. It is important to note that in patients with more severe neurogenic lesions, reinnervation may be inefficient resulting in MUP with parameters below confidence limits describing size (area, duration) [10].

The changes in MUP parameters (along with changed number of MUPs and changes in activation frequency of MUPs) will be reflected also in IP parameters.

Abnormalities of parameters evaluated by needle EMG are in principle non-specific, i.e. most abnormalities can occur both in neuropathic or myopathic conditions. It is the overall clinical picture that dictates interpretation of results. It has been suggested that the combination of MUP thickness and number of turns might be even more accurate [11] than previously suggested combination of MUP area, duration, and number of turns [12].

**CNEMG of the External Anal Sphincter**

The external anal sphincter (EAS) is the most practical indicator muscle for sacral myotomes because it is easy to access, has enough muscle bulk for exact EMG analysis, and its examination is not too uncomfortable.

The needle electrode is inserted into the subcutaneous EAS muscle about 1 cm from the anal orifice, to a depth of a 3-6 mm under the non-keratinised epithelium. For the deeper part of the EAS muscle 1-3 cm deep insertions are made at the anal orifice, at an angle of about 30° to the anal canal axis [13]. In most patients only examination of the subcutaneous EAS muscle is necessary. Separate examinations of the left and right EAS muscles are recommended. The needle is inserted into the middle of the anterior and posterior halves of each side (“quadrants”) of the EAS muscle. After insertion in two positions on each side the electrode is turned backwards and forwards in a systematic manner. At least 4 sites in each of the subcutaneous and/or the deeper EAS muscle are thus analysed [13, 14].

Use of quantitative MUP and IP analyses of the EAS is further facilitated by the availability of normative values [15] that can be introduced into the EMG systems’ software. It has been shown that normative data are not significantly affected by age, gender [15], number of uncomplicated vaginal deliveries [16], mild chronic constipation [17] and the part of EAS muscle (i.e. subcutaneous or deeper) examined [16].

Intramuscular electrode insertion into other perineal muscles and pelvic floor muscles is not standardised and is described in textbooks and primary literature.
3. **Single Fibre EMG (SFEMG)**

The SFEMG electrode has similar external proportions to a concentric needle electrode, but with a smaller recording surface. It will pick up activity from within a hemispherical muscle volume 300 µm in diameter, much smaller than the volume of 2-3 mm diameter from which a concentric needle electrode records [2]. Because of the arrangement of muscle fibres in a normal motor unit, a SFEMG needle will record only 1-3 single muscle fibres from the same motor unit.

The SFEMG parameter that reflects motor unit morphology is fibre density, which is defined as the mean number of muscle fibres belonging to an individual motor unit per detection site. To assemble these data, recordings from 20 different intramuscular detection sites are necessary [8].

SFEMG recording needles are very expensive, and disposable needles are not available.

4. **Kinesiological EMG**

Kinesiological EMG is used to assess patterns of individual muscle activity/inactivity during defined manoeuvres (Figure E 4), typically during urodynamics. As such, the specific interpretation of electrical activity within a muscle is based on its presence or absence, rather than the type of activity. Technical issues will be dealt here; the relevance for diagnostics will be discussed in the Chapter on dynamic testing.

Although either standard EMG equipment or EMG facilities contained within urodynamic systems can be used, the better visual and audio control provided by standard EMG equipment facilitate optimal electrode placement and improve recordings [18]. When using surface electrodes there are problems related to validity of signal (e.g., artefacts, contamination from other muscles). The quality of the EMG recorded from the external urethral sphincter (EUS) muscle is improved by a catheter-mounted surface electrode device that applies mild suction [19]. With intramuscular electrodes, the procedure is more invasive, and there are questions as to whether the whole muscle in large pelvic floor muscles is properly represented by the sampled muscle portions. Intramuscular electrodes should ideally be fine wire electrodes, as they do not dislodge, and no pain is induced with muscle contraction.

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. pubococcygei) can be voluntarily activated typically for less than 1 minute [20]. Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough reflex [21]. A consistent contraction sequence of the superficial and deep pelvic floor muscles is found in continent but not in incontinent women [22].

Sphincter activity during voiding is characterised by the cessation of all EMG activity prior to detrusor contraction. Needle electrodes are more useful than perineal patch electrodes to demonstrate MU quiescence during voiding [23]. A recent study using perineal surface patch electrodes confirmed that these electrodes are inappropriate [24].

Pathological incoordination of the detrusor and sphincter is called detrusor sphincter dyssynergia. In selected patients with neurogenic detrusor overactivity EMG of the EUS muscle can be also used to demonstrate the onset of detrusor contractions [20].

Apart from polygraph urodynamic recordings to assess detrusor-sphincter coordination, the diagnostic usefulness of kinesiologic EMG has not been established.

- **Surface Electromyography Using Noninvasive Electrode Arrays**

Recently, surface EMG recording using noninvasive electrode arrays and multichannel EMG amplifiers

---

**Figure E 4:** Kinesiological EMG recording from the urethral sphincter muscle of a healthy 53 years old continent female. Recruitment of motor units on reflex manoeuvres and on a command to contract is shown; regular continuous activity of motor units represents “tonic activity”. (Recorded with concentric needle electrode).
was introduced to the sphincter and pelvic floor muscles (eg, the EAS and puborectalis). Using this approach, investigators can localise muscle innervation zones and asymmetry in muscle innervation [25] and analyse discharge patterns of MUPs and propagation velocities along the muscle fibres [26]. Although observations in normal and pathological conditions have been published [27], the clinical value of these methods in diagnosing neurogenic sacral disorders has not yet been demonstrated.

5. CLINICAL APPLICATION OF EMG

• Neurogenic Conditions

Trauma, surgery, and neurological disease have all been implicated in denervation of pelvic floor and perineal muscles and pelvic organs. In a series of 194 consecutive patients referred for electrodiagnostic evaluation, quantitative needle EMG of the EAS muscles supported a diagnosis of a cauda equina or conus medullaris lesion in 36 patients, a lesion of the EAS muscle in 6, a pudendal nerve lesion in 2, and a sacral plexus lesion in 1 patient. Furthermore, neuropathic findings in the EAS were compatible with a diagnosis of multisystem atrophy in 11, and were most probably caused by severe polyneuropathy in 2 patients. In another 11 patients, the aetiology of the pathological findings could not be established at time of electrodiagnostic testing [28].

Lesions of the cauda equina or conus medullaris commonly cause pelvic floor dysfunction. These have mainly been a consequence of neural compression within the spinal canal caused by intervertebral disc herniation, spinal fractures, epidural haematomas, and, intraspinal tumours; or a result of spinal surgery, mainly on lumbar discs [29, 30]. Electrodiagnostic tests are also useful in the assessment of neurogenic lesions in children with spinal dysraphism [31]. After detailed clinical examination of the lumbosacral segments (with particular emphasis on perianal sensation), neurophysiological testing assesses the severity of the lesion and may clarify the diagnosis. In the authors’ series, 10 percent of patients with cauda equina lesions reported normal perianal sensation [32]. Electrodiagnostic tests that need to be considered are bilateral needle EMG of the EAS muscle and the bulbocavernosus muscle in subacute situations; and electrophysiologic evaluation of the bulbocavernosus reflex [33] (when this is absent or equivocal clinically) [34]. Detection of spontaneous denervation activity by needle EMG is common from approximately 3 weeks to several months after injury, and the bulbocavernosus muscle is particularly helpful in this respect. Later, MUP analysis becomes more important for demonstrating reinnervation. The bulbocavernosus reflex is useful for assessing the integrity of the sacral reflex arc in subjects with cauda equina or conus medullaris lesions [34]. Most of these lesions cause partial denervation; a traumatic lesion to the lumbosacral spine or pelvis is probably the only acquired condition in which complete denervation of the perineal muscles can be observed [35, 36, 37].

Following a cauda equina or a conus medullaris lesion, the MUP of pelvic floor and perineal muscles are prolonged and polyphasic, of increased amplitude, area, number of turns [6]. Surgical dissections can also affect the innervation of the sphincter and lead to loss of motor units and reinnervation of those surviving [38]. After pelvic trauma, gross changes of denervation and reinnervation may be detected in pelvic floor muscles. The bulbocavernous muscle is particularly useful in suspected recent minor partial denervation as it lacks on-going activity of low-threshold MU during relaxation. (In women the muscle is thin).

Neuropathic changes can also be recorded in sphincter muscles of patients with multiple system atrophy (MSA) [39]. MSA is a progressive neurodegenerative disease, which can be mistaken for Parkinson’s disease (PD). Urinary incontinence and erectile dysfunction occur, often some years before the onset of obvious neurological features [40]. Sphincter EMG has been used in distinguishing MSA from Parkinson’s disease. EMG is probably not helpful to distinguish MSA from the later stages of Parkinson’s disease and from progressive supranuclear palsy. Sphincter EMG may not be sensitive in the early phase of the disease [41, 42], and is not specific after 5 years of parkinsonism [43]. Among 30 patients with a pathological diagnosis of multisystem atrophy, 24 had abnormal, 5 had a borderline, and only 1 had a normal sphincter EMG [44]. Some studies have failed to demonstrate the effectiveness of MUP analysis in sphincter muscles [45, 46], probably because of the exclusion of late components from MUP duration [9]. Extensive discussion on the subject can be found elsewhere [47]. The changes of chronic reinnervation may also be found in progressive supranuclear palsy [48, 49] and in Machado–Joseph disease [50] in which neuronal loss in Onuf’s nucleus has also been demonstrated histologically [51].

In patients with acute idiopathic autonomic neuropathy and lower urinary tract (LUT) dysfunction the EMG of external sphincter muscles was reported as normal [52].

• Changes in Primary Muscle Disease

In skeletal muscle, the “typical” features of a myopathy are small, low amplitude polyphasic units recruited on mild effort. There are few reports of pelvic floor muscle EMG in generalised myopathy. In a nulliparous woman with limb-girdle muscular dystrophy, histology revealed involvement of pelvic floor muscles, but concentric needle EMG of the urethral sphincter was normal [53]. Myopathic EMG changes were observed in the puborectalis and the EAS in patients with myotonic dystrophy [54] but not in another group of patients with myopathy [55].
**Stress Incontinence**

Pelvic floor muscle denervation has been implicated in the pathophysiology of urodynamic stress incontinence (USI) [56]. EMG techniques have been used to identify sphincter injury after childbirth and to evaluate women with USI. Stress incontinence and genitourinary prolapse were associated with partial denervation of the pelvic floor [57]. The changes were most marked in women who were incontinent after delivery, who had a prolonged second stage of labour, and had given birth to heavier babies. In a recent study, nearly all EMG parameters showed significant differences between continent and SUI women consistent with better motor unit recruitment in continent women. Continent women had larger-amplitude, longer-duration MUPs with increased turns and better MUP recruitment during bladder filling ($P < 0.05$) [58].

Myogenic histological changes in pelvic floor muscles after vaginal delivery were also reported [59], with some EMG support by another group [60]. Myopathic EMG changes (i.e., short, small MUPs) may, however, be a consequence of deficient reinnervation [35]. There were claims urethral sphincter EMG can assist in selecting the type of surgery for patients with intrinsic sphincter deficiency [59].

Although CNEMG of the urethral sphincter seems the logical choice in patients with urinary incontinence of possibly neurological origin, only a small amount of pathological muscle tissue remains in many incontinent parous women, which makes EMG of the muscle impractical [38]. CNEMG findings generally will not affect therapeutic considerations [61].

**Idiopathic Faecal Incontinence**

"Idiopathic" faecal incontinence refers to patients in whom this symptom is not attributable to an underlying disorder, but it has been often implied that it is a neurogenic condition. Vaginal delivery has been shown to cause structural sphincter defects; it may cause outright sphincter denervation in rare cases, but its more widespread implication in causing "idiopathic" incontinence is controversial.
