CNEMG may be helpful in selected patients with faecal incontinence if a specific neurogenic condition (e.g., trauma or disease affecting the conus, sacral roots, sacral plexus or pudendal nerves) is suspected on clinical grounds. Turns/amplitude, but not MUP analysis has been claimed to detect evidence of denervation and subsequent reinnervation in postpartum women with mild anal incontinence [62].

**Idiopathic Urinary Retention in Women**

In the external urethral sphincter of young women with urinary retention (or obstructed voiding) complex repetitive discharges in profuse amounts (against a background of firing motor units) have been described, suggesting that these findings are of pathogenic and of diagnostic significance. The external urethral sphincter was reported to be hypertensive. A percentage of these women were hirsute and had polycystic ovaries [63, 64]. The presence of such activity in the needle EMG of the EUS of young women with non-obstructive urinary retention (Fowler’s syndrome) is the only predictor of the long-term success of therapeutic sacral neuromodulation [65]. The cause of this activity is unknown. In some women it may be the expression of an occult generalised dysautonomia [66].

Repetitive discharges are, however, prone to develop in chronically partially denervated sphincters, and are present even in a proportion of asymptomatic women [67]. The distinguishing feature of the spontaneous EMG activity defining the particular pathology in women with retention seems to be its abundance, but the issue remains disputed.

**EMG in Urodynamic and Functional Anorectal Studies**

In health, voiding is characterised by cessation of motor unit firing in the urethral sphincter prior to detrusor contraction, as can be demonstrated by recording of “kinesiological EMG”. Bladder-sphincter coordination is impaired with lesions between the lower sacral segments and the upper pons. Consequently, sphincter activity is not inhibited, and often increases before detrusor contraction (i.e., 'detrusor-sphincter dyssynergia'). On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described [68].

There are other clinical situations that mimic detrusor sphincter dyssynergia. Sphincter contraction or at least failure of relaxation during involuntary detrusor contractions can be seen in patients with Parkinson’s disease. The pelvic floor muscle contractions of the so-called non-neurogenic voiding dyssynergia may be a learned abnormal behaviour [69], and are a feature of dysfunctional voiding [64].

The pubococcygeus in the healthy female reveals similar activity patterns to the urethral and anal sphincters at most detection sites: continuous activity at rest, often some increase of activity during bladder filling, and reflex increases in activity during any activation manoeuvre performed by the subject such as talking, deep breathing, coughing. The pubococcygeus relaxes during voiding; the muscles on either side act in unison [20]. In stress-incontinent patients, the patterns of activation and the co-ordination between the two sides can be lost [70]. A delay in muscle activation on coughing has also been demonstrated, as compared to continent women [21].

Little is known about the complex activity patterns of different pelvic floor muscles (the urethral sphincter, urethrovaginal sphincter, anal sphincter muscle, different parts of the levator ani) during different
manoeuvres. It is generally assumed that they all act in a co-ordinated fashion functionally as one muscle. However there are demonstrable differences between the intra- and peri-urethral sphincter in healthy females [71] and in activation of the levator ani and the urethral sphincter [72]. Co-ordinated behaviour is frequently lost in abnormal conditions.

Kinesiological needle EMG analysis of the urethra with the patient at rest and coughing may predict the outcome after certain types of incontinence surgery [73].

Current concepts suggest that defecation requires increased rectal pressure co-ordinated with relaxation of the anal sphincters and pelvic floor muscles. Pelvic floor relaxation allows opening of the anorectal angle and perineal descent, facilitating faecal expulsion. During defaecation puborectalis activity is as a rule inhibited, but was unchanged in 9% and increased in 25% of healthy subjects [74]. Thus, while “paradoxical” puborectalis contraction during defecation is used to diagnose pelvic floor dyssynergia in patients with typical symptoms, this finding may be a variation of the normal.

b) Pudendal Nerve Conduction Tests

Measurement of motor conduction velocity is routinely used to evaluate limb motor nerves, distinguishing between a demyelinating and axonal neuropathy. To make the measurement requires access to the nerve at two well-separated points and measurement of the distance between them, a requirement that cannot be met in the pelvis. Another way to evaluate peripheral motor nerve function is the measurement of the motor latency of a muscle response, requiring only a single stimulation site. The muscle response is the compound muscle action potential (CMAP) or M-wave. Because in limb nerves the site of stimulation to obtain only the motor latency (without measuring the actual conduction velocity) is as a rule placed distally on the nerve, it is also called the distal (or terminal) latency. For the pudendal nerve the site of stimulation may be more or less “distally”, but the term distal or terminal has – in accordance to general clinical neurophysiology – become generally used. Distal motor latency can be measured by recording with a concentric needle electrode from the bulbocavernosus, the EAS and the urethral sphincter muscles in response to bipolar surface stimulation placed in the perianal/perineal region, or with selective needle stimulation of the pudendal nerve (branches) in the perineum.

The most widely employed technique to obtain pudendal nerve terminal motor latency (PNTML) relies on stimulation with a special surface electrode assembly fixed on a gloved index finger, known as the St Mark’s stimulator [75]. It consists of a bipolar stimulating electrode on the tip of the gloved finger with the recording electrode pair placed proximally on the base of the finger. The finger is inserted into the rectum or vagina and stimulation is applied close to the ischial spine. It is assumed that, using this approach, the pudendal nerve is stimulated close to the ischial spine, and that the response recorded is of the EAS muscle. In women, intravaginal stimulation and recording from the bulbocavernosus muscles has also been undertaken, with similar distal latencies [76]. However, the latency of such a response is typically only around 2 msec, which seems unusually short compared with the perineal technique and with conduction in the much thicker motor fibers of peripheral nerves in the limbs. It seems unlikely that the PNTML using the St. Mark’s electrode really evaluates conduction along the last 8 cm of the pudendal nerve. Stimulation of the terminal pudendal branches or pelvic floor muscles near their motor points seems more likely, and this is supported by the much longer PNTML (3.7 ± 0.9 msec) obtained with a monopolar intrarectal stimulation electrode [77].

If a catheter-mounted electrode is used for recording, EMG responses from the striated muscle of the urethral sphincter can be obtained. Experts differ in their estimation of validity of this test. A prospective evaluation of anorectal physiologic tests in 90 patients with faecal incontinence did not find that PNTML results changed treatment decisions [78]. Indeed, the American Gastroenterological Association statement indicated that “PNTML cannot be recommended for evaluation of patients with faecal incontinence” [79].

c) Anterior Sacral Root (Cauda Equina) Stimulation

Anterior root stimulation has been used to study conduction of the sacral nerve roots. Electrical stimulation with needle electrodes at vertebral laminae Th12-L1 elicit M-waves in the bulbocavernosus and EAS muscle [80].

Transcutaneous stimulation of deeply situated nervous tissue became possible with development of special electrical and magnetic stimulators. When applied over the spine, these stimulators activate the roots as they exit the vertebral canal. Needle EMG rather than non-selective surface electrodes should be used to record pelvic floor and particularly sphincter responses to electrical or magnetic stimulation of the cauda equina. These stimuli non-selectively depolarise underlying neural structures, thereby activating several muscles innervated by lumbosacral segments [81]. Lumbosacral stimulation often evokes a large stimulus artifact that can be decreased by positioning the ground electrode between the stimulating and recording electrodes [82]. Invasive percutaneous stimulation of individual roots in sacral foramina is used to identify patients with lower urinary and anorectal dysfunction who are likely to benefit from long-term stimulation, e.g. with the Interstim (Medtronic, Inc., Minneapolis, USA). Electrical stimulation of nerve roots at the level of the appropriate sacral foramina results in observable muscle contraction in the foot and perineum. These responses can be identified as MEP or reflex responses on the basis of their latency. Selective stimulation of
individual sacral roots is possible by appropriate positioning of surface stimulating electrodes [83].

In conclusion, demonstrating the presence of a perineal MEP on stimulation over lumbosacral spine may occasionally be helpful in patients without voluntarily activated muscles. It also identifies the particular nerve root before introducing therapeutic electrical stimulation. However, the clinical value of the test has yet to be established and there are no sensitivity and specificity data on test results in individual patients.

d) Motor Evoked Potentials

Using magnetic or electric stimulation, it is possible to depolarise the motor cortex and record a response from the pelvic floor. Magnetic cortical stimulation is better tolerated than electrical stimulation, which has been abandoned in awake subjects, but may be useful for intraoperative monitoring.

By performing the stimulation at two different sites (brain and spinal roots), it is possible to record three different conduction times: a total conduction time, a peripheral conduction time, and a central conduction time (Figure E5). The total conduction time corresponds to the transit time from brain to target muscle. The peripheral conduction time is the transit time from sacral roots to the muscle. The central conduction time is obtained by subtracting the peripheral conduction time from the total conduction time. The total conduction time can be measured both at rest and during a facilitation procedure. MEPs from the EAS, the urethral sphincter, the bulbocavernosus muscle, and the levator ani muscle have been reported, but normative values have only been obtained (for transcranial magnetic stimulation) for the urethral sphincter and the puborectal muscle in adult women [84]. A central conduction time of 15 to 16 msec without and 13 to 14 msec with facilitation is obtained for pelvic floor and sphincter muscles [85, 86, 87]. The necessity to use concentric needle EMG for recording has been reconfirmed [88].

Substantially longer central conduction times have been found in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls [87, 88, 89]. However all patients in this study had clinically recognisable cord disease. Nevertheless, MEPs may be useful in patients with unclear localization of spinal lesions [87].

Conceptually, MEP may help to differentiate between involvement of motor and sensory pathways. However, the clinical utility of these measurements is not established. MEP have opened an avenue of research on excitability of motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles the anal sphincter motor cortex has less intracortical inhibition [90].

2. SENSORY SYSTEM TESTS

There are several methods of sensory testing for the perineum, the genitourinary and anorectal tract. Clinical testing includes perineal and external genital skin sensation for light touch and pinprick, and sensation of bladder filling during cystometry. Anorectal sensory testing can be clinically assessed through rating of applied stimuli. More objective sensory testing can be performed with quantitative sensory testing (QST), which assesses sensory perception. For evaluation of the integrity of sensory pathways sensory neurography, and somatosensory evoked potentials (SEP) can be used.

a) Sensory Measurements During Cystometry

During routine cystometry bladder sensation is assessed by recording first sensation of bladder filling, first desire to void and strong desire to void.

Although not strictly a neurophysiologic test, measurement of electrical thresholds adds clinically non-obtainable information on sensory function of the lower urinary tract [91]. Bladder and urethral sensory thresholds have also been measured using electrical stimulation [91], and mechanical traction on the bladder trigone [92]. Electrical currents

Figure E 5: MEPs recorded by concentric needle in the external urethral sphincter of a 51-year-old-woman. Cortical (a), thoracic (b), and sacral (c) stimulation. Central motor conduction time (CMCT) is calculated as cortical - lumbar latency (** = 10.6 ms). Cauda equina motor conduction time is calculated as lumbar - sacral latency (* = 4.3 ms). (From (Brostrom et al., 2003a), with permission).
are applied to the bladder, urethra or genital skin using catheter-mounted or surface electrodes. High-frequency stimulation (> 20 Hz), with a stimulus duration of 0.5 or 1 msec is used because it is more easily perceived in the lower urinary tract. Measurement of sensory thresholds with such stimulation is reproducible, and normative data have been published [91]. To date it has been used in only a few conditions (e.g., painful bladder syndrome) [93]. There is no established clinical use for any of these tests other than simple reporting of sensation during cystometry.

In addition, palmar SSR and perineal surface EMG recordings can be used for more objectively demonstrating sensations during cystometry. The activity of both appears and increases in parallel with the first sensation of bladder filling, and with the first desire to void, respectively [94]. Further studies using these methods are needed to establish their clinical utility.

b) Assessment of Anorectal Sensation

Rectal sensation is assessed by progressively distending a balloon manually or by a barostat while measuring thresholds for first perception, desire to defecate, and severe discomfort. The intensity of perception during rectal distension can be recorded by a visual analogue scale during phasic distensions of graded intensity [95]. The rate and pattern of distension affect rectal perception and internal sphincter relaxation [96].

Anal sensation can be assessed by determining the perception threshold to an electrical stimulus or temperature change in the anal canal. Electrical testing does not activate mucosal receptors. Temperature perception on the proximal anal canal has been found to be reduced in patients with passive anal incontinence compared to those with urgency incontinence [97].

c) Quantitative Sensory Testing

Quantitative sensory testing (QST) of the urogenitoanal system should provide more objective and reproducible data than routine clinical testing. QST sensory modalities applied to the evaluation of urogenital function include vibration [98], temperature [99], and electrical current [100]. There is no commonly accepted, detailed, standardised test, and the specificity and sensitivity of the tests are not known. The relationship of cutaneous quantitative sensory tests to bladder and urethral sensation and function is unknown. The physiological, psychophysiological and methodological issues and controversies will not be addressed in this chapter.

d) Sensory Neurography

Nerve conduction velocities of the dorsal nerve of the penis can be calculated by placing a pair of stimulating electrodes across the glans and a pair of recording electrodes across the base of penis. A nerve action potential can be recorded with amplitude of about 10 µV. It can also be recorded by stimulating trans-rectally or transperineally. There is no known association between penile sensory neuropathy and bladder/sphincter dysfunction.

A few studies have recorded activity in sacral roots during electrical stimulation. Intraoperatively, when the sacral roots are exposed, compound sensory action potentials on stimulation of dorsal penile and clitoral nerve may be recorded directly [101]. This helps to preserve roots mediating perineal sensation in spastic children undergoing dorsal rhizotomy, and reduce the incidence of postoperative voiding dysfunction [102]. These tests are limited to their very specific intraoperative indications.

e) Somatosensory Evoked Potentials (SEP)

Somatosensory evoked potentials are electric waveforms of biological origin elicited by stimulation of a sensory nerve (or a sensory innervated skin area – dermatome). The most commonly performed tests in the urogenitoanal region are pudendal somatosensory evoked potentials (SEP), which assesses conduction in large fibre pathways between the site of nerve stimulation and the parietal sensory cortex. Potentials can also be measured at the spinal level (spinal SEP). Visceral (thin) fibre pathways are assessed by recording SEPs while stimulating the proximal urethra and bladder, although this is technically not depolarisation of nerves, but a mesh of afferents.

1. PUDENDAL SOMATOSENSORY EVOKED POTENTIALS

- Cerebral Pudendal SEP

On electrical stimulation of the dorsal penile/clitoral or perineal nerve, a cerebral SEP can be recorded. (Figure E 6) This SEP is as a rule of highest amplitude at the central recording site (Cz - 2 cm : Fz of the International 10-20 EEG System) and is highly reproducible. The first positive peak at about 40 ms (called P40) is usually clearly defined in healthy subjects using a stimulus 2-4 times stronger than the sensory threshold [103]. The presence and amplitude of subsequent negative and positive waves are quite variable between subjects. Classically described pudendal SEP techniques stimulate both dorsal penile/clitoral nerves, thus reducing the sensitivity of the test.

However, techniques of pudendal SEP that isolate each dorsal penile/clitoral nerve may be more sensitive for identifying pathology [104].

Pudendal SEPs have been advocated in patients with neurogenic bladder dysfunction, e.g. in multiple sclerosis [105]. However, even in patients with multiple sclerosis and bladder symptoms, the tibial
cerebral SEP was more often abnormal than the pudendal SEP. The combination of an abnormal pudendal SEP with a normal tibial SEP suggests isolated conus involvement [106]. The pudendal SEP was less useful than neurological examination for identifying neurological disease in patients with uro-genital symptoms [107]. Following spinal cord injury, tibial and pudendal SEPs may be of some value for predicting recovery in bladder control [108]. Cerebral SEP during penile/clitoral stimulation may be useful for intraoperative monitoring. Pudendal SEP were used to study the mechanism of sacral neuromodulation [109].

- Spinal Pudendal SEP

Stimulating the dorsal penile nerve and recording with surface electrodes at the level of the Th12-L2 vertebrae (and the S1, Th6 or iliac spine as reference) reveals the postsynaptic segmental spinal cord activity (the spinal SEP). Unfortunately, this spinal SEP may be difficult to record even in normal (and particularly in obese) subjects.

3. SACRAL REFLEXES

Clinically, two reflexes are commonly elicited in the lower sacral segments: [1] the penilo- or clitoro-cavernosus (i.e. bulbocavernosus) reflex; and [2] the anal reflex [110]. To elicit sacral reflexes, electrical [111-118], mechanical [115, 116, 119] or magnetic [120] stimulation can be used. Whereas the latter two modalities have only been applied to the penis [117-119], clitoris, and the suprapubic area [115], electrical stimuli can be applied to various sites: to the dorsal penile or clitoral nerve; perianally; and, using a catheter-mounted ring electrode, to the bladder neck/proximal urethra [121].

a) Sacral Reflex on Electrical Stimulation

Electrical stimulation of the dorsal penile or clitoral nerve elicits (somato-somatic) sacral reflexes in perineal muscles with a typical latency approx. 33 ms (29.9 ± 5.7 msec in one study in men) [117], traditionally called the bulbocavernosus reflex (Figure E 6). In addition to single-pulse electrical stimulation, two identical electrical pulses separated by a 3-msec interval can be used (i.e., double-pulse electrical stimulation) [117, 118]. Double-pulse electrical stimulation is more efficient in eliciting sacral reflexes [117]. Stimulation of the perianal skin, bladder neck or proximal urethra elicits sacral reflexes with latencies above 50 ms. This latency is longer compared to responses conveyed by the pudendal nerve, suggesting that the afferent limb for these responses involves visceral afferent fibres accompanying the pelvic nerves, which are thinly myelinated and have a slower conduction velocity than the thicker pudendal afferents. With visceral denervation (e.g. following radical hysterectomy) the viscero-somatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernosus (penilo-/clitoro-cavernosus) reflex is preserved. Loss of bladder-urethral reflex with preservation of bladder-anal reflex has been described with urethral afferent injury after recurrent urethral surgeries [122].

The longer latency anal reflex (the contraction of the EAS on stimulation of the perianal region) is quite variable thus limiting its usefulness as a diagnostic tool.

Figure E 6: SEPs (traces on the left) and sacral reflexes (traces on the right) in a healthy woman. Cerebral SEPs are recorded from Cz - 2 cm; sacral reflexes from the anal sphincter. The dorsal clitoral nerve is being stimulated with rectangular electrical pulses at 2 Hz. Stimulation and recording is performed with surface electrodes. The cerebral SEP and sacral reflex are recorded simultaneously. In the upper row the stimulation is just above sensory threshold, in the middle row the stimulation is 1.5, and in the lower row at 2-times sensory threshold (pulse duration 0.2 ms; two consecutive averages of 128 responses are superimposed).
On perianal stimulation, a short latency response can also be recorded, as a result of depolarisation of motor branches to the EAS, possibly involving antidromic travelling of the depolarisation, with “re-turning” of the depolarisation orthodromically to the sphincter at a branching point of the motor axon.

EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g. observing and palpating the contraction) in males and particularly in females [123]. In men, value of 40, 36 and 36 msec have been suggested as the upper limit of normal for the shortest latency obtained on eliciting a series of reflex responses using single, double and mechanical stimulation, respectively [117].

In men with cauda equina lesions penilo-cavernosus reflex could not be elicited in 64%, 47% and 47% of patients on single electrical, double electrical, and mechanical stimulation, respectively. Measurement of the reflex latency increased the sensitivity to record abnormalities for 17%, 36%, and 34%, respectively. Furthermore, it has been shown that sacral reflex measurement increase sensitivity of quantitative EMG of the EAS muscles from 73% to 81-83% using the different stimulation techniques mentioned [118].

Sacral reflex testing has been studied extensively and is used in many laboratories in everyday practice to demonstrate objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernous or penilo-/clitoro-cavernous reflex) was shown to be a complex response, often forming two components. The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernous reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response [112]. The second component has latency similar to the sacral reflexes evoked by stimulation perianally or from the proximal urethra, and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation.

During voiding sacral reflexes are un-elicitable but in the presence of spinal cord lesions such as myelodysplasia this normal suppression is lost.

Sacral reflex responses recorded with needle or wire electrodes can be analysed separately for each side from the EAS or bulbocavernous muscle. Using unilateral dorsal penile nerve blocks, the existence of two unilateral BCR arcs has been demonstrated. Thus by detection from the left and right bulbocavernous (and also the EAS) muscles separate testing of right and left reflex arcs can be performed. Some authors reported that the sensitivity of the test can be increased by use of the interside latency difference (normative limits: < 3 ms), but finding could not be confirmed by others (normative limits: < 7.2 ms) [117]. In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one on clinical elicitation, but not on neurophysiological measurements of the sacral reflexes.

As described above, penilo-cavernosus reflexes were absent in 47-64%, and delayed in additional 17-19% of patients with conus/cauda lesions. Of these patients 47% were incontinent for urine and 47% of faeces. However, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc, as demonstrated by pathologic quantitative EMG of the EAS in 79-86% of patients with conus/cauda lesions [118]. Furthermore, much delayed sacral reflex responses are compatible with normal bladder and sexual function as found in patients with hereditary motor and sensory demyelinating neuropathy. In a proportion of women with non-neurogenic sacral dysfunction clitoro-cavernosus reflex latencies were found to be much longer compared to those obtained in women with intact sacral function [124].

Sacral reflex recording is suggested as a complementary test to CNEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions [4].

In addition to latency, a number of other parameters can also be measured using electrical, but not mechanical stimulation. These are the sensory threshold (i.e., the stimulus strength (mA) at which subjects feels stimulation), and reflex threshold (i.e., the stimulus strength (mA) at which the reproducible penilo/clitoro-cavernosus reflex appears on the screen). They evaluate lower sacral sensory pathways, and excitation level of the sacral reflex pathway, respectively. Although for men normative data for these parameters are available [117], their utility in clinical situation remains unclear.

Continuous intraoperative recording of sacral reflex responses on penis/clitoris stimulation is feasible if double pulses or a train of stimuli are used [125].

b) Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicit BCR in both sexes and found to be a robust technique. Either a standard reflex hammer or a customised electromechanical hammer can be used. Using a reflex hammer, the stimulus is applied to a wooden spatula placed on the glans penis or clitoris [117, 118]. Such stimulation is painless and can be used in children [119]. The latency of the BCR elicted mechanically is comparable to the electrically elicted
reflex in the same patients, but depends on the electromechanical device used [117, 119].

4. AUTONOMICAL FUNCTION TESTS

Most uro-neurophysiological methods discussed so far assess myelinated fibres, but not the autonomic nervous system, especially the parasympathetic component, which is most relevant for pelvic organ functions. Methods for evaluating the autonomic nerves innervating the pelvic viscera are not available. Cystometry indirectly evaluates the parasympathetic innervation to the bladder. However, from a clinical neurophysiological point of view direct electrophysiological testing would be desirable.

a) Tests in Generalised Autonomic Neuropathy

Cardiovascular autonomic function tests are useful for identifying generalised autonomic dysfunction in patients with bladder or gastrointestinal motility disturbances.

In cases when a general involvement of thin fibres is expected, an indirect way to examine autonomic fibres is to assess thin sensory fibre function. Thin visceral sensory fibres are tested by stimulating the proximal urethra or bladder, and by recording sacral reflex responses or cerebral SEP.

b) Dartos reflex

In men, another approach to test lumbosacral sympathetic function is by neurophysiological measurement of the dartos reflex obtained by electrical cutaneous stimulation of the thigh. The dartos muscle is a sympathetically innervated dermal layer within the scrotum, distinct from the somatically innervated cremasteric muscle. A reliable and reproducible dartos reflex (i.e., scrotal skin contraction) with a latency of about 5 seconds has been demonstrated in healthy men [126].

c) Smooth Muscle Electromyography

Technical problems have so far limited smooth muscle electromyography of the detrusor muscle, and of genital smooth muscle. There is no evidence to prove the clinical utility of these tests in the evaluation of urinary tract function.

d) Sympathetic Skin Response (SSR)

The sympathetic nervous system mediates sweat gland activity in the skin. Changes in sweat gland activity lead to changes in skin resistance. On noxious stimulation (such as a sudden noise, electrical pulse, etc.) a potential shift can be recorded with surface electrodes from the skin of the palms and the soles, and has been reported to be a useful parameter in assessment of neuropathy involving non-myelinated nerve fibres. The response, known as the SSR, can also be recorded from perineal skin and the penis. Similarly, the SSR can be recorded from the genital region in women [127]. The SSR is a reflex, which consists of myelinated sensory fibres, a complex central integrative mechanism and a sympathetic efferent limb with postganglionic nonmyelinated C fibres. SSR is the only electrophysiological method directly testing sympathetic fibres. Limited literature exists regarding the relationship between SSR results and bladder dysfunction. A correlation has been shown between the absence of the SSR response in the foot and bladder neck dyssynergia following spinal cord injury [108]. Recording from the perineal region assesses sympathetic nerve function within the thoracolumbar cord [128].

III. EVIDENCE BASED USE OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Only complete absence of response can be regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not established.

Evidence-based medicine is founded on the assessment of evidence for and against the efficacy of particular types of therapeutic intervention. Clinical neurophysiology testing should thus demonstrate evidence that testing improves outcome (through treatment choice and patient selection), which would provide a strong basis for its use. However, testing and therapeutic intervention are different concepts, and neurophysiological testing has another important objective, which is not applicable to interventions and lies outside the scope of evidence-based medicine. It is to generate knowledge about the situation to be treated in a given patient, so that the practitioner can formulate rational treatment options based on evidence that is, he or she can practice "evidence-based medicine".

To judge the importance of this second objective different criteria are needed. Particularly in the referral setting, the physician is confronted with complicated cases in which the underlying pathophysiology is quite uncertain, and what is required is to identify all the factors that may be contributing. Neurophysiology is helpful in assessment of neurogenic dysfunction because it contributes to "evidence-based medicine", whether or not there is narrowly-defined "evidence" that it improves outcomes.

Of course, it remains true that we should seek evidence of the conventional kind for and against testing. Any test should be subjected to three questions:

1. Does the test have good technical performance?
2. Does the test have good diagnostic performance, ideally against a "gold standard" measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

Clinical diagnosis requires that measures obtained in individual patients be compared to population
norms with the intent of determining whether they are "normal" or "abnormal". Data can be classified as "abnormal" only with the understanding that they are compared to a sample from the normal population. Predictive statements are made possible by the use of tolerance limits. For most clinical neurophysiological tests, one-tailed tolerance limits are recommended. For any given limit of normality, there is a certain probability of falsely interpreting values (obtaining false-positives or false-negatives). Further confounding these issues is the practice of applying multiple criteria of abnormality. But ultimately, the adequacy of any given normal limit in differentiating between normal and abnormal must be supported by appropriate clinical or clinico-pathological correlations; for uro-neurophysiological techniques, such data are scarce.

1. USEFULNESS OF CLINICAL NEUROPHYSIOLOGICAL TESTS IN EVALUATION OF INDIVIDUAL PATIENTS

Whenever pathophysiology is uncertain or unpredictable, and especially if irreversible treatment is necessary or contemplated, it seems logical to gather quantitative knowledge of the dysfunction in order to make a rational treatment choice. In most patient groups with neurogenic incontinence, the pathophysiology is unpredictable and comprehensive urodynamic evaluation is essential in order to practice knowledge-based medicine. In selected patients from these groups, clinical neurophysiological testing will clarify issues related to the neural control of lower urinary tract, relevant for understanding pathophysiology. Most patients, however, will not require a precise definition of the neurological lesion.

As is generally true for electrophysiological tests, uro-neurophysiological examinations are particularly useful for substantiating the clinical diagnosis of a peripheral nerve lesion. The potential usefulness of testing in an individual patient needs to be analysed in the overall clinical setting. The indications for testing are guided primarily by expert opinion, not on definitely established criteria derived from controlled studies.

In the incontinent patient without other signs or symptoms of a neurological condition, neurophysiological testing is generally unnecessary. In patients with stress/urge, or mixed urinary incontinence electrophysiological testing is as a rule non-contributory [61].

2. USEFULNESS OF CLINICAL NEUROPHYSIOLOGICAL TESTS IN RESEARCH

Uro-neurophysiological techniques have been most often applied in research, for instance to elucidate the innervation of pelvic floor muscles; to study the physiology of contraction of sphincter muscle, to describe activation patterns of pelvic floor muscles. Suggestions of increased efficacy of sacral neurostimulation with the use of neurophysiological tests have been made [129]. As understanding pathophysiology and neural control is essential in the application of more sophisticated therapeutic methods, such as electrical stimulation techniques, there seems to be a continuing place for clinical neurophysiology in research on neurogenic urinary and anorectal dysfunction and their therapy.

### IV. CONSENSUS STATEMENT

1. CLINICAL NEUROPHYSIOLOGICAL TESTING

The information gained by clinical examination and urodynamic testing may be enhanced by uro-neurophysiological tests in selected patient groups with suspected neurogenic urinary incontinence with lesions within the nervous reflex arcs of sacral segments 2 – 5. Concentric needle EMG to diagnose denervation and reinervation of pelvic floor and perineal muscles, and sacral reflex testing to assess the continuity of the sacral reflex arc, are the recommended tests. (Level of Evidence: 2b; Grade of Recommendation: B)

Clinical neurophysiological testing should be performed in accredited laboratories, by trained and certified staff, with formal control of the quality of the results. Ideally, the uroneurophysiologist should be in liaison with general clinical neurophysiologists. It seems optimal to create interdisciplinary programs between urology, urogynaecology, proctology, and neurology departments. Organisation of such teams in tertiary medical centres should be encouraged.

2. TECHNICAL STANDARDS

Even in the more widely used "general" clinical neurophysiology there is no universal standardisation of tests. This is mainly due to different historical backgrounds of testing developed in different countries. The need to standardise methods is, however, recognised.

Proposals for standardisation for external anal sphincter CNEMG [4] and the bulbocavernous (penilo/clitoro-cavernousus) reflex [117] have been made, and seem to be widely adopted. (Level of Evidence: 2b, Grade of Recommendation: B)

3. FUTURE RESEARCH AREAS

Clinical neurophysiological methods should be further used to better define the neural control in lower urinary tract function, demonstrating both the nervous system’s “hardware” (integrity of anatomy) as well as “software” (level of activity, excitation thresholds) for co-ordinated urinary storage and voiding, in physiological and in pathological conditions. In particular, there is the opportunity to better define neurophysiological changes induced by therapeutic electrostimulation.

There is the challenge to develop tests to assess directly the sacral parasympathetic system.
F. OTHER INVESTIGATIONS

I. URINALYSIS

“Urinalysis is a fundamental test that should be performed in all urological patients” [1]. In patients with urinary incontinence, urinalysis is not a diagnostic test for the condition, but it is rather used to screen for haematuria, glucosuria, pyuria and bacteriuria. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved [2]. A positive urinalysis will prompt infection treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence in the female, urinalysis is recommended since 60% of women develop urgency symptoms at the time of urinary tract infection (UTI). Pyuria was found to be common among incontinent but otherwise asymptomatic, female patients. Pyuria was not necessarily associated with UTI, the significance of sterile pyuria in the elderly population is still unclear [3].

A Norwegian survey of general practitioners’ management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) [4]. Another survey suggested that urinalysis is one of the three-part assessment of UI together with patient history and physical examination [5]. The same apply, according to Stricker, for patient selection for collagen implant [6]. A minority of the reviewed papers suggested that urine culture should be carried out together with urinalysis [3, 7]. Urinalysis is also considered of importance in the evaluation of nursing home residents who are incontinent [8], in peri- and postmenopausal women [9], in older women reporting urinary incontinence [10]. Belmin et al., suggested that significant urine samples can even be obtained from disposable pads in elderly incontinent women [11, 12]. It is recommended that geriatric incontinent patients undergo history, physical examination, tests of lower urinary tract function and urinalysis. The latter test is proposed to rule out the presence of UTI [12]. The clinical relevance of asymptomatic bacteriuria in the elderly is controversial. Although DuBeau and Resnick suggest the use of urinalysis in the diagnostic algorithm to identify asymptomatic bacteriuria in incontinent residents of nursing homes [13], others consider that the condition does not require any treatment [11].

1. CONSENSUS STATEMENT

• It is considered standard practice to perform a urinalysis either by using a dipstick test or examining the spun sediment. (Level of Evidence 3, Grade of Recommendation C)
• If a dipstick test is used, it is recommended choosing of a “multiproperty” strip that includes testing for haematuria, proteinuria, glucose and ketones, leukocytes esterase (indicating the presence of leukocytes in the urine) and nitrite tests (suggesting bacteriuria). (Level of Evidence 3, Grade of Recommendation C)

2. FUTURE RESEARCH AREAS

• Needed to screen analysis of urinalysis in the diagnosis and treatment of UI, MUI and SUI

3. REFERENCES (SEE AT THE END OF THE CHAPTER)

II. BLOOD TESTS

The prevalence of renal damage or of biochemical abnormalities in the general population of patients with urinary incontinence is very low, but there are subgroups of patients where the prevalence can be higher (e.g., neurogenic incontinence, overflow incontinence). The routine use of a battery of common chemical and/or haematological tests in patients with urinary incontinence appears to be a prudent rule of good clinical practice in the following situations:

a) chronic retention with incontinence
b) neurogenic LUT dysfunction
c) when surgery is contemplated
d) when there is a clinical suspicion
e) sodium plasma concentration may be reduced in patients on desmopressin.

Special tests such as measurement of anti diuretic hormone (ADH) and atrial natriuretic poly-peptide have proven useful in research of enuresis in childhood and nocturia in the elderly [1, 2]. Changes in the circadian rhythm of these, and probably also other hormones regulating the renal excretion of water, will in the future contribute to a better understanding of pathophysiology. Synthetic ADH analogues have already come into clinical use for the treatment of nocturnal enuresis. However, the clinical value of these specific tests remains to be established.

III. TISSUE ANALYSIS

Since the last report of the International Consultation on Incontinence in 2008, several papers have been published based on the analysis of sample of tissues coming from patients with stress urinary incontinence.
Pelvic floor-supporting tissues are composed mainly of connective tissue in which fibrous elements such as collagen and elastic fibres and visco-elastic matrix based on proteoglycans are the predominant components of the so called extracellular matrix. Extracellular matrix is a complex network of numerous macromolecules that fulfill a large number of mechanical, chemical and biological functions [1]. While collagens and elastin fibres confer strength and elasticity to tissues, respectively, structural proteoglycans allow tissue cohesiveness. Specifically, collagen is the most prevalent component, with type I fibres usually well organised and associated with ligamentous tissue, while type III collagen is more common in the loose areolar tissue, which makes up the vaginal wall adventitia and surrounds the pelvic organs [2]. According to the molecular weight, indeed, proteoglycans are distinguished into large molecules (aggrecan, versican and perlecan) and small molecules, such as decorin, fibromodulin, biglycan, lumican and chondroadherin [3].

The organised structure of the matrix is due to a clear balance between the production of the different constituents and their breakdown. There are many proteolytic enzymes capable of degrading the elements of the extracellular matrix, falling into into three groups: the serine proteases, the cysteine proteases, and matrix metalloproteinases (MMPs) [4].

Several authors evaluated the expression of the different proteins as well as of their precursors and fragments of degradation. With regards to the metabolism of collagen, some studies seem to indicate that women with SUI have a reduced total collagen content in the skin and urogenital tissue [5-7], while other studies reported higher total collagen concentration and higher levels of mRNAs for type I and type III collagen in paraurethral connective tissue in patients with SUI or prolapsed and matched control women, showing controversial results. Some papers reported reduced expression of proteins such as p53 and p21 which normally cause cycle G1 arrest suggesting an increase in proliferation capacities for fibroblasts derived from human cardinal ligaments of patients with prolapse [2].

Other authors evaluated markers of collagen degradation. Specifically, Edwall et al. evaluated markers of collagen synthesis and breakdown such as the carboxy-terminal propeptide of type I procollagen (PICP), the carboxy-terminal telopeptide of type I collagen (ICTP), and the amino-terminal propeptide of procollagen III (PIIINP) in urogenital tissue homogenates and peripheral serum from 71 patients with SUI and 31 healthy control women [12]. After adjusting for age, BMI, parity, and hormonal status, the patients with SUI had significantly lower serum concentrations of PICP and significantly lower tissue concentrations of PIIINP and ICTP than the controls, suggesting reducing breakdown in the presence of unchanged synthesis of type I collagen and, regarding type III collagen, a potential reduction in either synthesis or breakdown, the second being considered more probable [12]. These data may lead to the hypothesis that SUI might be associated with impaired degradation of collagen, leading to reduced turnover and accumulation of aging collagen, negatively affecting the strength and elasticity of urogenital tissue. Further studies on transforming growth factor-β (TGF-β) identified the molecular basis of such mechanism, suggesting that over-expression of TGF-β might trigger the accumulation of aging collagen, inhibiting the expression of collagenases and increasing the production of the tissue inhibitor metalloproteinase [13-15]. Moreover, some genes, such as those of the Homebox A (HOXA) family, encoding transcription factors that regulate mammalian embryonic growth and development of the urogenital tract, have been shown to be underexpressed in patients with pelvic organ prolapse, suggesting a further molecular basis for the alterations in collagens [16].

Some other studies investigated the role of proteinases that may degrade elements of the extracellular matrix. Chen et al., evaluating full-thickness peri-urethral vaginal wall tissues from patients with SUI or prolapsed and matched control women, found significant decrease in mRNA and protein expressions of alpha-1 antitrypsin (ATT), a neutrophil elastase inhibitor in tissues from affected women, while no difference was found in neutrophil elastase and cathepsin K expressions [17]. Similarly, Gabriel et al. studied the expression of different MMPs in 17 women with prolapsed and (SUI) and/or pelvic organ prolapse aiming at evaluating the molecular bases of these conditions. The main targets of both preclinical and clinical research have been the pelvic floor-supporting tissues and the role of steroid hormones, with some intriguing linkages between the two lines of research.
18 control, identifying higher expression of MMP2 in patients with prolapse [18]. These studies allowed to hypothesize that altered catabolism of some components of the extracellular matrix might contribute to the connective tissue alterations observed in pelvic floor dysfunction.

Other studies were focused on the expression of small proteoglycans. Wen et al. studied mRNA and protein levels of biglycan, decorin, and fibromodulin in vaginal wall tissue from women with SUI and menstrual-cycle matched continent women [1]. Specifically, the authors demonstrated that the mRNA expression of fibromodulin was significantly lower in patients in the proliferative phase compared to controls, while decorin mRNA expression was higher both in the proliferative and secretory phases in the patients with SUI, supporting the hypothesis that the expression of such small proteoglycans was hormonally modulated and may contribute to the altered pelvic floor connective tissues of women with SUI [1].

Oestrogens interact with specific receptors which, when activated by the ligand, have conformational change, dimerisation and recruitment of co-factors, once translocated into the nucleus, these promote the expression of region of oestrogen-responsive genes, called the oestrogen response elements, leading to the synthesis of proteins [19]. More recently, selective modulators of oestrogens receptors have been identified, that act modulating the activity of the receptors, working as agonists, partial agonists, or antagonists in a tissue-dependent manner [20]. Studies on these molecules supported a new role of oestrogens in SUI and pelvic organ prolapse. Specifically, in a randomized controlled trial testing one of these molecules (levormeloxifene) as osteoporosis treatment, a 3.4-fold increase in the reporting of pelvic organ prolapse and an almost 5-fold increase in the reporting of urinary incontinence have been observed [21]. To explain such effect, the expression of more than 500 proteins have been studied in the rat model, showing that oestradiol induced the expression of metalloproteinase 7 and 14, reduced the expression of their inhibitors such as TIMP-3, while selective modulators of oestrogens receptors such as raloxifene had minimal effects on metalloproteinase 7, and maintained or restored expression of the mRNA for tissue inhibitor of metalloproteinases-3 (TIMP-3) and other components of the extracellular matrix, such as glypican, and biglycan [19]. Although the role of selective oestrogen-receptor modulators (SERMs) in the expression of the component of extracellular matrix has to be further clarified, these findings support the hypothesis that the increased occurrence of urinary incontinence and pelvic

G. CONCLUSIONS

Clinical research involving diagnostic accuracy and clinical benefit of imaging studies and other diagnostic tests is particularly difficult. Recommendation of a diagnostic test is based upon the evidence that the outcome of it provides valuable information for patient management and this often involves evaluating the outcome of surgery. Implementation of good clinical research in this area remains difficult and sometimes lacks adequate founding. We acknowledge that only a few of the imaging techniques and other investigations reviewed in the current chapter have been properly evaluated with respect to reproducibility, specificity, sensitivity and predictive value in connection with the diagnosis and management of urinary incontinence. Nevertheless, we acknowledge the great amount of work performed in the last four years and the continuous advancement in this field. The use of imaging and other investigations, described in this chapter, remains mostly based on expert opinion, common sense, availability and local expertise, rather than on evidence based clinical research. The diagnostic tests we considered can be subdivided into safety tests, tests with specific and selected indications, investigational tests.

Safety tests - Intended to protect patients’ health, they are indicated in all patients complaining of urinary incontinence. They include urinalysis and measurement of post-void residual urine. While a consensus is easily achieved for urinalysis, the clinical benefit and cost-effectiveness of PVR...
measurement in the primary evaluation of urinary incontinence needs to be confirmed in prospective studies.

Tests with specific and selected indications. Upper urinary tract imaging (as well as renal function assessment) may be indicated in cases of neurogenic urinary incontinence with risk of renal damage, chronic retention with incontinence, incontinence associated with severe genitourinary prolapse and suspicion of extraurethral incontinence. No other imaging technique is recommended in the primary evaluation of uncomplicated urinary incontinence and/or pelvic organ prolapse. Cystourethrography remains a reasonable option only in the preoperative evaluation of complicated and/or recurrent cases. Video urodynamics, is the gold standard in the evaluation of neurogenic incontinence, particularly in the paediatric population, although the clinical benefit of it remains unclear. In female urinary incontinence videourodynamics is not recommended except under specific complex circumstances. MRI remains the gold standard for the diagnosis of urethral diverticula although ultrasonography is a good alternative option. Lumbosacral spine X-rays have specific indications in children with suspect neurogenic incontinence without gluteosacral stigmata. Imaging of the CNS should be considered when a neurological disorder is suspected on the basis of clinical, imaging and neurophysiological findings. Urethrocystoscopy is indicated in cases of incontinence with microscopic haematuria, in the evaluation of recurrent or iatrogenic cases, in the evaluation of vesico-vaginal fistula and extra-urethral urinary incontinence.

Endoanal ultrasound and endocoil MRI are the gold standard for the evaluation of anal sphincter disorders, dynamic X-ray imaging remains the standard for evaluating rectal prolapse.

Investigational tests

Pelvic floor ultrasound is widely used as an adjunct to physical examination in patients with urinary incontinence and/or pelvic organ prolapse. Although the technique is rapidly evolving and much progress has been made in clinical research in this field, ultrasonography remains optional as evidence of its clinical benefit is not there yet.

MRI of the pelvic floor is rapidly gaining popularity in the evaluation of enteroceles and in the morphological analysis of pelvic floor muscles although evidence of its clinical benefit is still lacking. Both ultrasonography and MRI are the most rapidly evolving techniques and hold promises for potential future clinical applications.

Research in this area is also performed to improve our understanding of the pathophysiology of continence disorders and pelvic organ prolapse. Functional neuroimaging continues to provide new insight regarding functional anatomy of CNS related to vesicourethral function and dysfunction. The content of the draft reflects the composition of the Committee is made up of clinicians with a particular interest in a specific area of imaging and neurophysiology. The chapter certainly reveals the enthusiasm the authors poured in clinical research into this area but we believe that the methodology implemented by the Consultation is the best guarantee of a balanced opinion and evidence based recommendations. We hope that this chapter will stimulate clinical research in this field and will inspire those involved in the management of continence disorders and pelvic organ prolapse.

Neurophysiological testing should be part of the armamentarium available in the management of neurogenic incontinence and the establishment of good collaboration with neurophysiologists is recommended.

A. Introduction

The function of the lower urinary tract (LUT) is to store and periodically release urine, and is dependent on the activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. These structures form a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors [Andersson, 1993; de Groat and Yoshimura, 2001; Andersson and Wein, 2004; see, Andersson and Michel, 2011]. Malfunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in overflow incontinence. A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance [Wein, 2012].

Many drugs have been tried, but the results are often disappointing, partly due to poor treatment efficacy and/or side effects. The development of pharmacologic treatment of the different forms of urinary incontinence has been slow, but several promising targets and drug principles have been identified [Andersson 2007; 2011c; Colli et al., 2007; Athanasopoulos and Cruz, 2011].

In this report, we update the recommendations from the 2008 International Consensus meeting [Andersson et al., 2009]. The most relevant information obtained since the last meeting is briefly reviewed and summarised. Agents specifically used for treatment of urinary tract infections and interstitial cystitis, have not been included. Our clinical drug recommendations are based on evaluations made using a modification of the Oxford system (Table 1). The terminology used is that recommended by the International Continence Society (ICS) [Abrams et al., 2002].

I. PUBLICATION SEARCHES

The review undertook a comprehensive search of all major literature databases and the abstract books from several major conferences: American Urological Association, ICS, European Association of Urology, International Urogynaecological Association, International Consultation of Incontinence and Societe Internationale d’Urologie. There were no restrictions on the inclusion of publications by

II. CENTRAL NERVOUS CONTROL

In the adult individual, the normal micturition reflex is mediated by a spinobulbospinal pathway, which passes through relay centers in the brain (Figures 1-4). In infants, the central pathways seem to be organized as on-off switching circuits, but after the age of four to six years, voiding is initiated voluntarily by the cerebral cortex [de Groat et al., 1999; Beckel and Holstege, 2011]. Studies in humans and animals have identified areas in the brainstem and diencephalon (Figure 5) that are specifically implicated in micturition control, including Barrington’s nucleus or the pontine micturition center (PMC) in the dorsomedial pontine tegmentum [Fowler et al., 2008]. These structures directly excite bladder motoneurons and indirectly inhibit urethral sphincter motoneurons via inhibitory interneurons in the medial sacral cord. The periaqueductal grey (PAG) receives bladder filling information, and the pre-optic area of the hypothalamus is probably involved in the initiation of micturition. According to PET-scan and functional imaging studies in humans, these supraspinal regions are active during micturition [Blok et al., 1998; Nour et al., 2000; Athwal et al., 2001; Griffiths et al., 2007; 2008; Hruz et al., 2008; Mehnert et al., 2008; Tadic et al., 2008; Griffiths, 2011].

Bladder emptying and urine storage involve a complex pattern of efferent and afferent signalling in parasympathetic, sympathetic, somatic, and sensory nerves. These nerves are parts of reflex pathways, which either keep the bladder in a non-contracted state, enabling urine storage at low intravesical pressure, or which initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Contraction of the detrusor smooth muscle and relaxation of the outflow region result from activation of parasympathetic neurones located in the sacral parasympathetic nucleus (SPN) in the spinal cord at the level of S2-S4 [de Groat et al., 1993; Beckel and Holstege, 2011]. The postganglionic neurones in the pelvic nerve mediate the excitatory input to the human detrusor smooth muscle by releasing acetylcholine (ACh) acting on muscarinic receptors. However, an atropine-resistant component has been demonstrated, particularly in functionally and morphologically altered human bladder tissue (see below). The pelvic nerve also conveys parasympathetic fibres to the outflow region and the urethra. These fibres exert an inhibitory effect and thereby relax the outflow region. This is mediated partly by release of nitric oxide [Andersson and Persson, 1993], although other transmitters might be involved [Bridgewater and Brading, 1993; Hashimoto et al., 1993; Werkström et al., 1995].

III. PERIPHERAL NERVOUS CONTROL

Figure 1 : Components of the micturition reflex.
Figure 2: Activity in the micturition reflex during storage. The pontine micturition center is inhibited by impulses from the prefrontal cortex, afferent impulses unable to initiate micturition. Activities in the hypogastric and pudendal nerves keep the bladder relaxed and the outflow region contracted.

Figure 3: Activity in the micturition reflex during voluntary voiding. The inhibitory impulses from the prefrontal cortex pontine micturition center are removed and afferent impulses are able to initiate micturition. Activities in the hypogastric and pudendal nerves are inhibited, the outflow region is relaxed, and the bladder is contracted by the activity in the pelvic nerve.
Most of the sympathetic innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoraco-lumbar region (T10-L2) of the spinal cord [Beckel and Holstege, 2011]. The axons travel either through the inferior mesenteric ganglia and the hypogastric nerve, or pass through the paravertebral chain and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric and pelvic nerves [Lincoln and Burnstock, 1993].

The predominant effects of the sympathetic innervation of the lower urinary tract are inhibition of the parasympathetic pathways at spinal and ganglion levels (demonstrated in animals), and mediation of contraction of the bladder base and the urethra [shown in animals and man, see Andersson, 1993]. However, the adrenergic innervation of the bladder body is believed to inactivate the contractile mechanisms in the detrusor directly. Noradrenaline (norepinephrine) is released in response to electrical stimulation of detrusor tissues in vitro, and the normal response of detrusor tissues to released noradrenaline is relaxation [Andersson, 1993].

The somatic innervation of the urethral rhabdosphincter and of some perineal muscles (for exam-
ple compressor urethrae and urethrovaginal sphincter), is provided by the pudendal nerve [Beckel and Holstege, 2011]. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2-S4) in a region called Onuf’s (Onufrowicz’s) nucleus.

Most of the sensory innervation of the bladder and urethra reaches the spinal cord via the pelvic nerve and dorsal root ganglia [Kanai and Andersson, 2010]. In addition, some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord [Lincoln and Burnstock, 1993]. The most important afferents for the micturition process are myelinated Aδ-fibres and unmyelinated C-fibres travelling in the pelvic nerve to the sacral spinal cord, conveying information from receptors in the bladder wall to the spinal cord. The Aδ-fibres respond to passive distension and active contraction, thus conveying information about bladder filling [Janig and Morrison, 1986]. C-fibres have a high mechanical threshold and respond primarily to chemical irritation of the bladder mucosa [Habler et al., 1990] or cold [Fall et al., 1990]. Following chemical irritation, the C-fibre afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [Habler et al., 1990]. These fibres are normally inactive and are therefore termed “silent fibres”.

IV. PATHOGENESIS OF BLADDER CONTROL DISORDERS

As pointed out previously, bladder control disorders can be divided into two general categories: disorders of filling/storage and disorders of voiding [Wein, 2012]. Storage problems can occur as a result of weakness or anatomical defects in the urethral outlet, causing stress urinary incontinence. Failure to store also occurs if the bladder is overactive, as in the overactive bladder (OAB) syndrome. The prevalence varies with the criteria used for diagnosis, but according to Irwin et al. [2006], using the ICS definition of 2002 [Abrams et al., 2002], the overall prevalence of OAB, based on computer assisted telephone interviews (the EPIC study) was 11.8%; rates were similar in men and women and increased with age [Irwin et al., 2006]. A similar study based on a cross Canada telephone survey found the prevalence of OAB to be 13 % in men and 14.7% in women [Herschorn et al., 2008]. In a Finnish study, taking into account bother, the prevalence of clinically meaningful OAB was much lower than reported in these studies [Vaughan et al., 2011].

OAB (symptomatic diagnosis) is often assumed to be caused by detrusor overactivity (DO; urodynamic diagnosis), even if this does not always seem to be the case [Hyman et al., 2001; Digesu et al., 2003; Hashim and Abrams, 2004; Aschkenazi et al., 2007]. DO/OAB can occur as a result of sensitization of afferent nerve terminals in the bladder or outlet region, changes of the bladder smooth muscle secondary to denervation, or consequent upon damage to the central nervous system (CNS) inhibitory pathways, as can be seen in various neurological disorders, such as multiple sclerosis, cerebrovascular disease, Parkinson’s disease, brain tumors, and spinal cord injury [Andersson and Pehrson, 2003; Ouslander, 2004; Banakhar et al., 2012; Wein and Dmochowski, 2012]. Urinary retention and overflow incontinence can be observed in patients with urethral outlet obstruction (e.g. prostate enlargement), decreased detrusor contractility, or both), neural injury, and/or diseases that damage nerves (e.g. diabetes mellitus), or in those who are taking drugs that depress the neural control of the bladder or bladder smooth muscle directly [Wein, 2011].

V. BLADDER CONTRACTION

Normal bladder contraction in humans is mediated mainly through stimulation of muscarinic receptors in the detrusor muscle [Andersson and Wein, 2004] (Figure 6). Atropine resistance, i.e. contraction of isolated bladder muscle in response to electrical nerve stimulation after pretreatment with atropine, has been demonstrated in most animal species, but seems to be of little importance in normal human bladder muscle [Andersson, 1993; Bayliss et al., 1999]. However, atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions have been reported in normal human detrusor and may be caused mainly by adenosine triphosphate (ATP) [Andersson, 1993; Bayliss et al., 1999, Andersson and Wein, 2004; Kennedy et al., 2007]. ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G-protein-coupled receptor family (P2Y) [Ford and Cockayne, 2011]. Seven P2X subtypes and eight P2Y subtypes have been identified. In several species (rabbit, cat, rat, and human), various studies suggested that multiple purinergic excitatory receptors are present in the bladder [de Groat and Yoshimura, 2001; Ford and Cockayne, 2011]. Immunohistochemical experiments with specific antibodies for different P2X receptors showed that P2X1 receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder. Excitatory receptors for ATP are present in parasympathetic ganglia, afferent nerve terminals, and urothelial cells [de Groat and Yoshimura, 2001]. P2X3 receptors, which have been identified in small-diameter afferent neurons in dorsal root ganglia, have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus
of afferent nerves. In P2X3 knockout mice, afferent activity induced by bladder distension was significantly reduced [Cockayne et al., 2000; Ford et al., 2006; Ruggieri et al., 2006; Ford and Cocke-eyne, 2011]. These data indicate that purinergic receptors are involved in mechanosensory signaling in the nonprimate mammalian bladder.

A significant degree of atropine resistance may exist in morphologically and/or functionally changed bladders, and has been reported to occur in hypertrophic bladders [Sjögren et al., 1982], interstitial cystitis [Palea et al., 1993], neurogenic bladders [Wammack et al., 1995], and in the aging bladder [Yoshida et al., 2001]. The importance of the NANC component to detrusor contraction in vivo, normally, and in different micturition disorders, remains to be established [Andersson, 2006].

VI. MUSCARINIC RECEPTORS

The neurotransmitter ACh acts on two classes of receptors, the nicotinic and the muscarinic receptors. While the former play a role in the signal transduction between neurones or between neurones and skeletal muscle (e.g. in the distal urethra), the signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors [Abrams and Andersson, 2007]. Importantly, the endogenous muscarinic receptor agonist ACh is not necessarily derived only from parasympathetic nerves in the urinary bladder, but can also be formed and released non-neuronally by the urothelium [Bschleiper et al., 2007; Mansfield et al., 2005; Zarghooni et al., 2007, Andersson, 2011]. Five subtypes of muscarinic receptors have been cloned in humans and other mammalian species, which are designated M1-5 [Caulfield and Birdsall 1998]. Based upon structural criteria and shared preferred signal transduction pathways, the subtypes can be grouped into M1, M3 and M5 on the one hand and the subtypes M2 and M4 on the other. The former prototypically couple via pertussis toxin-insensitive Gq proteins to stimulation of a phospholipase C followed by elevation of intracellular calcium and activation of a protein kinase C, whereas the latter prototypically couple via pertussis toxin-sensitive Gi proteins.

Figure 6: Muscarinic M3 receptor-mediated detrusor activation. Calcium influx and activation of the Rhoki-nase system are the main pathways mediating activation of the contractile system in the detrusor.
to inhibition of adenylyl cyclase and modulation of several ion channels [Caulfield and Birdsall, 1998]. While sensitive molecular techniques such as reverse transcriptase polymerase chain reaction can detect mRNA for all five subtypes in the mammalian bladder [Abrams et al., 2006; Hegde, 2006], studies at the protein level, e.g. based upon radioligand binding, have typically detected only M2 and M3 receptors, with the former dominating quantitatively [Abrams et al., 2006; Hegde, 2006, Andersson, 2011]. Inhibitory pre-junctional muscarinic receptors have been classified as M2 in the rabbit and rat, and M4 in the guinea-pig, rat and human [d’Agostini et al., 2000; see Andersson, 2011] bladder. These receptors appear to be of the M1 subtype in the rat and rabbit urinary bladder, but have also been detected in human bladders. The muscarinic facilitatory mechanism seems to be upregulated (M3 receptors) in overactive bladders from chronic spinal cord transected rats.

Apparently, most muscarinic receptors in the bladder are found on the smooth muscle cells of the detrusor. While the detrusor expresses far more M2 than M3 receptors, it appears that detrusor contraction under physiological conditions is largely if not exclusively mediated by the M3 receptor [Hegde et al., 1997; Chess-Williams et al., 2001; Fetscher et al., 2002; Kories et al., 2003; Schneider et al., 2004a, b]. Studies in knock-out mice confirm this conclusion [Matsui et al., 2000, 2002; Stengel et al., 2002; Ehler et al., 2007]. Under physiological conditions M2 receptor-selective stimulation causes little contraction [Schneider et al., 2005a], but rather appears to act mainly by inhibiting \( \beta \)-adrenoceptor-mediated detrusor relaxation [Hegde et al., 1997; Ehler et al., 2007; Matsui et al., 2003]. It has been proposed that M2 receptors can also directly elicit bladder contraction under pathological conditions [Braverman et al., 1998; 2002; 2003; 2006; Pontari et al., 2003], but such observations have not been confirmed by other investigators using distinct methodological approaches [Schneider et al., 2005a; b].

Based upon the prototypical signalling pathway of M3 receptors [Caulfield and Birdsall, 1998] and the presence of phospholipase C stimulation by muscarinic agonists in the bladder [Kories et al., 2003; Schneider et al., 2005a] it had originally been believed that muscarinic receptor-mediated contraction is largely mediated by an activation of phospholipase C [Ouslander, 2004]. While some earlier data had supported this concept, it now appears clear that, at least in rat, mice and humans, muscarinic receptor-mediated bladder contraction occurs largely independent of phospholipase C [Schneider et al., 2004; Wegener et al., 2004; Frazier et al., 2007]. Rather, alternative signalling pathways such as opening of L-type calcium channels and activation of a rho-kinase (Figure 6) appear to contribute to muscarinic receptor-mediated bladder contraction in a major way [Frazier et al., 2008]. More recently, muscarinic receptors have also been identified in the urothelium [Chess-Williams, 2002; Kumar et al., 2005]. Similarly to the findings in bladder smooth muscle, the muscarinic receptors in the urothelium mainly belong to the M2 and M3 subtype, with the former dominating quantitatively [Mansfield et al., 2005; Bschleiper et al., 2007]. At present the functional role of muscarinic receptors in the urothelium has largely been studied indirectly, i.e. by investigating the effects of urothelial removal or of administration of pharmacological inhibitors. These data indicate that muscarinic stimulation of the urothelium causes release of an as yet unidentified factor which inhibits detrusor contraction [Hawthorn et al., 2000; Wuest et al., 2005; Sadananda et al., 2008]. Some data indicate that muscarinic receptors in the urothelium may partly act by releasing nitric oxide (NO) [Andersson et al., 2008a]. Muscarinic receptor blockade in urothelial cells may also reduce ATP release induced by stretch [Young et al., 2012]. Thus, it appears that muscarinic receptors in the urothelium also contribute to the regulation of overall bladder function but their specific roles in health and disease have not been fully established.

Assuming an involvement of muscarinic receptors in physiological voiding contractions of the bladder, numerous studies have explored whether or not the activity of the muscarinic system may play a causative role in bladder dysfunction. This could involve, e.g., an enhanced expression of such receptors and/or an increased functional responsiveness. In vitro, an increased sensitivity to muscarinic receptor stimulation was found in both idiopathic and neurogenic overactive human detrusors [Stevens et al., 2006]. However, according to Michel and Barendrecht [2008] the overall balance of available studies suggests that the muscarinic receptor system is not hyperactive under conditions of DO and, if anything, can be even hypoactive [Michel and Barendrecht, 2008]. This does not exclude a contribution to DO of ACh and muscarinic receptor stimulation during bladder filling (see below). It appears that the contribution of muscarinic mechanisms to the overall regulation of bladder contractility decreases in favour of non-cholinergic mechanisms under pathological conditions [Yoshida et al., 2001; 2008; Rapp et al., 2005]. These observations may help to explain the moderate efficacy of muscarinic receptor antagonists relative to placebo in controlled clinical studies [Herbison et al., 2003; Chapple et al., 2005; 2008; Novara et al., 2008; Shamiyian et al., 2008].
B. Drugs used for treatment of overactive bladder symptoms/ detrusor overactivity

It has been estimated that more than 50 million people in the developed world are affected by urinary incontinence, and an abundance of drugs has been used for treatment (Table 2). Helfand and co-workers showed that in a cohort of 7,244,501 patients over 45 years with an OAB diagnosis, 24.4% of these were treated mainly with antimuscarinic agents; 75.6% went untreated. Only 25.6% of those treated were men. [Helfand et al., 2009]. As underlined by several other subcommittees, drugs may be efficacious in some patients, but they do have side effects, and frequently are not continued indefinitely. Hence it would be worth considering them as an adjunct to conservative therapy.

I. ANTIMUSCARINIC (ANTICHOLINERGIC) DRUGS

• Mechanism of action

Antimuscarinics block, more or less selectively, muscarinic receptors irrespective of location [Abrams and Andersson, 2007; Andersson 2011b] (Figure 7). The common view is that in OAB/DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the lower urinary tract [Andersson, 2004, 2007]. Furthermore, antimuscarinics are usually competitive antagonists. This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased, otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, but in the dose range used for beneficial effects in OAB/DO (Figure 8), there is little evidence for a significant reduction of the voiding contraction [Finney et al., 2006]. However, there is good experimental evidence that the drugs act during the storage phase by decreasing the activity in afferent nerves (both C- and Aδ-fibres) from the bladder [De Laet et al., 2006; Ijima et al., 2007] (Figure 9).

As mentioned previously, muscarinic receptors are found on bladder urothelial cells where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest [Andersson, 2002; Birder and de Groat, 2007], but whether the muscarinic receptors

**Figure 7: Important sites of action of antimuscarinics.**

on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues [2004; 2006; 2008] found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and, at least partly, generated by the urothelium. There is also indirect clinical evidence for release of ACh during bladder filling. Smith and co-workers [1974] found that in patients with recent spinal-cord injury, inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch and colleagues [2001] inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or urinary incontinence. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of overactive bladder, but in no patients without specific complaints suggesting DO. Thus, during the storage phase, ACh and ATP may be released from both neuronal and non-neuronal sources (eg, the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB/DO and represent possible targets for antimuscarinic drugs.

**Pharmacologic properties**

Generally, antimuscarinics can be divided into tertiary and quaternary amines [Guay, 2003, Abrams and Andersson, 2007]. They differ with regards to lipophilicity, molecular charge, and even molecular size, tertiary compounds generally having higher lipophilicity and molecular charge than quaternary agents. Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl-tolterodine), oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the CNS, dependent on their individual physicochemical properties. High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood brain barrier, but in some cases, such as darifenacin, that is compensated by active transport out of the CNS by the product of the MDR1 gene. Quaternary ammonium compounds, like propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects [Guay 2003]. They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increases in heart rate, and dryness of mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites [Guay 2003]. The most commonly involved P450 enzymes are CYP2D6, and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration/effect of the antimuscarinic and/or interacting drug. Antimuscarinics secreted by the renal tubules (eg trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism. Some antimuscarinics and their active metabolites are excreted in urine in amounts that may affect the mucosal muscarinic receptors from the luminal side. This has not yet been demonstrated to imply superior clinical efficacy [Andersson et al., 2008b].

**Figure 8:** Rationale for use of antimuscarinics for treatment of OAB/DO. Blockade of muscarinic receptors at both detrusor and non-detrusor sites may prevent OAB symptoms and DO without depressing the contraction during voiding. The «Therapeutic window for OAB» can be obtained in most patients with recommended doses of antimuscarinics.

**Figure 9:** Influence of darifenacin on volume-related nerve activity in Aδ afferents (A) and C afferents (B) in the rat pelvic nerve. From Iijima et al. *Eur Urol.* 2007 Sep;52(3):842
Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence [Andersson, 2004, Andersson et al., 2009]. However, currently used drugs lack selectivity for the bladder, and effects on other organ systems may result in side effects, which limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow angle glaucoma.

Theoretically, drugs with selectivity for the bladder could be obtained, if the subtype(s) mediating bladder contraction, and those producing the main side effects of antimuscarinic drugs, were different. Unfortunately, this does not seem to be the case. One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical only in a limited number of patients.

Several antimuscarinic drugs are and have been used for treatment of OAB/DO. For some of them, documentation of effects is not based on randomized controlled trials (RCTs) satisfying currently required criteria, and some drugs can be considered as obsolete (e.g., emepaprom). Information on these drugs has not been included, but can be found elsewhere [Andersson, 1988; Andersson et al., 1999].

1. ANTIMUSCARINICS WITH “SPECIFIC” ACTION

Below data on the different antimuscarinics are presented. These drugs are assumed to block only muscarinic receptors (motivating the term “specific”). The amount of information for the individual drugs varies, and so does the degree of details from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug.

a) Atropine sulfate

Atropine (dl-hyoscyamine) is rarely used for treatment of OAB/DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with neurogenic DO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials [Ekström et al., 1992; Glickman et al., 1995; Deaney et al., 1998; Enskat et al., 2001; Fader et al 2007]. It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with neurogenic DO [Fader et al., 2007].

The pharmacologically active antimuscarinic component of atropine is l-hyoscyamine.

Assessment

Although still used, few clinical studies are available to evaluate the antimuscarinic activity of l-hyoscyamine sulfate [Muskat et al., 1996]. For assessment, see Table 2.

b) Darifenacin hydrobromide

Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the gastrointestinal tract after oral administration, and extensively metabolised in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range [Skerjanec, 2006]. UK-148,993, UK-73,689, and UK-88862 are the three main circulating darifenacin metabolites of which only UK-148,993 is said to have significant anti-muscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects [Michel and Hegde, 2006]. The metabolism of darifenacin by CYP3A4 suggests that co-administration of a potent inhibitor of this enzyme (e.g., ketoconazole) may lead to an increase in the circulating concentration of darifenacin [Kerbusch et al., 2003].

Darifenacin is a relatively selective muscarinic M3 receptor antagonist. In vitro, it is selective for human cloned muscarinic M3 receptors relative to M1, M2, M4 or M5 receptors. Theoretically, drugs with selectivity for the M3 receptor can be expected to have clinical efficacy in OAB/DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes [Andersson, 2002]. However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity, but also on its pharmacokinetics, and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg per day. The clinical effectiveness of the drug has been documented in several RCTs [Haab et al., 2004; Cardozo and Dixon 2005; Steers et al., 2005; Chapple et al., 2005; Foote et al., 2005; Hill et al., 2006; Haab et al., 2006; Zinner et al., 2006; Chapple et al., 2007; Abrams et al., 2008, Chancellor et al., 2008; Dwyer et al., 2008; for reviews, see Guay, 2005; Zinner, 2007; Novara et al., 2008; Chapple et al., 2008]. Haab et al. [2004] reported a multicentre, double-blind, placebo-controlled, parallel-group study which enrolled 561 patients (19–88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomised [1:4:2:3] to once-daily oral darifenacin controlled-release tablets: 3.75 mg (n=53), 7.5 mg (n=229) or 15 mg (n=115) or matching placebo (n=164) for 12 weeks. Patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean volume voided), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads and nocturnal awakenings due to OAB using an electronic diary during weeks 2, 6 and 12 (directly preceding clinic visits). Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg, respectively, was significantly superior
to placebo for (median) improvements in micturition frequency (7.5 mg: -1.6; 15 mg: -1.7; placebo -0.8, frequency of urgency per day [-2.0; -2.0; -0.9], and number of incontinence episodes leading to a change in clothing or pads [-4.0; -4.7; -2.0]. There was no significant reduction in nocturnal awakenings due to OAB. The most common adverse events were mild-to-moderate dry mouth and constipation with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth and discontinuation related to constipation was rare (0.6% placebo versus 0.9% darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosing (7.5 or 15 mg), was found to be effective and well-tolerated [Steers et al., 2005]. A 2-year open label extension study of these investigations [i.e., Haab et al., 2004; Steers et al., 2005], confirmed a favorable efficacy, tolerability and safety profile [Haab et al., 2006].

A review of the pooled darifenacin data from the three phase III, multicentre, double blind clinical trials in patients with OAB was reported by Chapple et al. [2005] After a 4-week washout/run-in period, 1,059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least six months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, -8.8 [-68.4%; placebo -54%, P<0.004]; 15 mg, -10.6 [-76.8%; placebo 58%, p<0.001]. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated.

The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg 0.6% of patients; darifenacin 15 mg 2.1%; placebo 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (>65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability and safety profile [Foote et al., 2005, Zinner et al., 2005; Hill et al. 2006].

The time-to-effect with darifenacin was analyzed in a pooled analysis of efficacy and safety data from 1,059 patients participating in three double-blind 12-week studies Khullar et al [2011]. Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days.

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin, on the ‘warning time’ associated with urinary urgency. Warning time was defined as the time from the first sensation of urgency to the time of voluntary micturition or incontinence. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks’ washout, 2 weeks’ medication-free run-in and a 2-week treatment phase [Cardozo and Dixon, 2005]. Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant (p<0.004) increase in mean warning time with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to -1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a ≥30% increase in mean warning time. There were methodological problems associated with this study; it utilized a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centred environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study [Zinner et al., 2006] on 445 OAB patients, darifenacin treatment (15 mg) resulted in numerical increases in warning time, however, these were not significant compared to placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health related quality of life (HRQoL) in patients with OAB [Abrams et al., 2008], and such improvements were sustained as shown in a two-year extension study [Dwyer et al., 2008]. It was shown that neither the positive effects on micturition variables, nor on HRQoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioural modification programme including timed voiding, dietary modifications and Kegel exercises [Chancellor et al., 2008].

Since darifenacin is a substrate for the P-glycoprotein drug efflux transporter [Miller et al., 2011;
To study whether darifenacin had any effect on QT/QTc intervals [Serra et al., 2005] performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steadystate therapeutic (15 mg) and supratherapeutic (75 mg) doses, alongside controls receiving placebo or moxiloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic Tmax versus placebo were −0.4 and −2.2 milliseconds in the darifenacin 15mg and 75 mg groups, respectively, compared with +11.6 milliseconds in the moxiloxacin group (P < .01). The conclusion was that darifenacin does not prolong the QT/QTc interval.

Darifenacin 15 mg per day given to healthy volunteers did not change heart rate significantly compared to placebo [Olshansky et al., 2008].

**Assessment**

Darifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and tolerability and safety seems acceptable.

c) **Fesoterodine fumarate**

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxy-methyltolterodine (5-HMT) by non-specific esterases [Michel, 2008, Malhotra et al., 2009a]. This compound, which is is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic receptor antagonist [Ney et al., 2008]. All of the effects of fesoterodine in man are thought to be mediated via 5-HT3, since the parent compound remains undetectable upon oral dosing. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Since the renal clearance of 5-HMT is about 250 mL/min, with >15% of the administered fesoterodine dose excreted as unchanged 5-HM, this raises the possibility that 5-HMT also could work from the luminal side of the bladder [Michel, 2008]. The bioavailability of fesoterodine, averaging 52%, was independent of food intake and the drug may be taken with or without a meal [Malhotra et al., 2009b]. Peak plasma concentration of 5-HMT is reached at 5 h following oral administration and has a half-life of 7–9 h [Malhotra et al., 2008]. The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function due to the combination of renal excretion and hepatic metabolism of 5-HMT [Malhotra et al., 2009c; de Mey et al., 2011].

The clinical efficacy and tolerability of fesoterodine have been documented in several RCTs [Chapple et al., 2007; Nitti et al., 2007; Dmochowski et al., 2010; Herschhorn et al., 2010; Kaplan et al., 2010; Nitti et al., 2010; see Dell’Utri et al., 2012]. In a multicenter, double-blind, double-dummy RCT with tolterodine ER, 1132 patients were enrolled and received treatment [Chapple et al., 2007]. The trial showed that both the 4 and 8 mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8 mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER. Only one subject from the fesoterodine 8 mg group and one subject from the tolterodine ER group withdrew from the study due to dry mouth. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs [Khullar et al., 2008]. Fesoterodine 8 mg performed better than the 4 mg dose in improving urgency and urge UI as recorded by 3-day bladder diary, offering the possibility of dose titration.

A head to head placebo controlled trial has been completed comparing fesoterodine 8mg to tolterodine extended release 4mg and placebo [Herschorn et al., 2010]. The study randomized 1,590 patients to assess the primary outcome of reduced urgency incontinence episodes at 12 weeks. Fesoterodine produced statistically significant improvements in urgency incontinence episodes, complete dry rates (64.0% vs. 57.2%, p = 0.015), mean voided volume per void (+32.9 ml vs. +23.5 ml, p = 0.005), and in patients’ assessments of bladder related problems as measured by OAB questionnaire (except sleep domain), Patient Perception of Bladder Condition (40% vs. 33% with > 2 point improvement, p < 0.001), and Urgency Perception Scale (46% vs. 40% with improvement, p = 0.014) compared with tolterodine. The clinical significance of these statistically significant findings is questionable as there was no difference between agents with respect to number of micturitions, urgency episodes, and frequency-urgency sum per 24 hours. The improved efficacy of fesoterodine came at the cost of greater dry mouth (27.8% vs. 16.4%), headache (5.6% vs. 3.4%), constipation (5.4% vs. 4.1%), and withdrawal rates (6% vs. 4%). Nonetheless, this first head to head trial comparing two drugs in class supports the use of fesoterodine 8mg for additional benefit over tolterodine ER 4 mg.

Wyndaele et al. [2009] reported the first flexible-dose open-label fesoterodine trial, which was conducted at 80 different centres worldwide and comprised 516 participants (men and women) >18 years who self-reported OAB symptoms for at least 3 months...
before screening and had been treated with either tolterodine or tolterodine ER within 2 years without symptom improvement. Approximately 50% opted for dose escalation to 8 mg at week 4. Significant improvements from baseline to week 12 were observed in micturitions, urgency urinary incontinence episodes, micturition-related urgency episodes and severe micturition-related urgency episodes per 24 h. Significant improvements from baseline were observed in QoL parameters. Dry mouth (23%) and constipation (5%) were the most common adverse events; no safety issues were identified.

The largest double-blind, double-dummy, flexible-dose fesoterodine RCT, which was conducted at 210 different centres with a total of 2,417 patients enrolled, was performed by Kaplan et al. [2010]. All patients were healthy, >18 years of age and self-reported OAB symptoms for at least 3 months. The 960 patients who received fesoterodine 8 mg showed significantly greater mean improvements at week 12 in most efficacy parameters (diary variables) than those receiving either tolterodine ER or placebo; UUI and urgency episodes, micturition frequency and MVV. No statistically significant changes were shown in reduction of nocturnal micturitions compared with the tolterodine group, whereas when comparing the mean changes in nighttime micturition with the placebo group a significant difference was found. This phase III study confirmed the superiority of fesoterodine 8 mg over tolterodine ER 4 mg for improving of UUI and urgency episodes and 24-h micturitions but not for MVV and nocturia. In another RCT of flexible-dose fesoterodine, Dmchowski et al. reported statistically significant improvements at week 12 in the mean number of micturition per 24 h and in both UUI and urgency episodes. Between groups, difference in nocturnal micturition was not statistically significant.

Nitti et al. [2010] determined whether the presence of DO in patients with OAB and urgency urinary incontinence was a predictor of the response to treatment with fesoterodine in a phase 2 randomized, multicentre, placebo-controlled trial. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose-proportional and associated with significant improvements in OAB symptoms, indicating that the response to OAB pharmacotherapy in patients with UUI was independent of the urodynamic diagnosis of DO.

Kelleher et al. [2008] evaluated the effect of fesoterodine on HRQoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies Chapple et al., 2007; Nitti et al., 2007] were analysed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine extended release (tolterodine-ER) 4 mg. By the end of treatment, all active-treatment groups had significantly improved HRQoL compared with those on placebo. In a post hoc analysis of data pooled from these studies, significant improvements in all KHQ domains, ICIQ-SF scores, and bladder related problems were observed at months 12 and 24 compared to open label baseline [Kelleher et al., 2011]. The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

Malhotra et al. [2010] performed a thorough QT study to investigate the effects of fesoterodine on cardiac repolarization in a parallel-group study. Subjects were randomly assigned to receive double-blind fesoterodine 4 mg, fesoterodine 28 mg, or placebo or open-label moxifloxacin 400 mg (positive control) for 3 days. Electrocardiograms (ECGs) were obtained on Days -1 (baseline), 1, and 3. The primary analysis was the time-averaged changes from baseline for Fridericia’s-corrected QT interval (QTcF) on Day 3. Among 261 subjects randomized to fesoterodine 4 mg (n = 64), fesoterodine 28 mg (n = 68), placebo (n = 65), or moxifloxacin 400 mg (n = 64), 256 completed the trial. The results indicated that fesoterodine is not associated with QTc prolongation or other ECG abnormalities at either therapeutic or supratherapeutic doses.

Assessment

Fesoterodine has a well-documented beneficial effect in OAB (Table 2), and the adverse event profile seems acceptable.

d) Imidafenacin

Imidafenacin (KRP-197/ONO-8025, 4-(2-methyl-1H-imidazol-1-yl)-2,2-diphenylbutanamide) is an antagonist for the muscarinic ACh receptor with higher affinities for M3 and M1 receptors than for the M2 receptor. Metabolites of imidafenacin (M-2, M-4 and M-9) had low affinities for muscarinic ACh receptor subtypes [Kobayashi, Yageta et al. 2007]. The drug blocks pre- as well as postjunctional muscarinic receptors and was shown to block both detrusor contractions and acetylcholine release [Murakami, Yoshiida et al. 2003]. The receptor binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than submaxillary gland or colon [Yamada, Seki et al. 2011], and in rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect here than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made.

Imidafenacin is well absorbed form the gastrointestinal tract and its absolute bioavailability in human is 57.8% [Ohmori, Miura et al. 2007; Ohno, Nakade et al. 2008]. It is rapidly absorbed with maximum plasma concentration occurring 1-3h after oral administration [Ohno, Nakade et al. 2008]. Metabolites in the plasma are produced mainly by
first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs [Kanayama, Kanari et al. 2007].

Kitagawa et al. [Kitagawa, Kuribayashi et al. 2011] reported that the subjective efficacy of imidafenacin was observed from 3 days after the commencement of administration and that mean total OABSS decreased gradually during 2 weeks after administration.

A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety/tolerability, and dose-response relationship of imidafenacin [Homma, Yamaguchi et al. 2008]. Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin/day (99 patients), 0.2 mg of imidafenacin/day [100], 0.5 mg of imidafenacin/day [101], or a placebo [101]. After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo was observed (P < 0.0001). Compared with the placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency, and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased dose-dependently. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment due to dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

A randomized, double-blind, placebo- and propiverine-controlled trial of 781 Japanese patients with OAB symptoms were conducted by Homma et al.[Homma and Yamaguchi 2009]. They were randomized to imidafenacin (324), propiverine [310], or a placebo [147]. After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group (P < 0.0001). The non-inferiority of imidafenacin compared with propiverine was confirmed for the reduction in using incontinence episodes (P = 0.0014, non-inferiority margin: 14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine (P = 0.0101). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group (P < 0.0001). However, there were no clinical arrhythmia and clinical arrhythmic events in any of the treatment groups.

The long-term safety, tolerability, and efficacy imidafenacin was studied in Japanese OAB patients [Homma and Yamaguchi 2008], of whom 478 received treatment and 376 completed a 52-week program. Imidafenacin was well tolerated, the most common adverse event being a dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 through week 52. After 52 weeks, imidafenacin produced mean changes from baseline in the number of incontinence episodes (-83.51%), urgency incontinence episodes (-84.21%), voiding frequency (-2.35 micturitions/day), urgency episodes (-70.53%), and volume voided per micturition (28.99 mL). There were also significant reductions from baseline in all domains of the King’s Health Questionnaire. received the treatment and 376 patients completed the 52-week program. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or post-void residual volume.

A 52-week prospective, open randomized comparative study to evaluate the efficacy and tolerability of imidafenacin (0.2 mg/day) and solifenacin (5 mg/day) was conducted in a total of 41 Japanese patients with untreated OAB [Zaitsu, Mikami et al. 2011]. They were randomly assigned to imidafenacin and solifenacin groups. There was no difference in OABSS and KHQ scores between the two groups, but the severity and incidence of adverse events caused by the drugs showed increased differences between the groups with time. The severity of dry mouth and the incidence of constipation were significantly lower in the imidafenacin group (P = 0.0092 and P = 0.0013, resp.). An important limitation of this study is the low number of patients. Only 25 patients (17 males 8 females) were available for long-term analysis.

Assessment.

Imidafenacin seems to be effective and to have an acceptable tolerability. However, the documentation is relatively scarce and the drug is not yet available in the Western countries.

e) Propantheline bromide

Propantheline is a quaternary ammonium compound, non-selective for muscarinic receptor subtypes, which has a low (5 to 10%) and individually varying biological availability. It is metabolized (metabolites inactive) and has a short half-life (less than 2 h) [Beermann et al., 1972]. It is usually given in
a dose of 15 to 30 mg 4 times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher dosages are required. Using this approach in 26 patients with detrusor overactivity contractions [Blaiivas et al., 1980] in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline 15 mg four times daily. The range of dosages varied from 7.5 to 60 mg four times daily. In contrast, Thüroff et al. [1991] comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo, in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency and incontinence related to DO (154 patients), found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic DO), and with dose titration, Holmes et al. [1991] found no differences in efficacy between oxybutynin and propantheline. Controlled randomized trials (n=6) reviewed by Thüroff et al [1998], confirmed a positive, but varying, response to the drug.

**Assessment**

Although the effect of propantheline on OAB/DO has not been well documented in controlled trials satisfying standards of today, it can be considered effective, and may, in individually titrated doses, be clinically useful (Table 2). No new studies on the use of this drug for treatment of OAB/DO seem to have been performed during the last decade.

f) Solifenacin succinate

Solifenacin succinate (YM905) is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45-68 hours [Kuipers et al., 2002; Smulders et al., 2002; 2004]. It undergoes significant hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) Cmax and AUC0-inf were increased by only approximately 40% and 56%, respectively [Swart et al., 2006]. Solifenacin has a modest selectivity for M3 over M2 (and M1) receptors [Abrams and Andersson, 2007]. Supporting an effect on sensory function by solifenacin, 15 women with DO receiving 10 mg/day of the drug showed an increase in the area under the bladder-volume sensation curve [Lowenstein et al., 2011] Solifenacin also increased maximum bladder capacity, a finding in agreement with other studies Tanaka et al., 2010; Hsiao et al., 2011.

Two large-scale phase 2 trials with parallel designs, comprising men and women, were performed [Chapple et al., 2004a, Smith et al., 2002]. The first dose-ranging study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO [Chapple et al., 2004a]. Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase 3 studies of patients with OAB included at least 8 micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (-2.21), 10 mg (-2.47), and 20 mg (-2.75), but not in patients receiving placebo (-1.03) or tolterodine (-1.79). This effect was rapid with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there was numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. As the 5 mg and 10 mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies.

The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (USA) [Smith et al., 2002]. This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested in solifenacin trials and these findings demonstrate efficacy as early as one week. The 5 mg, 10 mg, and 20 mg dosing groups experienced statistically significant increases in volume voided; the 10 mg solifenacin dose was associated with statistically significant reductions in episodes of incontinence.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice daily), or placebo [Chapple et al., 2004b]. It should be noted that this study was powered only to compare active treatments to placebo. Compared with placebo (-8%), mean micturitions/24 h were significantly reduced with solifenacin 10 mg (-20%), solifenacin 5 mg (-17%), and tolterodine (-15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily. Cardozo et al. [2004] randomized 911 patients to 12-week once daily treatment with solifenacin 5 mg, solifenacin 10 mg or placebo. The primary efficacy variable was change from baseline to study end.
point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia and incontinence episodes per 24 hours, and mean volume voided per micturition. Compared with changes obtained with placebo (-1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.37) and 10 mg (-2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg: -1.63, 61%; 10 mg: -1.57, 52%), but not with placebo (-1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and mean volume voided per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs 2.3% with placebo). A 40-week follow up of these studies [i.e., Chapple et al., 2004b and Cardozo et al., 2004] demonstrated that the favourable profile, both in terms of efficacy and tolerability was maintained over the study period [Haab et al., 2005].

The STAR trial [Chapple et al., 2005; 2007] was a prospective, double blind, double-dummy, two-arm, parallel-group, 12-week study was conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and TOLT-ER 4 mg once daily in OAB patients. The primary effect variable was micturition frequency. After 4 weeks of treatment patients had the option to request a dose increase, but were dummyed throughout as approved product labelling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was “non-inferior” to tolterodine concerning the primary effect variable, micturition frequency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (-2.85 vs -2.42), incontinence (-1.60 vs -0.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (-1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30 and 6.4%, tolterodine 23 and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups.

Luo et al. [2012] performed a systematic review and meta-analysis of solifenacin RCTs and provided a comprehensive assessment regarding the efficacy and safety of the drug. Their results which largely confirmed what could be deduced from previously published information, indicated that solifenacin could significantly decrease the number of urgency episodes per 24 h, micturitions per 24 h, incontinence episodes per 24 h, nighttime micturitions per 24 h, and UUI episodes per 24 h, and improve volume voided per micturitions compared with the placebo or tolterodine treatment.

A number of studies and reviews have further documented the effects of solifenacin [Cardozo et al., 2006; Chapple et al., 2006; 2007; Maniscalco et al., 2006, see also Chapple et al., 2008; Novara et al., 2008; Toglia et al., 2009; Vardy et al., 2009; Serels et al., 2010; Luo et al., 2012], including men with OAB without bladder outlet obstruction [Kaplan et al., 2010;] In a pooled analysis of four RCTs, Abrams and Swift (2005) demonstrated positive effects on urgency, frequency and nocturia symptoms in OAB dry patients. In an analysis of four phase III clinical trials, Brubaker and FitzGerald [2007] confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg: -0.6, p<0.025; with 10 mg: -0.6, p<0.001 vs placebo: -0.4) but without nocturnal polyuria. A positive impact on nocturia and sleep quality in patients with OAB treated with solifenacin has also been reported in other studies [Takao et al., 2011; Yokoyama et al., 2011] Kelleher et al. [2006] and Staskin and Te [2006] presented data showing efficacy in patients with mixed incontinence.

A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (> 65 years) patients, and also showed a high level of persistence in a 40 week extension trial [Wagg et al., 2005]. Post-hoc analysis of two12-week, open label, flexible-dosing studies on 2645 patients over 65 years of age with OAB, revealed that solifenacin was associated with improvements in measures assessing patients’ perception of their bladder problems, symptom bother, and aspects of health-related quality of life [Capo et al., 2011]. Solifenacin was equally well tolerated in younger (<65 years) and older (>65 years) patients [Herschorn et al., 2001]. An exploratory pilot study with single doses of solifenacin 10 mg to 12 elderly volunteers suggested no clear propensity to impair cognitive functions [Wesnes et al., 2009].

Improvement of QoL by solifenacin treatment has been documented in several studies [Kelleher et al., 2005; Garely et al., 2006]. In 30 patients with multiple sclerosis, van Rey and Heesakkers [2011] improved OAB symptoms as well as neurogenic disease-specific QoL measures.

Information on solifenacin treatment in children is scare. In a prospective open label study in 72 children (27 with neurogenic bladders) Bolduc et al.[2010] improved urodynamic capacity and im-
proved continence. Chart review of 138 children with therapy resistant OAB treated with solifenacin increased mean voided volume and improved continence [Hoebekke et al., 2009].

In female volunteers, aged 19 to 79 years, the effect of 10 mg and 30 mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multi-dose, randomized, double-blind, placebo and positive-controlled (moxifloxacin 400 mg) trial. The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 4, 13: 90%CI) compared to the 10 mg (2 msec, -3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Michel et al. [2008] studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, post-marketing surveillance study. They concluded that “In real-life conditions, i.e. with inclusion of large numbers of patients with cardiovascular co-morbidities and taking comedication, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure”.

**Assessment**

Solifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and the adverse event profile seems acceptable.

**g) Tolterodine tartrate**

Tolterodine is is a tertiary amine, rapidly absorbed and extensive metabolized by the cytochrome P450 system (CYP 2D6). The major active 5-hydroxy-methyl metabolite (5-HMT) has a similar pharmacological profile as the mother compound [Nilvebrant et al., 1997], and significantly contributes to the therapeutic effect of tolterodine [Brynze et al., 1997; Brynne et al., 1998]. Both tolterodine and 5-HMT have plasma half-lives of 2-3 h, but the effects on the bladder seem to be more long-lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for <1-2.4% of the dose; 5 – 14% of 5-HMT is eliminated in the urine [Brynze et al., 1997]. Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim et al. [2005] and Chuang et al., [2008], do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT, implies limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects [Hills et al., 1998, Clemett et al., 2001; Salvatore et al., 2008]. However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT due to a low activity of CYP 2D6 [Diefenbach et al., 2008].

Tolterodine has no selectivity for muscarinic receptor subtypes, but is claimed to have functional selectivity for the bladder over the salivary glands [Stahl et al., 1995; Nilvebrant et al. 1997b]. In healthy volunteers, orally given tolterodine in a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug [Stahl et al., 1995]. However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated.

Animal experiments have suggested that antimuscarinics may affect signaling from the bladder [Andersson, 2011b]. Confirming data in humans were found by Vijaya et al. [2012]. In a randomized, placebo-controlled study, they evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO in comparison to placebo, by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 (described as urgency) and 250 Hz upon both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz (P-value <0.05).

Tolterodine is available as immediate-release (TOLT-IR; 1 or 2 mg; twice daily dosing) and extended-release (TOLT-ER) forms (2 or 4 mg; once daily dosing). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability [Van Kerrebroeck et al. 2001].

Several randomised, double blind, placebo-controlled studies on patients with OAB/DO (both idiopathic and neurogenic DO), have documented a significant reduction in micturition frequency and number of incontinence episodes [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment), and the OPERA (Overactive Bladder; Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily [Appell et al., 2001] in a 12-week randomized, double blind, parallel-group study including 378 patients with OAB. Participants had between 7 and 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main...
outcome measures adjusted for baseline (see also below: oxybutynin chloride). Dry mouth, the most common adverse event, was reported by 33% and 28% of participants taking OXY-ER and TOLT-IR, respectively. Rates of central nervous system and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study [Diokno et al., 2003], OXY-ER at 10 mg/d or TOLT-ER at 4 mg/d were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence (primary end point), total (urgency and non-urgency) incontinence, and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8 and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n=391) or TOLT-ER (n=399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable; including adverse events involving the central nervous system.

In the ACET (Antimuscarinic Clinical Effectiveness Trial) [Sussman and Garely, 2002] study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4 mg group (12%) than either the OXY-ER 5 mg (19%) or OXY-ER 10 mg groups (21%). More patients in the OXY-ER 10 mg group than the TOLT-ER 4 mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4 mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2 mg group, 59% in the OXY-ER 5 mg group and 60% in the OXY-ER 10 mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; p=0.05). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the the open label design of the study.

Zinner et al. [2002] evaluated the efficacy, safety, and tolerability of TOLT-ER in older (> or =65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments, safety, and tolerability endpoints were evaluated, relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; > or =65: ER 24.3%, placebo 7.2%). A few patients (< 2%) experienced severe dry mouth. No central nervous system (cognitive functions were not specifically studied), visual, cardiac (per electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg qd were comparable in the two age cohorts (<65: 5.5%; > or =65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman et al. [2003] presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n=398) or placebo (n=374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine upon experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo (P<.001).

In the IMprovement in Patients: Assessing symptomatic Control with Tolterodine ER (IMPACT) study [Elinoff et al., 2005], the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open label, primary care setting. Patients with OAB symptoms for >3 months received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients' most bothersome symptom: incontinence, urgency episodes, nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms
can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs [Dmochowski et al., 2007a; 2007; Bavrecha et al., 2008; Choo et al., 2008; Coyne et al., 2008; Rogers et al., 2008; Rovner et al., 2008a; see further: Novara et al, 2008, Chapple et al., 2008]. Importantly, the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo was performed. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500 ms absolute QTc or 60ms change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval [Malhotra et al., 2007].

Olshansky et al. [2008] compared the effects on heart rate of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day in healthy volunteers. They found that tolterodine, but not darifenacin, significantly increased mean heart rate per 24 hours. The proportion of subjects with an increase >5 beats/min was significantly greater in those receiving TOLT-ER (25% than with darifenacin (8.9%).

Hsiao et al. [2011] compared the urodynamic effects, therapeutic efficacy and safety of solifenacin [5 mg] versus tolterodine ER [4 mg] treatment in women with the OAB syndrome. Both solifenacin and tolterodine had similar urodynamic effects, therapeutic efficacy and adverse events, however, tolterodine had a greater effect in increasing heart rate than solifenacin.

In a prospective, open study, Song et al. [2006] compared the effects of bladder training and/or tolterodine as first line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with bladder training (BT), tolterodine (2 mg twice daily) or both for 12 weeks. All treatments were efficacious, however, combination therapy was the most effective. Mattiasson et al. [2003] compared the efficacy of tolterodine 2 mg twice daily plus simplified bladder training (BT) with tolterodine alone in patients with OAB in a multicenter single blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine + BT than with tolterodine alone (33% vs. 25%; p<0.001), while the median percentage increase in volume voided per void was 31% with tolterodine + BT and 20% with tolterodine alone (p<0.001). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine + BT (-87%). It was concluded that the effectiveness of tolterodine 2mg twice daily can be augmented by a simplified BT regimen. However, Millard et al. [2004] investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence, however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program. In a 16-week, multicenter, open label study tolterodine extended release plus behavioral intervention resulted in high treatment satisfaction and improved bladder diary variables in patients who had previously been treated and were dissatisfied with tolterodine or other antimuscarinics [Klutke et al., 2009].

Abrams et al. [2006] studied the safety and tolerability of tolterodine for the treatment of OAB symptoms in men with BOO. They found that tolterodine did not adversely affect urinary function in these men. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. It was suggested that antimuscarinics can be safely administered in men with BOO. Lee et al. [2008] reviewed the safety and efficacy of antimuscarinic agents in treating men with BOO and OAB and emphasized their safety and efficacy. They also concluded that combination therapy of antimuscarinic and α1-AR antagonists improves the symptoms effectively without increasing the incidence of acute urinary retention.

The beneficial effect of TOLT-ER in men with benign prostatic enlargement (BPE) and LUTS, including OAB, has been well documented. Both as monotherapy, but in particularly in combination with α1-adrenoceptor (AR) antagonist, TOLT-ER was found effective [Kaplan et al., 2006; Höfner et al., 2007; Kaplan et al., 2008a; 2008b; Rovner et al., 2008; Roehrborn et al., 2008]. This effect was obtained irrespective of prostate size, and was not associated with increased incidence of acute urinary retention (AUR) [Roehrborn et al., 2008]. A large, 26-week, multicenter, randomized, double-blind, placebo-controlled, three-period crossover study enrolled women aged ≥18 years that were diagnosed with OAB and reported ≥8 micturitions/24 hr and ≥4 urgency episodes/week on 5-day bladder diary at baseline [Marenck et al.2011]. Subjects were randomized to 1 of 10 treatment sequences and received three of five treatments, each for 4 weeks with 4-week washout periods: standard-dose pregabalin/tolterodine ER (150 mg twice daily [BID]/4 mg once daily [QD], n=102), pregabalin alone (150 mg BID, n=105), tolterodine ER alone (4 mg QD, n=104), low-dose pregabalin/tolterodine ER (75 mg BID/2 mg QD, n=105), and placebo (n=103). Subjects completed 5-day diaries at the end of treatment and washout periods. The primary endpoint was change from baseline to week 4 in mean voided volume (MVV) per micturition. Baseline-adjusted changes in MVV were significantly greater after
treatment with standard-dose pregabalin/tolterodine ER (39.5 ml) versus tolterodine ER alone (15.5 ml; \( P<0.0001 \)), and with pregabalin alone (27.4 ml) versus tolterodine ER alone (\( P=0.005 \)) and placebo (11.9 ml; \( P=0.0006 \)). Treatments were generally well tolerated; discontinuation rates due to adverse events were 4\%, 2\%, 5\%, 0\%, and 1\% with standard- and low-dose pregabalin/tolterodine ER, pregabalin/tolterodine ER, and placebo, respectively. See further section on Combinations.

Assessment

Both the IR and ER forms of tolterodine have a well-documented effect in OAB/DO (\( \text{Table 2} \)), and are well tolerated.

h) Trospium chloride

Trospium is a quaternary ammonium compound with a biological availability less than 10\% [Fusgen and Hauri, 2000; Doroshenko et al., 2005]. The drug has a plasma half-life of approximately 20 h, and is mainly (60\% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model [Kim et al., 2006]. Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system [Beckmann-Knopp et al., 1999; Doroshenko et al., 2005]. It is expected to cross the blood-brain to a limited extent since it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain [Gever et al., 2009]. This was demonstrated by Staskin et al. [2010], showing that trospium chloride levels in CSF samples were undetectable on Day 10 at steady-state peak plasma concentration concurrent with measureable peak plasma values. Clinically, trospium seems to have no negative cognitive effects [Fusgen and Hauri, 2000; Todorova et al., 2001; Widemann et al., 2002; Staskin et al., 2010; Chancellor et al., 2012].

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions [Ucket et al., 2000].

Several RCTs have documented positive effects of trospium both in neurogenic [Stöhrer et al., 1991; Madersbacher et al., 1995; Menarini et al., 2006] and non-neurogenic DO [Allousi et al., 1998; Cardozo et al., 2000; Junemann et al., 2000; Halaska et al., 2003; Zinner et al., 2004a; Rudy et al., 2006; Staskin et al., 2007; Dmochowski et al., 2008]. In a placebo-controlled, double blind study on patients with neurogenic DO [Stöhrer et al., 1991], the drug was given twice daily in a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximal detrusor pressure and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and neurogenic DO, trospium and oxybutynin were equieffective; however, trospium seemed to have fewer side effects [Madersbacher et al., 1995].

The effect of trospium in urgency incontinence has been documented in several RCTs. Allousi et al. [1998] compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3 weeks duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo et al. [2000] investigated 208 patients with DO, who were treated with trospium 20 mg twice daily for two weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 ml; placebo 254 to 255 ml) and in maximum bladder capacity (from 329 to 356 ml; placebo 345 to 335 ml) in the trospium treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann et al. [2000] compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary endpoint, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7\% and 9\%, respectively).

Halaska et al. [2003] studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial comprised a total of 358 patients with urgency syndrome or urgency incontinence. After randomisation in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning, and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction of the micturition frequency, incontinence frequency, and a reduction of the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 ml after 26 weeks and 115 ml after 52 weeks (\( P=0.001 \)). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65\% of the patients treated with trospium and 77\% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the
mouth. An overall assessment for each of the drugs revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin due to better tolerability.

Zinner et al. [2004] treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo-controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinent episodes per 24 hours. Secondary efficacy variables were change in average of volume per void, voiding urgency severity, urinations during day and night, time to onset of action and change in Incontinence Impact Questionnaire. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37) and urgency incontinent episodes 59% compared to placebo (-1.29; 44%). It significantly increased average volume per void (32 ml; placebo: 7.7 ml) and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43; placebo: 0.17) - and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%) and headache (6.5%; placebo 4.6%). In a large US multicenter trial with the same design, and including 658 patients with OAB, Rudy et al. [2006] confirmed the data by Zinner et al [2004], both with respect to efficacy and adverse effects.

Dose escalation seems to improve therapeutic efficacy. In a 12-week, randomised, double-blind, phase IIIb study including 1658 patients with urinary frequency plus urgency incontinence received trospium chloride 15 mg TID (n = 828) or 2.5 mg oxybutynin hydrochloride TID (n = 830). After four weeks, daily doses were doubled and not readjusted in 29.2% (242/828) of patients in the trospium group, and in 23.3% (193/830) in the oxybutynin group, until the end of treatment. At study end, there were no relevant differences between the “dose adjustment” subgroups and the respective “no dose adjustment” subgroups (trospium: P = 0.249; oxybutynin: P = 0.349). After dose escalation, worsening of dry mouth was higher in both dose adjusted subgroups compared to the respective “no dose adjustment” subgroups (P < 0.001). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups [Bödeker et al., 2010].

An extended release formulation of trospium allowing once daily dosing, has been introduced [Silver et al., 2010], and its effects tested in controlled trials [Staskin et al., 2008; Dmochowski et al., 2008; Chancellor et al., 2010; MacDiarmid et al., 2011; Sand et al., 2011a; b; c; Zinner et al., 2011]. These studies demonstrated similar efficacy as found with previous formulations, but include experiences in e.g., elderly patients (>75 years), obese patients, and in patients who use multiple concomitant medications. The most frequent side effects were dry mouth (12.9% ; placebo 4.6) and constipation (7.5%; placebo 1.8) [Dmochowski et al., 2008].

Intravesical application of trospium may be an interesting alternative. Frölich et al. [1998] performed a randomised, single-blind, placebo-controlled, mono-centre clinical trial in 84 patients with urgency or urgency incontinence. Compared to placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. Interestingly, intravesical trospium does not seem to be absorbed [Walter et al., 1999], thus offering an opportunity for treatment with minimal systemic antimuscarinic effects.

**Assessment**

Trospium has a well-documented effect in OAB/DO, and tolerability and safety seems acceptable (Table 2).

### 2. ANTIMUSCARINICS WITH “MIXED” ACTION

Some drugs used for treatment of the OAB-syndrome/DO have been shown to have more than one mechanism of action. They all have a more or less pronounced antimuscarinic effect and, in addition, an often poorly defined “direct” action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage operated Ca2+ channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsade de pointes) in some patients [Connolly et al., 1991; Stewart et al., 1992].

#### a) Oxybutynin chloride

Oxybutynin is a tertiary amine that is well absorbed, and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P-450 system (CYP3A4) into multiple metabolites. The primary metabolite, N-desethyloxybutynin (DEO) has pharmacological properties similar to the parent compound [Waldeck et al., 1997], but occurs in much higher concentrations after oral administration [Hughes et al., 1992]. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active
Oxybutynin has several pharmacological effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically, but probably plays no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent [Kachur et al., 1988]. Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions [Waldeck et al., 1997; Nilvebrant et al., 1988]. The drug was shown to have slightly higher affinity for muscarinic M1 and M3 receptors than for M2 receptors [Nilvebrant et al., 1986; Norhona-Blob et al., 1991], but the clinical significance of this is unclear.

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy and most of the newer anti-muscarinic agents have been compared to it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other anti-muscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosing schedules and side-effect profile [Appell et al., 2001; Diokno et al., 2003; Dmochowski et al., 2002]. An extended release oxybutynin (OXY-ER) once daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosing regimen and the potential for improved patient compliance and tolerability. Some of the available formulations of oxybutynin were overviewed by McCrery and Appell [2006].

Immediate-release oxybutynin (OXY-IR). Several controlled studies have have shown that OXY-IR is effective in controlling DO, including neurogenic DO [Yarker et al., 1995; Andersson and Chapple, 2001]. The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff et al. [1998] summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24 h was 33% (data on placebo not presented). The overall "subjective improvement" rate was reported as 74% (range 61% - 100%). The mean percent of patients reporting an adverse effect was 70 (range 17% - 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved quality of life of patients suffering from overactive bladder in a large open multicenter trial. In this study, patients' compliance was 97% and side effects, mainly dry mouth, were reported by only 8% of the patients [Amarenco et al., 1998]. In nursing home residents (n=75), Ouslander et al. [1995] found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double blind, cross-over trial. On the other hand, in another controlled trial in elderly subjects (n=57), oxybutynin with bladder training was found to be superior to bladder training alone [Szonyi et al., 1995].

Several open studies in patients with spinal cord injuries have suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit [Szolar et al., 1996; Kim et al., 1996].

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose-limiting [Baigrie et al., 1988; Jonville et al., 1992]. The effects on the electrocardiogram of oxybutynin were studied in elderly patients with urinary incontinence [Hussain et al., 1998]; no changes were found. It cannot be excluded that the commonly recommended dose 5 mg x 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg x 2 with following dose-titration would reduce the number of adverse effects [Amarenco et al., 1998].

**Extended release oxybutynin (OXY-ER).** This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy [see Arisco et al., 2009]. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared to OXY-IR. DEO is still formed through the hepatic cytochrome P-450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR [Appell et al., 2003]. Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day [Chancellor et al., 2001].

The effects of OXY-ER have been well documented [Siddiqui et al., 2004]. In the OBJECT study [Appell et al., 2001], the efficacy and tolerability of 10 mg OXY-ER was compared to a twice daily 2 mg dose
of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6 to 6.1%; TOLT-IR 24.1 to 7.8), total incontinence (OXY-ER from 28.6 to 7.1%; TOLT-IR 27.0 to 9.3), and frequency (OXY-ER from 91.8 to 67.1%; TOLT-IR 91.6 to 71.5) and both medications were equally well tolerated. The basic study was repeated as the OPERA study [Dioikno et al., 2003] with the difference that this study was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg) and the results were quite different. In this study there was no significant difference in efficacy for the primary endpoint of urgency incontinence, however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies IR entities of one drug should no longer be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with OXY-IR. In the 1999 study [Anderson et al., 1999], 105 patients with urgency or mixed incontinence were randomized to receive 5-30 mg OXY-ER once daily or 5 mg of OXY-IR 1-4 times/day. Dose titrations began at 5 mg and the dose was increased every 4-7 days until one of three endpoints was achieved. These were 1) the patient reported no urgency incontinence during the final two days of the dosing period; 2) the maximum tolerable dose was reached; the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percentage reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR but dry mouth was reported statistically more often with OXY-IR. In the 2000 study [Versi et al., 2000], 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily. As in the 1999 study, OXY-ER again achieved a >80% reduction in urgency and total incontinence episodes and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naïve patients included, as all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naïve population [Gleason et al., 1999].

In an RCT comparing different daily doses of oxybutynin (5, 10 and 15 mg), Corcos et al. [2006] found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day.

In a multicentre, prospective, observational, flexible-dosing Korean study, Yoo et al. [2012] investigate the prescription pattern and dose distribution of OXY-ER in patients the OAB syndrome in actual clinical practice. The dosage of for each patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12 week treatment period. Efficacy was measured by administering the Primary OAB Symptom Questionnaire (POSQ) before and after treatment. Patients were also administered, the patient perception of treatment benefit (PPTB) questionnaire at the end of the study. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5-10 mg/day oxybutynin ER as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment and 89.3% were satisfied.

**Transdermal oxybutynin (OXY-TDS).** Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study [Davila et al., 2001] comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinence episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study [Dmochowski et al., 2002] the 3.9-mg daily dose patch significantly (vs placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9: placebo from 5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 ml; placebo from 175 to 182 ml). Furthermore, dry mouth rate was similar to placebo (7% vs 8.3%). In a third study [Dmochowski et al., 2003] OXY-TDS was compared not only to placebo but to TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritis in 14% and erythema in 8.3% with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, 2-way crossover study [Appell et al., 2003]. Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism to DEO compared to OXY-ER which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski et al. [2005] analyzing the combined results of two RCTs concluded that transdermal
Oxybutynin was shown to be efficacious and well tolerated. The most common systemic side effect was dry mouth (7.0% vs placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1%. Also Cartwright and Cardozo [2006], reviewing published and presented data concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects lower that with oral antimuscarinics – however, this benefit was offset by the rate of local skin reaction. The reviews of Sahai et al. [2008] and Staskin and Salvador [2010] largely confirmed these conclusions, which also have been supported by further studies [Cartwright et al., 2011].

**Oxybutynin topical gel.** Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. Oxybutynin topical gel (OTG) was approved by the US FDA in January 2009. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area [Staskin et al., 2009]. The 1 gram application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentrations and a “favorable” N-desethyloxybutynin metabolite: oxybutynin ratio believed to minimizing antimuscarinic side effects [Staskin and Robinson, 2009]. In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks [Staskin et al., 2009]. The mean number of urgency episodes, as recorded by 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm (P <0.0001). Urinary frequency decreased by 2.7 episodes per day and voided volume increased by 21 mL (versus 2.0 episodes [P = 0.0017] and 3.8 mL [P = 0.0018], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It was felt that improved skin tolerability of the gel over the OXY transdermal patch delivery system was secondary to lack of adhesive and skin occlusion. The gel dries rapidly upon application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site [Dmochowski et al., 2011]. The evolution of the transdermal gel allows greater patient tolerability and improved compliance. This was confirmed by Sand et al. [2012] showing that in 704 women with OAB OTG significantly reduced the number (mean ± standard deviation) of daily incontinence episodes (OTG, -3.0 ± 2.8 episodes; placebo, -2.5 ± 3.0 episodes), reduced urinary frequency, increased voided volume, and improved select health-related quality-of-life domains vs placebo. Dry mouth was the only drug-related adverse event significantly more common with OTG (7.4%) than with placebo (2.8%).

**Other administration forms.** Rectal administration [Collas and Malone-Lee, 1997] was reported to have fewer adverse effects than the conventional tablets. Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults [Lose and Nordgaard, 2001; Fader et al., 2007; George et al., 2007; Guerra et al., 2008], although adverse effects may occur [Kasabian et al., 1994; Palmer et al., 1997].

**Effects on cognition.** Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population but also in children [see, e.g., Kay et al., 2006; Klausner al Steers, 2007; Kay and Ebinger, 2008]. This factor should be taken into consideration when prescribing the drug.

**Assessment.**

Oxybutynin has a well-documented efficacy in the treatment of OAB/DO (Table 2). Despite the adverse effect profile, it is still an established therapeutic option.

**b) Propiverine hydrochloride**

Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine have been reviewed by Madersbacher and Murz [2001]. The drug is rapidly absorbed (tmax 2 h), but has a high first pass metabolism, and its biological availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100-times above the therapeutic doses in man [Walter et al., 2003]. Several active metabolites are formed which quantitatively and qualitatively differ from the mother compound [Haustein et al., 1988; Muller et al., 1993; Wuest et al., 2006; Zhu et al., 2008; Sugiyama et al., 2008]. Most probable these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified [Michel and Hegde, 2006]. The half-life of propiverine itself is about 11-14 h. An extended release preparation was shown to be effective [Junemann et al., 2006; May et al., 2008]. Oral absorption of propiverine is site-dependent and influenced by dosage form and circadian/tide– dependent elimination processes [May et al., 2008].

Propiverine has combined antimuscarinic and calcium antagonistic actions [Haruno, 1992; Tokuno et al., 1993]. The importance of the calcium antagonistic component for the drug’s clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes. The effects of propiverine on cardiac ion channels and action potentials were investigated by Christ et al., [2008]. Propiverine blocked in a concentration-dependent manner HERG channels expressed in HEK293 cells, as well as native I(Kr) current in ventricular myocytes of guinea pig. However, action potential duration was not prolonged in guinea-pig and human ventricular
tissue, and the investigators concluded that their results did not provide evidence for an enhanced cardiovascular safety risk with the drug.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al [1998] collected 9 randomized studies on a total of 230 patients, and found a 17% reduction in micturitions per 24 hours, a 64 ml increase in bladder capacity, and a 77% (range 33-80%) subjective improvement. Side effects were found in 14% (range 8-42%). In patients with neurogenic DO, controlled clinical trials have demonstrated propiverine’s superiority over placebo [Stöhrer et al., 1999]. Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate and placebo [Wehnert et al., 1989], and propiverine, oxybutynin and placebo [Wehnert et al., 1992; Madersbacher et al., 1999], have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared [Stöhrer et al., 2007]. The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin.

Also in children and adolescents with neurogenic DO, propiverine was found to be effective [Schulte-Baukloh et al., 2006; Grigoleit et al., 2006], with a low incidence rate of adverse events: <1.5% [Grigoleit et al., 2006]. A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5–10 yr was performed by Marschall-Kehrel et al. [2009]. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary endpoints included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well-tolerated: 23% of side-effects were reported for propiverine and 20% for placebo.

In a randomised, double-blind, multicentre clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days [Junemann et al., 2005]. The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary endpoint. Secondary endpoints were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, post void residual urine, and quality of life. It was found that the mean maximum cystometric capacity increased significantly (p < 0.01) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolerodine group. The scores for the quality of life improved comparably in both groups.

Madersbacher et al. [1999] compared the tolerability and efficacy of propiverine (15 mg three times daily) oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin. Dorschner et al. [2000] investigated in a double-blind, multicentre, placebo-controlled, randomized study, the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years), suffering from urgency, urgency incontinence or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine – 2 out of 49 patients). Resting and ambulatory electrocardiograms indicated no significant changes. The cardiac safety of propiverine was further studied by Donath et al. [2011] in two comprehensively designed mono-centric ECG studies (including 24 healthy females, followed by a second study on 24 male patients with coronary heart disease (CHD) and a pathological Pardee–Q-wave in the ECG). Both studies were placebo-controlled and compared the effects of single (30 mg s.i.d.) and multiple dosing (15 mg t.i.d.) of propiverine hydrochloride in a crossover design over 6 and 13 days, respectively. They were performed to investigate the influence of propiverine hydrochloride and its main metabolite propiverine-N-oxide on cardiac function with respect to QTc prolongation, QTc dispersion and T-wave shape. No negative effects on cardiac safety could be demonstrated.

Abrams et al. [2006] compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring (AUM) parameters, safety, and tolerability in OAB patients. Patients (n=77) received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. They found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had
a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

Yamaguchi et al. [2008] performed a multicentre, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at endpoint in number of voids/24 hours, urgency, incontinence, urge incontinence and nocturia episodes, volume voided/void, restoration of continence and quality of life (QoL) were examined. It was found that at endpoint, there were greater reductions in mean (SD) voids/24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL vs placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided vs propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg. Wada et al. [2011] performed a prospective nonrandomized crossover study of female OAB patients, assigned alternately to treatment with propiverine (20 mg) for 8 weeks then solifenacin(5 mg) for 8 weeks or solifenacin for 8 weeks then propiverine for 8 weeks. At baseline, 8th week and 16th week, symptoms were assessed using overactive bladder symptom score (OABSS). Of the 121 patients enrolled 83 were analysed. Both drugs were effective. Urgency was further improved after switching from propiverine to solifenacin, but not after switching from solifenacin to propiverine. Solifenacin was better tolerated than propiverine.

In another multicentre, prospective, parallel, doubleblind, placebo-controlled trial, Lee et al. [2009] studied the effects of 30 mg propiverine/day in 264 OAB patients (mean age 52.2 years), 221 of whom had efficacy data available from baseline and at least one on-treatment visit with >75 compliance. The study was focused on improving urgency. Overall, among patients treated with propiverine, 39% rated their treatment as providing 'much benefit', compared with 15 % in the placebo group. Adverse events reported by 32 (22.5%) and 10 (12.7%) patients in the propiverine and placebo group were all tolerable.

Masumori et al. [2011] examined prospectively the efficacy and safety of propiverine in patients with overactive bladder (OAB) symptoms who poorly responded to previous treatment with solifenacin, tolterodine or imidafenacin. Of 73 patients enrolled (29 males and 44 females, median age 71 years), 52 completed the protocol treatment. The OABSS was significantly improved by propiverine treatment. The scores of OAB symptoms (nighttime frequency, urgency and urge incontinence) except daytime frequency also improved significantly. No increase in PVR was observed. The most frequent adverse event was dry mouth (13.7%), followed by constipation (6.8%).

In a non-controlled study in patients with wet OAB the efficacy of propiverine on symptoms and quality of life was confirmed [Komatsu et al. 2009].

**Assessment**

Propiverine has a documented beneficial effect in the treatment of OAB/DO (Table 2), and seems to have an acceptable side effect profile.

c) **Flavoxate hydrochloride**

Flavoxate is often discussed as a drug with mixed actions, however, its main mechanism of action may not be antimuscarinic.Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% [Guay, 2003]. The drug is extensively metabolized and plasma half-life was found to be 3.5 h [Sheu et al., 2001]. Its main metabolite (3-methylflavone-8-carboxylic acid, MFCA) has been shown to have low pharmacological activity [Cazzulani et al., 1988; Caine et al., 1991]. The main mechanism of flavoxate's effect on smooth muscle has not been established. The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterase, and to have local anesthetic properties; no antimuscarinic effect was found [Guarneri et al., 1994]. Uckert et al. [2000], on the other hand, found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable. It has been suggested that pertussis toxin-sensitive G-proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, since intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhythmic bladder contractions in anesthetized rats [Oka et al., 1996].

The clinical effects of flavoxate in patients with DO and frequency, urgency and incontinence have been studied in both open and controlled investigations, but with varying rates of success [Ruffman, 1988]. Stanton [1973] compared emepronium bromide and flavoxate in a double-blind, cross-over study of patients with detrusor overactivity and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered as 200 mg 3 times daily. In another double-blind, cross-over study comparing flavoxate 1200 mg/day with that of oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency, and utilising both clinical and urodynamic criteria, Milani et al. [1993] found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators, comparing the effects of flavoxate with those of placebo, have not been able
to show any beneficial effect of flavoxate at dosages up to 400 mg three times daily [Briggs et al., 1980; Chapple et al., 1990; Dahm et al., 1995]. In general, few side effects have been reported during treatment with flavoxate. On the other hand its efficacy, compared to other therapeutic alternatives, is not well documented (Table 2).

**Assessment**

No RCTs seem to have been performed with flavoxate during the last decade. The scarcity of documented clinical efficacy should be considered before using the drug.

3. CLINICAL USE OF ANTIMUSCARINICS

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned. Herbison et al. [2003] stated in a widely discussed article: “Anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo. The benefits are, however, of limited clinical significance” Large meta-analyses of studies performed with the currently most widely used drugs [Chapple et al., 2005; 2008; Novara et al., 2008], clearly show that antimuscarinics are of significant clinical benefit. Novara et al. [2008] reviewed 50 RCTs and 3 pooled analyses, which they considered of good methodological quality. They concluded that still more clinical studies are needed to decide which of the drugs should be used as first-, second-, or third-line treatment. Reviewing information from more than 12,000 references, Chapple et al. [2008], based their conclusions (“antimuscarinics are efficacious, safe, and well tolerated treatments”) on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

The durability of the effects of antimuscarinics is not known and the relapse rate of symptoms after discontinuation of treatment has not been systematically studied. In 173 women with OAB symptoms for >6 months, Lee et al.[2011] studied in a prospective, randomized, open-label, trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6-months. The relapse rate was 62%, and the request for treatment was 65 %, indirectly suggesting an efficacy of treatment. None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, imidafenac, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as a first-line treatment for all OAB/DO patients. Optimal treatment should be individualized, implying that the patient’s co-morbidities and concomitant medications, and the pharmacological profiles of the different drugs, should be taken into consideration [Chapple et al., 2008].

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata et al. [2012] analyzed 86 trials, 70 with parallel and 16 with cross-over designs (31,249 adults). They concluded that when the prescribing choice is between oral immediate release oxybutynin or tolterodine, tolterodine might be preferred for reduced risk of dry mouth. ER preparations of oxybutynin or tolterodine might be preferred to immediate release preparations because there is less risk of dry mouth. Comparing solifenacin and immediate release tolterodine, solifenacin might be preferred for better efficacy and less risk of dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy, but has higher risk of withdrawal due to adverse events and higher risk of dry mouth.

Several studies have documented that the persistence with prescribed antimuscarinic therapy for overactive bladder is low [Kelleher et al., 2005; Basra et al.,2008; Sears et al; Wagg et al., 2012]. The most common causes seem to be lack of efficacy and adverse effects. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg et al. [2012] analysed prescription data for patients receiving antimuscarinics for treatment of the OAB syndrome over a 12-month period. At 12 months, they found that the proportions of patients still on their original treatment were: solifenacin 35%, tolterodine ER 28%, propiverine 27%, oxybutynin ER 26%, trospium 26%, tolterodine IR 24%, oxybutynin IR 22%, darifenacin 17%, and flavoxate 14%. The longest mean persistence was reported for solifenacin (187 days versus 77 – 157 days for the other treatments). Gomes et al. [2012] compared the persistence of oxybutynin or tolterodine therapy among older patients newly prescribed one of these drugs. This was a retrospective cohort study of Ontarians aged 66 years and older. Persistence with treatment was defined on the basis of refills for the drug within a grace period equal to 50% of the prescription duration. The authors identified 31,996 patients newly treated with oxybutynin and 24,855 newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, p < 0.0001). The median time to discontinuation of oxybutynin and tolterodine was 68 and 128 days, respectively. Kessler et al. [2011] analyzed 69 trials enrolling 26,229 patients with OAB with the aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and trospium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first choice drugs to start the treatment of OAB, except for oral oxybutynin dosages of ≥ 10 mg/day, which may have more unfavorable adverse event profiles.

Even if the use of antimuscarinics are associated with many adverse effects, they are generally
considered to be ‘safe’ drugs. However, among the more serious concerns related to their use is the risk of cardiac adverse effects, particularly QT prolongation and induction of polymorphic ventricular tachycardia (torsade de pointes), and increases in heart rate (HR) [Andersson and Olshansky, 2007; Andersson et al., 2011]. QT prolongation and its consequences are not related to blockade of muscarinic receptors, but rather linked to inhibition of the hERG potassium channel in the heart. However, the experiences with terodiline, an antimuscarinic drug that caused torsade de pointes in patients [Connolly et al., 1991; Stewart et al., 1992], have placed the whole drug class under scrutiny.

The parasympathetic actions on the heart (Figure 10) opposes the excitatory actions of the sympathetic nervous system, and slows the heart rate (Figure 11). An elevated resting HR has been linked to overall increased morbidity and mortality, particularly in patients with cardiovascular diseases. The prevalence of CV comorbidities was found to be significantly higher in patients with than without OAB [Andersson et al., 2010]. Since mean changes in HR reported in population studies might not be applicable to an individual patient, and particularly in patients at risk of cardiac disease, even moderate increases in HR might be harmful. The potential of the different antimuscarinic agents to increase HR and/or prolong the QT time has not been extensively explored for all agents in clinical use. Differences between drugs cannot be excluded, but risk assessments based on available evidence are not possible.

II. DRUGS ACTING ON MEMBRANE CHANNELS

1. CALCIUM ANTAGONISTS

Calcium channels play an important role in the regulation of free intracellular calcium concentrations and thereby contribute to the regulation of smooth muscle tone [Berridge, 2008] Two major groups of calcium channels include the voltage-gated [Catterall et al., 2003] and the store-operated channels [Leung et al., 2008]. While both can contribute to the maintenance of smooth tone in general, store-operated calcium channels apparently contribute only to a limited if any extent to the regulation of bladder smooth muscle tone [Schneider et al., 2004 a; b]. On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type [Frew and Lundy, 1995] and L-type channels [Wuest et al., 2007]. The latter appears to be of particular importance as inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in

Figure 10 : Cardiac control via the autonomic nervous system. Acetylcholine, released from parasympathetic nerve terminals activate muscarinic receptors that mediate decrease in heart rate, decrease in force of contraction, and decrease in conduction velocity.
vitro with tissue from multiple mammalian species, including humans [Frazier et al., 2008]. However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species [Wuest et al., 2007]. In confirmation of the role of L-type calcium channels, it has been shown that knock-out mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility [Wegener et al., 2004].

While these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical installation of the calcium channel inhibitor verapamil, the muscarinic receptor antagonists oxybutynin and trospium and placebo to patients with urgency or urgency incontinence. While the two muscarinic receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function [Fröhlich et al., 1998]. In a clinical study of limited size the calcium channel inhibitor nimodipine (30 mg per day) did not significantly improve the number of incontinence episodes as compared to placebo [Naglie et al., 2002]. Larger studies with clinical endpoints related to effects of calcium channel inhibitors have not been reported in incontinent patients (based upon a Medline search using the MeSH terms “calcium channel blockers” and “urinary incontinence”). Moreover, it should be noted that despite a long-standing and wide-spread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro and the lack of clinical data are not fully clear, but it may relate to pharmacokinetic properties of the currently used drugs which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses. At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction (Table 2). No new information has been added since the assessment in 2008 [Andersson et al., 2009].

2. POTASSIUM CHANNEL OPENERS

In a similar fashion to calcium channels, potassium channels also contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist [Gutman et al., 2003; Petkov et al., 2012]. With regard to bladder function, ATP-dependent (KATP) and big calcium-activated (BKCa) channels have been studied most intensively. The BKCa channels also appear to be important physiologically as their activation can cause hyperpolarization of bladder smooth muscle cells and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, e.g., β-adrenoceptor agonists [Frazier et al., 2008]. Openers of both KATP [Howe et al., 1995; Hu et al., 1997; Martin et al., 1997] and

---

**Figure 11:** Autonomic receptors controlling heart rate. Acetylcholine, released from parasympathetic nerve terminals, activate muscarinic M2 receptors that mediate a decrease in heart rate. Inhibition of these receptors by antimuscarinics may increase heart rate.
BKCa channels [Hu et al., 1997; Sheldon et al., 1997] have been shown to induce bladder smooth muscle relaxation in various mammalian species, but the density of some types of potassium channels may differ markedly between species. Some potassium channel openers have also been shown to suppress non-voiding detrusor contractions in vivo in animal models of DO [Howe et al., 1995; Martin et al., 1997; Tanaka et al., 2003] and this also includes activators of the KCNQ type of potassium channels [Streng et al., 2004]. Although potassium channel openers are believed to mainly act directly on smooth muscle cells [Gopalakrishnan and Shieh, 2004; Petkov et al., 2012], they may also at least in part affect bladder function by modulating the activity of afferent neurones [Tanaka et al., 2003].

While the above data demonstrate the potential of potassium channel openers to inhibit non-voiding detrusor contractions, these channels are expressed not only in bladder, but also e.g. in vascular smooth muscle. Therefore, potassium channel openers may also affect cardiovascular function, and in effective doses may considerably lower blood pressure [Howe et al., 1995; Shieh et al., 2007]. While some compounds of this class have a certain degree of selectivity for the bladder as compared to the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the KATP opener ZD0947 has been reported [Chapple et al., 2006]. While ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one due to a lack of selectivity for bladder over cardiovascular tissues (Table 2).

Another way to use potassium channels to normalize bladder function was suggested by Christ et al. [2001] in a rat model of detrusor hyperactivity. They injected “naked” hSlo/pcDNA3 (maxiK channel) into the bladder and found a significant amelioration of the hyperactivity. As to whether this principle can be therapeutically useful in man is currently under investigation.

III. α-ADRENOCEPTOR (AR) ANTAGONISTS

It is well documented that α1-AR antagonists can ameliorate lower urinary tract symptoms in men [Andersson, 2002; McVary et al., 2011; Oelke et al., 2011; Lepor et al., 2012]. Currently used α1-AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of BPH [Lepor et al., 2012]. However, in a study where tamsulosin was given alone, or together with tolterodine, to patients with male LUTS and OAB symptoms, monotherapy with the drug was not effective [Kaplan et al., 2006]. In an RCT from Korea, doxazosin monotherapy resulted in only minimal effects in IPSS storage subscore, urgency episodes and no improvement in the patient perception of bladder condition (PPBC) [Lee et al., 2011]. Thus, there is no convincing evidence that α-AR antagonists, given as monotherapy, are effective in patients with storage symptoms only.

A pivotal question is if better efficacy and/or tolerability can be obtained by highly subtype selective drugs than with the commonly used alternatives. α1-ARs include three receptor subtypes, α1A, α1B, and α1D, that are structurally and pharmacologically distinct and have different tissue distributions [Andersson and Gratzke, 2007]. α1A-ARs are the predominant subtype in the human prostate, where they mediate smooth muscle contraction. A fourth subtype, α1L, also present in human prostate, is derived from the same gene as α1A, but α1L- and α1A-receptors have different pharmacologic properties and bind some α-AR antagonists with different affinities. The precise structural relationship between the two subtypes remains to be elucidated.

Selectivity for α1B-AR has been considered disadvantageous from a cardiovascular point of view [Schwinn et al., 2004; Schwinn and Roehrborn, 2008]. Kojima et al. [2008]] studied the expression of α1-AR in the transitional zone of prostates from 55 patients with BPH, comparing patients treated with tamsulosin presumed to block α1A-ARs and naftopidil presumed to block α1D-ARs. However, the selectivity of naftopidil for α1D- vs α1A-ARs is modest [Take et al., 1998] and its use as a tool to separate between α1-AR subtypes is questionable. Nevertheless, the tamsulosin and naftopidil groups were classified as α1A-AR dominant (22 and 12 patients) and α1D-AR dominant (11 and 16, respectively). The efficacy of tamsulosin and naftopidil differed depending on the dominant expression of the α1-AR subtype in the prostate. Tamsulosin was more effective in patients with dominant expression of the α1A-AR subtype, whereas naftopidil was more effective in those with dominant expression of the α1D-AR subtype. In another study, the same group assessed whether there was a direct correlation between the prostatic expression of α1-AR subtype mRNA and severity of LUTS or bladder outlet obstruction [Kojima et al., 2010]. They found no direct correlation between the expression of α1-AR subtype mRNA in the prostate and severity of LUTS or BOO, although there was a significant regression of this expression with patient age. Kojima et al. [2010] concluded that the expression level of α1-AR subtype mRNA in the prostate could be a predictor of the efficacy of subtype selective α1-AR antagonists in patients with BPH, and
suggested that genetic differences were responsible for the diverse responses to the drugs.

Silodosin (KD-3213), which has a high selectivity for α1A-ARs [Tatemichi et al., 2006a; b; Lepor and Hill, 2010; Yoshida et al., 2011], had clinically good effects on both voiding and storage symptoms in men with BPH [Kawabe et al., 2005; Yoshida et al., 2007; Marks et al., 2009a; Chapple et al., 2010; Morganroth et al., 2010; Yoshida et al., 2011]. Chapple et al. [2010] conducted a multicenter double-blind, placebo- and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo. A total of 1228 men ≥50 yr of age with an International Prostate Symptom Score (IPSS) ≥13 and a urine maximum flow rate (Qmax) >4 and ≤15ml/s were selected at 72 sites in 11 European countries. The patients were entered into a 2-wk wash-out and a 4-wk placebo run-in period. A total of 955 patients were randomized (2:2:1) to silodosin 8 mg (n=381), tamsulosin 0.4 mg (n=384), or placebo (n=190) once daily for 12 wk. Its overall efficacy was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo. There was no significant difference between the two α1-AR antagonists and the placebo in terms of Qmax. There was also no difference between the two α-AR antagonists for the QoL parameter, whereas both were better than the placebo. Active treatments were well tolerated, and discontinuation rates due to adverse events were low in all groups (2.1%,1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively). The most frequent adverse event was silodosin was a reduced or absent ejaculation during orgasm (14%), a reversible effect as a consequence of the potent and selective α1A-AR antagonism of the drug. The incidence was higher than that observed with tamsulosin (2%); however, only 1.3% of silodosin-treated patients discontinued treatment due to this adverse event. Silodosin treatment improved DO and obstruction grade by decreasing detrusor opening pressure, detrusor pressure at Qmax, bladder outlet obstruction index and Schafer’s obstruction class significantly [Yamanishi et al., 2009]. In a different open, nonblinded prospective study silodosin 8 mg lead to a significant increase in bladder capacity at first desire to void with no significant change in maximum cystometric capacity. In the voiding phase mean detrusor pressure at maximum flow significantly decreased, mean bladder outlet obstruction index decreased significantly and obstruction grade as assessed by the Schaef er nomogram improved significantly [Matsukawa et al., 2009].

It thus seems that selective blockade of α1A-ARs is a clinically effective approach, and silodosin is an effective and well-tolerated treatment for the relief of both voiding and storage symptoms in male patients with LUTS, even if treatment is associated with a high incidence of ejaculatory dysfunction.

Interest has also been focussed on the α1-ARs (α1D), specifically in the bladder [Schwinn et al., 2004; Schwinn and Roehrborn, 2008], assuming that these receptors were responsible for storage symptoms. However, the inter-relationship between the α1D-ARs in the human detrusor smooth muscle and the pathophysiology of LUTS is unclear. Naf"topidil was shown to significantly improve the OAB symptom score [Sakai et al., 2011] and urgency episodes [Yokoyama et al., 2009]. Ikemoto et al. [2003] gave tamsulosin and naftopidil to 96 patients with BPH for 8 weeks in a crossover study. Whereas naftopidil monotherapy decreased the I-PSS for storage symptoms, tamsulosin monotherapy decreased the I-PSS for voiding symptoms. However, this difference (which was suggested to depend on differences in affinity for α1-AR subtypes between the drugs) could not be reproduced in a randomized head to head comparison between the drugs [Gotoh et al, 2005]. Based on available evidence, it therefore cannot be concluded that the α1D-ARs on the detrusor smooth muscle are the main therapeutic target. However, α1D-ARs may have effects on different locations in the bladder beside the detrusor smooth muscle: the detrusor vasculature, the urothelium, and the afferent and efferent nerve terminals and intramural ganglia [Andersson and Gratzke, 2007]. The importance and functional role of this observation remain to be established.

In females, treatment with OAB, α1-AR antagonists seem to be ineffective. In an RCT, comprising 364 women with OAB, no effect of tamsulosin vs placebo could be demonstrated [Robinson et al., 2007]. On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were treated (with modest success) with an α1-AR antagonist [Kessler et al., 2006, Low et al., 2008]. It should be remembered that in women, these drugs may produce stress incontinence [Dwyer and Teele, 1992].

In patients with neurogenic DO, treatment with α1-AR antagonists was moderately successful [Abrams et al., 2003].

IV. β-ADRENOCEPTOR AGONISTS

In isolated human bladder, non-subtype selective β-AR agonists like isoprenaline have a pronounced inhibitory effect, and administration of such drugs can increase bladder capacity in man [Andersson, 1993]. However, the β-ARs of the human bladder were shown to have functional characteristics typical of neither β1-, nor β2- ARs, since they could be blocked by propranolol, but not by practolol or metoprolol (β1) or butoxamine (β2) [Nergard et al., 1977; Larsen, 1979]. On the other hand, early receptor binding studies using subtype selective ligands, suggested that the β-ARs of the human detrusor are primarily of β2 subtype [Andersson...
1993], and favourable effects on DO were reported in open studies with selective β2-AR agonists such as terbutaline [Lindholm and Lose, 1986]. In a double-blind investigation clenbuterol 0.01 mg 3 times daily was shown to have a good therapeutic effect in 15 of 20 women with DO [Gruneberger, 1984]. Other investigators, however, have not been able to show that non-subtype selective β-AR agonists represent an effective therapeutic principle in elderly patients with DO [Castleden and Morgan, 1980], or in young patients with myelodysplasia and DO [Naglo et al, 1981].

However, three subtypes (β1, β2, and β3) have been identified in the detrusor of most species, including humans [Andersson and Arner, 2004; Michel and Vrydag, 2006]. Also the human urothelium contains all three receptor subtypes [Ot- suka et al., 2008]. Studies, using real-time RT-PCR, have revealed a predominant expression of β3-AR mRNA in human detrusor muscle [Nomiya and Yamaguchi, 2003; Michel and Vrydag, 2006, , Igawa et al., 2010] and the functional evidence for an important role in both normal and neurogenic bladders is convincing [Fujumura et al., 1999; Igawa et al., 1999; Takeda et al., 1999; Morita et al., 2000; Igawa et al., 2001; 2010; Biers et al., 2006; Michel and Vrydag, 2006; Badawi et al., 2007; Leon et al., 2008]. The human detrusor also contains β2-ARs, and most probably both receptors are involved in the physiological effects (relaxation) of noradrenaline in this structure [Andersson and Arner 2004; Michel and Vrydag, 2006; Igawa et al., 2010].

The generally accepted mechanism by which β-ARs induce detrusor relaxation in most species, is activation of adenylyl cyclase with the subsequent formation of cAMP (Figures 12 and 13). However, there is evidence suggesting that in the bladder K+ channels, particularly BKCa channels, may be more important in β-AR mediated relaxation than cAMP [Hudman et al., 2000; Frazier et al., 2005; Uchida et al., 2005; Frazier et al., 2008]. Aizawa et al. [2010] showed that the β3-AR agonist, CL316,243, could inhibit filling-induced activity in mechanosensitive Aδ-fibers, but not in C-fiber primary bladder afferents of the rat bladder. However, the drug was able to inhibit prostaglandin (PG) E2-induced C-fiber mediated hyperactivity.

Since β-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated [Murakami et al., 2007; Otsuka et al., 2008]. Murakami et al. [2007] found that the relaxation responses of the detrusor were not influenced

![Figure 12: During bladder filling, there is normally no parasympathetic nervous outflow to the bladder and no release of acetylcholine (ACh). The sympathetic nervous system is active and releases noradrenaline (NA) that via β3 adrenoceptors stimulates adenylyl cyclase (AC) and generation of cyclic AMP (cAMP) which mediates relaxation of the bladder. In addition, β3-adrenoceptor stimulation activate K+ channels, stimulating outflow of K+, which causes hyperpolarisation and inhibition of Ca2+ inflow.](image-url)
by the urothelium. However, isoprenaline was more potent at inhibiting carbachol contractions in the presence of the urothelium than in its absence. It was suggested that this might reflect the release of an inhibitory factor from the urothelium. Further support for this hypothesis was given by Otsuka et al. [2008]. However, to what extent a urothelial signaling pathway contributes in vitro and in vivo to the relaxant effects of β-AR agonists in general, and β3-AR agonists specifically, remains to be elucidated.

The in vivo effects of β3-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics), β3-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume [Fujimura et al., 1999; Woods et al., 2001; Takeda et al., 2002; Kaidoh et al., 2002; Igawa et al., 2010]. For example, Hicks et al. [2007] studied the effects of the selective β3-AR agonist, GW427353, in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid evoked bladder hyperactivity, without affecting voiding.

A number of β3-AR selective agonists are currently being evaluated as potential treatment for OAB in humans including GW427353 (solabegron) and YM178 (mirabegron) [Colli et al., 2007; Igawa et al., 2010; Saito et al., 2011; Tyagi and Tyagi, 2011] (Figure 14).

**Mirabegron.** Takusagawa et al. [2012] found that mirabegron was rapidly absorbed after oral administration. It circulates in the plasma as the unchanged form, its glucuronic acid conjugates and other metabolites. Of the administered dose, 55% is excreted in urine, mainly as the unchanged form, and 34% is recovered in feces, almost entirely as the unchanged form. Mirabegron is highly lipophilic and is metabolized in the liver via multiple pathways, mainly by cytochrome P450 3A4 and 2D6 (CYP2D6) [van Gelederen et al., 2009]. In a Phase I pharmacokinetic study, sixteen healthy volunteers, phenotyped as either poor or extensive metabolizers of CYP2D6 were enrolled The volunteers received a 160 mg single oral dose after overnight fasting. Poor metabolizers excreted a slightly higher urinary fraction of mirabegron (15.4±4.2%) than extensive metabolizers (11.7±3.0%). Tmax in both extensive and poor metabolizers was about
2 hours and the terminal elimination half-life (t1/2) approximately 23-25 hours.

Chapple et al. [2008] reported the results of a phase IIA trial of mirabegron in patients with OAB. The Blossom trial, conducted in several European countries, was a proof of concept study. It enrolled 314 patients with OAB symptoms - 262 patients were randomly assigned to 4 groups: placebo, mirabegron 100 mg bid, mirabegron 150 mg bid, and tolterodine 4 mg qd for a 4-week treatment period. The primary endpoint was efficacy, and the primary efficacy variable was the change in the mean number of micturitions per 24 hours as recorded on a frequency/volume chart. In both mirabegron groups significant improvements in the mean number of micturitions per 24 hours were found compared with the placebo group (−2.19 and −2.21 vs. −1.18, respectively). Mean volume voided was dose-dependently increased in the mirabegron groups, and the change reached significance in the mirabegron 150 mg group. Urgency episodes per 24 hours decreased significantly in both mirabegron groups compared with the placebo group. No severe adverse events were reported and treatment was generally well tolerated. A small, mean increase in pulse rate with mirabegron 150 mg (5 beats per minute) was demonstrated, but this was not associated with a clinically significant increase in adverse events such as tachycardia and palpitations. This successful phase IIA trial was followed by a phase IIB trial in OAB patients carried out in Europe [Chapple et al., 2010]. This trial was a dose-ranging study of once-daily mirabegron (an extended release formula of mirabegron) with multiple arms (placebo, mirabegron 25 mg, 100 mg, 150 mg, and 200 mg qd, for a 12-week treatment period), and the primary endpoint was to evaluate the dose-response relationship on efficacy. The mean number of micturitions per 24 hours decreased dose-dependently, and the decreases were statistically significant with mirabegron 50 mg, 150, and 200 mg compared with placebo. The mean volume voided per micturition increased dose-dependently, and the increases were significant with mirabegron 50 mg and more. Adverse events were experienced by 45.2% of the patients - the incidence of adverse events was similar among all treatment groups (placebo 43.2% vs. mirabegron 43.8-47.9%). The overall discontinuation rate owing to adverse events was 3.2% (placebo 3.0% vs. mirabegron 2.4-5.3%). The most commonly reported adverse events considered treatment-related was gastrointestinal disorders, including constipation, dry mouth, dyspepsia, and nausea. There was no patient-reported acute retention. No significant difference in ECG parameters between

![Figure 14: The β3-adrenoceptor is the predominating β-adrenoceptor subtype in the bladder. Stimulation by highly selective β3-adrenoceptor agonists like mirabegron and solabegron may inhibit symptoms of overactive bladder without affecting the ability to empty the bladder.](image-url)
the groups was demonstrated. However, a small but significant increase in mean pulse rate was observed after mirabegron 100 mg and 200 mg (1.6 and 4.1 beats per minute, respectively), although this was not in associated with an increase in cardiovascular adverse events.

Nitti et al. [2011] reported on a phase III multicentre, randomized, double-blind, parallel-group, placebo-controlled trial of mirabegron in North America. They enrolled 1328 patients ≥18 years with OAB symptoms for ≥3 months. Patients who completed a 2-week, single-blind, placebo run-in and had ≥8 micturitions/24 h and ≥3 urgency episodes/72 h (with or without incontinence) during a 3-day micturition diary period, were randomized to receive placebo, or mirabegron 50 or 100 mg once daily for 12 weeks. Co-primary endpoints were change from baseline to final visit (study end) in the mean number of incontinence episodes/24 h and micturitions/24 h. Efficacy was assessed according to patient micturition diaries and safety assessments included adverse event (AE) reporting. Patients were randomized and received study drug (placebo: n=453; mirabegron 50 mg: n=442; mirabegron 100 mg: n=433). Mean age was 60.1 years, 74.3% were female, 29.7% had urgency incontinence, 38.1% had mixed stress/urgency incontinence with urgency predominant and 32.2% had frequency without incontinence. At the final visit, mirabegron 50 and 100 mg showed statistically significant improvements in the co-primary efficacy endpoints and mean volume voided/micturition compared with placebo. Statistically significant benefits were achieved at the first-measured time point of Week 4. The incidence of AEs was similar across the placebo and mirabegron 50 and 100 mg groups (50.1, 51.6 and 46.9%, respectively). The most common (≥3%) AEs in any treatment group were hypertension (6.6, 6.1 and 4.9%, respectively), urinary tract infection (1.8, 2.7 and 3.7%), headache (2.0, 3.2 and 3.0%) and nasopharyngitis (2.9, 3.4 and 2.5%).

Khullar et al. [2011] performed a similarly designed study in Europe and Australia, enrolling 1978 patients, which included a fourth arm in which tolterodine SR 4 mg was used as a comparator. Like the American study, Khullar et al. [2011] found that mirabegron caused a statistically significant improvement from baseline compared with placebo in the number of urgency incontinence episodes and number of micturitions per 24 hours. Mirabegron 50 and 100 mg was numerically superior to tolterodine in these two key OAB symptoms, but the study was not powered for further analysis. Mirabegron 50 and 100 mg was well tolerated, no differences being found between the placebo arm and the two mirabegron arms. In particular, the incidence of hypertension or UTI were identical. In contrast with tolterodine, no increased dry mouth incidence was observed with mirabegron.

Mirabegron has been shown to be effective in the treatment of the OAB syndrome and has been approved for clinical use on this indication in Japan. The Japanese label contains a warning: “Avoid administration to patients of reproductive age”. Mirabegron is currently under consideration for approval in Europe (EMA). In the US, the drug was approved in June 2012.

A positive effects of solabegron in patients with the OAB syndrome has also been documented in an RCT [Ohlstein et al., 2012].

V. PHOSPHODIESTERASE (PDE) INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [Andersson, 1999; Andersson and Wein, 2004]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [Andersson and Arner, 2004]. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach [Andersson et al., 1997; 2007; 2011]. There are presently 11 families of PDEs, some of which preferentially hydrolyse either cAMP or cGMP [Uckert et al., 2006] (Figure 15).

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. [2006] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferentially inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside, and to agents acting via the cGMP system [Truss et al., 2000]. However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone [Truss et al., 2001]. Significant dose-dependent relaxations were also induced by human cAMP analogs [Truss et al., 2001]. With these studies as a background, Truss et al. presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders, and not responding to standard antimuscarinic therapy [Truss et al., 2000]. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter [Truss et al., 2001]. Studies with other PDE 1 inhibitors than vinpocetine (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.
PDE 4 (which also preferably hydrolyses cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [Longhurst et al., 1997] and rat [Kaiho et al., 2008] bladder strips, and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder [Gillespie and Drak., 2004; Nishiguchi et al., 2007]. Previous experiences with selective PDE 4 inhibitors showed emesis to be a dose-limiting effect [Giembycz, 2005]. If this side action can be avoided, PDE 4 inhibition seems to be a promising approach.

Oger and co-workers showed that PDE5-inhibitor sildenafil-induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K(+) channel-dependent signalling pathways, with a minor contribution from NO [Oger et al., 2010]. In combination with the α1-AR antagonist doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle and their combination provided a significant benefit when targeting relaxation of both tissues [Oger et al., 2008].

In-vivo, several studies have indicated a role for PDE5-inhibitors in the regulation of micturition function. Systemic vardenafil reduced both non-voiding contractions and bladder afferent nerve firing in unanesthetized, decerebrate, spinal cord injury rats, indicating potential mechanisms by which PDE5-Is improve storage symptoms in SCI patients [Behr-Roussel et al., 2010]. The effect of vardenafil on OAB-symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (SHR) [Morelli et al., 2009a; Morelli et al., 2009b]. Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment [Morelli et al., 2009b]. Thus, besides relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalfil was shown to increase prostate tissue oxygenation in SHR and human vesicoureteral-refluxary artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalafil in vitro; these results suggest another possible mechanism through which PDE5i exert beneficial effects on LUT symptoms [Morelli et al., 2011].

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [Andersson and Arner, 2004]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. examined the effects of isoproterenol, prostaglandin E1 and E2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra [Morita et al., 1994]. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al. [2006] characterized the distribution of PDE 5, cGMP and PKG1 in female pig and human urethra,
and evaluated the effect of pharmacological inhibition of PDE-5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONO-ate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE-5 IR could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE-5 inhibitors at high concentrations. Fibbi et al. [2009] confirmed that the highest expression and biological activity of PDE5 was found in bladder. However, a consistent PDE5 expression and activity was also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fibre afferent activation, it was shown that the NO/cGMP signalling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather on the motor component of the micturition reflex [Caremel et al., 2010].

The observation that patients treated for erectile dysfunction with PDE5 inhibitors had an improvement of their LUTS, has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS [Sairam et al., 2002], this observation has been confirmed in several well designed and conducted RCTs. To date, 12 RCTs are available comparing the effect of PDE5 inhibitors alone to placebo and the combination of alpha-blockers and PDE5 inhibitors vs alpha-blockers alone [Bechara et al., 2008; Gacci et al., 2011; Kaplan et al., 2007; Liguori et al., 2009; McVary et al., 2007a; b; Porst et al., 2009; 2011; Roehrborn et al., 2008; Stief et al., 2008; Tamimi et al., 2010; Tuncel et al., 2010]. In these studies, different PDE5 inhibitors and different doses were administered.

PDE5-inhibitors significantly improve IPSS and IIEF scores, but not Qmax when compared to placebo. According to a recent meta-analysis by Gacci and co-workers, differences in IPSS score were significantly lower in older and obese patients [Gacci et al., 2011]. The combination of PDE5-inhibitors and alpha-blockers lead to significant improvements of the IPSS and IIEF score as well as Qmax when compared to the use of alpha-blockers alone. Recently, Dmochowski showed that tadalafil once daily for LUTS had no significant effect on bladder function as measured by detrusor pres-sure at maximum urinary flow rate or such as maximum detrusor pressure and bladder outlet obstruction index while improving IPSS [Dmochowski et al., 2010]. PDE5-inhibitors were generally shown to be safe and well tolerated.

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS/OAB and their site(s) of action largely remain to be elucidated. If the site of action were the smooth muscles of the outflow region (and the effect relaxation), an increase in flow rate should be expected. In none of the trials referred to such an effect was found. (However, see Oelke et al.[2012]). On the other hand, there are several other structures in the LUT that may be involved, including those in the urothelial signaling pathway (urothelium, interstitial cells, and suburothelial afferent nerves). In general, it is believed that major mechanisms contributing to LUTS include reduced nitric oxide/cyclic guanosine monophosphate signaling pathway, increased RhoA kinase pathway activity, autonomic overactivity, increased bladder afferent activity and pelvic ischemia [Andersson et al., 2011].

In practical considerations it has to be mentioned that only tadalafil has been recently approved for the treatment of LUTS due to benign prostatic obstruction; long-term experience with PDE5 inhibitors in patients with LUTS is still lacking [Oelke et al., 2011]. In addition, insufficient information is available on the combination of PDE5 inhibitors with other LUTS medications such as 5-alpha-reductase-inhibitors.

VI. ANTIDEPRESSANTS

Several antidepressants have been reported to have beneficial effects in patients with DO [Lose et al., 1989; Martin and Schiff, 1984]. The use of antidepressants was shown to be an independent risk factor for lower urinary tract symptoms suggestive of benign prostatic hyperplasia in a community based population of healthy aging men (Krimpen Study) [Kok et al., 2009].

1. IMIPRAMINE

Imipramine is the only drug that has been widely used clinically to treat this disorder. Imipramine has complex pharmacological effects, including marked systemic antimuscarinic actions [Baldesarini, 1985] and blockade of the reuptake of serotonin and noradrenaline [Maggi et al., 1989], but its mode of action in DO has not been established [Hunsballe and Djurhuus, 2001]. Even if it is generally considered that imipramine is a useful drug in the treatment of DO, no good quality RCTs that can document this have been retrieved. It has been known for a long time that imipramine can have favourable effects in the treatment of nocturnal enuresis in children with a success rate of 10-70% in controlled trials [Glazener et al., 2003; Hun-
sballe and Djurhuus, 2001]. It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine [Bigger et al., 1977; Giardina et al., 1979]. Children seem particularly sensitive to the cardio-toxic action of tricyclic antidepressants [Baldessarini, 1985]. The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have have been performed during the last decade [Hunsballe and Djurhuus, 2001; Natalin et al., 2009]. No good quality RCTs have documented that the drug is effective in the treatment DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

A prospective (no controls) study the impact of the “three-drug therapy” (antimuscarinic, alpha-blocker and tricyclic antidepressants) on the treatment of refractory detrusor overactivity (DO) showed a significant increase on bladder capacity and decreases on urgency, urge-incontinence and frequency. Objective urodynamic data as well as symptom score improved significantly with triple therapy [Natalin et al., 2009].

Selective serotonin-reuptake-inhibitors (SSRIs) have been tested with regard to their effects on OAB symptoms. Milnacipran hydrochloride, a serotonin-norepinephrine reuptake inhibitor (SNRI), or paroxetine hydrochloride, a selective serotonin reuptake inhibitor, were analyzed in a prospective open trial in neurogenic OAB-patients. Milnacipran reduced daytime urinary frequency, improved the quality of life index and increased bladder capacity as shown in urodynamic studies. No such changes were noted in the other categories of the lower urinary tract symptoms questionnaire or urodynamic studies, or in the paroxetine group [Sakakibara et al., 2008].

2. DULOXETINE

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Katofiasz et al., 2002; Thor and Katofiasc, 1995]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser and Chancellor, 2003]. In a placebo-controlled study, the drug showed efficacy in patients with OAB [Steers et al., 2007]. The number of micturition episodes, the primary outcome, was reduced by 2 in the duloxetine arm and by 0.5 in the placebo arm. Episodes of urgency incontinence were also significantly reduced by duloxetine. These data have not been reproduced so far in another trial. However, the high withdrawal rate observed across all studies in which the drug was evaluated for SUI, affecting 20-40% of the patients at short-term and up to 90% in long-term studies, do not predict clinical utility of duloxetine in OAB.

VII. CYCLOOXYGENASE (COX) INHIBITORS

Prostanoids (prostaglandins and thromboxanes) are synthesized by cyclooxygenase (COX) from a common precursor, arachidonic acid. Prostanoids may be involved in the control of bladder function under normal and pathological conditions, including DO and OAB. Human bladder mucosa has the ability to synthesize eicosanoids [Jeremy et al., 1987], and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma [Downie and Karmazyn, 1984; Leslie et al., 1984]. Even if prostaglandins cause contraction of human bladder muscle, it is still unclear whether prostaglandins contribute to the pathogenesis of unstable detrusor contractions. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

Cardozo et al. performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dosage of 50 mg 3 times daily [Cardozo et al., 1980a]. The drug was shown to have favourable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache and gastrointestinal symptoms. Palmer studied the effects of flurbiprofen 50 mg × 4 versus placebo in a double-blind, cross-over trial in 37 patients with idiopathic DO (27% of the patients did not complete the trial) [Palmer, 1983]. Active treatment significantly increased maximum contrac-tile pressure, decreased the number of voids and decreased the number of urgent voids compared to baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO, compared with bromocriptine in a randomized, single-blind, cross-over study [Cardozo and Stanton, 1980b]. The incidence of side effects was high, occurring in 19 of 32 patients.

Although these early clinical studies with nonselective COX inhibitors showed some promise in the treatment of these disorders, the drugs were not further developed for this indication mainly due to side effects. The interest in the use of selective COX-2 inhibitors was hampered by concerns about long-term cardiovascular toxicity with these drugs.
Intra vesical pharmacological therapy for LUTS stems from the fact that circumventing systemic administration of active compounds offers two potential advantages. First, high concentrations of pharmacological agents can be given to the bladder tissue producing enhanced local effects. Second, drugs inappropriate for systemic administration due to off target effects can be safely used. Attractive as it may be, intravesical pharmacological therapy should still be considered as a second line treatment in patients refractory to oral therapy or patients who do not tolerate its systemic side effects. However, this statement is based on the assumption that intervention therapy should follow oral medication. Research aiming at defining if patients subgroups will benefit of intravesical therapy as first line is clearly necessary. An ongoing trial to define tolerability and cost effectiveness of daily antimuscarinic therapy versus a single intra-detrusor injection of 100U of BoNT/A for treatment of urgency urinary incontinence is at this moment under way [Visco et al., 2012].

1. BOTULINUM TOXIN

a) Mechanism of action of BONT

Botulinum toxin (BoNT) is a neurotoxin produced by Clostridium botulinum. Of the seven subtypes of BONT, sub-type A (BONT-A) has the longest duration of action, making it the most relevant clinically. BoNT/A is available in three different commercial forms, with the proprietary names of Botox®, Dysport®, Xeomin®, and Prosigne. Although the toxin is the same, it is wrapped by different proteins which modify the relative potency of each brand. This was the basis for the introduction of the non-proprietary names onabotulinum toxin A (onabotA), abobotulinum toxin A (abobotA) and incobotulinum toxin A (incobotA) for Botox®, Dysport® and Xeomin®, respectively. Prosigne is the proprietary name of a BoNT/A produced in China, which currently does not have a known non-proprietary name. Although potency of each one is usually expressed in units (U) the doses are not inter-changeable. Clinical dose conversion studies for the lower urinary tract do not exist. Available information indicates that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Nevertheless these equivalences should be approached with caution. Comprehensive reviews have been produced during the last few years. [Chapple and Patel., 2006; Nitti, 2006; Patel et al., 2006; Dinis et al., 2007; Karsenty et al., 2008; Apostolidis et al., 2009; Silva and Cruz, 2009; Dowson et al., 2010; Duthie et al., 2011; Mangera et al., 2011].

Most of the information available about intravesical application of BoNT/A derives from the use of onabotA (Botox®). However, in addition to sub-type A, some studies have investigated the effect of detrusor injection sub-type B, rimabotulinumtoxinB (proprietary names being Miobloc™ or Neurobloc™ according to countries). For further details see section 9.1.13 below.

BoNT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles. The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin.

Figure 16: Mechanism of action of botulinum toxin (BoNT). BoNT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles. The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin.
cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kDa (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin. BotNT/A cleaves SNAP 25 rendering the SNARE complex inactive [Humeau et al., 2000; Chancellor et al., 2008]. Subtype B, acts preferentially through the inactivation of VAMP [Humeau et al., 2000].

BotNT/A application was extensively evaluated in striated muscle. In this tissue paralysis occurs by prevention of acetylcholine (ACh) release from cholinergic motor nerve endings [Humeau et al., 2000]. Accumulation of neurotransmitter containing synaptic vesicles is followed by terminal axonal degeneration. Striated muscle paralysis recovers within 2 to 4 months time. During this time axons develope lateral sprouts and eventually regenerate completely [de Paiva et al., 1999].

In the human bladder SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sympathetic and sensory fibers [Coelho et al., 2011]. Almost all parasympathetic nerves express the two proteins [Coelho et al., 2011]. As these nerves play a fundamental role for detrusor contraction during voiding, the blockade of ACh release is believed to play an essential role in detrusor hypo- or acontractility that follows BoNT/A injection in the bladder. In accordance with this view, it was shown that in normal or SCI animals BoNTA treatment decreased the bladder contractions evoked by electrical stimulation of spinal nerves without altering intrinsic contractions [Ikeda et al., 2012]. However cholinergic axon sprouting concomitant with clinical remission could not be documented in the detrusor [Haerkamp et al., 2004].

Bladder sensory impairment is also expected to play an important role in the final effect of BoNT/A bladder injection. About half of the peptidergic sensory fibers express SV2 and SNAP25 [Coelho et al., 2011]. BoNT/A inhibits the spinal cord release of glutamate, substance P (SP) and CGRP from sensory nerves [Purkiss et al., 2000; Aoki et al., 2005; Meng et al., 2007] as well as the release of neuropeptides at the peripheral extremities [Rapp et al., 2006; Lucioni et al, BJU Int, 2008]. BoNT/A has also been shown to reduce the suburothelial immunoreactivity for TRPV1 or P2X3 [Apostolidis et al., 2005]. Morenilla Palao et al. [2004] have shown that BotNT/A impedes TRPV1 trafficking from intracellular vesicles to the neuronal membrane, a process that is also dependent on SNARE proteins. All these mechanisms may contribute to the recent observation that BoNT/A reduces afferent firing from bladder afferents and antidromic release of neuropeptides [Ikeda et al., 2012]. Although SV2 and SNAP-25 immunoreactivity has not been detected in urothelial cells [Coelho et al., 2011], urothelial function seems also compromised after BoNT/A administration. BotNT/A has been shown to inhibit ATP release from urothelium in animal models of spinal cord injury [Khera et al., 2004; Smith et al., 2008]. Therefore, it is not surprising that administration of BoNT/A to inflamed rat bladders reduces spinal c-fos counts at the L6 and S1 spinal cord segments [Vemulakonda et al., 2005].

Cleaved, inactive SNAP-25 appears rapidly after BoNT/A injection. In the guinea-pig a robust expression of cleaved SNAP 25 could be detected already at 12 hours and maximum intensity could be detected at 24 hours with little changes afterwards. In guinea-pigs cleaved SNAP-25 expression was restricted to nerve fibers. Almost all parasympathetic fibers, either preganglionic and postganglionic were affected while less than half of the sensory fibers express the cleaved protein [Coelho et al., 2012a; b]. In the human urinary bladder cleaved SNAP 25 could be detected in NDO patients up to 11 months after BoNT/A injection. [Schulte-Baukloh et al., 2007]. The longer duration of cleaved SNAP 25 in the detrusor smooth muscle than in striated muscles, has no firm explanation at the moment. However the longer persistence of the inactive form of SNAP-25 plus the involvement of pre and post-ganglionic parasympathetic neurons may contribute to persistence of the BoNT/A effect in the bladder.

Interstitial cells (ICs) in the suburothelium form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that ICs act as modulators of bladder behaviour [Wiseman et al., Apostolidis et al., 2006]. However, the expression of connexin 43 is not altered by BoNT/A [Roosen et al, 2009]. Hence, at the moment a firm evidence for the action of BoNT/A on ICs is scant.

BotNT/A may decrease the levels of neurotrophic agents in the bladder tissue. Levels of Nerve Growth Factor (NGF) [Giannantoni et al., Liu et al., 2009] and Brain-derived Neurotrophic Factor (BDNF) [Pinto et al., 2010] have been shown to decrease in the bladder and/or urine following BoNT/A injections. As both neurotrophins have paramount roles for growth, maintenance and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism whereby BotNT/A acts upon the bladder.

b) BotNT/A effects on bladder histology

There is no evidence that repeated injections of onabotA into the detrusor muscle cause inflammatory infiltrates, fibrotic activity or apoptosis within the bladder wall [Comperat et al., 2006, Apostolidis et al., 2008, Kessler et al.]. Rather the reverse, one study demonstrated that NDO patients treated with BotNT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. The presence of eosiophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].
When the treatment was first described in 1999 for NDO patients, onabotA was diluted in normal saline in order to obtain a concentration of 10 units/ml [Schuch et al., 2000]. Under visual control through a rigid cystoscope and a flexible 6 Fr injection needle, 30 injections of 1 ml (10 units of onabotA) were done in 30 different bladder wall locations above the trigone to prevent vesico-urethral reflux. Additional refinements have been added to this technique along the following years, including the use of a local anaesthetic agent (4% lidocaine) and a flexible cystoscope [Harper et al., 2003]. The recent demonstration that onabotA 200 U applied in 30 injection sites (1 ml saline each) above the trigone is preferable to 300 U in NDO patients (200 U in 30 injection sites is the approved protocol by medical authorities) reduces the amount of onabotA per injection site to 6.66 U/ml. For abobotA larger studies used a similar technique albeit the number of injections was only 20 [del Popolo et al., 2008; Grise et al., 2010]. The number of units per injection site is obviously different taking in consideration that 500-1000 U are used [del Popolo et al., 2008]. The volume of saline at each injection site is commonly 1 ml but volumes so low as 0.25 ml per site were also used [Grise et al., 2010].

The effect of BONT/A after increasing the dose per injection site and decreasing the number of injected sites was investigated in one study. Patients were randomized to receive 300 U either in 10 or 30 sites [Karsenty et al., NAU, 2005]. The authors reported that 10 site injection was quicker and less painful and that no differences in efficacy between the two procedures could be detected up to 24 weeks. In accordance, it was found that patients receiving 300 U of onabotA distributed over 30 injection sites (30 ml of fluid in total) or the same dose of toxin distributed over 10 injection sites (10 ml of fluid in total) had a similar distribution of the fluid, as determined by MRI. About 1/3 to 1/4 of the total detrusor volume was covered by the two protocols, respectively [Mehnert et al., 2009].

When considering IDO or BPS/IC patients the most relevant aspects in the injection protocol is the smaller amount of toxin at each site, as most studies used onabotA 100 or 200 U or abobotA 500 U [see Mangera et al., 2011, Giannantoni et al., 2012 for reviews]. Another variable at stake is the trigone injection. The suggested risks of injecting bladder trigone were never demonstrated, whether onabotA or abobotA was used [Karsenty et al., 2007; Citeri et al., 2008; Mascarenhas et al., 2008; Pinto et al., 2010]. A few studies have, therefore, compared trigonal versus trigonal sparing protocols in IDO patients. A recent trial randomised 22 IDO patients to receive abobotA 500 U administration in 20 injections (1 ml each) sparing the trigone against 15 off the trigone plus 5 injections in the trigone [Manecksha et al., 2011]. Mean postvoid residual volumes and clean intermittent self-catheterisation rates between the two groups were similar. However the change from baseline of the OABSS score was greater in the trigone injected group.

Another study compared 10 trigonal injections versus 40 detrusor or suburothelial injections of 100 U of onabotA in IDO patients [Kuo, 2007]. The most effective protocol was the 40 detrusor injections because it brought more robust symptomatic improvement which lasted longer. The trigone injection only protocol was the less effective and durable of the three, although the risk of urinary retention was null [Kuo, 2007]. The suburothelial protocol brought intermediate results, worse than the detrusor but better than the trigone only technique [Kuo, 2007]. Pinto et al. [2010] injected 100 U distributed by 10 sites only in the trigone in 26 women with BPS/IC: No cases of voiding dysfunction were observed. PVR remained normal and bladder contractility index was not changed by onabotA.

Another variable of the injection technique is the volume of the saline used to reconstitute the toxin. Most studies used 1.0 mL per injection, although a few used 0.5 ml [Grosse et al., 2005; Schulte-Baukloh et al., 2005], 0.2 mL [Kuo et al., 2004], 0.25 ml [Grise et al., 2010] or even 0.1 mL per injection site [Rapp et al, Urology, 2004]. In a recent experimental study the amount of cleaved SNAP-25 induced by a fixed amount of onabotA was directly related with the volume of the injection [Coelho et al., 2012]. Thus more controlled studies designed to compare different number and locals of injection and the volume of each injection are necessary.

BoNT/A does not cross the urothelium if instilled in the bladder [Coelho et al., 2012]. Onabot/A instillation in the bladder encapsulated in liposomes may eventually overcome the urothelial barrier and induced distinctive bladder effects [Chuang et al., 2009]. However this technology has not yet been tested in humans. In contrast, electromotive administration seems to overtake this problem, at least in children. In 15 children with NDO due to myelomingocele, a 10F indwelling catheter containing a silver spiral electrode was placed in the bladder, after providing a local transurethral anaesthesia with 2% lidocaine. The bladder was filled with saline and 10 U/kg of abobotA was added. A maximal current of 10 mA (100 mA increment/s) for 15 minutes was applied using abdominal pads [Kajbafzadeh et al., 2010]. The urodynamic and symptomatic results were excellent (see below). Skin erythema and burning sensation were the only side effects reported with this method. If this technique can be applied to adults it is not known. However, it would certainly simplify BoNT/A administration.

**d) Effect of Bont/A on NDO adult patients**

OnabotA 200 U is by now approved by FDA and by several European countries to treat NDO in SCI and MS patients. This was in part the consequence of the
findings of two large pivotal phase 3 studies where efficacy and safety of onabot A in about 700 patients with NDO was compared against placebo in patients with NDO and incontinence caused by multiple sclerosis (EDSS ≤ 6.5) or spinal cord injury below T1 [Cruz et al., 2011; Ginsberg et al., 2012]. About 60% of the patients were taking antimuscarinics and maintained the same dose throughout the study. Two doses, 200 and 300 U of onabotA were compared against placebo. Primary outcome measure was the change from baseline in week episodes of urinary incontinence at week 6 after treatment. Secondary outcome measures included the change from baseline in maximum cystometric capacity, maximum detrusor pressure during first involuntary detrusor contraction and quality of life using the I-QOL total score. Both studies yielded similar findings. In the first study [Cruz et al., 2011] onabotA significantly reduced UI and improved QOL in both MS and SCI patients, with no clinically relevant differences between the two doses. At week 6 mean change from baseline in weekly incontinence episodes was -21.8 in onabotA 200U, -19.4 with 300U and -13.2 with placebo (p < 0.01). At the same time point 7.6%, 38.0%, and 39.6% of patients in the placebo, 200U, and 300U onabotA groups, respectively, were fully continent. The proportion of patients with no IDC was around 60% after onabotA 200 and 300 groups but only 17.4% after placebo. In the second study [Ginsberg et al., 2012], onabotA resulted in a 23.0%, 26.7% and 27.4% change from baseline in the incontinence episodes in the placebo, and 200 and 300 groups, respectively. Furthermore, 36% and 41% of patients in the 200 and 300 U groups, respectively, achieved dry status, contrasting with 10% in the placebo arm. In both studies, detrusor pressure and cystometric capacity increased significantly in the two onabotA groups, without clinically relevant differences between the two doses [Cruz et al., 2011; Ginsberg et al., 2012]. Patients could request a retreatment 12 weeks after initial treatment. Median time for saline treated patients was about 90 days and 250 to 300 days for those treated with 200 or 300 onabotA, without differences between the two doses [Cruz et al., 2011; Ginsberg et al., 2012]. No differences were found between patients with SCI or MS in terms of clinical response to onabotA [Cruz et al., 2011; Ginsberg et al., 2012].

The most common adverse event was UTI [Cruz et al., 2011; Ginsberg et al., 2012]. In the SCI population, the majority of which was performing CIC at baseline, the incidence was similar across all treatment groups (around 50%). In the MS population, it was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%) in the study by Cruz et al. [2011] whereas the incidence of UTI was similar, around 50%, after 200 and 300 onabotA doses in the study by Ginsberg et al., [2012]. This was related with dose dependent incidence of de novo CIC in MS patients (12.2% after saline, 29.5 after 200U, 42.2 after 300U [Cruz et al., 2011]. Ginsberg et al. [2012] observed that the incidence of CIC in patients not catheterizing at baseline was dose dependent, 10% on placebo, 35% on 200 U and 42% on 300 U, and mainly affected MS patients. The higher incidence of adverse events and the lack of clinically advantages of 300 U led to the approval of 200 U dose in NDO.

These pivotal phase 3 trials confirms observations coming from smaller trials. Schurch et al., [2005] randomized 59 NDO patients due to spinal cord injury to received onabotA 200 U, 300 U or placebo. OnabotA treated patients had a significant reduction in incontinence episodes and amelioration of urodynamic parameters versus placebo, that were still sustained 6 month post-treatment. In an additional subanalysis, onabotA also improved quality of life over placebo [Schurch et al., 2007]. No differences between onabotA 200 and 300 U were detected [Schurch et al., 2005]. A Canadian multicenter double-blind study [Herschorn et al., 2011] randomised 57 patients with NDO secondary to spinal cord injury or multiple sclerosis and urinary incontinence despite current antimuscarinic treatment to onabotA 300 U (28) or placebo (29). The mean daily number of incontinence episodes was significantly lower for onabotA than for placebo at week 6 (1.31 vs 4.76, p=0.0001). This effect was sustained at weeks 24 and 36. onabotA induced improvements were also seen in urodynamic and quality of life parameters and were maintained up to week 36.

Although not officially approved for NDO, abobotA has been the object of investigation in a few comparative clinical trials. A small study randomized a total of 31 NDO patients due to spinal cord injury, myelomeningocele, trauma at birth, multiple sclerosis and myelitis to intravesical injections of abobotA 500 U or placebo [Ehren et al., 2007]. Patients in the abobotA arm had a significantly higher cystometric capacity at 6 and 12 weeks, lower maximum detrusor pressure and episodes of urinary incontinence and less consumption of antimuscarinic drugs. Efficacy and safety of abobotA were, additionally, investigated in NDO patients that had abandoned antimuscarinic therapy. Two doses, 500 U (n = 39) or 750 U (n = 38) were compared. Complete continence at day 30 was observed in 22 patients (56.4%) and 28 patients (73.7%) receiving 500Uor 750U. The median delay in the reappearance of leakages was 168 days. Although there was a trend towards a greater improvement with 750 U, no statistically significant differences in terms of clinical and urodynamic variables and QoL were found between the treatment groups. Tolerance was excellent and equivalent for both doses.

The symptomatic improvement brought by BoNT/A injection in the bladder does not coincide with the moment of injection. The onset of BoNT/A effect was evaluated in a small open-label prospective study that specifically investigated the chronology of the symptomatic changes. Some improvement in urgency, nocturia and frequency could already be demonstrated as soon as 2 days after neurotoxin
injection in NDO patients [Kalsi et al., 2008]. In SCI and MS patients treated with onabotA, 200 or 300U, significant decrease in the number of incontinence episodes over placebo was first detected at week 2 after injection [Cruz et al., 2011].

A recent subanalysis of a phase 3 study showed that similar reductions in urinary incontinence episodes and proportion of patients fully dry were achieved, regardless of antimuscarinic use. Moreover, increment of maximal cystometric, decrease in detrusor pressure, improvement in quality of and median time to patient request for re-treatment were similar in anticholinergic users and non-users [Sievert et al., 2012]. These observations go along with those made Reitz et al. [2004] and Grosse et al. [2005] who concluded that a substantial proportion of SCI patients could reduce or interrupt anti-muscarinic medication after BoNT/A injection.

Multiple Sclerosis patients represent a particular subgroup of patients in whom a careful analysis of the efficacy and safety of BoNT/A additional attention if voluntary voiding is present before treatment. Cohort studies clearly suggest that using onabotA 300 U reduces markedly episodes of urinary incontinence. Highly significant improvements in urgency, incontinence episodes, frequency, nocturia and urodynamic parameters (bladder capacity, volume to detrusor overactivity and maximal detrusor pressure) were observed. However, most of the patients required CIC to empty the bladder after receiving onabotA 300 U [Kalsi et al., 2007; Khan et al., 2011]. In spite of this drawback, improvement in quality of life was quite remarkable indicating that patients may prefer CIC to incontinence [Kalsi et al., 2007; Khan et al., 2011]. A subanalysis of the large pivotal phase 3 study for 154 MS patients was recently reported [Cruz et al., 2011]. Fifty received saline injections, 51 onabotA 200U and 53 onabotA 300U. Weekly episodes of urinary incontinence decreased 18.1, 24.4 and 25.9 at week 6 after saline, 200 U and 300 U, respectively. About 40% of onabotA treated patients were dry at that visit, without relevant differences between the two doses. Quality of life and urodynamic parameters improved in both onabotA groups, also without relevant differences between 200 and 300 U. However, there was a dose dependent increase in post-void residual that led to CIC 2.6%, 24.3% and 37.5% of the patients after saline, 200U or 300U, respectively [Cruz et al., 2011]. Urinary infections were also higher after 200 U (58.5%) than after 300 U (70%). Therefore this subanalysis indicates that 200 U should be preferred to 300 U in for MS patients.

Whether lower that 200 U onabotA can still be effective in controlling urinary incontinence in MS patients without impairing pretreatment voluntary voiding, it is yet unclear. A pilot study with 12 MS patients with a mean EDSS of 5.0 (3.0-7.5) treated with onabotA 100 U seems to indicate that this is a valid alternative [Mehnert et al., 2010]. Daytime and night-time frequency, urgency and pad use significantly decreased while maximum bladder capacity increased. Post-void residual volume increased moderately during the initial 12 weeks but no patients required CIC. Median time to re-injection was 8 months. So, additional studies specifically designed to evaluated onabotA 100 U seems warranted in MS patients with voluntary voiding.

e) BONT/A and UTI in adult NDO patients

UTI are one of the most frequent adverse event of BoNT/A injection. In a phase 3 trial in SCI patients performing CIC, the incidence after saline or onabotA 200 and 300 U was similar, around 50%, reflecting the fact that most patients were on CIC across the three groups before treatment. In the MS population, the incidence of UTI was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%). This was eventually related with a dose dependent increase in post void residual and incidence of de novo CIC in MS patients receiving onabotA (12.2% after saline, 29.5 after 200U, 42.2 after 300U) [Cruz et al., 2011]. In a similar phase 3 trial, Ginsberg et al. [2012] found a similar incidence of UTI, of about 50%, in SCI and MS patients whether 200U or 300U were used. Although most of these infections were non-complicated, a careful exclusion of active UTI at the moment of injection and a cautious UTI screening after each BoNT/A bladder treatment seems justifiable.

A consequence of BONT/A treatment only recently noticed is a decrease in the incidence of severe urinary tract infections in NDO patients. In 30 SCI patients Gamé et al. [2008] observed that the number of pyelonephritis, orchitis and prostatitis in the 6 month before onabotA 300U, 1.75±1.87 per patient, decreased to 0.2±0.41 in the first 6 month after treatment. In 17 SCI patients that received onabotA injections for a period of 6 years, the number of urinary tract infection at the sixth year was 1.8±0.5 per year, significantly lower than at baseline, 6.7±2.1 [Giannantoni et al., 2008]. In a multicentre, cross-sectional retrospective cohort study, data from 214 NDO patients treated in 7 German centers were collected. The rate of urinary tract infections in 12 months proceeding and in the 12 months following onabotA was 68% and 28%, respectively [Boy et al., 2008]. The reason for these findings is unclear but may lie in a decreased maximum detrusor pressure resulting in less bladder wall ischemia and vesico-ureteral reflux [Wefer et al., 2009].

f) BONT/A in IDO patients

The enthusiasm of investigators rapidly produced a reasonable number of pilot studies investigating BoNT/A in patients with IDO refractory to antimuscarics. Although proper dose-escalating studies capable of defining ideal doses were lacking, investigators opted for the administration of BoNT/A in doses smaller than those initially used in NDO. That is the reason why most pilot studies used either onabot 200 U or abobot 500 U ([see list at the end, see also Mangera et al., 2011] and 4 RCT trials compared...
onabotA 200 U against placebo [Sahai et al., 2007; Brubaker et al., 2008; Flynn et al., 2009; Tincello et al., 2012]. Due to high incidence of voiding dysfunction associated with the use of onabotA 200U in IDO patients one large cohort, 100 patients, investigated the effect of onabot 100 U. Two dose escalating placebo controlled studies [Dmochowski et al., 2010; Rovner et al., 2011; Denys et al., 2012] investigated the ideal dose of onabotA. That dose seems to be 100 U. However, data from pivotal phase 3 studies with this dose are not yet available.

The largest placebo controlled RCT carried out until the moment was conducted in 8 centers in UK (the RELAX study) and randomised a total of 240 women with refractory DO to receive onabotA 200 U or placebo distributed by 20 bladder wall sites above the trigone (10 U/1ml) [Tincello et al., 2012]. Primary outcome was voiding frequency per 24 h at 6 months. Secondary outcomes included urgency and incontinence episodes and quality-of-life data. A total of 122 women received onabotA and 118 received placebo. Median leakage episodes were already significantly reduced by week 6 and at 6 months were 1.67 in onabotA vs 6.0 in the placebo group. Continence was more common after onabotA (31% vs 12%). Significant decreases also occurred in voiding frequency (8.3 vs 9.67) and in daily urgency episodes (3.83 vs 6.33). Quality of life scores were better in the toxin group. Urinary tract infections (31% vs 11%) and voiding difficulty requiring CIC (16% vs 4%) were more common after onabotA [Tincello et al., 2012].

Only one placebo controlled RCT on IDO [Sahai et al., 2007] included male patients (onabotA 200 U: 9 females and 7 males; Placebo 11 females and 8 males). Maximum cystometric capacity was the primary outcome measure and changes in overactive bladder symptoms, post-void residual, maximum detrusor pressure during filling cystometry, reflex detrusor volume and Quality of Life questionnaires were secondary outcome measures. Follow-up occurred at 4 and 12 weeks after injection, at which point the study was unblinded. Significant improvement in maximum cystometric capacity, urinary frequency and incontinence episodes were observed at 4 and 12 weeks in patients treated with BONT/A. Urgency was also significantly reduced over placebo only at 4 weeks. Post-void residual increased at 4 weeks but differences to placebo became insignificant by 12 weeks. Despite significant improvements in quality of life observed among patients treated with BONT/A, 37.5% of them required intermittent self-catheterization to empty the bladder. Two additional small RCT compared onabotA 200 U against placebo in women with IDO. Brubaker et al. [2008] randomized 28 women for onabotA 200 U and 15 for placebo. Approximately 60% of the women who received toxin had a clinical response based on the Patient Global Impression of Improvement. The median duration of their responses was 373 days, significantly longer than the 62 days for placebo. Post-void residual urine increased in 43% of the women in the BONT/A group (12 out of 26 women) and urinary tract infection developed in 75% of these women (9 of 12). These numbers exceeded by far the expected ranges and forced the suspension of the trial. Median duration of urinary retention after the first injection was approximately 2 month but increased to 5 months at a second injection [Brubaker et al., 2008].

Flynn et al. [2009] reported the preliminary results of a study comparing onabotA 200 or 300 U against placebo in patients with urinary incontinence. The primary outcome measure was the number of incontinence episodes per 24 hours whereas 24 hours pad weights, number of pads, voiding frequency, nocturia and urodynamic parameters at cystometry were secondary outcomes. Until the moment only 15 patients received onabot 200 or 300 U and 7 placebo, distributed by 10–12 sites above the trigone. Incontinence episodes were halved and pads per day were reduced by 2/3 in the onabotA group whereas no changes occurred in the placebo group. No changes were observed in nocturia, daily voiding frequency, peak flow or detrusor pressure in either group. Post-voiding residual over 200 ml was observed in the onabotA group. Four subjects experienced UTI, 2 in onabotA and 2 in the placebo group.

The obvious necessity of reducing micturition dysfunction in IDO patients treated with onabotA 200 U led to the investigation of the efficacy and safety of lower doses. Schmid et al. [2006] injected onabotA 100 U in 100 IDO patients refractory to antimuscarinic therapy. Treatment remained highly effective, incontinence and urgency sensation disappearing in 86% and 82% of patients, respectively, during an average period of 6 months. Temporary urinary retention only occurred in 4% of the cases, with additional 15% reporting moderate voiding difficulties.

The utterly necessary dose escalating studies were only recently accessible. Dmochowski et al. [2010] conducted a phase 2, multicenter, randomized, double-blind study were 288 females and 25 males with IDO experiencing ≥8 urgency incontinence episodes per week and ≥8 or more micturitions per day. They were randomized to receive 50, 100, 150, 200 or 300 U onabotA or placebo in 20 sites above the trigone (0.5 ml of fluid injected per site). A dose response was observed at week 12 for full continence (15.9%, 29.8%, 37.0%, 40.8%, 50.9% and 57.1% in the placebo, and 50, 100, 150, 200 and 300 U groups, respectively. However, during the full time course of the study, clear differentiation among doses of 100 to 300 U was not always apparent. MCC had small increases in placebo (49.5 ml), 50 U (50 ml) and 100 U (71 ml). At higher doses the increment become marked larger, 101 ml, 91 ml and 130 ml in 150 U, 200 U and 300 U groups [Dmochowski et al., 2010]. For other parameters like frequency and urgency, the magnitude of change was consistently less and a dose dependent response was not evident. A sustained response was absent in the placebo and 50 U
group compared to groups receiving 100 U or more. The proportion of patients with posttreatment PVR of 200 ml or greater was dose dependent and patients requiring CIC were 0%, 3.6%, 9.1%, 12.7%, 18.2%, and 16.4 for placebo, and 50, 100, 150, 200 and 300 U groups, respectively. Another common adverse event were UTI, 16.3%, 33.9%, 44%, 48.1% and 34.5% for placebo, and 50, 100, 150, 200 and 300 U groups, respectively [Dmochowski et al., 2010].

The conclusions was that 100 U may be the dose that appropriately balances the symptom benefits with most common adverse events, in particular the risk of CIC due to increase post-void residual urine. Another dose-escalating study randomized 107 patients (87.9% women) for placebo or onabotA (50 U, 100 U or 150 U) applied through 15 injections of 1ml each above the trigone [Denys et al., 2011]. A >50% improvement in urgency and urgency incontinence versus baseline, the primary end point, was observed in 65% and 56% of patients who received 100 U and 150 U, the difference being only numerically superior to placebo. Complete continence was observed in 55% and 50% patients after 100 U and 150 U, respectively. Urodynamic improvements were consistent with 100 U and 150 U but not with 50U. The proportion of patients with a high PVR was low in all groups [Denys et al., 2011].

Two additional non-placebo controlled RCT also support onabotA 100 U as the ideal dose for IDO. Cohen et al [2009] randomized 44 OAB-dry and wet patients to receive 100 U or 150 U. No significant differences in clinical or urodynamic outcome measures were noted between the two doses. QOL was significantly improved in both groups with no difference between 100 U or 150 U. Altaweel et al. [2011] randomized 11 patients for onabotA 100U and 11 patients to onabota 200U. No clinical or urodynamic differences were detected between the 2 groups at 3 months follow-up. Urinary retention occurred in 2 patients in the 200 U and in 1 patient in the 100 U arm.

Successful OAB treatment with onabotA does not appear to be related to the existence of DO. In a sub-analysis of the dose finding study for onabotA, no differences in outcomes were found between those with and those without baseline DO [Rovner et al., 2011]. Likewise, in a cohort of 5 male and 27 female patients with OAB and without DO, improvement in frequency and urinary incontinence was observed after treatment with onabotA [Kanagarajah et al., 2011]. Two doses were tested, 100 and 150U, without any clinically relevant differences between them [Kanagarajah et al., 2011].

A small open-label prospective study specifically investigated the chronology of the onabot 200 U in IDO patients. Urgency, nocturia and frequency improved as soon as 4 days in IDO patients, therefore slightly later than in NDO cases [Kalsi et al., 2008].

These positive data must, nevertheless, be weighed against a recent negative trial for onabotA 100 U [Dowson et al., 2011]. The RCT enrolled 23 patients with a diagnosis of OAB without DO refractory to antimuscarinics to receive intradetrusor injections of either botn-A (100 U Botox) or saline (placebo). An interim analysis was performed and the trial halted as a result of poorly perceived patient benefit. Storage symptoms remained statistically unchanged following onabotA while 3 patients in the treatment arm initiated CIC [Dowson et al., 2011].

In IDO, BoNT/A is recommended for patients refractory to antimuscarinics, that is, patients that do not respond or do not tolerate the first line medication. In a retrospective analysis of the efficacy of 100-150 U of onabotA BTX-A injections in 85 patients, treatment was more successful in patients who did not tolerate anticholinergics than in those who abandoned the medication due to poor efficacy (86% vs. 60%, respectively) [Makovey et al., 2011].

g) BONT/A in children and elderly patients

In children, the dose of BONT/A should be calculated according to body weight. Doses of between 12 U/kg of weight up to a maximum dose of 300 U [Schulte-Baukloh et al., 2002] and 4 U/Kg [Corcos et al., 2002] have been used for onabotA. The maximum suggested for abobotA is 20 U/kg up to a maximum of 400 U [Altaweel et al., 2006; Akbar et al BJU Int 2007]. BoNT/A has been essentially assayed in children with myelomeningocele [Schulte-Baukloh et al., 2002; 2003; Corcos et al., 2002; Riccabona et al., 2004; Kajbafzadeh et al., 2006; Altaweel et al., 2006]. Like in adults, the toxin increased bladder capacity and decreased maximal detrusor pressure. In 26 children with a mean age of 6.9 years, 19 of them (73%) became completely dry between clean intermittent catheterizations while 88% reported a global improvement in urine incontinence. Interestingly, in 11 (73%) out of the 15 children who had vesicoureteral reflux before injection, reflux either disappeared or decreased in grade. BONT/A also improved bowel function in 66% of the children with intestinal problems [Kajbafzadeh et al., 2006]. The success rate in terms of continence and cessation of antimuscarinic medication may, however, be substantially inferior to that seen in adults, potentially due to irreversible bladder wall changes associated with longstanding detrusor overactivity [Altaweel et al., 2006]. In a group of 20 children with myelomeningocele continence was achieved in only 13 children. At a second injection, this number also did not change appreciably [Altaweel et al., 2006].

Electromotive administration of BoNT/A may represent a substantial breakthrough among children. In 15 children with NDO due to myelomeningocele, electromotive administration of abobotA instilled in the bladder in a dose of 10 U/kg, proved very effective and safe. The mean reflex volume (99 ± 35 ml to 216 ± 35 ml) and maximal bladder capacity (121 ±39 ml to 262 ± 41 ml) increased substantially while maximal detrusor pressure decreased
from 75 ± 16 cm H2O to 39 ± 10 cm H2O. Urinary incontinence improved in 12 patients (80%), [Kajbafzadeh et al., 2011].

To date, two case series have looked at the use of BoNT/A in children with non-neurogenic OAB refractory to the anti-cholinergics. Both studies have shown an excellent response to treatment [Hoebeke et al., 2006; Marte et al., 2010]. Data have been updated recently [McDowell et al., 2011]. A total of 57 children of both gender received abobotA 12 U/kg up to a maximum dose of 480 U in multiple bladder sites. A total disappearance of OAB symptoms occurred in 66% and a partial improvement in 19% of the patients. About half of the cases had repeated injections after a mean time slightly exceeding 6 months. No cases of voiding dysfunction or UTI were reported [McDowell et al., 2011].

Elderly patients represent, as well, a very special population where urgency and incontinence are not only very distressful but also particularly prevalent. Nevertheless, only 1 study specifically addressed efficacy and safety of BoNT/A in elderly patients. Twenty one patients with refractory IDO (18 females and 3 males) with a mean age of 81.2 years (range 75 to 92) received onabotA 200 U in 20 bladder sites [White et al., 2008]. A significant decrease in the number of daily voids, from 11.4 ± 1.67 to 5.19 ± 0.83 and incontinence pads per day, from 4.0 ± 0.89 to 1.3 ± 0.60, occurred. One month after treatment 16 of the 21 patients (76%) reported greater than 50% improvement in symptoms after 1 injection while only 3 did not show improvement after 2 injections [White et al., 2008]. Mean time to deterioration was 7.12 months. There were no treatment related complications.

**h) Effect of BoNT/A on quality of life**

Firm evidence that BoNT/A bladder injection in IDO patients increase quality of life can be extracted from several RCT in which QoL changes were in most cases secondary outcome parameters.

A multicenter, randomized, double blind placebo controlled trial by Schurch et al. [2007] which randomized 59 NDO patients with urinary incontinence for onabotA 200U or 300U or placebo. I-QOL scores improved significantly over placebo, at all time points whether 300U or 200U were used. A single center, double blind, placebo controlled study was performed by Ehren et al. [2007]. Thirty-one NDO patients with incontinence were randomized to abobotA 500 U or placebo. Patients in the abobotA group showed improved quality-of-life parameters compared to the placebo group. The Canadian multicenter double-blind study [Herschorn et al., 2011a] that randomised to onabotA 300 U or placebo 57 incontinent patients with NDO secondary to spinal cord injury or multiple sclerosis also found significant advantage of onabotA in terms of I-QoL score. One pivotal phase 3 study used the I-Qol questionnaire to evaluate quality of life changes in SCI and MS patients randomized to 200 and 300 U of onabotA or placebo. Change from baseline was 24 points for both onabotA doses at 6 and 12 weeks but only 11 points at week 6 and 8 points at week 12 in the placebo group. The I-QoL questionnaires requires that a minimum change of 11 point occur in order to QoL to be detectable by patients, a barrier that was overcome by both onabotA doses [Cruz et al., 2011]. Improvements were present both in SCI and MS patients. In another large phase 3 trial these data were totally confirmed [Ginsberg et al., 2012]. Interestingly, a comparison in QoL in patients performing and non-performing CIC in the placebo, 200U and 300U arms did not show differences in patient perception, indicating that improvement in the continence condition was a more relevant outcome [Ginsberg et al., 2012].

Improvement in QoL was also found in a study that compared abobot 500 U versus /750 in a NDO population predominantly suffering from SCI. A disease- and organ-specific Qualieve questionnaire with four domains (limitations, constraints, fears, and feelings) was used to assess the Specific Impact of Urinary Problems on QoL. The initial evaluation was repeated at days 30, 90, 180, and 360. Identical improvements were detected for the two doses [Grise et al., 2010].

The importance of continence for patients quality of life is also confirmed by the study of 43 MS patients treated with onabotA 300 U [Kalsi et al., 2007]. Although 98% of patients had to perform CIC after treatment, there were sustained improvements in all quality-of-life scores with a mean duration of effect was 9.7 months. Results were maintained with repeat treatments for 11.7 months. These results were confirmed in a larger MS cohort by Khan et al. [2011]. Urogenital Distress Inventory and Incontinence Impact Questionnaire 7 scores showed considerable improvement 4 weeks after onabotA 300 U treatment even when repeated 6 times. Again, the fact that 76% of the patients were dry seemed more relevant for QoL score than the necessity of CIC that was required by almost all patients [Khan et al., 2011].

Two RCT compared quality of life after BoNT/A administration to IDO patients. Sahai et al. [2009] used the King’s Health Questionnaire (KHQ) at baseline and at 4 and 12 weeks, after injection of onabotA 200 U or saline in 16 and 18 patients of both genders. Overall QoL was significantly improved in the onabotA treated patients compared with placebo in the KHQ subdomains, ‘Incontinence Impact’, ‘Emotions’, ‘Physical imitations’, ‘Social Limitations’ and ‘Severity Measures’ at all time points. Other subdomains were improved only at some follow-up visits. The RELAX study that randomised a total of 240 women with refractory IDO to receive onabotA 200 U or placebo [Tincello et al., 2012] showed significant improvement in ICiQ-SF and I-Qol scores. However, none of the questionnaires were restored to the normal score (0 for ICiQ; 100 for IQOL)[Tincello et al. 2012]. The dose finding study by Dmochowski et al. [2010] in which placebo and onabotA 50, 100, 150, 200 and 300 U were compared showed a sustained improve-
ment in the King’s Health Questionnaire score only in patients that received doses of 100 U or higher. In contrast, patients randomized to onabotA 50 U had changes similar to those observed after placebo [Dmochowski et al., 2010]. The dose finding study by Denys et al. [2011] showed an I-QoL improvement in patients receiving onabotA 100 U and 150 U, though at some time points scores were only numerically higher than in placebo or 50U groups. The general health status, as measured by the EQ-5D visual analogue scale also improved in patients that received 100 or 150 U [Denys et al., 2011].

i) Side effects of bladder wall injection of BoNT/A

The most frequent side effects reported after intradetrusor BoNT/A injection are bladder pain and urinary infections [Karsenty et al., 2008; Del Popolo et al., 2008]. Hematuria may also occur, most of the times mild in nature. The most dangerous one, paralysis of the striated musculature due to circulatory leakage of the toxin has never been reported. Transient muscle weakness was, nevertheless, reported with abobotA application in several studies [Wyndaele and Van Dromme, 2002; Akbar et al., 2007; Del Popolo et al., 2008]. Among 199 NDO patients followed during 8 years, 5 developed hypostenia when injected with after abobotA 1000 U [Del Popolo et al., 2008]. In another study with 44 patients, 3 adults also treated with 1000 units developed muscular weakness which subsided after 5 to 7 weeks [Akbar et al., 2007]. No such cases were reported with onabotA [Karsenty et al., 2008]. The reason for the lack of transient muscle weakness among Botox-treated patients is unclear but might be related with the larger size of its molecule which limits diffusion into the blood stream. Anyway, the risk of hypostenia associated with abobotA might be avoided by using lower doses of the toxin, no more that 750 units for adults and 20 units/kg for children [Akbar et al., 2007, Del Popolo et al., 2008]. In addition, caution should be used in selecting high risk patients for botulism including children, patients with low pulmonary reserve or patients with myasthenia gravis. Aminoglycosides should be avoided during BoNT-A treatment since they might blockade motor plates and therefore enhance BoNT/A effect.

The risk of vesicoureteral reflux, which for long precluded trigonal injections [Schurch et al., 2000b, Reitz et al., 2004] seems unfounded [Karsenty et al, J Urol, 2007; Mascarenhas et al., 2008; Citeri et al., 2008; Eichel et al, 2008].

The most feared complication of BoNT/A application in patients with voluntary voiding is urinary retention and a transient necessity to perform CIC. It is, therefore, strongly recommended that in patients with spontaneous voiding BoNT/A administration is preceded by a complete information of this risk. Caregivers should ideally teach CIC to each patient before toxin injection.

In one cohort of 137 MS patients, 65% of whom relied on CISC to empty their bladder, repeated onabotA 300 U injections systematically increase that percentage to 95% [Khan et al., 2011]. In a subanalysis of MS patients with an EDSS around 5 included in the pivotal phase 3 RCT in which NDO patients were randomized for placebo, onabot 200 or 300 U the incidence of de novo CIC was dose dependent, 2.6%, 24.3% and 37.5%, respectively [Cruz et al., 2011]. A reduction of onabotA to 100 units might not be enough to solve the inconvenience. In a small cohort of 12 MS patients with a mean EDSS of 5, 25% of the patients required CIC or a suprapubic cathether to empty the bladder [Mehnert et al., 2010]. Future studies are needed in this area.

In IDO patients injected in the detrusor the rate of urinary retention or high post-voiding residuals requiring CIC is dose dependent [Dmochowski et al., 2010]. After injection of onabot 200 U 16-40% of the treated patients needed CIC [Kuo et al., 2004; 2005; Popat et al., 2005; Sahai et al., 2007; Brubaker et al., 2009; Dmochowski et al., 2010; Tincello et al., 2012]. With onabotA 100 U the risk was substantially lower, from 4% to 13% [Schmid et al., 2006; Kuo, 2007; Dmochowski et al., 2010; Cohen et al., 2009]. Onabot 50 U was associated with the lower risk of increasing postvoid residuals and de novo CIC, 3.6%. [Dmochowski et al., 2010]. In contrast, detrusor injection of onabotA 100 U restricted to the trigone [Kuo et al., 2007; Kuo et al., 2010] were devoid of any risk of dysfunctional voiding. The same lack of dysfunctional voiding after trigonal injections onabotA 100U was confirmed by Pinto et al. [2010] in BPS/IC women.

At this moment it is not possible to identify beforehand patients that will develop voiding difficulty after BoNT/A injection. The positive or negative status of the ice water test does not correlate with the risk of urinary retention after onabotA injection in NDO patients [Huwyler et al., WJU 2007]. A retrospective analysis of 217 patients receiving their first intravesical BoNTA injection for refractory IDO in a tertiary center concluded that risk factors for dysfunctional voiding and urinary retention included male gender (p = 0.013), baseline postvoid residual (PVR) > 100 ml (p = 0.003) and onabotA > 100 U (p = 0.029) [Kuo et al., 2010]. Also in a retrospective analysis of a cohort of 67 patients with IDO treated with onabotA 200 U CIC was necessary in 19 (28%). When compared to those not requiring CIC, those that started CIC had lower pretreatment maximum flow rate (15 vs 22 ml/s, P=0.003), lower projected isovolumetric pressure (43 vs 58, P=0.02) and lower bladder contractility index (113 vs 180, P=0.001) [Sahai et al, BJU Int 2009].

Another common adverse event related with intradetrusor injection of BoNT/A is UTI. In NDO patients due to SCI, almost all doing CIC at baseline, the risk of UTI in patients receiving onabotA, whether 200 U or 300 U was similar to those treated with placebo, slightly above 50% [Cruz et al., 2011]. The Canadian study randomised 57 NDO patients to placebo or
onabotA 300U. NDO was mostly due to SCI and the incidence of UTI was similar, 55% and 57%, respectively in the placebo and onabotA groups [Herschorn et al., 2011]. However, in MS patients the risk was dose-dependent, 32%, 58.5% and 70%, respectively, eventually related with the increase in post-voiding urine residual volume and necessity of performing CIC in the MS population [Cruz et al., 2011]. In the cohort of 137 MS patients subjected to repeated injections of onabot 300 U and almost all emptying the bladder by CIC, after the 3-day prophylactic course further antibiotics for UTI were required in 9% of the total of 327 treatment sessions. Low dose long-term antibiotic prophylaxis was needed in additional 17% of the patients [Khan et al., 2011]. An word of caution should however be left here. Most of these UTI were mild in nature. Severe infections like pyelonephritis, orchites or prostatitis seem to be substantially reduced after BoNT/A treatment of NDO [Game et al, 2008].

In IDO patients the risk of UTI is higher in males than in females [Kuo et al., 2010] and may well affect more than 1/3 of the patients. In RCT comparing placebo against onabot 200U the incidence of UTI was 0% vs 7% [Sahai et al., 2007], 22% vs 44% [Brubaker et al., 2009] or 11% vs 31% [Tincello et al., 2012], respectively. This adverse event seems to be dose related, eventually associated with the post-voiding urine volume increase. Domochowski et al. [2010] detected UTI in 16.3%, 33.9%, 44%, 48.1% and 34.5% of patients randomized for placebo, and 50, 100, 150, 200 and 300 U groups, respectively.

Although it is a concerned frequently rose by caregivers, at this moment there is no evidence that repeated BoNT/A injections cause detrusor atrophy or bladder wall fibrosis. Whether onabotA or abobotA were used, repeated injections in NDO patients in the short to medium term did not decrease bladder compliance which would presumably be the case if fibrosis were to develop [Reitz et al., 2007; Del Popolo et al., 2008]. Histological inspection of injected bladders did not show inflammatory changes, fibrosis, or dysplasia after repeated treatments and independently of the neurogenic or non-neurogenic origin of the detrusor overactivity [Haferkamp et al., 2004; Compérat et al., 2006; Apostolidis et al., 2008]. Rather the reverse, one study demonstrated that NDO patients treated with BoNT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. Curiously, the presence of eosinophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

j) Effectiveness of repeated injections in NDO and IDO patients

Median time for NOD patients due to SCI or MS to request a retreatment was around 300 days after onabotA 200 or 300 U but only 92 days after placebo [Cruz et al., 2011]. Therefore for patients that respond to BoNT/A a programme of reinjections is inevitable. The mean duration of the BoNT/A effect after repeated injections seems to remain stable, without any evidence of tachyphylaxis.

Three studies were identified that assessed the effect of repeated injections of onabotA and abobotA in NDO patients. A cohort of 199 patients with spinal cord lesions treated with abobotA 500 U to 1000 U was analyzed retrospectively, after 8 years of repeated injections. The intervals of between injections remained constant. Urodynamic improvements, patients satisfaction with treatment and number of pads or other protective devices was also constant after treatments [Del Popolo et al., 2008]. Intervals exceeded 12 months in 19.5% of the patients, ranged between 10-12 months in 40.2%, was < 10 months in 30.5% and < 6 months in only 10% of the patients [Del Popolo et al., 2008].

In another study, 20 consecutive NDO (SCI 18, MS 2) patients received at least five intradetrusor injections of onabotA 300 U in 30 sites above the trigone. Intervals between injections remained constant, between 193 and 199 days. Clinical continence improved significantly after the first injection and then remained constant after repeat injections. The median reflex volume increased from a 200 ml at baseline to values between 440 and 500 ml at follow-up studies. The presence of NDO decreased by 60–75%. Maximum cystometric capacity increased more than 2 folds and maximum detrusor pressure from a median of 70 cm H2O to values of about 20 cmH2O [Reitz et al., 2007].

In a MS cohort with137 patients who underwent detrusor onabot 300 U, 99 (72%) returned for a second treatment, and 47, 25, 14 and 5 returned for re-treatments 3 to 6, respectively. The median interval for 1st, 2nd , 3rd, 4th, and 5th re-injections ranged between 12 and 13 months. The outcome in terms of continence did not differ among treatments [Khan et al., 2011].

Four studies were identified that analyzed repeated injections in IDO patients. In general, longer duration of BoNT/A effect and a relatively higher rate of treatment drop out is seen among IDO patients.

From a cohort of 34 IDO patients treated with onabotA 200 U, 58% received a 2nd injection and 26% received a 3rd and 4th injection. Significant improvements in OAB symptoms, QoL and urodynamic parameters were observed after each injection as compared with baseline, without differences in efficacy parameters between the 1st and last treatment. When analyzing the reasons why 20 out of the 34 patients abandoned the programme, the fear of CIC (25%) and poor response (20%) were the leading causes [Sahai et al., 2010].

This study was recently updated for 100 patients [Dowson et al., 2012]. A statistically significant reduction in frequency, urgency, and urge urinary
incontinence were seen following onabotA 200 U injection compared to baseline. Such improvement was again maintained after repeated injections. The mean inter-injection interval was 322 days. Interestingly, 37% of the patients stopped treatment after the first two injections, dropouts being rare thereafter. The most common reason for discontinuing treatment was poor efficacy (13%). CIC related issues was pointed out by 11% of patients in spite of the incidence of CIC after the first injection being 35% [Dowson et al., 2012].

In a prospective, observational study after 1 single onabotA 100 U injection, 26 patients were followed up for 2 years. One was a primary failure, 3 were lost to follow-up, and 11 patients had a repeated injection at 5–26 months. At 2 years 7 of the remaining 11 patients were recommended repeated injection or another treatment, and four required no other treatment.

Schmid et al. [2008] reported on 25 women and 5 men that received repeated [2] injections of onabotA for treatment of IDO. The interval between two subsequent treatments ranged between 4 and 26 months (mean 12 months). Improvement of OAB symptoms, quality of life and urodynamic parameters were observed after reinjection.

k) Cost-effectiveness of BoNT/A

Economic aspects of BonT/A are a concern due to the price of the drug and the need for repeated cystoscopies, very often performed under general anaesthesia and under close monitoring to detect and treat eventual episodes of autonomic dysreflexia. Nevertheless, In UK, in a cohort of 101 patients with detrusor overactivity, 63 of whom of neurogenic origin, BonT/A treatment was shown to be cost-effective in both NDO and IDO cases [Kalsi et al, 2006]. Costs were based on the resources used by typical patients in UK and in the cost-effectiveness of 200-300 U BoNT/A (Botox) compared with standard care [Kalsi et al., 2006]. In Germany a multicenter cost analysis showed that BonT/A (onabotA) treatment halved costs for incontinence aids and for urinary tract infection treatment in 214 NDO patients. In patients using incontinence aids, mean costs per patient decreased from €2 to €1 per day, whereas the mean cost of drugs to treat UTIs per patient decreased from €163 to €8 per year [Wefer et al., 2009].

Also in NDO patients, break-even point for BoNT/A and augmentation cystoplasty costs may be reached at five years. However BoNT/A may be substantially more cost-effective if the duration of effect of each injection is superior to 5 months or if the complications associated with augmentation cystoplasty overtake 40% of the patients [Padmanabhan et al., 2011].

For OAB/IDO, an assessment of costs, from a US payer perspective, extending up to 3 years, was made for 3 interventions, sacral neuromodulation, BoNTA, and augmentation cystoplasty in patients refractory to antimuscarinics. The initial treatment cost was $22,226, $1,313, and $10,252 for sacral neuromodulation, BoNTA, and augmentation cystoplasty respectively. Three years after initiating treatment, the cumulative cost was $26,269, $7651, and $14,337 respectively. Sensitivity analyses revealed that sacral neuromodulation persisted as the most costly intervention [Watanabe et al., 2010].

l) Comparisons between different BoNT/A brands

Systematic head-to-head comparisons between the different brands of BoNT/A are still lacking. Within each brand very few studies compared different doses for neurogenic or idiopathic DO. However, meta-analysis and systematic reviews are already available which give some light on this important topic.

A recent metanalysis identified 19 randomised or quasi-randomised controlled trials for OAB/DO treatment in adults in which at least one management arm involved intravesical injection of botulinum toxin. Comparison interventions could include no intervention, placebo, lifestyle modification, bladder retraining, pharmacological treatments, surgery, bladder instillation techniques, neuromodulation, and different types, doses, and injection techniques of BoNT/A. Most patients in the studies had neurogenic DO, but some included patients with idiopathic DO. All studies demonstrated superiority of botulinum toxin to placebo. Lower doses of onabotA (100 to 150 U) appeared to have beneficial effects, but larger doses (300 U) may have been more effective and longer lasting, but with more side effects [Duthie et al., 2011].

Mangera et al. [2011] in a systematic review identified good-quality studies that evaluated onabotulinumtoxinA for all the indications in adults. However that was not the case with abobotA. Although this does not imply that onabotA is more effective than abobotA, it should be a consideration when counseling patients on the use of botulinum toxin in urologic applications. The two preparations should not be used interchangeably, either in terms of predicting outcomes or in determining doses to be used.

The only study available that compares two different brands used onabotA 200 or 300 U against the Chinese BoNT/A Presigne in the same dosage. Improvement in MCC was significantly greater with onabotA Botox versus Presigne (+103.3% vs. +42.2%; P = 0.019). Continence was achieved by week 12 in 16 onabotA recipients (76.2%) and in 10 Presigne recipients (47.6%; P = 0.057) [Gomes et al., 2010]. Future studies seems, therefore, justified to assess the relative potencies of the different brands of BoNT/A.

m) BONT/B

Some humans repeatedly injected with BONT-A may develop resistance to the toxin, possibly due to antibody formation. Although this event seems very rare in the case of bladder injections, a minimum interval of 3 months between two BoNT/A injections is gener-
ally recommended to decrease its occurrence. If resistance appears, recent reports [Dykstra et al., 2003; Pistolesi et al., 2004; Reitz et al., 2004] investigated the replacement of BONT-A serotype by BONT-B. At this moment empiric doses of BoNT/B are being used as there is no clear potency equivalents for the two serotypes and between BoNT/B brands.

In 3 patients with spinal NDO, bladder injection of 5000 UI [Pistolesi et al., 2004] or 7500 UI [Reitz and Schurch, 2004] of BONT-B (Neurobloc ®) restored bladder function for 6 months [Reitz and Schurch, 2004]. Interestingly, 1 patient experienced dry mouth and dry eyes that resolved within 20 days. As this side effect was not reported after bladder BONT-A application, it is possible that different toxin serotypes have some different degrees of organ affinity. Dykstra et al. [2003] carried on a dose escalation study with BONT-B (rimabotB in 15 female patients with OAB. They used doses of 2500, 3750, 5000, 10,000, and 15,000 U injected at 10 sites. Only 1 patient failed to respond and a clear dose-dependent effect, was observed, with the longest response seen in those injected with 15,000 U. Two patients, both injected with 15,000 U, experienced dry mouth and general malaise. In another study involving IDO and NDO patients, in which rimabotB 5000 U were used, Hirst and coworkers [2007] observed a limited duration of action, with most of the symptomatic beneficial effects wearing off by 10 weeks in most of the patients. The short duration of action for BONT-B at safe doses may, therefore, limit the clinic usefulness of this serotype.

n) BONT/A in IC/PBS

BONT/A significantly inhibits the nocuous sensory input from the bladder [Vemulakonda et al., 2005; Rapp et al., 2006; Lucione et al., 2008]. Therefore several pilot studies were carried out in the last few years. None is placebo controlled, a fact that limits the scientific value of the observations. On the other hand different techniques of administration have been assessed. These two facts may explain some heterogeneity of results.

The first pilot study with 13 females observed that, 9 (69%) had subjective improvement after onabotA 100 or 200 U injected in the trigone and above the trigone. Mean scores in the Interstitial Cystitis Symptom Index and the Interstitial Cystitis Problem Index improved by 71% and 69%, respectively. Daytime frequency, nocturia, and pain measured by a Visual Analogue Scale (VAS) decreased by 44%, 45%, and 79%, respectively. Symptom improvement lasted a mean of 3.7 months (range 1 to 8) [Smith and Chancellor, 2004]. In another pilot study with 15 patients, Giannantoni et al. [2006; 2008] reported similar observations after bladder injection of onabotA 200 U (150U above the trigone, 50 U in the trigone). Subjective improvement at 1 and 3 month follow-up occurred in 86% of the patients but at 5-month only persisted in 26.6% . Importantly, 9 patients experienced moderate to severe voiding difficulties [Giannantoni et al., 2006; 2008] A third study could not demonstrate any effect of onabotA in 13 IC/PBS patients treated with onabotA 100–300 U in the bladder [Davies et al., 2006].

Three other studies, which added substantial modifications to the above protocol, reported, on the contrary, considerable improvement in clinical and urodynamic outcomes after BoNT/A administration.

A prospective, randomized study enrolled 67 patients with refractory IC/PBS Of these, 44 patients received suburothelial injection of onabotA 200 U [15] or 100 U [29] followed by cystoscopic hydrodistention 2 weeks later. The control group (23 patients) only received hydrodistention. The IC/PBS symptom score significantly decreased in all three groups, but VAS pain reduction and urodynamic improvement were only observed at 3 months in the arms that received onabotA, without any relevant differences between the two doses. A successful result at 12 and 24 months was reported in 55% and 30% of onabotA treated patients, respectively, compared with only 26% and 17% in the control group. The validity of these positive long-term results should however be interpreted with caution since all patients remained on baseline pentosan polysulphate throughout the study [Kuo and Chancellor, 2009].

Taking in consideration that most of the bladder nociceptors course in the trigone, Pinto et al. [2010] restricted 100 U onabotA injections to the trigone, in 10 sites (10 U/ 1 ml each. Twenty six women with positive findings at cystoscopy and biopsy were enrolled. All patients reported subjective improvement at 1- and 3-month follow-up in pain, daytime and nighttime voiding frequency, O’Leary-Sant score and QoL. Bladder volume to first pain and maximal cystometric capacity more than doubled. Treatment remained effective in >50% of the patients for 9 months. Retreatment was equally effective in all cases, with similar duration of the effect [Pinto et al., 2010]. No cases of dysfunctional voiding were reported after trigonal injections of onabotA 100U. Also PVR at urodynamics and bladder contractility index were not impaired [Pinto et al., 2010].

The third was a small placebo controlled trial comparing periurethral injections of onabotA 50U (n=9) versus saline (n=11). The rationale was to investigate the participation of periurethral somatic afferents to pain. The solution, 2 ml, was injected in the region of the bladder neck, at the 3 o’clock and 9 o’clock positions. Unfortunately, there was no differences between the onabotA and the at 3-month follow-up in terms of symptoms.

At this moment, without a well conducted placebo controlled RCT it is difficult to state how effective is BoNT/A in BPS/IC. However, taking in consideration the effects the toxin induces in nociceptors and in the urothelium and the favourable results of the two largest clinical trials, it is tempting to suggest that further assessments are warranted.
2. CAPSAICIN AND RESINIFERATOXIN (RTX)

a) Rationale for intravesical vanilloids

The rationale for intravesical vanilloid application in patients with detrusor overactivity (DO) was offered by the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent upon a sacral micturition reflex [de Groat, 1997]. The C-fiber micturition reflex is usually inactive but it was shown that it is enhanced in patients with chronic spinal-cord lesions above sacral segments [de Groat, 1997] in those with chronic bladder outlet obstruction [Chai et al., 1998] and in those with IDO [Silva et al., 2002]. In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of suburothelial C-fibers expressing TRPV1 [Brady et al., 2004]. Curiously, NDO patients who responded better to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas non-responders experienced a non-significant variation [Brady et al., 2004]. A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX [Apostolidis et al., 2005; 2006].

Changes in suburothelial C-fibers expressing neuropeptides [Smet et al. 1997] or TRPV1 [Liu and Kuo, 2007] were also reported in patients with and sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the over-expression of the receptor in the bladder mucosa [Liu and Kuo, 2007]. In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only increased but also inversely correlated with the bladder volume at first sensation of filling during cystometry further indicating that TRPV1 play a role in premature bladder sensation [Liu et al., 2007].

b) Intravesical capsaicin

Intravesical capsaicin for NDO was studied in 6 non-controlled [Fowler et al., 1992; Fowler et al., 1994; Geirsson et al., 1995; Das et al., 1996; Cruz et al., 1997, De Ridder et al., 1997] and 1 controlled clinical trial [de Seze et al., 1998]. Capsaicin was dissolved in 30% alcohol and 100-125 ml (or half of the bladder capacity if lower than that volume) of 1-2 mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. Best clinical results were found among patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70-90% the patients [Fowler et al., 1994, Cruz et al., 1997; De Ridder et al., 1997]. In patients with complete spinal cord lesions the success rate was much lower [Geirsson et al., 1995].

Only one small randomized controlled study compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin and found a significant regression of the incontinence and urge sensation. In contrast, only 1 among the 10 patients that received ethanol had clinical improvement [de Seze et al., 1998].

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. In particular, the possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions has progressively restrained its use. The relevance of capsaicin might however be back with a recent observation by de Séze et al.[2006] with a new capsaicin formulation. They conducted a double blind placebo controlled study with a glucidc solution of capsaicin in 33 NDO patients. The glucidic-capsaicin treated group showed improvement both in symptoms and urodynamic parameters above the comparator arm. The global tolerance of this new capsaicin formulation was excellent [de Séze et al., 2006].

c) RTX in NDO

Resiniferatoxin (RTX) has the advantage over capsaicin in being much less pungent [Cruz et al., 1997]. Intravesical RTX application in NDO patients was evaluated in five small open-label studies (Cruz et al., 1997; Lazzeri et al., 1997; 1998; Silva et al., 2000; Kuo 2003). Different RTX concentrations, 10 nM, 50 nM, 100 nM and 10 μM were tested. RTX brought a rapid improvement or disappearance of urinary incontinence in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency. Furthermore, RTX also increased the volume to first detrusor contraction and maximal cystometric capacity. In general, in patients receiving 50-100 nM RTX the effect was long-lasting, with a duration of more than 6 month being reported. In patients treated with 10 μM doses, transient urinary retention may occur [Lazzeri et al., 1998].

In a recent placebo-controlled study, the urodynamic effects of RTX in NDO patients was specifically evaluated. Only in the RTX arm a significant increase in first detrusor contraction and maximal cystometric capacity was found [Silva et al., 2005]. RTX also caused a significant improvement in urinary frequency and incontinence [Silva et al., 2005].

RTX, 600 nM was compared against BONT/A (Botox, 300U) in a study involving 25 patients with NDO due to chronic spinal cord injury. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BONT/A turned out to be more effective.

d) RTX in IDO

The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 ± 109 ml to 440 ± 153 ml at 30 days, and to 391 ± 165 ml at 90 days. An increase in mean MCC from 291 ± 160 ml to 472 ± 139 ml at 30 days and to 413 ± 153 ml at 90 days was also observed.
These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency [Silva et al., 2002]. Subsequent small open label studies confirmed these observations using either a single high (50-100 nM) or multiple low (10 nM) dose approaches [Kuo, 2003; Dinis et al., 2004; Kuo et al., 2005].

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials [Kuo et al., 2006; Rios et al., 2007]. Kuo et al. [2006] randomised 54 patients to receive 4 weekly instillations of a low concentration RTX solutions (10 nmol/L) or the vehicle solution, 10% ethanol in saline [Kuo et al., 2006]. Three months after completing the 4 intravesical treatments, the RTX treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group, 14.2% and 7.1% respectively. At 6 months treatment remained effective in 50% patients in the RTX group but only in 11% in the placebo group [Kuo et al., 2006]. Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 ml of either RTX 50 nM or placebo. Patients were followed-up only for 4 weeks. During this period a single 50 nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence [Rios et al., 2007].

e) RTX and urgency

The involvement of bladder C-fibers in IDO has led some investigators to explore the role of these sensory afferents to the genesis of urgency. In a non-controlled study involving 12 male patients with LUTS associated with BPH, mean IPSS halved following intravesical administration of RTX (50 nmol/L). The decrease in IPSS was largely due to improvements in scores related to urgency, in addition to improvement in nocturia and frequency [Dinis et al., 2005]. In another open-label study 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain/discomfort, and without urodynamic evidence of DO received one single 50 nM RTX solution. A trend towards an improvement of urgency was noticed [Apostolidis et al., 2006].

In a quasi-randomised study, 23 OAB patients with refractory urgency entered a 30 day run-in period in which medications influencing the bladder function were interrupted. At the end of this period patients filled a 7-day bladder diary. Then, patients were instilled with 100 ml of 10% ethanol in saline (vehicle solution) and 30 days later a second 7-day diary was collected. Finally, patients were instilled with 100 ml of 50 nM RTX in 10% ethanol in saline and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 ± 11. At 1 and 3 months after RTX instillation the number of episodes of urgency decreased to 39 ± 9 (p = 0.002) and 37 ± 6 (p = 0.02), respectively [Silva et al., 2007].

f) Intravesical RTX and IC/PBS

TRPV1 involvement in pain has stimulated the investigation of RTX as a treatment for bladder pain in IC/PBS. After desensitization of bladder C-fibers, RTX reduces the spinal expression of c-fos, a pain evoked gene, in animal models of cystitis [Dinis et al., 2004]. TRPV1 knock-out mice, which do not express the receptor in the bladder, do not experience an increase in the frequency of bladder reflex contractions or in the expression of c-fos in the spinal cord during cystitis [Charrua et al., 2007]. Patients with IC/PBS have more TRPV1 expressing sensory fibers in their bladder mucosa than normal individuals [Mukerji et al., 2006].

In a placebo-controlled study of 18 patients with IC/PBS, Lazzeri et al. [2000] reported an improvement in pain and urinary frequency after administration of intravesical RTX in 10 nmol/L concentration. This effect was short-lasting, eventually due to the use of a low dose of RTX. Chen and co-workers conducted a dose-escalating study and concluded that the most commonly reported adverse event with RTX was pain during instillation. However, at 10 or 5 nM RTX was safe and could improve bladder pain [Chen et al., 2005]. Additionally, 3 non-controlled studies have also reported bladder pain improvement after intravesical RTX [Lazzeri et al., 2004; Apostolidis et al., 2006; Peng and Kuo, 2007]. A randomized, double-blind study in 163 patients with IC/PBS, in which several doses of intravesical RTX (10 nmol/L, 50 nmol/L, and 100 nmol/L) were compared with placebo, failed, however, to show any advantage for the neurotoxin over placebo in terms of overall symptoms, pain, urgency, frequency, nocturia, or average voided volume during 12 weeks of follow up [Payne et al., 2005].

IX. OTHER DRUGS

1. BACLOFEN

Gamma-amino-butyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex at several points along its central pathway [de Groat, 1997; Pehrson et al., 2002]. Experimental data suggest the GABAergic system as an interesting target for bladder dysfunc-
tion therapy. Baclofen intrathecally attenuated oxy-
hemoglobin induced detrusor overactivity, suggest-
ing that the inhibitory actions of GABA(B) receptor agonists in the spinal cord may be useful for control-
ling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [Pehrson et al, 2002]. In spinal intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssyner-
gia (DSD)-like changes whereas intrathecal applica-
tion of baclofen induced urethral relaxation during isovolumetric bladder contractions [Miyazato et al., 2009]. After spinal cord injury (SCI), Miyazato et al.
[2009] found signs of hypofunction of the GABAergic system (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased), and showed that activation of GABA(A) and GABA(B) receptors in the spinal cord inhibited DO as evidenced by a reduction in non-voiding contractions. GABA(B) receptor activation preferentially reduced DO prior to inhibiting voiding contractions while GABA(A) receptor activation inhibited DO and voiding contraction at the same concentration.

As a GABA agonist on GABA(B) receptors, baclofen was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier [Taylor and Bates, 1979]. Baclofen is one of the most effective drugs for the treatment of spasticity following spinal cord injury, traumatic or hypoxic brain injury, and cerebral palsy [Ochs, 1993], and intrathecal baclofen was shown to be useful in some patients with spasticity and bladder dysfunction [Bushman et al., 1993]. Baldo et al. [2000] found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric whereas maximal detrusor pressure decreased. At ten days the volume to first detrusor contraction had increased from 143 ml to 486 ml. In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

1. α1-AR ANTAGONISTS WITH ANTIMUSCARINICS

Traditionally, male lower urinary tract symptoms (LUTS) were thought to result from benign prostatic obstruction (BPO) secondary to benign prostatic enlargement (BPE). However, male LUTS may arise from prostatic pathology, bladder dysfunction, or both. Thus, diagnosis and appropriate treatment of men with OAB symptoms are complex and difficult. α1-AR antagonists remain the most widely used pharmacologic agents for relief of bladder outlet flow resistance, as they relax prostatic and urethral smooth muscle tone, the dynamic component of BPO [Andersson and Gratzke, 2010; Lepor et al., 2012]. In contrast, antimuscarinics, which function by competitively blocking the muscarinic receptors, are the first-line pharmacologic treatment for OAB [Andersson et al., 2009]. Given the prevalence of combined voiding and OAB symptoms as well as the finding that the QoL of these patients is affected primarily by the symptoms of OAB, it might be logical for this category of patients to be given antimuscarinic drugs [Ruggieri et al., 2005].

A variety of such combinations have been evaluated. Several randomized, controlled trials demonstrated that the combination treatment of antimuscarinic drugs and α1-AR antagonist was more effective at reducing male LUTS than α1-AR antagonists alone in men with OAB and coexisting BPO [Saito et al., 1999; Athanasopoulos et al., 2003; Lee et al., 2004; 2005; Kaplan et al., 2006; 2008]. Therapeutic benefit of combining an antimuscarinic agent (propiverine) with α1-AR antagonists (tamsulosin), as compared to α1-AR antagonists alone, was reported by Saito and colleagues [Saito et al., 1999]. The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than the α1-AR antagonist-alone group. The post-void residual (PVR) was unchanged in both groups, and there was only one case (1.5%) of acute urinary retention (AUR) with the combined treatment.

Subsequently, Lee et al. [2005] compared the efficacy and safety of combination therapy with propiverine and doxazosin in 211 men with urodynamically confirmed bladder outlet obstruction (BOO) and OAB symptoms for 8 weeks. Compared with the doxazosin arm, the patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores of international prostate symptom score (IPSS). Patient satisfaction was significantly higher in the combination group. There was also a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

A large-scale, multicenter, randomized, double-blind, placebo-controlled trial (the TIMES study) demonstrated the efficacy and safety of tolterodine extended release (ER) alone, tamsulosin alone, and the combination of both in 879 men with OAB and BPO [Kaplan et al., 2006]. In the primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 (p<0.001 vs. placebo; p=0.001 vs. tolterodine ER; p=0.03 vs. tamsulosin). In the secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin compared with placebo experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia. However, there were no significant differences between tamsulosin monotherapy and placebo for any diary variables at week 12. Patients receiving tolterodine ER plus tamsulosin demonstrated significant improvements in total IPSS (−8.02 vs. placebo, −6.19, p=0.003) and QoL (−1.61 vs. −1.17, p=0.003). Although there were significant improvements in the total IPSS among patients who received tamsulosin alone, the differences in total IPSS among patients that received tolterodine ER versus placebo were not significant. The combination of antimuscarinics and α1-AR antagonists may be the most effective therapy in men with OAB symptoms in the presence of BPO.

X. COMBINATIONS
significantly improved urgency variables and patient-reported outcomes. Moreover, this group of patients reported increased satisfaction with the treatment as well as willingness to continue the treatment. Another subanalysis [Kaplan et al. 2008] of data from the TIMES study examined the effects of the drugs on urinary symptoms as assessed by the IPSS. Based on this subanalysis, the authors concluded that tolterodine ER plus tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms. However, these results should be considered with caution, as they were derived from post-hoc analysis of the TIMES data.

Maruyama et al. [2006] reported different results in their prospective, randomized, controlled study in which naftopidil (25-75 mg/day), an α1d-AR antagonist, alone or in combination with propiverine hydrochloride (10-20 mg/day) or oxybutynin hydrochloride (2-6 mg/day), was administered for 12 weeks to 101 BPH patients. In the study, the IPSS and QoL index improved significantly in both groups, with no marked differences between groups. Maximum flow rate (Qmax) and PVR tended to improve in both groups, again with no differences between groups. However, median post-therapeutic PVR was significantly larger in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, p = 0.021). There were significantly more patients with increased residual urine volume relative to unchanged residuals in the combination therapy (22.9%) group versus the monotherapy group (5.0%, p = 0.038). The authors of this study concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than monotherapy. Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased residual urine volume was significantly greater in the combination therapy group than the monotherapy group.

The results of another study using low-dose antimuscarinic therapy was published by Kang et al. [2009]. They evaluated the efficacy and safety of combined treatment with tamsulosin 0.2 mg and propiverine hydrochloride 10 mg compared with tamsulosin monotherapy. After 3 months, both groups showed significant improvements in IPSS, QoL, voided volume, Qmax, and PVR, but only the QoL index was significantly different between groups in favor of the combination group. No cases of AUR were recorded in this low-dose study.

Medical therapy to reduce detrusor overactivity in a neurogenic bladder has focused on antimuscarinic therapy, which increases bladder capacity, decreases bladder filling pressure, and improves compliance [Goessl et al., 1998; Stohrer et al., 2007]. Although antimuscarinics combined with clean intermittent catheterization is the most commonly recommended medical therapy for neurogenic bladder, the results are sometimes unsatisfactory, and many patients continue to have poor bladder compliance and remain incontinent [Razdan et al., 2003]. MacGuire reported that α-AR antagonists decreased bladder pressure with filling and increased capacity, and that the addition of an antimuscarinic enhanced these effects, indicating that α-AR antagonists and the antimuscarinic had a synergistic effect on detrusor tone in the decentralized bladder [McGuire and Savastano, 1985]. This finding led to the widespread use of α1-AR antagonists in the treatment of neurogenic bladder (Chancellor et al., 1994; Swierzewski, Gormley et al. 1994; Abrams et al., 2003). Swierzewski treated 12 patients with spinal cord injury who had poor bladder compliance, despite therapy with clean intermittent catheterization and an antimuscarinic, with 5 mg terazosin for bladder management (Swierzewski et al., 1994). After 4 weeks, compliance increased by 73%, bladder pressure decreased by 36 cmH2O, and capacity increased by 157 mL. These results support the theory that α-AR antagonists and antimuscarinics have a synergistic effect on the bladder in the neurogenic population.

In a retrospective chart review, combination therapy with an antimuscarinic agent, an α1-AR antagonist, and imipramine produced superior results to those obtained using a single agent in patients with neurogenic bladder dysfunction [Cameron et al. 2009]. These patients showed significant improvement in clinical parameters and compliance, and decreased bladder pressures at capacity. It has been shown that in the decentralized human detrusor, there may be an increase in α-1-AR sites sites and a switch to α-1-AR mediated contractile function from the typical β-AR mediated relaxation function during bladder filling [Sundin et al. 1977]. The tricyclic antidepressant imipramine is a muscarinic receptor agonist and a direct smooth muscle inhibitor that decreases bladder overactivity by blocking the reuptake of serotonin. Other effects include the peripheral blockade of noradrenaline, stimulating the β ARs at the dome of the bladder, and decreasing bladder contractility [Hoebeke and Vande Walle, 2000]. These results suggest that targeting multiple receptors may maximize the effectiveness of pharmacological treatment of neurogenic bladder and should be considered in patients in whom treatment with antimuscarinics alone fails.

2. COMBINED ANTIMUSCARINICS

Although antimuscarinic agents are the first choice of treatment for patients with OAB symptoms, these drugs do not always lead to the desired effect of detrusor stability and continence, especially for patients with spinal cord injury or neurologic diseases such as multiple sclerosis or meningomyelocele. In these patients, the goal of urological therapy is to maintain continence and to reduce intravesical pressure. When antimuscarinic treatment fails,
however, invasive procedures such as the injection of botulinum toxin, intravesical application of drugs, or surgery are necessary.

A combined antimuscarinic regimen was evaluated as a non-invasive alternative by Amend and colleagues [Amend et al., 2008] for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dosed antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dosed antimuscarinic monotherapy. The study drugs were tolterodine, oxybutynin, and trospium. After a 4-week combined regimen, incontinence episodes decreased and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side-effects were comparable to those seen with normal-dosed antimuscarinics. Those positive findings were speculated to be due to: 1) synergistic activation of different muscarinic receptors or interactions of receptors on different parts of the bladder wall, 2) undiscovered faster metabolism of antimuscarinics requiring an increased dosage of different antimuscarinic drugs, and/or 3) down-regulation of subdivisions of antimuscarinic receptors under monotherapy that may lead to better susceptibility of other subdivisions when treated by the second drug. The combined regimen needs further investigation to verify its efficacy as a non-invasive alternative for patients in whom antimuscarinic monotherapy fails.

3. ANTIMUSCARINICS AND 5α-REDUCTASE INHIBITORS

The standard first-line medical therapy for men with moderate-to-severe LUTS is an α1-AR antagonist, a 5α-reductase inhibitor, or combination therapy with both. Both α1-AR antagonist and 5α-reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance. Alpha1-AR antagonists decrease smooth muscle tone in the prostate and bladder neck, while 5α-reductase inhibitors reduce prostate volume. As mentioned, several trials have demonstrated the efficacy and safety of the combination therapy of antimuscarinics and α1-AR antagonist for patients with OAB and coexisting BPO. However, post hoc analyses of the TIMES study [Kaplan et al., 2006] suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates [Roehrborn et al., 2008; Roehrborn, Kaplan et al., 2009]. Chung and co-workers conducted an open-label, fixed-dose study to assess the efficacy and safety of tolterodine ER in combination with dutasteride in men with a large prostate (≥30 g) and persistent OAB symptoms after α1-AR antagonist therapy who had been unsuccessfully treated with dutasteride alone [Chung et al. 2010]. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months and α1-AR antagonist therapy had failed. All patients were given 4 mg tolterodine ER daily for 12 weeks and had discontinued α1-AR antagonist before the start of the study. At 12 weeks, the frequency (−3.2/24hrs, p < 0.02), urgency (19.2%, p < 0.03), number of severe OAB episodes (71.4%, p < 0.05), and incidence of nighttime voiding (−0.9, p < 0.003) were found to have decreased significantly from baseline. The IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 (p < 0.001). Storage symptoms decreased from 9.8 to 4.5 (p < 0.001). Dry mouth occurred in four (7.5%) subjects, constipation in one (2%), and decreased sexual function in two (3.9%). Post-void residual increased by 4.2 mL, Qmax decreased by 0.2 mL/s, and no patients went into retention. The authors concluded that the combination of tolterodine and dutasteride was effective, safe, and well-tolerated in men with large prostates with persistent OAB symptoms and LUTS secondary to BPO.

The results of this study indicate that antimuscarinics are safe and effective in selected patients with OAB and BPO when used in combination with 5α-reductase inhibitors. Further studies are required to verify the efficacy of antimuscarinics combined with 5α-reductase inhibitors in these patients.

4. α1-AR ANTAGONISTS WITH 5A-REDUCTASE INHIBITORS

It has been well established that the combinations of α1-AR antagonists with 5α reductase inhibitors (doxazosin finasteride: MTOPS; dutasteride+ tamsulosin: CombAT) can improve clinical outcomes and reduce the incidence of BPH and LUTS progression measured as symptom worsening, retention or progression to surgery [McConnell et al., 2003, Roehrborn et al., 2010].

XI. FUTURE POSSIBILITIES

1. PERIPHERALLY ACTING DRUGS

a) Vitamin D3 receptor analogues

It is well known that vitamin D affects skeletal muscle strength and functional efficiency, and vitamin D insufficiency has been associated with notable muscle weakness. The levator ani and coccygeus skeletal muscles are critical components of the pelvic floor and may be affected by vitamin D nutritional status. Weakened pelvic floor musculature is thought to be associated with the development of urinary incontinence and fecal incontinence symptoms. Aging women are at increased risk for both pelvic floor dysfunction and vitamin D insufficiency. However, to date, only small case reports and observational studies have shown an association between insufficient vitamin D and pelvic floor dysfunction symptom severity (Parker-Autry et al., 2012). Rat and human bladders were shown to express receptors for vitamin D [Crescioli et al., 2005],...
which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D3 have also been shown to inhibit benign prostatic hyperplasia (BPH) cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells [Crescioli et al., 2002; 2003; 2004]. Experiments in rats with bladder outflow obstruction [Schröder et al., 2006] showed that one of the analogues, BXL-628, at non-hypercalcemic doses, did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle which occurred with increasing bladder weight [Schröder et al., 2006]. The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007]. Ureteral expression of his pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO [Peters et al., 2006; Christ and Andersson, 2007]. In rats with outflow obstruction, previous elocalcitol-treatment improved the effects of tolterodine on bladder compliance [Streng et al., 2012]. It was suggested that in rats elocalcitol exerted additional beneficial actions on outflow obstruction-induced functional changes during the filling phase of micturition. This supports combined therapy in BPH-related LUTS. If the results are valid in humans, combined therapy with the drug would be of value.

The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that BXL628 was able to arrest prostate growth within 12 weeks in men aged ≥50 years with prostatic volume > 40 ml [Colli et al., 2006]. In an RCT enrolling 120 female patients with OAB, where the primary endpoint was an increase in the mean volume voided, a significant increase vs placebo (22% vs 11%) was demonstrated [Colli et al., 2007]. Whether or not vitamin D receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further RCTs. However, currently, the development of the drug seems to be stopped [Tiwari, 2009].

b) TRP channel antagonists

The transient receptor potential (TRP) channel superfamily has been shown to be involved in nociception and mechano-sensory transduction in various organ systems, and studies of the LUT have indicated that several TRP channels, including TRPV1, TRPV4, TRPM8, and TRPA1, are expressed in the bladder, and may act as sensors of stretch and/or chemical irritation [Araki et al., 2008; Everaerts et al., 2008; Andersson et al., 2010; Araki, 2011]. TRPV1 and TRPV4 channels have been found to be expressed in the urinary bladder [Tominaga et al., 1998; Birder et al., 2001; Gevaert et al., 2007]. TRPV1 is present and active both in the urothelium and in the nerve fibers of several species including humans [Ji et al., 2002; Charrua et al., 2009a]. TRPV4 was initially described in the urothelium of rodents and humans [Janssen et al., 2011]. Co-expression of the two receptors was observed in 20% of rat urothelial cells [Kullmann et al., 2009]. Recent observations indicate, however, that TRPV4 may also be expressed in bladder afferents. In fact, about 30% of L6 dorsal root ganglia neurons that project to the urinary bladder co-express TRPV1 and TRPV4 [Cao et al., 2009; Charrua et al., 2012a]. The physiological meaning of this observation is unclear.

TRPV1 KO mice have a normal or quasi-normal phenotype. In awake animals, the only change detected in TRPV1 KO mice was a smaller volume per void when compared with wild type (WT) controls [Birder et al., 2001]. In cystometries performed under anesthesia, the TRPV1 KO mice phenotype seems also very benign. Some studies reported that this animals have totally normal cystometric traces [Charrua et al., 2007]. However, other studies showed that TRPV1 KO mice develop a few non-voiding contractions preceding the voiding contraction [Birder et al., 2001; Frias et al., 2012]. Accordingly, TRPV1 antagonists (GRC 6211) did not show any relevant effect on bladder activity of intact rodents [Charrua et al, 2009b]. In contrast with TRPV1 KO mice, the micturition phenotype of TRPV4 KO animals is clearly abnormal. TRPV4 KO mice are incontinent, most probably due to incomplete bladder emptying [Gevaert et al., 2007]. Cystometric studies carried out under physiological conditions revealed that TRPV4 KO mice have an marked increase in the inter-contraction interval when compared to wild-type (WT) littermates. [Gevaert et al., 2007; Birder et al. 2002]. Likewise, TRPV4 antagonists (HC-067047) decreased the frequency of bladder contractions and increased the inter-contraction interval [Everaerts et al, 2010]. These observations indicated that TRPV4 has a role in the control of normal micturition reflex.

Indisputably, TRPV1 or TRPV4 have a role in the increase of micturition frequency associated with cystitis [Charrua et al., 2007; Everaerts et al., 2010]. While inhaled WT mice exhibit bladder hyperactivity and intense spinal Fos expression after different forms of bladder inflammation, including acetic acid or bacterial extracts, TRPV1 KO mice have normal cystometries and normal spinal fos expression [Charrua et al., 2007]. The same holds true for TRPV4. In fact, TRPV4 KO mice exhibit significantly lower voiding frequencies and larger voided volumes than WT after inflammation with cyclophosphamide [Everaerts et al, 2010].

The blockade of TRPV1 and TRPV4 with specific antagonist confirm the observations carried out in knock-out animals. As a matter of fact, the TRPV1 antagonist GRC 6211 or the TRPV4 antagonist HC-067047 both abolish the increase of micturition frequency associated with chemical cystitis [Everaerts et al. 2010; Charrua et al., 2009b]. Recently,
it was shown that the systemic co-administration of TRPV1 and TRPV4 antagonist was more effective in treating the cystitis-induced increase of micturition frequency than the individual application of each antagonist [Charrua et al., 2012b]. In particular, the effect could be observed at very low doses of the TRPV1 and TRPV4 antagonists, which had no effect when given isolated. This observed effect might be the answer to overcome the eventual adverse events related with the application of some of these antagonists [Planells-Cases et al., 2011]. Just to mention a few, TRPV1 antagonists are associated with hyperthermia and increased risk of cardiac ischemia [Avelino et al., 2012] while TRPV4 antagonists may eventually precipitate urinary retention and overflow incontinence [Gevaert et al., 2007].

It is known for long that TRPV1 is involved in the emergence of neurogenic detrusor overactivity following spinal cord transaction [Avelino & Cruz, 2006]. Quite recently a TRPV1 antagonist GRC 6211 has been shown to decrease reflex detrusor overactivity in rats after chronic spinal cord transaction. With increasing doses it was possible to obtain a total suppression of bladder activity [Santos-Silva et al., 2012]. The clinical relevance of this finding will certainly be further investigated in the future.

There seem to be several links between activation of different members of the TRP superfamily and LUTS/DO/OAB, and further exploration of the involvement these channels in LUT function, normally and in dysfunction, may be rewarding. However, proof of concept studies in humans are still lacking.

c) Prostanoid receptor agonists/antagonists

Recent developments in the field of prostanoid receptors may open new possibilities to use selective prostanoid receptor antagonists for DO/OAB treatment [Aoki et al., 2009; Jones et al., 2009]. There is evidence suggesting that PGE2 contributes to the pathophysiology of DO/OAB: PGE2 infused into the bladder induces DO in humans and animals, increases PGE2 production in DO models and there are high concentrations of PGE2 in the urine of patients with OAB [McCafferty et al., 2008]. PGE2 is an agonist at EP receptors 1 to 4, all G-protein coupled, which mediate its physiological effects. Based on studies using knockout (KO) mice and EP1 receptor antagonists, it was suggested that the effects of PGE2 on bladder function were mediated through EP1 receptors [Schröder et al., 2004]. EP receptors can be found on urothelium/urothelium, in detrusor smooth muscle and in intramural ganglia [Wang et al., 2008; Rahnama’i et al., 2010; Rahnama’i et al., 2011]. Functionally, it has been proposed that modulation of bladder activity exerted via EP1 receptors occurs via an afferent mechanism. Schröder et al. [2004] found no difference in urodynamic parameters between unobstructed EP1 receptor KO and WT mice. However, EP1 receptor KO mice did not respond to intravesical PGE2 instillation, while WT mice developed DO. The lack of EP1 receptor did not prevent bladder hypertrophy due to partial bladder outflow obstruction but after obstruction WT mice had pronounced DO, while this was negligible in EP1 receptor KO mice.

Lee et al. [2008] found that in normal rats a selective EP receptor antagonist significantly increased bladder capacity, micturition volume and micturition intervals. The antagonist significantly decreased the stimulatory effects of PGE2, and decreased the frequency and amplitude of non-voiding contractions in animals with BOO. More recently it has been shown that also EP3 receptor KO mice have a diminished response to bladder infusion of PGE2, and demonstrate an enhanced bladder capacity under basal conditions [Jones et al., 2009]. This findings suggest an important contribution for EP3 receptors in the modulation of bladder function under physiological conditions as well as under conditions of enhanced PGE2 production evoking DO. Thus, EP1 and EP3 receptors may have a role in PGE2 mediated DO.

Interestingly, activation of EP3 receptors evoked diuresis and EP3 receptor antagonism was found to induce an antidiuretic effect [Jugus et al., 2009]. Thus, to modulate bladder activity, it appears that the EP3 receptor has a role in regulating urine production. Both effects may be useful for treatment of DO/OAB. It cannot be denied that EP1/EP3 receptors constitute interesting and promising targets for drugs aimed at DO/OAB treatment. However, a randomised, double-blind, placebo-controlled phase II study to investigate the efficacy and safety of the EP-1 receptor antagonist, ONO-8539, in patients with the overactive bladder syndrome suggests that the role of EP1 receptor antagonism in the management of OAB syndrome is minimal [Chapple et al., 2011].

d) Intraprostatic Injections of drugs

Intraprostatic injection therapy is probably the oldest minimally invasive surgical therapy for BPH and has been investigated for over 100 years with renewed interest recently. There are different injectables and various routes of administration, transperineal, transrectal and transurethral.

1. Ethanol

Ethanol injection is one of the most investigated intra-prostatic therapies and have been investigated for more than a decade [Goya et al., 1999]. However, the mechanism of action, patient selection and application of ethanol (the number of injection sites and the injection volume) have not been well investigated and long-term results are scarce. It seems that ethanol causes inflammation, coagulative necrosis with protein denaturation and cell membrane lysis, and, finally, sloughing of prostatic tissue resulting in cavity
formation [Plante et al., 2003]. The majority of trials demonstrated a significant reduction in symptoms and post-void residual volume as well as a significant improvement in Qmax and QoL and prostate volume also decreased significantly in the majority of studies [Goya et al., 2004; Grise et al., 2004; Plante et al., 2007; Sakr et al., 2009]. The durability of clinical effects beyond 1 year seems poor. One trial with a mean follow-up of 3 years showed a retreatment rate of 41% [Goya et al., 2004].

2. BoNT-A

BoNT-A investigation for the treatment of benign prostatic enlargement (BPE) due to benign prostatic hyperplasia (BPH) started in 2003 [Maria et al., 2003] after the experimental study by Doggweiler et al. [1998] demonstrating prostatic atrophy in the rat after intraprostatic injection of the neurotoxin. In an exploratory study, which involved injection of 200 U of onabotA in moderate to large prostate glands, a rapid prostate volume decrease was induced and still present at 12 months [Maria et al., 2003]. Following this study, Kuo [2005] reported similar findings when injecting prostate glands of 50 ml or larger. BoNT-A injection in smaller prostate glands caused a much lesser reduction in prostate volume, but a 15% reduction was still observed [Chuang et al., 2005; Chuang et al., 2006c]. Independent of the extent of prostate volume reduction, improvement of LUTS and flow were consistently reported [Maria et al., 2003; Kuo, 2005; Chuang et al., 2005; Chuang et al., 2006c], while a decrease in total serum PSA were observed only in some studies [Maria et al., 2003; Guercini et al., 2005]. In a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of BPH, Crawford and coworkers concluded that intraprostatic injection of 100 or 300 units of onabotA passed predetermined criteria for treatment efficacy and safety (30% improvement from baseline to 3 months in American Urological Association symptom index and/or maximum urinary flow rate and safety). The ideal dose was not found, but it seemed that 100 unit dose may be preferable to similar efficacy with reduced costs and adverse effects [Crawford et al., 2011]. Some serious adverse events were reported, including 3 cases of urosepsis related to the onabotA injection. Other minor adverse events reported were urinary tract infection, pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford ED et al., 2011].

Silva et al. [2008], selected a particular group of patients with high co-morbidity in which more invasive treatments were contraindicated. Intraprostatic BoNT-A injection was carried out transrectally, under ultrasound guidance. Twenty-one men with large BPE, 70±10 ml, on chronic indwelling catheter for at least 3 mo who were not candidates for surgery because of poor general condition received 200 U BoNT-A in the transition zone. Baseline prostate volume of decreased to 57±10 ml at 1mo and to 47±7ml at 3 months. At 1 month, 16 patients (76%) could resume voiding with a mean Qmax of 9.0±1.2 ml/s. At 3 months, 17 patients (81%) voided with a mean Qmax of 10.3±1.4 ml/s. Residual urine was not significant and mean serum total PSA showed a slight decrease [Silva et al., 2008]. The analysis of 11 patients of the initial cohort showed that the duration of prostate atrophy after the single injection of 200U of BoNT-A was found to be about 18 months [Silva et al., 2009b].

Intraprostatic injection of BoNT/A seems devoid of sexual adverse events. Sixteen sexually active men aged > 60 years with BPH/benign prostatic enlargement (BPE) refractory to standard medical therapy received 200U of BoNT/A by transrectal route. Erectile function was evaluated using the International Index of Erectile Function – Short Form (IIEF-5) questionnaire. Orgasmic/ejaculatory function and libido were evaluated using questions 9, 10, 11 and 12 of the IIEF – Long Form. Intraprostatic injection of BoNT-A did not cause deterioration of any domain of sexual function [Silva et al., 2011].

Although necrosis of the gland at the places of BoNT-A injection could explain the rapid volume reduction, transrectal ultrasound examination of the glands, performed in these or in previous studies [Maria et al., 2003; Kuo, 2005; Chuang et al., 2005; Silva et al., 2008], was unable to detect signs of cavitation that indirectly could suggest the presence of necrosis. Therefore, the reason for the decreased prostate volume should be more appropriately related to the widespread apoptosis detected in the gland after BoNT-A administration. Apoptosis was reported in rats, dogs, and humans, and affected both the epithelial and stromal components [Doggweiler et al., 1998; Chuang et al., 2005; Chuang et al., 2006b; Chuang et al., 2006d, Silva et al., 2009a].

Although until now, no important side-effects have been reported after intraprostatic injection of the neurotoxin in doses ranging between 100 and 300 U, a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of benign prostatic hyperplasia, was recently published [Crawford et al., 2011]. OnabotA prostatic injection met the two safety criteria proposed, (a dose failed if: 1- a life threatening, disabling or fatal event was determined to be related to the onabotA injection, or 2- 40% or more of the participants reported a moderate or severe side effect related to the botulinum toxin injection). Nonetheless, some serious AEs were reported, including 3 cases of urosepsis related to the onabotA injection and the remaining events were judged not related to the injection. Other minor AEs reported were urinary tract infection,
pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford et al., 2011].

3. NX-1207

NX-1207 is a new drug under investigation for the treatment of LUTS associated with BPH. It is a new therapeutic protein of proprietary composition with selective pro-apoptotic properties [Shore, 2011]. The drug is injected directly into the directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to non-regressive prostate shrinkage and both short- and long-term symptomatic improvement. Information about the drugs is scarce and mostly published in abstract form and not yet in the peer-reviewed literature. Two US Phase II trials have been performed [Shore, 2011]. One of them was a multicenter, randomized, non-inferiority study involving 32 clinical sites with 85 subjects and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Subjects and investigators on NX-1207 were double-blind as to dosage. The primary endpoint was change in AUASI at 90 and 180 days for a single injection of NX-1207 as compared to finasteride on a non-inferiority basis. Inclusion criteria included an AUA Symptom Score ≥ 15, diminished peak urine flow (< 15 ml/s) and a prostate size of > 30 and < 70 mg. The mean AUA Symptom Score improvement in 90 days in the intent to treat group was 9.71 points for 2.5 mg NX-1207 (n = 48) versus 4.13 points for finasteride (n = 24) (p = 0.001) and 4.29 for 0.125 mg NX-1207 (n = 7) (p = 0.034). The 180-day results also were positive (NX-1207 2.5 mg non-inferior to open-label finasteride).

No significant changes in serum testosterone or serum PSA levels in the NX-1207 cohorts. There were no reported adverse effects on sexual function. Two US multicenter, double-blind, placebo-controlled Phase III studies are currently underway. The results of such studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

4. PRX302

PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming protoxin that requires proteolytic processing by prostate-specific antigen (PSA) [Sing et al., 2007]. The safety and efficacy of PRX302 was evaluated in men with moderate to severe BPH [Denmeade et al., 2010]. The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS >12, a quality of life (QoL) score >3, and prostate volumes between 30 and 80 g. Fifteen patients were enrolled in phase 1 studies, and 18 patients entered phase 2 studies. Subjects received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase 1 subjects received increasing concentrations of PRX302 at a fixed volume; phase 2 subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax), IIEF, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase 1 study and 64% of men in the phase 2 study treated with PRX302 had >30% improvement compared to baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving >1 ml of PRX302 per deposit had the best response overall. There were no deleterious effect on erectile function. Adverse events were mild to moderate and transient in nature. The major study limitation was the small sample size. The promising safety profile and evidence of efficacy in the majority of treated subjects in these phase 1 and 2 studies supports further development of PRX302 as a minimally invasive, targeted treatment for BPH. However, no further studies, verifying the initial data, seem to have been published.

e) Cannabinoids

There is increasing evidence that cannabinoids can influence micturition in animals as well as in humans, both normally and in bladder dysfunction [Ruggieri, 2011]. The effects of the cannabinoids are exerted via two types of well defined receptors, CB1 and CB2, distributed widely in the body. However, additional receptor subtypes cannot be excluded [Pertwee et al., 2010; Ruggieri 2011]. Both in the CNS and in peripheral tissues, CB1 and CB2 receptors have been identified; centrally CB1 and peripherally CB2 receptors seem to be predominant [Pertwee et al., 2010; Ruggieri, 2012] (figure 17). CB1 as well as CB2 receptors have been identified in all layers of the human bladder [Merriam et al., 2008; Gratzke et al., 2009; Tyagi et al., 2009; Walczak et al., 2009]; their expression in the urothelium was found to be significantly higher than in the detrusor, and the expression of CB1 was higher than that of CB2 [Tyagi et al., 2009]. Gratzke et al. [2009] found higher expression of CB2 receptors, but not CB1 receptors, in the mucosa than in the detrusor. Compared to the detrusor, larger amounts of CB2 receptor containing nerves that also expressed TRPV1 or CGRP were observed in the suburothelium. Nerve fibers containing CB2 receptors and VACHT (cholinergic neurons) were located in the detrusor. In general, activation of CB1 peripherally has been associated with vasodilation and motility changes via suppression of release of neurotransmitters, whereas activation of CB2 appears to induce anti-inflammatory, antinociceptive, and immunosuppressive actions [Pertwee et al., 2010; Ruggieri, 2011]. Several animal studies have suggested a modulatory role of CB2 receptors in both afferent signalling and cholinergic nerve activity [Gratzke et al., 2009; 2010; 2011]. Thus, in vivo the selective CB2 receptor agonist, cannabinor, increased micturition intervals and volumes, and
increased threshold and flow pressures, suggesting that peripheral CB2 receptors may be involved in sensory functions. In rats with partial urethral obstruction treated daily for 14 days with cannabinor, bladder weight was lower, the ability to empty the bladder was preserved and nonvoiding contraction frequency was low compared to those in controls.

The key enzyme for the degradation of anandamide and other endogenous cannabinoids, is fatty acid amide hydrolase (FAAH, Figure 18). FAAH was found to be expressed in rat and human urothelium and was coexpressed with CB2 receptors. In rats, a FAAH inhibitor altered urodynamic parameters that reflect sensory functions, suggesting a role for the endocannabinoid system in bladder mechanoafferent functions [Strittmatter et al., 2011].

It has not been established whether the effects of the cannabinoids are exerted in the CNS (brain, spinal cord) or peripherally. In a preliminary report Blywert et al. [2003] demonstrated an effect of combined CB1/ CB2 receptor activation on detrusor overactivity in rats with spinal cord transection, which seemed to exclude the brain as a main site of action.

The clinical experiences the cannabinoid treatment of micturition disturbances inclung LUTS are limited [Ruggieri, 2011], but both open-label and placebo-controlled studies have demonstrated that orally administered cannabinoid modulators may alleviate neurogenic overactive bladder (OAB) symptoms refractory to first-line treatment [Brady et al., 2004; Freeman et al., 2006; Kavia et al., 2010]. Brady et al. [2004] evaluated the efficacy of 2 whole plant extracts (δ9-tetrahydrocannabinol and cannabidiol) of Cannabis sativa in patients with advanced MS and refractory LUTS. Urinary urgency, the number and volume of incontinence episodes, frequency and nocturia decreased significantly following treatment. Freeman et al. [2006] tested in a subanalysis of a multicenter trial (the CAMS study) whether cannabinoids could decrease urge incontinence episodes without affecting voiding in patients with MS. The CAMS study randomized 630 patients to receive oral administration of the cannabis extract δ9-tetrahydrocannabinol or matched placebo. Based on incontinence diaries a significant decrease in incontinence episodes was demonstrated.

Kavia et al. [2010] assessed the efficacy, tolerability and safety of Sativex® (nabiximols) as an add-on therapy in alleviating bladder symptoms in patients with MS. They performed a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and overactive bladder (OAB). The primary endpoint, reduction in daily number of urinary incontinence episodes from baseline to end of treatment (8 weeks), showed little difference between Sativex and placebo. However, four out of seven secondary endpoints were significantly in favour of Sativex, including number of episodes of nocturia, number of voids/day, and number of daytime voids. The improvement in I-QOL was in favour of Sativex, but did not reach statistical significance.

Systemic cannabinoids have effects on the lower urinary tract that may have a therapeutic potential; local delivery (intravesical, spinal) may be possible, but more information is needed. The mechanisms of cannabinoid receptors in control of the human LUT

![Figure 17](image_url)

**Figure 17**: CB2 receptors in the urothelium/lamina propria. The effects of the cannabinoids are exerted via two types of well defined receptors, CB1 and CB2, distributed widely in the body. Both in the CNS and in peripheral tissues, CB1 and CB2 receptors have been identified; centrally CB1 and peripherally CB2 receptors seem to be predominant.
is incompletely known, and further research is necessary for the development of novel cannabinoid drugs for treatment of LUT disorders.

2. CENTRALLY ACTING DRUGS

Many parts of the brain seem to be activated during storage and voiding [see, Griffiths 2007; Fowler et al., 2008; Griffiths and Tadic, 2008], and there is increasing interest in drugs modulating the micturition reflex by a central action [Andersson and Pehrson, 2003]. Several drugs used for pain treatment also affect micturition; morphine and some antiepileptic drugs being a few examples (Figure 19). However, central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, since selective actions may be difficult to obtain. Holstege [2005], reviewing some of the central mechanisms involved in micturition, including the periaqueductal gray (PAG) and the pontine micturition center (PMC), suggested that “the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level.”

a) Gonadotropin-releasing hormone antagonists

The beneficial effects of the 5α-reductase inhibitors, finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments, for example, antiandrogens or gonadotropin-releasing hormone (GnRH; also known as luteinizing hormone-releasing hormone: LHRH) agonists is either poor or at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density following long-term androgen ablation [Schroeder et al., 1986; Peters et al., 1987; Bosch et al., 1989; Eri and Tveter, 1993]. With GnRH antagonists submaximal, non-castrating blockade of the androgen testosterone and consequently of dihydrotestosterone (DHT) can be achieved, thus avoiding medical castration. Several GnRH antagonists – such as cetrorelix, oza-relix and teverelix - have been tested in Phase IIA/ IIB clinical trials for their ability to improve LUTS in patients with BPH [Colli and Tanko, 2011].

Debruyne et al.[2008] demonstrated in a phase 2 RCT that the LHRH antagonist cetrorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS > 13, peak urinary flow rates 5-13 ml/s), rapidly caused a significant improvement in the mean IPSS: the peak decrease was -5.4 to -5.9 vs -2.8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment of male LUTS.

Figure 18: Metabolism of and distribution of fatty acid amide hydrolase (FAAH; cannabinoid degrading enzyme) immunoreactivity in the rat urothelium
Due to these results, two phase III studies were conducted in the United States and Europe [AEterna Zentaris]; in the US study, 637 men were randomized to receive either two doses of placebo or cetrorelix on weeks 2 and 26. The drug showed no statistically significant benefit in improving IPSS. In addition, cetrorelix did not have a significant effect on peak flow rate or prostate volume versus placebo. It is difficult to reconcile this lack of efficacy given favorable prior results. A subsequent multicenter European trial also failed to show any treatment-related efficacy of cetrorelix. The experience with cetrorelix highlights the importance of randomized, placebo-controlled trials that are appropriately powered to show clinical benefit and safety.

b) Gabapentin

Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders [Striano and Striano 2008]. It was originally designed as an anticonvulsant GABA (y-aminobutyric acid) mimetic capable of crossing the blood-brain barrier [Manef et al., 2003]. The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial [Manef et al., 2003]. It has been suggested that it acts by binding to a subunit of the α2δ unit of voltage dependent calcium channels [Gee et al., 1996; Striano and Striano, 2008]. Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

Carbone et al. [2006] reported on the effect of gabapentin on neurogenic DO. They found a positive effect on symptoms and significant improvement in urodynamic parameters, and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and non-neurogenic DO. Kim et al. [2004] studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinics. They found that 14 out of 31 patients improved with oral gabapentin.

The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other α2δ ligands (e.g., pregabalin and analogs) will offer new therapeutic alternatives, but convincing RTC are still lacking.

c) Tramadol

Tramadol is a well-known analgesic drug [Grond and Sablotzski, 2004]. By itself, it is a weak μ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ-receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake [Grond and Sablotzski, 2004]. This profile is of particular interest, since both μ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS/OAB/DO, as shown in a placebo controlled study with duloxetine [Steers et al., 2008].

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction [Pehrson et al., 2003]. Tramadol also inhibited DO induced by apomorphine in rats [Pehrson and Andersson, 2003] – a crude model of bladder dysfunction in Parkinson’s disease. Singh et al. [2008] gave tramadol epidurally and found the drug to increase bladder capacity and compliance, and to delay filling sensations without adverse effects on voiding. Safarinejad and Hooseini [2006] evaluated in a double-blind, placebo-controlled, randomized study, the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol sustained release every 12 h for 12 weeks. Clinical evaluation was performed at baseline and every two weeks during treatment. Tramadol significantly (p<001) reduced the number of incontinence periods per 24 hours from 3.2+/−3.3 to 1.6+/−2.8) and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. Even if tramadol may not be the best suitable drug for treatment of LUTS/OAB, the study suggests efficacy for modulation of micturition via the μ-receptor.

d) NK1-receptor antagonists

The main endogenous tachykinins, substance P (SP), neurokinin A (NKA) and neurokinin B (NKB), and their preferred receptors, NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micturition control [Lecci and Maggi, 2001; Saffroy et al., 2003; Covenas et al., 2003]. NK1 receptor expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micturition reflex induced by bladder filling has been demonstrated [Ishizuka et al., 1994] in normal, and more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced detrusor overactivity was reduced by blocking NK1...
receptor-expressing neurons in the spinal cord, using intrathecally administered substance P-saponin conjugate [Seki et al., 2002]. Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 1995a].

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses, and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction [Gu et al., 2000]. Intracerebroventricular administration of NK1 and NK2 receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 2000]. Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK-1 receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting [Massaro and Lenz, 2005], significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly urgency urinary incontinence), as shown in a well designed pilot RCT [Green et al., 2006]. The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total urinary incontinence and urgency incontinence episodes, and urgency episodes. Aprepitant significantly (p<0.003) decreased the average daily number of micturitions (-1.3+/-1.9) compared with placebo (-0.4+/-1.7) at 8 weeks. The average daily number of urgency episodes was also significantly (p<0.047) reduced (-23.2+/-32%) compared to placebo (-9.3+/-40%), and so were the average daily number of urgency incontinence and total urinary incontinence episodes, although the difference was not statistically significant. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. Since this initial proof of concept study suggested that NK-1 receptor antagonism hold promise as a potential treatment approach for OAB symptoms, a randomized, double-blind, multicenter trial enrolled 557 adults with overactive bladder (8 or more average daily micturitions and 1 or more daily urge incontinence episodes) [Frenkel et al., 2010]. After a 1-week placebo run-in the patients were randomized to treatment with 8 weeks of daily 0.25, 1 or 4 mg serlopopitan, 4 mg tolterodine extended release or placebo. Patients kept 7-day voiding diaries. The primary end point was change from baseline in micturitions per day. Secondary end points included urgency, total incontinence, urge incontinence episodes and incidence of dry mouth. Of the 557 patients randomized, 476 completed the trial and had valid efficacy data for analysis. Mean change from baseline in daily micturitions was significantly greater for 0.25 (-1.1) and 4 mg (-1.1) serlopopitan, and for tolterodine (-1.5) than for placebo (-0.5), but not for 1 mg serlopopitan (-0.8). No serlopopitan dose response was demonstrated. Tolterodine was numerically superior to all doses of serlopopitan in mean micturitions per day and secondary end points. The incidence of dry mouth on serlopopitan (3.3%) was comparable to placebo (4.6%) and lower than tolterodine (8.8%). Serlopopitan was generally well tolerated.

NK-1 receptor antagonists may have a role in the treatment of overactive bladder but at least the compounds tested so far does not offer advantages in efficacy compared to tolterodine.

A different approach, modulation of neuropeptide release rather than NK receptor blockade, was tested in a pilot study with cizolirtine, which is a substance-P and CGRP release modulator at the spinal cord level. The modulation of substance-P and CGRP is probably related to the increase of extracellular levels of noradrenaline and serotonin. Cizolirtine 200 and 400 mg were compared to placebo in 79 OAB patients. Although the decrease in key OAB symptoms was significantly higher in the active arms, adverse events were reported in 68% and 81% of the patients on cizolirtine 200 and 400mg. More commonly reported side effects were gastro-intestinal in nature, including dry mouth and vomiting [Martinez-Garcia et al., 2008]. No further developments of this compound have been reported.

C. Drugs used for treatment of stress incontinence in women

Many factors seem to be involved in the pathogenesis of stress urinary incontinence (SUI) in women: urethral support and function, bladder neck support and function of the nerves and musculature of the bladder, urethra, and pelvic floor [Delancey, 1997; Mostwin et al, 2005, Koelbl, Nitti et al, 2009; Chapelle and Milsom, 2012]. Pure structural factors cannot be treated pharmacologically. However, SUI in women is generally thought to be characterized by decreases in urethral transmission pressure and, in most cases, resting urethral closure pressure [Henriksson et al, 1979; Hilton et al, 1983, Koelbl and Nitti, 2009]. It, therefore, seems logical that increasing urethral pressure should improve the condition.

Factors which may contribute to urethral closure include the tone of the urethral smooth and striated muscle (the rhabdosphincter) and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacological evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released noradrenaline [Andersson, 1993; Andersson and Wein, 2004; Andersson and Wein, 2012]. A contributing factor to SUI, mainly in elderly
women with lack of estrogen, may be lack of mucosal function. The pharmacological treatment of SUI (Table 3) aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated musculature, either directly or through increased motorneuron activity. Several drugs may contribute to such an increase [Andersson and Wein, 2012], but relative lack of efficacy or/and side effects have limited their clinical use.

### I. α-ADRENOCEPTOR AGONISTS

Several drugs with agonistic effects on peripheral α-ARs have been used in the treatment of SUI. Relatively recently, a central role of noradrenaline (NA) in increasing the excitability of urethral rhabdosphincter motorneurons in the rat analogue of Onuf’s nucleus, an effect due at least in part to α1-AR receptor dependent depolarization. This could contribute to the mechanism by which NA reuptake inhibitors improve SUI [Yashiro et al, 2010]. Ephedrine and norephedrine (phenylpropanolamine; PPA) seem to have been the most widely used [Andersson and Wein, 2012]. The original United States Agency for Healthcare Policy and Research Guidelines [Agency for Healthcare Policy and Research, 1992] reported 8 randomized controlled trials with PPA, 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) were listed as 0% to 14%, percent reduction in incontinence as 19% to 60%, and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3% respectively. The most recent Cochrane review on the subject [Alhasso et al, 2005, reprinted virtually unchanged in 2008] assessed randomized or quasi-randomized controlled trials in adults with stress urinary incontinence which included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 11, midodrine in 2, norpinephrine in 3, clenbuterol in 3, terbutaline in 1, eskornade in 1 and RO 115-1240 in 1). The authors concluded, “there was weak evidence to suggest that use of an adrenergic agonist was better than placebo in reducing the number of pad changes and incontinence episodes, as well as, improving subjective symptoms”. There was not enough evidence to evaluate the merits of an adrenergic agonist compared with estrogen, whether used alone or in combination. Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects due to adrenergic stimulation, they caused discontinuation in only 4% of the total.

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations [Andersson and Wein, 2012]. Kernan et al. [2000] reported the risk of hemorrhagic stroke to be 16 times higher in women less than 50 years of age who had been taking PPA as an appetite suppressant (statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant). There was no increased risk in men. PPA has been removed from the market in the United States. It is still allowed as a treatment for SUI in a few countries. Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some [Bent et al., 2003] had suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003, the Food and Drug Administration of the US decreed such a ban, a move which has survived legal appeal.

Midodrine and methoxamine stimulate α1-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate at best, and the clinical usefulness seems to be limited by adverse effects [Alhasso et al., 2003; Radley et al., 2001; Weil et al., 1998].

Attempts continue to develop agonists with relative selectivity for the human urethra. Musselman et al. [2004] reported on a phase 2 randomized crossover study with RO 115-1240, a peripheral active selective α1A/1L-AR partial agonist [Blue et al., 2004] in 37 women with mild to moderate SUI. A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug. PF-3774076, a CNS penetrating partial α1A-AR agonist, increased peak urethral pressure in dogs and was selective with respect to α1B and α1D receptors.

but heart rate and blood pressure changes caused significant concern (Conlon et al., 2009). Furuta et al. [2009] reported that the α2-AR can inhibit the release of glutamate presynaptically in the spinal cord and proposed that α2-AR antagonists would be useful as a treatment for SUI. This hypothesis awaits testing.

II. β-ADRENOCOCEPTOR AGONISTS

Clenbuterol. β-AR stimulation is generally conceded to decrease urethral pressure [Andersson, 1993], but β2-AR agonists have been reported to increase the contractility of some fast contracting striated muscle fibers and suppress that of slow contracting fibers of others [Fellenius et al., 1980]. Some β-AR agonists also stimulate skeletal muscle hypertrophy – in fast twitch more so than slow twitch fibers [Kim et al., 1992]. Clenbuterol has been reported to potentiate the field stimulation induced contraction in rabbit isolated periurethral muscle preparations, an action which is suppressed by propanolol and greater than that produced by isoprotererol [Kishimoto et al., 1991]. These authors were the first to report an increase in urethral pressure with clinical use of clenbuterol and to speculate on its potential for the treatment of SUI. Yaminishi et al. [1994] reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs, abolished by β-AR blockade.

Yasuda et al. [1993] described the results of a double blind placebo controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad usage per day, and overall global assessment. Pad weight decreased from 11.7± 17.9g to 6.± 12.3g for drug and from 18.3± 29.0g to 12.6± 24.7g for placebo, raising questions about the comparability of the 2 groups. The “significant” increase in MUCP was from 46.0± 18.2 cm H2O to 49.3± 19.1 cm H2O, versus a change of -1.5 cm H2O in the placebo group. 56/77 patients in the clenbuterol group reported some degree of improvement versus 48/88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles. Ishiko et al. [2000] investigated the effects of Clenbuterol on 61 female patients with stress incontinence in a 12-week randomized study, comparing drug therapy to pelvic floor exercises. The frequency and volume of stress incontinence and the patient’s own impression were used as the basis for the assessment of efficacy. The improvement of incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi et al. [1997] reported positive results with clenbuterol (20 mg b.i.d. for 1 month) in 9 of 14 patients with mild to moderate stress incontinence after radical prostatectomy. No subsequent published reports have appeared. Further well-designed RTCs investigating effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.

There have been no recent reports of clinical trials with α1- or β-AR agonists or antagonists for SUI.

III. β-ADRENOCCEPTOR ANTAGONISTS

The theoretical basis for the use of β-AR antagonists in the treatment of stress incontinence is that blockade of urethral β-ARs may enhance the effects of noradrenaline on urethral α-ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence [Gleason et al., 1974; Kaisary, 1984] but there are no RTCs supporting such an action. In the Gleason et al. [1974] study, the beneficial effects become manifest only after 4 to 10 weeks of treatment, a difficult to explain phenomenon. Donker and Van der Sluis [1976] reported that β-AR blockade did not change UPP in normal women. Although suggested as an alternative to α-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β-AR blockade.

IV. SEROTONIN-NORADRENALINE UPTAKE INHIBITORS

1. IMIPRAMINE

Imipramine, among several other pharmacological effects has classically been reported to inhibit the reuptake of noradrenaline and serotonin in adrenergic nerve endings. In the urethra this could be expected to enhance the contractile effects of noradrenaline on urethral smooth muscle. Gilja et al. [1984] reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean maximal urethral closure pressure (MUCP) from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement. Lin et al. [1999] assessed the efficacy of imipramine (25 mg imipramine three times a day for three months) as a treatment of genuine stress incontinence in 40 women with genuine stress incontinence. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of “successful treatment” was 60% (95% CI 11.8-75.2). There are no RTCs on the effects of imipramine on SUI. No subsequent published reports have appeared.

Interestingly, Gillman [2007] reported that clomipramine had far greater 5HT reuptake inhibition than imipramine and roughly similar NA reuptake inhibition. Desipramine and reboxetine had greater NA reuptake inhibition (desipramine superior), with less effects than imipramine on 5HT uptake (desipramine superior).

2. DULOXETINE

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been
shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Thor et al., 1995; Katofiasc et al., 2002]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser et al., 2003]. The sphincteric effects were reversed by α1 adrenergic (praxosin) and 5HT2 serotonergic (LY 53857) antagonism, while the bladder effects were mediated by temporal prolongation of the actions of serotonin and norepinephrine in the synaptic cleft [Fraser et al., 2003]. Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 h [Sharma et al., 2000].

Thor et al. [2007] described the mechanisms of action and the physiologic effects of duloxetine. 5HT (serotonin) and NA terminals are dense in spinal areas associated with lower urinary tract functioning especially around the pudendal nerve neurons in Onuf’s nucleus. These are projections from separate areas in the brain stem. Glutamate is the primary excitatory neurotransmitter in the spinal cord, activating the pudendal neurons in Onuf’s nucleus causing contraction of the urethral rhabdosphincter (Figure 20). The rhabdosphincter innervation is proposed as distinct from that of the levator ani [Thor and de Groat, 2010]. The responsiveness of the rhabdosphincter motor neurons to glutamate is modulated (facilitated) by 5HT (through 5HT2 receptors) and NA (through α1 -ARs). 5HT and NA, however, only modulate, and, when micturition occurs, glutamate excitation and the rhabdosphincter contraction cease. Excitatory effects on urethral sphincter activity are shared to a lesser extent by receptors for 5HT1A (indirect through a supraspinal stimulation), TRH, Vasopressin, NMDA and AMPA; inhibitory effects are similarly mediated by κ2 opioid, α1 ARs, GABA-A, GABA-B and glycine receptors [Thor and de Groat, 2010]. Some CNS penetrant selective 5HT2C agonists have been found to increase urethral muscle tone and inhibit micturition reflexes in animal models, and these are additional candidates for clinical development for the treatment of SUI [Brennan et al., 2009, Andrews et al., 2011].

Several RTCs have documented the effect of duloxetine in SUI [Norton et al., 2002; Dmochowski et al. 2003; Millard et al., 2004]. A Cochrane review of the effects of duloxetine for stress urinary incontinence in women is available, the last substantive amendment listed as 25 May 2005 [Mariappan et al., 2005]. Fifteen reports were deemed eligible for analysis, 9 primary studies and 6 additional reports related to 1 or 2 of the primary references. An additional analysis “performed under the auspices of the Cochrane Incontinence Group” was performed on just the 9 primary trials comparing duloxetine and placebo, and published separately [Mariappan et al., 2007]. The results can be summarized as follows. Subjective “cure” in the duloxetine 80 mg daily (40 mg b.i.d.) was higher than in the placebo group (10.8%)

Figure 20: The striated urethral sphincter is innervated by the pudendal nerve, which contains the axons of motor neurons whose cell bodies are located in Onuf’s nucleus. Glutamate exerts a tonic excitatory effects on these motor neurons, and this effect is enhanced by noradrenaline (NA) and serotonin (5-HT), acting on α1- adrenoceptors and 5-HT2-receptors, respectively. By inhibition of the reuptake of noradrenaline and serotonin, duloxetine increases the contractile activity in the striated sphincter (nicotinic receptors: + Nic). DC = dorsal commissure; DH = dorsal horn; VH = ventral horn; LF = lateral funiculus; ACh = acetylcholine

691
vs 7.7%, overall RR = 1.42; 95% CI, 1.02-1.98; p = 0.04). The estimated absolute size of effect was about 3 more patients cured of every 100 treated. Objective cure data, available from only 1 trial, showed no clear drug/placebo difference. Duloxetine showed greater improvement in I-QOL (WMD for 80 mg: 4.5; 95% CI 2.83-6.18, p<0.00001). Adverse effects in 6 trials were analyzed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event and the incidence ranged from 23-25% and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness and insomnia, overall RR 1.30 (95% CI, 1.23-1.37). Across these 6 trials 17% in the drug group withdrew, 4% in the placebo arm. In the 2007 article, the authors conclude by saying that further research is needed as to whether management policies incorporating duloxetine are clinically effective and cost effective compared to other current minimally invasive and more invasive approaches in patients with varying severity of SUI, and that “longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications”.

Hurley et al. [2006] characterized the safety of duloxetine for treatment of SUI in women, using an integrated database generated from four published placebo-controlled clinical trials. The database included 1913 women randomized to duloxetine (N=958) or placebo (N=955), examining adverse events (AEs), serious adverse events (SAEs), vital signs, electrocardiograms, and laboratory analytes. AEs occurring initially or worsening during the double-blind treatment period were considered treatment-emergent (TEAE). Differences between duloxetine-treated and placebo-treated groups were compared statistically. Common TEAEs included: nausea (23.2%), dry mouth (13.4%), fatigue (12.7%), insomnia (12.6%), constipation (11.0%), headache (9.7%), dizziness (9.5%), somnolence (6.8%), and diarrhea (5.1%). Most TEAEs that emerged early were mild to moderate, rarely worsened, and resolved quickly. Overall AE discontinuation rates were 20.5% for duloxetine and 3.9% for placebo (P<0.001). Most discontinuations (83%) occurred within the first month of treatment. SAEs were uncommon and did not differ between treatments. Statistically significant, but clinically unimportant mean increases in heart rate (2.4 bpm) and systolic and diastolic blood pressure (<or=2 mmHg) occurred. No arrhythmogenic potential was observed and any rare, transient, asymptomatic increases in hepatocellular enzymes normalized. The authors concluded that duloxetine was safe and tolerable, although transient AEs were not uncommon. Hashim and Abrams [2006] suggested, to reduce the risk of nausea, to begin with a dose of 20 mg twice daily for 2 weeks, then to increase to the recommended 40 mg b.i.d. dosage.

Ghoniem et al. [2005] randomized women with SUI to 1 of 4 treatment combinations: duloxetine alone (40 mg b.i.d.), pelvic floor muscle training, combination and placebo. Overall, drug with or without PFMT was superior to PFMT alone or placebo, while pad results and QOL data favored combination therapy to single treatment. Car dozzo et al. [2004] reported that 20% of women awaiting continence surgery changed their minds while taking duloxetine. Duckett et al. [2006], offered a 4-week course to women awaiting a TVT operation. Thirty-seven percent (of 73) declined. Excluding women for whom concomitant prolapse surgery was planned, 8/33 (24%) scheduled for incontinence surgery alone came off the list. Sixteen (48%) discontinued duloxetine because of AEs, 9 (27%) found the drug ineffective.

Bent et al. [2008], reported on the effects of 12 weeks of duloxetine (40 mg b.i.d.) vs placebo in a large group of women with MUI. For SUI episodes, the mean IEF (incontinence episode frequency) per week decreased 58.9% with drug [7.69 to 3.93] vs 43.3% for placebo [8.93 to 6.05]. Interestingly, corresponding decreased for UUI episodes were 57.7% vs 39.6%. Both sets of values are statistically significant, but the baselines are different and the absolute change for SUI amounted to -3.76 episodes per week for drug, -2.87 for placebo. Nausea was reported by 18% of patients on drug, 4.5% on placebo. Corresponding percents for other AEs include, dry mouth (12 vs 2.8), dizziness (9.7 vs 2.4), constipation (8.3 vs 4.2), fatigue (6.7 vs 2.8). Nausea and dizzi- ness were less common in a subgroup taking concurrent antidepressants. Women 65 years and older with SUI or stress predominant MUI (S-MUI) were given duloxetine (40 mg b.i.d. after a 2-week start on 20 mg b.i.d.) or placebo for 12 weeks by van Leeuwen et al [2008]. They conclude, “this study supports the use of duloxetine in elderly women with SUI or S-MUI”. The data show an absolute change in SUI + S-MUI episodes of -11.7 and -6.9 IEF/week (drug and placebo) and median percent changes of -52.5% vs -36.7% from 24h diaries, both significant at p<0.001. However, the changes for SUI alone were -53% vs -42% (NS) while for S-MUI alone they were -51.6% vs -32.7% (p<0.001). Nausea was less than in other trials (7.5% vs 3.1%), perhaps due to the lower starting dose. Other AEs included fatigue (14.2% vs 5.4), constipation (10.4 vs 0.8), dizziness (9.0 vs 4.6), excess sweating (5.2 vs 0).

Schagen van Leeuwen et al. [2008] investigated efficacy and safety of duloxetine in elderly women with stress urinary incontinence or stress-predominant mixed urinary incontinence. Dulox etine-treated patients had a significantly greater decrease from baseline to endpoint in mean incontinence episode frequency/week than placebo-treated patients (-52.47% vs. -36.70%). The
responder rate (> or =50% reduction in incontinence episode frequency/week) was 57.1% in the duloxetine group and 35.2% in the placebo group (P<0.001). Significant benefits of duloxetine were also demonstrated for weekly continent pad usage, mean time between voids, incontinence quality of life questionnaire scores (P<0.001), and global impression of improvement ratings (P<0.001). Patients with depressive symptoms and cognitive impairments were few and changes were insignificant.

Persistence on duloxetine was studied by Vella et al. [2008] who found that only 31% of an original cohort of 228 were still taking drug beyond 4 weeks, 12% at 4 months, 10% at 6 months, and 9% at 1 year. Fifty-six percent of the discontinuations were attributed to side effects, 33% to lack of efficacy, Bump et al. [2008], however, reported that the positive effects of duloxetine were maintained in patients who continued treatment up to 30 months, but admitted that this subgroup was likely to include predominantly patients who had favorable responses. The number decreased from 1424 in this cohort at 3 months to 368 at 30 months Shaban et al. [2010] concluded that duloxetine is “optional second line for women not willing or unfit for surgery after warning against side effects as recommended by NICE guidelines in the UK”. Similar sentiments are expressed by Robinson and Cardozo [2010].

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union [European Medicines Agency, Scientific Discussion, 2005] in women with moderate to severe incontinence (defined as 15 or more episodes per week). It was withdrawn from the FDA consideration process in the United States for the treatment of SUI, but is approved for the treatment of major depressive disorder (20-30 mg b.i.d. initially, 60 mg once daily maintenance), diabetic peripheral neuropathic pain (60 mg once daily), generalized anxiety disorder (60 mg once daily, fibromyalgia (30 mg once daily initially, 60 mg once daily maintenance) and chronic musculoskeletal pain (30 mg once daily initial,60 mg once daily as maintenance. The product information contains a “black box” warning of “increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders”, noting also that “depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide” [Prescribing Information, revised September 2011, Eli Lilly and Company, Indianapolis, Indiana 46285]. Other warnings and precautions in the U.S. in the United States Product Information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease), orthostatic hypotension, serotonin syndrome (general statement regarding SSRIs and SNRIs), abrupt discontinuation (may result in dizziness, paresthesias, irritability and headache), inhibitors of CYP1A2 (such as ciprofloxacin), thioridazine (do not administer concomitantly) potent inhibitors of CYP2D6 (may increase concentration), and others. Adverse events for 6801 drug and 4487 placebo treated patients reported in the US Product Information (treatment for the indications mentioned) are nausea (24% vs 8%), dry mouth (13 vs 5), fatigue (10 vs 5), somnolence (10 vs 3), insomnia (10 vs 6), constipation (10 vs 4), dizziness (10 vs 5).

D. Stress urinary incontinence in men

Although a problem of significant magnitude, especially after radical prostatectomy (RP) for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention.

Intrinsic sphincter function is the most important outlet factor maintaining continence in men. Urethral support is less important, and there is no entity similar to the hypermobility phenomenon in women. The proximal urethral sphincter extends from the bladder neck through the prostatic urethra. Its function is removed by radical prostatectomy. The distal urethral sphincter includes the rhabdosphincter, urethral smooth muscle and extrinsic pararethral skeletal muscle, extending from the prostatic urethra below the verumontanum through the membranous urethra [Koelbl, Nitti et al, 2009]. Tsakiris et al [2008] searched for articles on drug treatment of male SUI published between 1966 and June 2007 and did a generalized database search in addition. Nine trials were identified using alpha adrenergic agonists, beta-2 antagonists or SNRIs. Only one of these included a comparison arm [Filocamo et al, 2007], 40 mg b.i.d. duloxetine plus pelvic floor exercise (PFE) vs PFE with placebo. The results suggested a positive effect of drug, but were a bit confusing. Of those patients completing the 4 month trial [92/112] 78% of the drug treated patients vs 52% of those in the placebo group were “dry”. However, one month after the end of the study, the corresponding figures were 46% vs 73%, a shift still observed 2 months later. The authors of the review article suggested further larger and well designed studies on duloxetine for this potential usage.

Cornu et al. [2011] reported a series of post RP men with SUI or MUI (stress predominant) randomized to duloxetine [I5] and placebo [I6] after a 2-week placebo run in. Dosage was 20 mg b.i.d. for 7d, 40 mg b.i.d. for 67d, 20 mg for 14d. Subjects were at least 1 year post surgery. Outcome measures included percent decrease in IEF, 1h pad test and various QOL measures. Statistical significance for IEF percent decrease occurred only at week 8 & 12 (-) 52.2 ± 38.6% vs (+)19 ± 43.5%) but there was clearly a trend at 4 weeks. There was no statistical difference in 1h pad test weights but there was in various QOL scores. A 50-100% decrease in IEF was seen at 12
weeks in over half of the patients. Adverse events for drug and placebo included fatigue (50 vs 13%), insomnia (25 vs 7), libido loss (19 vs 7), constipation (13 vs 7), nausea (13 vs 7), diarrhea (13 vs 7), dry mouth (6 vs 0), anorexia (6 vs 0), and sweating (25 vs 20). Drawbacks and concerns are the small number (the original proposed sample size was 90) and the lack of any placebo effect on IEF and QOL. There were 4 men with MUI in the drug group, 5 in the placebo group. Results for SUI and UUI were not separated. One would logically not expect improvement to continue after drug withdrawal unless a permanent change occurred in behavior, anatomy or neuromuscular function. In an uncontrolled usage study on men with post RP SUI, Serra et al [2011] reported that the benefit remained in 85% after the drug was stopped. In that series, 25% of patients withdrew because of AEs and 33% because of lack of effect.

Usage of duloxetine for SUI in the male is universally off label. A drug for this indication would be welcome. Larger controlled and better designed studies are necessary to provide conclusive positive or negative data on this subject.

E. Drugs to treat overflow incontinence/acute urinary retention

Urinary incontinence most often results from involuntary bladder contractions and/or too little resistance generated by the bladder outflow tract during the storage phase of the micturition cycle (urgency incontinence and stress incontinence, respectively). More rarely, incontinence can also occur because of too little pressure generation and/or too much outflow resistance, which can lead to a markedly distended bladder and urinary retention and, secondarily, overflow incontinence [Abrams et al., 2002].

Based upon theoretical reasoning, animal studies [Kamo et al., 2005; Gu et al., 2004], and reports of drugs that can cause overflow incontinence [Anders et al., 1985], a variety of medical approaches to the treatment of overflow incontinence have been proposed [Chutka and Takahashi, 1998; Diokno AC, 2004; Hampel et al., 2005]. Treatment may aim to increase bladder contractility, decrease bladder outlet resistance, or both. Theoretically, all drugs that improve decreased sensation (and increase afferent activity) or drugs that increase detrusor contractile force could be useful. Alternatively, agents that decrease outflow resistance, thereby restoring an appropriate balance between detrusor strength and urethral resistance, could be used.

These drugs include direct or indirect muscarinic receptor agonists, α1-AR antagonists, choline esterase inhibitors, prostaglandins (PG), and skeletal muscle relaxants [Diokno AC, 2004]. The use of muscarinic receptor agonists, such as bethanechol, to stimulate detrusor muscarinic receptors, or choline esterase inhibitors, such as distigmine, to reduce the degradation of acetylcholine, is based upon the idea that stimulation of muscarinic receptors may overcome a hypocontractile detrusor [Barendrecht et al., 2007]. However, a recent systematic review of controlled clinical studies that used direct and indirect parasympathetic agonists in patients with an underactive detrusor reported that these drugs do not provide consistent benefits and may even be harmful. The available information indicates that muscarinic receptor agonists and choline esterase inhibitors have little, if any, beneficial effects on preventing and treating detrusor underactivity. While there is a theoretical basis for the use of β-agonists to relax the sphincter, no definite improvements in symptoms have yet been demonstrated [Riedl et al., 2000; Dasgupta et al., 2003; Barendrecht et al., 2007; Ahmad et al. 2009]. As bethanechol exerts its effect on intact smooth muscle cells only, it is of limited use for the treatment of bladder atony. Idiopathic detrusor atony is poorly responsive to medical treatment [Noel et al. 2010].

The use of α1-AR antagonists has repeatedly been shown to be beneficial in patients with acute urinary retention due to benign prostatic enlargement [McNeill et al., 2004; 2005; Fitzpatrick et al., 2012]. These drugs are believed to facilitate bladder emptying by relaxing tone at the bladder neck. Administration of alfuzosin 10 mg daily almost doubles the likelihood of a successful trial without a catheter, even in patients who are elderly with a PVR > 100 mL. Continued use of alfuzosin significantly reduced the risk of BPH surgery in the first 3 months; however, this effect was not significant after 6 months [Fitzpatrick and Kirby, 2006; Emberton et al., 2008; Kalejaiye et al., 2009]. Thus, α1-AR antagonists provide rapid symptom relief from outlet obstruction caused by benign prostatic enlargement and delay the time to acute urinary retention; however, they do not decrease the overall risk of acute urinary retention or surgery [Emberton et al., 2008; Edwards, 2008; Fitzpatrick et al., 2012].

Acute urinary retention may occur after surgery. Buckley and Lapitan [2010] reviewed drugs used for treatment of post-operative urinary retention either alone or in combination, assessing cholinergic agents, α1-AR blockers, sedatives and prostaglandins. A statistically significant association between intravesically administered prostaglandins and successful voiding was detected, but no such association was found for the other drugs investigated. When cholinergic agents were combined with sedative there was an improved likelihood of spontaneous voiding compared with placebo.

There are some potential new agents for the treatment of an underactive bladder. Misoprostol, a cholinesterase inhibitor, and cholinergic agents are potential candidates for the treatment of the under-
active bladder, but their safety and lack of benefit is of concern. Novel muscarinic receptor manipulation using the presynaptic M2 receptor antagonist or postsynaptic allosteric receptor enhancement is promising. The prokinetics used in gastroenterology and the smooth muscle ionotropics used in cardiology warrant consideration. The use of trophic factors such as insulin-like growth factor and nerve growth factor may improve muscle and nerve function in the lower urinary tract. Furthermore, the use of stem cells, regenerative medicine, and gene therapy might facilitate improved contractility in a weak detrusor [Chancellor et al., 2008].

However, these agents have never been tested systematically in patients with overflow incontinence; there have been no randomized controlled trials to demonstrate the effectiveness and safety of these agents. Therefore, there is no empirical basis to select medical treatments for overflow incontinence and all previously recommended treatments must be rated as “expert opinion” at best. Better systemic studies are required to determine the best medical treatment for overflow incontinence. Any medical treatment for overflow incontinence should be compared to catheterization or surgery.

F. Hormonal treatment of urinary incontinence

I. OESTROGENS

1. OESTROGENS AND THE CONTINENCE MECHANISM

The oestrogen sensitive tissues of the bladder, urethra and pelvic floor all play an important role in the continence mechanism. For women to remain continent the urethral pressure must exceed the intra-vesical pressure at all times except during micturition. The urethra has four oestrogen sensitive functional layers all of which have a role in the maintenance of a positive urethral pressure 1) epithelium, 2) vasculature, 3) connective tissue, 4) muscle.

Two types of oestrogen receptor, (α and β) have been identified in the trigone of the bladder, urethra and vagina as well as in the levator ani muscles and fascia and ligaments within the pelvic floor [Smith et al., 1990; Copas et al., 2001; Gebhardt et al., 2001]. After the menopause oestrogen receptor α has been shown to vary depending upon exogenous oestrogen therapy [Fu et al., 2003]. In addition exogenous oestrogens affect the remodeling of collagen in the urogenital tissues resulting in a reduction of the total collagen concentration with a decrease in the cross linking of collagen in both continent and incontinent women [Falconer et al., 1998; Keane et al., 1997]. Studies in both animals and humans have shown that oestrogens also increase vascularity in the peri-urethral plexus which can be measured as vascular pulsations on urethral pressure profilometry [Robinson et al., 1996; Endo et al., 2000; Versi and Cardozo, 1986].

2. OESTROGENS FOR STRESS URINARY INCONTINENCE

The role of oestrogen in the treatment of stress urinary incontinence has been controversial despite a number of reported clinical trials [Hextall, 2000]. Some have given promising results but this may have been because they were small observational and not randomised, blinded or controlled. The situation is further complicated by the fact that a number of different types of oestrogen have been used with varying doses, routes of administration and duration of treatment.

Fantl et al.[1996] treated 83 hypo-oestrogenic women with urodynamic stress incontinence and/or detrusor overactivity with conjugated equine oestrogens 0.625 mg and medroxyprogesterone 10 mg cyclically for three months. Controls received placebo tablets. At the end of the study period the clinical and quality of life variables had not changed significantly in either group. Jackson et al. [1996] treated 57 post menopausal women with urodynamic stress or mixed incontinence with Oestradiol 2 mg or placebo daily for six months. There was no significant change in objective outcome measures although both the active and placebo groups reported subjective benefit.

Two meta analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee the use of oestrogens to treat all causes of incontinence in post menopausal women was examined [Fantl et al., 1994]. Of 166 articles identified, which were published in English between 1969 and 1992, only six were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost, Maximum urethral closure pressure increased significantly but this result was influenced by only one study showing a large effect.

In the second meta-analysis Sultana and Walters [1990] reviewed eight controlled and 14 uncontrolled prospective trials and included all types of oestrogen treatment. They also found that oestrogen therapy was not an efficacious treatment for stress urinary incontinence but may be useful for the often associated symptoms of urgency and frequency. Oestrogen when given alone therefore does not appear to be an effective treatment for stress urinary incontinence.

Several studies have shown that oestrogen may have a role in combination with other therapies e.g. α-adrenoceptor agonists. However, phenylpropa-
malamine (the most widely used α-adrenoceptor agonist in clinical practice) has now been restricted or banned by the US Food and Drug Administration (FDA).

In a randomised trial Ishiko et al. [2001] compared the effects of the combination of pelvic floor exercise and oestriol (1 mg per day) in 66 patients with post menopausal stress urinary incontinence. Efficiency was evaluated every three months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress incontinent patients in both groups three months after the start of therapy and concluded that combination therapy with oestriol plus pelvic floor exercise was effective and could be used as first line treatment for mild stress urinary incontinence. Unfortunately this has not been reproduced in other clinical trials.

Thus even prior to the more recently reported secondary analyses of the heart and oestrogens/progestogen replacement study (HERS) [Grady et al., 2001] and women’s health initiative (WHI) [Hendrix et al., 2005] it was already recognised that oestrogen therapy had little effect in the management of urodynamic stress incontinence [Al-Badr et al., 2003; Robinson and Cardozo 2003].

3. OESTROGENS FOR URGENCY URINARY INCONTINENCE AND OVERACTIVE BLADDER SYMPTOMS

Oestrogen has been used to treat post menopausal urgency and urge incontinence for many years but there have been few controlled trials to confirm that it is of benefit [Hextall, 2000]. A double blind multi centre study of 64 post menopausal women with “urge syndrome” failed to show efficacy [Cardozo et al., 1993]. All women underwent pre-treatment urodynamic investigation to ensure that they had either sensory urgency or detrusor overactivity. They were randomised to treatment with oral oestriol 3 mg daily or placebo for three months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Oestriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another randomised controlled trial from the same group using 25 mg oestradiol implants confirmed the previous findings [Rufford et al., 2003], and furthermore found a high complication rate in the oestradiol treated patients (vaginal bleeding).

Symptoms of an overactive bladder increase in prevalence with increasing age and lower urinary tract symptoms and recurrent urinary tract infections are commonly associated with urogenital atrophy. Whilst the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritis and dyspareunia, greater improvement in cytological findings and higher serum oestradiol levels [Cardozo et al 1998]. Overall vaginal oestradiol has been found to be the most effective in reducing patient symptoms although conjugated oestrogens produced the most cytological change and the greatest increase in serum oestradiol and oestrone. The most recent meta analysis of intravaginal oestrogen treatment in the management of urogenital atrophy was reported by the Cochrane group in 2003 [Suckling et al 2003]. Overall 16 trials including 2129 women were included and intravaginal oestrogen was found to be superior to placebo in terms of efficacy although there were no differences between types of formulation. 14 trials compared safety between the different vaginal preparations and found a higher risk of endometrial stimulation with conjugated equine oestrogens as compared to oestradiol.

Thus theoretically there could be a role for combination treatment with an anti muscarinic agent and vaginal oestrogen in post menopausal women. However, the two clinical trials which have been reported to date differ in their outcome. Tseng et al.[2009] showed superior efficacy in terms of symptom improvement for the overactive bladder when Tolterodine was used with vaginal oestrogen cream as opposed to Tolterodine alone. However, Serati et al. [2009] found no difference between Tolterodine with or without topical oestrogen in women with symptomatic detrusor overactivity.

4. EVIDENCE REGARDING OESTROGENS AND INCONTINENCE FROM LARGE CLINICAL TRIALS

The HERS study included 763 post menopausal women under the age of 80 years with coronary heart disease and intact uteri [Grady et al., 2001]. It was designed to evaluate the use of oestrogen in secondary prevention of cardiac events. In a secondary analysis 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated oestrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (N=768) or placebo (N=757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared to 21% assigned to hormones whilst 27% of the placebo group worsened compared with 39% of the hormone group (P=0.001). This difference was evident by four months of treatment, for both urgency and stress urinary incontinence. The number of incontinence episodes per week increased an
average of 0.7 in the hormone group and decreased by 0.1 in the placebo group (p < 0.001). The authors concluded that daily oral oestrogen plus progestogen therapy was associated with worsening urinary incontinence in older post menopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.

The Women’s Health Initiative (WHI) was a multi centre double blind placebo controlled randomised clinical trial of menopausal hormone therapy in 27347 postmenopausal women age 50-79 years enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23296 participants at baseline and one year [Hendrix et al., 2005]. The women were randomised based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg per day of conjugated equine oestrogen (CEE) plus 2.5 mg per day of medroxyprogesterone Acetate (CEE+MPA), whereas those who had undergone hysterectomy received oestrogen alone (CEE). At one year hormone therapy was shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline. The risk was highest for stress urinary incontinence CEE+MPA: RR, 1.7 95% confidence interval CI (1.61-2.18); CEE alone RR 2.15 mg, 95% CI, 1.77-2.62, followed by mixed urinary incontinence CEE+MPA: RR 1.49 95% CI 1.10-2.01. On CEE alone RR was 1.79 95% CI, 1.26-2.53. The combination of CEE and MPA had no significant effect on developing urge urinary incontinence RR, 1.15; 95% CI, 0.99-1.34 but CEE alone increased the risk RR 1.32; 95% CI, 1.10-1.58. For those women experiencing urinary incontinence at baseline frequency worsened in both active groups CEE+MPA; RR, 1.38 95% CI 1.28-1.49; CEE alone: RR, 1.47 95% CI, 1.35-1.61. Quantity of urinary incontinence worsened at one year in both active groups, CEE+MPA: RR, 1.20 95% CI, 1.06-1.76; CEE alone: RR, 1.59 95% CI, 1.39-1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities CEE+MPA: RR 1.18 95% CI, 1.06-1.32. CEE alone: RR 1.29 95% CI, 1.15-1.45 at one year. Thus based on this secondary analysis of data from a huge study conjugated equine oestrogen alone or in combination with Medroxyprogesterone Acetate was shown to increase the risk of urinary incontinence amongst continent women and worsen urinary incontinence amongst asymptomatic women after one year of therapy.

The Nurses Health Study [Grodstein et al., 2004] was a biennial postal questionnaire starting in 1976. In 1996 39436 post menopausal women aged 50-75 years was reported no urinary leakage at the start of the study were followed up for four years to identify incident cases of urinary incontinence. 5060 cases of occasional and 2495 cases of frequent incontinence were identified. The risk of developing urinary incontinence was increased amongst post menopausal women taking hormones compared to women who had never taken hormones (oral oestrogen: RR1.54 95% CI 1.44, 1.65; transdermal oestrogen: RR1.68, 95% CI 1.41, 2.00; oral oestrogen with progestin: RR1.34, 95% CI 1.24, 1.44; transdermal oestrogen with progestin: RR1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

The most recent meta analysis of the effect of oestrogen therapy on the lower urinary tract has been performed by the Cochrane Group [Cody et al., 2009] and is notable as the conclusions are starkly different from those drawn from the previous review [Moehrer et al., 2003]. Overall 33 trials were identified including 19313 continent women (1262 involved in trials of local administration) of which 9417 received oestrogen therapy.

Systemic administration (of unopposed oral oestrogens – synthetic and conjugated equine oestrogens) resulted in worse incontinence than placebo (RR1.32; 95% CI: 1.17-1.48). Although this is heavily influenced by the size of the WHI study [Hendrix et al 2005]. When considering combination therapy there was a similar worsening effect on incontinence when compared to placebo (RR1.11; 95% CO: 1.04-1.08). There was some evidence suggesting that the use of local oestrogen therapy may improve incontinence (RR0.74; 95% CI: 0.64-0.86) and overall there were 1-2 fewer voids in 24 hours and less frequency and urgency.

The authors conclude that local oestrogen therapy for incontinence may be beneficial although there was little evidence of long term effect. The evidence would suggest that systemic hormone replacement using conjugated equine oestrogens may make incontinence worse. In addition they report that there are too few data to comment reliably on the dose type of oestrogen and route of administration.

II. OTHER HORMONES

Progesterone and progestogens are thought to increase the risk of urinary incontinence. Lower urinary tract symptoms especially stress urinary incontinence have been reported to increase in the progestogenic phase of the menstrual cycle [Hexell et al., 2001]. In similar studies progesterone has been shown to increase beta adrenergic activity leading to a decrease in the urethral closure pressure in female dogs [Raz et al., 1973]. However, in the WHI there appeared to be no difference whether or not progestin was given in addition to oestrogen [Hendrix et al., 2005].
Selective oestrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both oestrogenic and anti oestrogenic effects. In the clinical trials of levormeloxifene there was a fourfold increase in the incidence of incontinence leading to cessation of the clinical trial [Hendrix et al., 2001]. However raloxifene has not been shown to have any effect at all on urinary incontinence [Waetjen et al., 2004]. There are no reported clinical trials evaluating the effect of androgens, and in particular Testosterone, on urinary incontinence in women.

**Assessments, hormone treatment**

Oestrogen has an important physiological effect on the female lower urinary tract and its deficiency is an aetiological factor in the pathogenesis of a number of conditions. However the use of oestrogen either alone or in combination with progestogen has yielded poor results. The current level 1 evidence against the use of oestrogen for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events and therefore the secondary analyses have only been based on self reported symptoms of urinary leakage without any objective data. Despite this all of these large randomised controlled trials show a worsening of pre-existing urinary incontinence both stress and urgency and an increased new incidence of urinary incontinence with both oestrogen and oestrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine oestrogen and this may not be representative of all oestrogens taken by all routes of administration.

In a systematic review of the effects of oestrogens for symptoms suggestive of an overactive bladder the conclusion was that oestrogen therapy may be effective in alleviating OAB symptoms, and that local administration may be the most beneficial route of administration [Cardozo et al., 2004]. It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency and urge incontinence may be a manifestation of urogenital atrophy in older post menopausal women rather than a direct effect on the lower urinary tract [Robinson and Cardozo, 2003]. Whilst there is good evidence that the symptoms and cytological changes of urogenital atrophy may be reversed by low dose (local) vaginal oestrogen therapy there is currently no evidence that oestrogens with or without progestogens should be used in the treatment of urinary incontinence.

**III. DESMOPRESSIN**

The endogenous hormone vasopressin (also known as anti-diuretic hormone) has two main functions: it causes contraction of vascular smooth muscle and stimulates water reabsorption in the renal medulla. These functions are mediated by two specific vasopressin receptors of which there are two major subtypes, namely the V1 and V2 receptors. The V2 subtype is particularly important for the anti-diuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to central diabetes insipidus, and genetic defects in the gene encoding the V2 receptor can cause nephrogenic diabetes insipidus [Insel et al., 2007]. Accordingly, decreased vasopressin levels are believed to be important in the pathophysiology of polyuria, specifically nocturnal polyuria, which can lead to symptoms such as nocturia [Matthiesen et al., 1996; Weiss et al., 2011a]. Nocturia is currently defined by the International Continence Society (ICS) as the complaint that an individual has to wake at night one or more times to void. It is, however, ”an under-reported, understudied, and infrequently recognized problem in adults” [Weiss et al., 2011b]. Nocturia leads to decreased quality of life [Kupelian et al., 2011], and has been associated with both increased morbidity and mortality [Nakagawa et al., 2010; Kupelian et al., 2012]. While it remains largely unknown in which fraction of patients nocturia can indeed be explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioural factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist. While it remains largely unknown in what fraction of patients nocturia is explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioural factors that can explain it (e.g. excessive fluid intake) is usually considered to indicate decreased vasopressin levels [Bosch and Weiss., 2011, Weiss et al., 2011b]. Based upon these considerations, vasopressin receptor agonists have been used to treat nocturia, both in children and in adults. Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for anti-diuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and nasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration [Rittig et al., 1998]. Because of symptomatic hyponatremia with water intoxication which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin [Thumfart et al. 2005; Robson et al. 2007; Van de Walle et al. 2010], the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin. An oral lyophilisate (MELT) formulation requiring no concomitant fluid intake is currently available. In a recent open-label, randomized, cross-over study, desmopressin MELT was shown to have similar levels of efficacy and safety at lower doses than the tablet formulation of desmopressin in children. A recent study confirmed the superior pharmacodynamic charac-
The use of desmopressin in children with nocturnal enuresis was comprehensively reviewed by the Cochrane Collaboration in 2002 [Glazener et al. 2002]. These authors evaluated 47 randomized controlled trials involving 3448 children, of whom 2210 received desmopressin. According to their analysis, desmopressin was effective relative to placebo in reducing bed-wetting (e.g. a dose of 20 μg resulted in a reduction of 1.34 wets/night (95% CI 1.11; 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that desmopressin suppresses symptom enuresis but does not cure the underlying cause. Additionally, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an enuresis alarm resulted in a greatly improved short-term success rate and decreased relapse rates [Alloussi et al. 2011]. The combination of desmopressin and antimuscarinics resulted in better short- and long-term success rates as well as a lower relapse rate than desmopressin alone [Austin et al., 2008; Alloussi et al., 2009]. For non-responders to desmopressin, replacement of desmopressin with other medications such as tricyclic antidepressants or loop diuretics could be of benefit, whereas muscarinic receptor antagonists may be ineffective in such children (De Guchtenaere et al., 2007; Neveus and Tullus, 2008).

Other studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults. A search for these studies in Medline using the terms “desmopressin” and “nocturia” was performed and limited to clinical studies of de novo nocturia, i.e. those that excluded subjects in whom childhood enuresis persisted into adulthood. Several previous studies investigated the use of desmopressin for the treatment of nocturia in the context of multiple sclerosis [Eckford et al., 1994;1995]. One study with single dose administration reported a reduction in nocturnal polyuria, but by design did not assess nocturia [Eckford et al., 1995]. Three placebo-controlled double-blind studies with a small patient number (16-33 patients total per study) reported a significant reduction in nocturia [Hilton et al., 1983; Eckford et al., 1994; Valiquette et al., 1996]. Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 h after desmopressin administration rather than nocturia as their primary endpoint. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious [Kinn and Larsson, 1990; Fredrikson, 1996; Hoverd and Fowler, 1998]. While desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment due to asymptomatic or minimally symptomatic hyponatremia [Valiquette et al., 1996]. Accordingly, desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients [Cvetkovic and Plosker, 2005]. In a small open-label study, desmopressin was also reported to reduce nocturnal polyuria in spinal cord injury patients [Zahariou, Karagiannis et al. 2007].

Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurological damage. The recruited patient populations were based upon different criteria, including having at least two nocturia episodes per night or having nocturnal polyuria. Earlier studies mostly used a desmopressin dose of 20 μg given either orally [Asplund et al., 1999] or intranasally [Hilton and Stanton, 1982; Cannon et al., 1999], and tended to be very small (≤25 patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1-0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults [Mattilsson et al., 2002; Lose et al., 2004; van Kerrebroeck et al., 2007]. A total of 632 patients entered the dose-titration phase and 422 patients entering the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose titration phase, all patients in the NOCTUPUS trials were washed-out following the dose-titration phase and in order to be randomized, it was a requirement that the patients returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2 or 0.4 mg) is effective in both men and women aged ≥18 years with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared to 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was defined as ≥50% reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo. In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10-12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response (Lose et al. 2004). An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects [Johnson et al. 2006].

Around 75% of community-dwelling men and women with nocturia (≥2 voids/night) have nocturnal

699
polyuria (NP) [Rembratt et al., 2003; Swithinbank et al. 2004]. The key urological factors most relevant to nocturia are NP and OAB in women [Irwin, Abrams et al., 2008], and NP and benign prostatic hyperplasia (BPH) in men. About 74% of women with OAB have nocturia and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP; 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or bladder outlet obstruction [Chang et al., 2006]. Therefore, desmopressin combination therapy with α1-AR antagonists and/or antimuscarinics should be considered for patients with treatment-resistant nocturia. Seventy-three percent of α1-AR antagonist-resistant BPH patients experienced a ≥50% reduction in nocturnal voids with oral desmopressin [Rembratt et al., 2003; Yoong et al., 2005]. A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low dose (0.1 mg) oral desmopressin in elderly (≥65 years) patients reported that low dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH [Wang, Lin et al. 2011]. Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, non-randomized pilot study of men believed to have BPH, desmopressin was reported to improve not only nocturia, but also to reduce the overall international prostate symptom score (IPSS) [Chancellor et al., 1999]. An exploratory, placebo-controlled double-blind study in women with daytime urinary incontinence reported that intranasal administration of 40 μg desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al., 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg oral desmopressin reported a reduction in voids along with an improvement in quality of life (QoL) [Hashim et al., 2009]. While these data indicate that desmopressin may be effective in treating voiding dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared to placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side-effects of desmopressin usage is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. The risk of hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume [Rembratt et al. 2003]. Based on a meta-analysis, the incidence is around 7.6% [Weatherall; 2004]. Increased age and female gender are well-known risk factors for the development of desmopressin-induced hyponatremia. Bae et al. [2007] assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (greater than 3 voids nightly), who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication 24-hour circadian studies were performed to monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment. Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration serum sodium should be assessed regularly, at least every 6 months.

Little focus has been on exploring gender differences in the antidiuretic response to desmopressin. Juul et al. [2011] found an increasing incidence of hyponatremia with increasing dose, and at the highest dose level of 100 μg decreases in serum sodium were approximately twofold greater in women over 50 yr of age than in men. A new dose recommendation stratified by gender was suggested in the treatment of nocturia: for men, 50- to 100 μg melt was suggested to be an efficacious and safe dose, while for women a dose of 25 μg melt was recommended as efficacious with no observed incidences of hyponatremia. Initiation of desmopressin is currently not indicated for patients aged ≥65 years. The mechanisms behind desmopressin-induced hyponatraemia are well understood, and serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk of developing the condition. Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to recommended dosing, should be followed to minimize the risk of hyponatremia [Vande Walle et al., 2007]. Desmopressin is useful for patients with nocturia as well as for children with nocturnal enuresis. The drug has been proven to be well-tolerated and effective by several randomized, placebo-controlled trials and is recommended as a first-line treatment (either as monotherapy or in combination with other agents) for patients who have been appropriately evaluated and whose nocturia is related to NP, whether or not this is accompanied by BPH or OAB. For assessment, see Table 2.
G. Considerations in the Elderly

1. ANTUSCARINIC AGENTS

1. EFFICACY AND TOLERABILITY

The efficacy of antimuscarinic agents for treating symptoms of overactive bladder and urge urinary incontinence in older people is similar to that observed in younger and middle-aged adults. Age-related pooled results or sub-analyses from randomized controlled trials of tolterodine [Malone-Lee et al., 2001, Zinner et al., 2002], solifenacin (Wagg et al., 2006), darifenacin [Foote et al., 2007], fesoterodine [Kraus et al., 2010, Sand et al., 2012], and trospium chloride [Sand et al., 2011] indicate that reductions of 25-75% in urgency urinary incontinence episodes can be expected with use of these agents in older (65+) adults. Higher doses may be needed in those over age 75 [Kraus et al., 2010]. In a post-marketing surveillance study of darifenacin, Michel et al. [2010] found that increasing age was negatively associated with improvements in urgency episodes and incontinence, with a statistically significant, but non-clinically relevant effect (0.01 more urgency episodes per year of age). Older adults may derive greater benefit from use of a combined drug and behavioral therapy regime as compared to treatment with drug therapy alone [Burgio et al., 2000]. Dry mouth is the most frequently reported treatment-related adverse event, however overall tolerance has been reported as good to excellent with fewer treatment-motivated withdrawals in recent trials of older patients persisting on antimuscarinic therapy [Sand et al., 2012, Sand et al., 2011]. Constipation is also common and may be particularly bothersome for older adults already suffering from chronic bowel dismotility [Meek et al., 2011, Gallegos-Orozco et al., 2012].

However, the therapeutic effectiveness and tolerability of antimuscarinic agents in the elderly in the real world practice setting may differ from results obtained in randomized controlled trials for several reasons. First, research trials generally exclude individuals with concomitant consumption of other antimuscarinic agents. In practice, older adults are a heterogeneous group, often consuming many medications that may augment, desensitize or alter the response to antimuscarinic therapy. As well, there is a higher prevalence of comorbidity among the elderly, which can further reduce treatment efficacy and heighten the potential for side effects to occur (see the Section on Incontinence in the Frail Elderly). Failure to acknowledge the multifactorial nature of urinary incontinence in the elderly often leads to suboptimal treatment. Urgency symptoms may be exacerbated by consumption of caffeinated beverages, pelvic floor muscle weakness, diuretics or other functional and systemic dysfunctions. Treatment should therefore address all possible etiologies, and not be limited to a solitary intervention.

2. COGNITIVE SAFETY

A growing body of literature has emerged to address the concern that antimuscarinic agents used to treat symptoms of overactive bladder may cross the blood-brain barrier and provoke subtle or not so subtle cognitive impairment [Callegari et al., 2011; Jakobsen SM et al., 2011; Wagg et al., 2010; Pagoria et al., 2011]. Large randomized controlled trials were not designed to adequately measure central nervous system adverse events [Paquette et al., 2011]. As a result, evidence on the relative risk of different antimuscarinic agents for crossing the blood brain barrier and inducing changes in cognitive comes primarily from in-vitro studies and experimental studies using detailed neuropsychological testing.

Early studies suggested that administration of antimuscarinic agents such as scopolamine could impair memory and attention in older adults, and possibly induce hallucinations and confusion [Flicker et al., 1992; Sperling et al., 2002]. Oxybutynin in particular, due to its small molecular size and increased propensity to cross the blood-brain barrier, has consistently shown potential to elicit cognitive impairment in new users after a single high dose of this agent or at steady state, and should be avoided in the elderly [Donellan et al., 1997; Katz et al., 1998; Kay et al., 2008, Wesnes et al., 2009]. Katz et al. [1998] used a double-blind, placebo-controlled cross-over design to test a convenience sample of 12 healthy continent older adults, and revealed cognitive decrements on seven of fifteen cognitive measures resulting from oxybutynin use. Impairments were observed in verbal learning, memory, reaction time, attention, concentration and psychomotor speed. In a sleep study, oxybutynin was found to significantly alter EEG patterns compared to placebo [Todorova et al., 2001]. Oxybutynin was compared to darifenacin and placebo in a 3-week randomized multicentre double-blind parallel-group study in 150 healthy volunteers aged 60-83 [Kay et al., 2006]. Darifenacin produced no impairments compared to placebo at 3-weeks, but oxybutynin caused significant memory deterioration in delayed recall compared to the other two groups. Darifenacin was associated with significantly slower reaction times than placebo in the Divided Attention Test, but not in other tests of information processing speed. Oxybutynin also reduced accuracy scores for immediate recall in one of three tests. Wesnes et al. [2009] showed in a single-dose crossover study with 12 healthy older volunteers that oxybutynin IR 10 mg induced significant deficits in attention and memory compared to placebo, whereas solifenacin 10 mg did not.

Studies with the antimuscarinic agents solifenacin, trospium chloride ER and darifenacin suggest that these agents confer significantly lower cognitive risk than oxybutynin. Administration of trospium chloride ER to 12 cognitively intact adults with overactive bladder aged 65-75 was found to have no effect on memory testing with the Hopkins Verbal Learning
Test on day 10 post-administration compared to baseline, and was also found to be undetectable in the cerebral spinal fluid of participants [Staskin et al., 2010]. In a study of darifenacin among 129 older adults aged 65-84, no significant effects on cognition were observed (memory scanning sensitivity, speed of reaction time, and word recognition) compared with placebo [Lipton et al., 2005]. No data on fesoterodine and memory were found.

New onset delirium also does not appear to be a significant concern in patients taking antimuscarinic agents. Although several published case reports have documented the acute onset of delirium following initiation of tolterodine, incontinent adults with and without dementia [Womack and Heilman, 2003; Salvatore et al., 2007; Edwards et al., 2002; Williams et al., 2004; Tsao et al., 2003], these deficits resolved upon discontinuation or dose reduction of tolterodine. In a randomized controlled study of extended-release oxybutynin in nursing-home residents with mild to severe dementia, there was no incidence of delirium over the duration of the study [Lackner et al., 2008]. Furthermore, more recent evidence puts into question the traditionally held belief that new use of anticholinergic agents provokes incident delirium in hospitalized older patients [Campbell et al., 2011; Luukkanen et al., 2011].

Taken together, increasing evidence suggests that with the exception of oxybutynin, use of the other antimuscarinic agents poses little or no cognitive risk to otherwise healthy older adults with symptoms of overactive bladder. However, two caveats apply. First, the integrity of the blood brain barrier may be compromised in many older adults with cerebrovascular disease, diabetes, or certain forms of dementia, with the results of studies in healthy older adults not generalizable to frailer individuals [Kay et al., 2005]. Second, long-term use of antimuscarinic agents over months or years may yield more detrimental cognitive effects than single dose or short-term use. A number of large observational studies have linked chronic consumption of antimuscarinic drugs with an increased risk of cognitive impairment, although most studies simultaneously examined the cumulative effect of drugs with any antimuscarinic properties rather than each drug class alone. [Ancelin et al., 2006; Campbell et al., 2009; Fox et al., 2011]. The Eugenia study of aging randomly recruited 372 adults 60 years and older from Montpellier, France, and showed that antimuscarinic drug users displayed significantly poorer reaction time, attention, immediate and delayed visuospatial memory, narrative recall, and verbal fluency than did non drug users [Ancelin et al., 2006]. A 2-year longitudinal study of 13,000 participants enrolled in the Medical Research Council Cognitive Function and Ageing Study also showed that use of medication with antimuscarinic effects was associated with a 0.33-point greater decline in the Folstein Mini Mental Status Exam score (95% confidence interval (CI)=0.03-0.64, P=.03) than not taking antimuscarinics. Two-year mortality was also greater for those taking (OR=1.68; 95% CI=1.30-2.16; P<.001) anticholinergics. Many commonly prescribed medications in the elderly possess antimuscarinic properties [Chew et al., 2008], so the results may not be specific to bladder antimuscarinics. Other antimuscarinic medication include, among others, amytriptyline, clozapine, olanzapine, paroxetine, furosemide, hydrocortone, lansoprazole, levofloxxacin, and metformin.

Clinicians who remain wary of prescribing antimuscarinic agents for frail older adults with symptoms of overactive bladder are suggested to proceed with caution in prescribing these medications and fully weigh the risk-benefit ratio in light of other therapeutic options that can be equally effective for urgency and mixed incontinence in the elderly. If antimuscarinics are to be prescribed, a short cognitive screen (such as the Montreal Cognitive Assessment http://www.mocatest.org) or even a full neuropsychological test battery for those patients who are concerned or at risk, before and after initiating therapy might reveal whether subtle impairments have been induced. This is especially pertinent because patients are often unaware of their memory deficits [Kay et al., 2006]. A proxy informant, such as the patient’s spouse or a relative, may be able to provide more reliable information on possible cognitive changes resulting from the drugs.

A frequently asked clinical question is whether antimuscarinic agents used to treat incontinence should be contraindicated in patients with dementia already taking cholinesterase inhibitors, as the mechanisms of these two medications are diametrically opposed. A number of small studies have shown that cholinesterase inhibitors used to improve cognition in Alzheimer’s disease precipitate urinary incontinence [Hashimoto et al., 2000]. A Japanese study followed 94 patients with mild to moderate dementia treated with donepezil [Hashimoto et al., 2000]. Seven patients developed urinary incontinence, although the event was transient in most patients. In Scotland, among 216 patients with Alzheimer’s disease initiating treatment with a cholinesterase inhibitor, incontinence was precipitated in 6.6%, and those with existing incontinence worsened [Starr, 2007]. Epidemiologic studies also show associations between cholinesterase inhibitors and incontinence [Gill et al., 2005; Roe et al., 2002]. In a large population-based cohort study of 44,884 adults with dementia carried out in Canada, those who were dispensed cholinesterase inhibitors were more likely to subsequently receive an antimuscarinic drug for incontinence compared to those not receiving cholinesterase inhibitors (hazard ratio 1.55, 95% confidence interval 1.39-1.72) [Gill et al., 2005]. This finding was confirmed by a separate study in the U.S. documenting a two-fold risk of taking oxybutynin in dementia patients treated with donepezil compared to those not treated with donepezil [Roe et al., 2002].
the addition of a 3-month trial of propiverine 20 mg/day to donepezil in twenty-six cognitively impaired older adults, and found improved dryness rates with no deleterious effect on cognition [Sakakibara et al., 2009]. A 6-month study also compared the effects of trospium, galantamine, or trospium plus galantamine in 178 older adults with urge incontinence (n=99), dementia (n=43) or dementia and incontinence (n=36) respectively [Isik et al., 2009]. Treatment with 45-60 mg/day of trospium chloride and combined use of trospium with galantamine 24 mg/day was found to have no adverse effect on cognitive or physical function scores in this group of patients. A larger observational study of 3,563 long-term care residents with dementia also failed to document an increased rate of cognitive decline with combined use of a cholinesterase inhibitor and antimuscarinic therapy (oxybutynin or tolterodine) compared to cholinesterase therapy alone [Sink et al., 2008]. However, a 50% faster rate of physical function decline was observed in higher-functioning participants on dual therapy compared to cholinesterase inhibitor therapy alone. This evidence suggests the competing mechanisms of the antimuscarinics and cholinesterase inhibitors may indeed have clinical consequences in some, but not all patients.

3. Cardiac safety. Another serious side effect of antimuscarinic drugs in the elderly is the risk of cardiac adverse effects and increased mortality, particularly due to increases in heart rate, prolongation of the QT interval, and induction of polymorphic ventricular tachycardia. These have been previously discussed, and it has been noted that studies specific to the elderly are lacking [Andersson et al., 2011]. Only one study prospectively examined the effect of anticholinergic drug use in 400 community-dwelling older people (aged 75-90 years) with stable cardiovascular disease in Helsinki, Finland [Usuvaara et al., 2011]. Bladder antimuscarinic agents were not examined individually, but were considered in a cumulative assessment of all drugs with antimuscarinic properties being taken by the same individual. The unadjusted follow-up mortality was 20.7% and 9.5% among users and non-users of antimuscarinic drugs, respectively (p = 0.010). However, the use of drugs with antimuscarinic properties was not a significant predictor of mortality in multivariate analysis after adjustment for age, sex and other comorbidities (hazard ratio 1.57; 95% CI 0.78, 3.15).

4. Drug/drug interactions in the elderly. Rates of polypharmacy (> 5 drugs per patient) are high in the geriatric population, and cause potential for drug-drug interactions that increase toxicity or reduce the efficacy of antimuscarinic agents [Chancellor and Miguel, 2007]. The relationship between the number of drugs and potential drug-drug interactions in the elderly is alarming. Consumption of 5 to 7 and 8 to 10 drugs places older adults at a 4-fold and 8-fold increased risk of potentially serious drug-drug interactions respectively, compared with consumption of 2 to 4 drugs [Johnell & Klarin, 2007]. Drug-drug interactions frequently involve isoenzymes of the hepatic cytochrome CYP450 system [Zakrzewski-Jakubiak et al., 2011]. Of the antimuscarinic drugs, tolterodine, darifenacin, solifenacin, and oxybutynin are extensively metabolized by CYP450 and are at greater risk of having altered drug metabolism due to hepatic-based drug-drug interactions. Trospium is eliminated renally as unchanged drug, suggesting that it has lower potential for CYP450 drug-drug interactions [Sand et al., 2011]. Trospium may therefore represent a safer treatment option in the context of polypharmacy in the elderly.

II. DESMOPRESSIN – EFFICACY AND SAFETY IN THE ELDERLY

Desmopressin (DDAVP) (0.1–0.2 mg) reduces nocturia in older persons [Rezakhanlia et al., 2011; Fu et al., 2011; Johnson et al., 2006], but has been associated with significant dose-related hyponatremia in 2-20% of older patients [Fu et al., 2011; Johnson et al., 2006; Weatherall 2004]. Both female sex and increasing age are risk factors for the development of hyponatremia [Callreus et al., 2005; Rembratt et al., 2006; Juul et al., 2010]. A lower starting dose (0.025 mg) for the melt form has been suggested for older women [Juul et al., 2010] but requires further study. Caution is recommended for the initiation of desmopressin in adults aged 65 years and older at the current time.

III. BOTULINUM TOXIN A IN OLDER ADULTS

To date no studies have stratified the results of trials using BoNTA for the treatment of urinary incontinence in patients with neurogenic bladder according to age. The risk of catheterization due to high post-void residual urine volumes following treatment with botulinum toxin may be higher in older adults, as they are at higher risk of elevated residuals, but this requires systematic investigation.

IV. OTHER

None of the other drug classes have undergone rigorous evaluation in the elderly, however a number of general guidelines apply. Use of α1-AR agonists and tricyclic antidepressants are discouraged in the elderly due to blood pressure considerations. Uncontrolled systolic hypertension could occur with the former agents and orthostatic hypotension leading to falls with the latter. There is no evidence that hormonal agents are of benefit for urgency or stress incontinence in older women, although local estrogens may be indicated to treat symptomatic vaginal atrophy. Finally, removal of any offending agents that could be contributing to incontinence should be considered.

A. Introduction

In this chapter the diagnostic and treatment modalities of urinary incontinence in childhood will be discussed. In order to understand the pathophysiology of the most frequently encountered problems in children, the normal development of bladder and sphincter control will be discussed.

The underlying pathophysiology will be outlined and the specific investigations for children will be discussed. For general information on epidemiology and urodynamic investigations the respective chapters are to be consulted.

I. NORMAL DEVELOPMENT OF BLADDER AND SPHINCTER CONTROL

Normal bladder storage and voiding involve low-pressure and adequate bladder volume filling followed by a continuous detrusor contraction that results in bladder emptying, associated with adequate relaxation of the sphincter complex. This process requires normal sensation and normal bladder outlet resistance. The neurophysiological mechanisms involved in normal bladder storage and evacuation include a complex integration of sympathetic, parasympathetic and somatic innervations which is ultimately controlled by a complex interaction between spinal cord, brain stem, mid-brain and higher cortical structures [1].

Achievement of urinary control is equally complex and as yet not fully understood: various developmental stages have been observed [2,3].

In newborns the bladder has been traditionally described as “uninhibited”, and it has been assumed that micturition occurs automatically by a simple spinal cord reflex, with little or no mediation by the higher neural centres. However, studies have indicated that even in full-term foetuses and newborns, micturition is modulated by higher centres and the previous notion that voiding is spontaneous and mediated by a simple spinal reflex is an oversimplification [4]. Foetal micturition seems to be a behavioural state-dependent event: intrauterine micturition is not randomly distributed between sleep and arousal, but occurs almost exclusively while the foetus is awake [4].

During the last trimester the intra-uterine urine production is much higher than in the postnatal period (30ml/hr) and the voiding frequency is approximately 30 times every 24 hours [5].

Immediately after birth voiding is very infrequent during the first few days of life. The first void may only take place after 12 to 24 hours. After the first week frequency increases rapidly and peaks at the age of 2 to 4 weeks to an average of once per hour. It then decreases and remains stable after 6 months to about 10 to 15 times per day. After the first year it decreases to 8 to 10 times per day, while voided volumes increase by three- to fourfold.

During the postnatal period, micturition control mechanisms undergo further changes and extensive modulation. Using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings it has been shown that even in newborns the bladder is normally quiescent and micturition does not occur during sleep [6].

This inhibition (or lack of facilitation) of detrusor contractions during sleep is also observed in infants with neurogenic bladder dysfunction who have marked detrusor overactivity while they are awake. In response to bladder distension during sleep, an infant nearly always exhibits clear electroencephalographic evidence of cortical arousal, facial grimaces or limb movements, or actual awakening. Sleeping infants are always seen to wake up before the bladder contracts and voiding occurs. This arousal period may be transient and the infant may cry and move for a brief period before micturition and then shortly afterward go back to sleep. Because this wakening response is already well established in newborns, it follows that the control of micturition probably involves more complicated neural pathways and higher centres than has been appreciated. There is also strong evidence that a pronounced reorganisation of pre-existing synaptic connections and neural pathways
involved in bladder control occurs during the early postnatal period.

In newborns micturition occurs at frequent intervals and may have an intermittent pattern although bladder emptying efficiency is usually good. In over 80 percent of voids the bladder empties completely [7].

During infancy voiding pressures are much higher than in adults. It has also been noted that these pressures are higher in boys than in girls (mean pdet max of 118 vs. 75 cm H2O, respectively) [8,9].

These higher detrusor pressures decrease progressively with increasing age. In up to 70 percent of infants (up to the age of 3 years) with normal lower urinary tracts, intermittent patterns of voiding were observed. They tend to disappear with increasing age, and are thought to represent variations between individual infants in the maturation of detrusor and sphincteric co-ordination during the first 1 to 2 years of life. Videourodynamic studies have confirmed these findings [6,8,9,10,11].

Between the age of 1 and 2, conscious sensation of bladder filling develops. The ability to void or inhibit voiding voluntarily at any degree of bladder filling commonly develops in the second and third years of life. Central inhibition is crucial to obtain continence.

During the second and third year of life, there is progressive development towards a socially conscious continence and a more voluntary type of micturition control develops. The child becomes more aware of the sensation of bladder distension and the need to urinate, as well as social norms and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time, then actively initiate urination even when the bladder is not completely full, and allows urination to proceed to completion. During the first years of life, gradual development to an adult type of voluntary micturition control that conforms to the social norms depends on an intact nervous system, in addition to at least three other events occurring concomitantly:

1. a progressive increase in functional storage capacity.
2. maturation of function and control over the external urinary sphincter.
3. and most importantly achievement of volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit a micturition reflex [12].

The final steps are usually achieved at the age of 3 to 4 years when most children have developed the adult pattern of urinary control and are dry both day and night. The child has learned to inhibit a micturition reflex and postpone voiding and voluntarily initiate micturition at socially acceptable and convenient times and places. This development is also dependent on behavioural learning and can be influenced by toilet training, which in turn depends on cognitive perception of the maturing urinary tract.

It is understandable that this series of complex events is highly susceptible to the development of various types of dysfunction. Various functional derangements of the bladder-sphincter-perineal complex may occur during this sophisticated course of early development of normal micturition control mechanisms. These acquired “functional” disorders overlap with other types of bladder functional disturbances that may have a more organic underlying pathophysiological basis.

II. NORMAL VALUES

1. NORMAL BLADDER CAPACITY

The bladder capacity increases during the first 8 years of life roughly with 30 ml per year, so with an average capacity of 30 ml in the neonatal period, a child’s bladder volume can be calculated as $Y = 30 + 30X$, where $Y$ = capacity in ml and $X$ = age in years (Figure 1) [13].

Hjälmås described a linear correlation that could be used up to 12 years of age: in boys, $Y = 24.8X + 31.6$, in girls $Y = 22.6X + 37.4$, where $Y$ is capacity in ml, and $X$ is age in years [14].

It should be noted that these data were obtained during cystometric investigations. Cystometric capacity is generally less than normal bladder volumes. Obviously, the relation between age and bladder capacity is not linear for all ages, nor is the relation between body weight and bladder capacity [15].

Another formula to calculate bladder capacity in infants is: bladder capacity (ml) = 38 + (2.5 x age (mo)) [11].

Kaefer and co-workers demonstrated that a non-linear model was the most accurate for the relation between age and bladder capacity, and they determined two practical linear equations:

$Y = 2X + 2$ for children less than 2 years old, and $Y = X/2 + 6$ for those 2 years old or older; $Y$ = capacity in ounces, $X$ = age in years (Figure 2) [16].

None of these formulas have been acquired from a population based study and do not reflect normal bladder capacity. Normal bladder capacity should be regarded as the maximum voided volume of urine and shows huge variation. Recent work of Rittig et al looked at Maximum Voided Volumes (MVV). 2836 daytime voids showed a reasonably good correlation with the Koff Formula, if first morning voids were neglected [17].

Girls were found to have a larger capacity than boys, but the rate of increase with age was not
significantly different between them. Data on ‘normal’ bladder capacity have been obtained in continent children undergoing cystography, with retrograde filling of the bladder.

Data obtained from the International Reflux Study indicate that there is not a linear relation between age and capacity and that there is a huge variability. (Figure 3) [18].

2. NORMAL VOIDING

The micturition frequency of the foetus during the last trimester is approximately 30 per 24 hours. It decreases to 12 during the first year of life, and after that it is gradually reduced to an average of 5±1 voidings per day [11, 16].

The normal range for the micturition frequency at age seven is 3 to 7 [19].

By age 12, the daily pattern of voiding includes 4-6 voids per day [20].

Mattson and Lindström emphasize the enormous variability of voiding frequencies in children: also in individual children, the weight-corrected diuresis could vary up to 10-fold [21].

3. NORMAL VOIDING PRESSURES

Bladder dynamics in children have demonstrated developmental changes with age. Detrusor pressures at voiding in children after the age of 2 years are similar to adults, with a mean maximum pressure of 66 cm H2O in boys, and 57 cm H2O in girls [22].

These pressures are lower than those reported in infancy by Yeung et al, who found boys having pressures of 118 cm H2O and girls 75 cm H2O [6].

4. NORMAL URINARY FLOW RATES

Urinary flow rates in normal children have been only minimally described. Szabo et al published nomograms for flow rates vs. age in normal children [23].

Figure 1: Bladder capacity using the formula
\[ Y = 30 + 30X \]
\((Y = \text{capacity in ml, } X=\text{age in years})\)

Figure 2: Bladder capacity using the formula
\[ Y = (2X + 2) \times 28.35\text{ml} < 2\text{ years} \]
\[ Y = \left(\frac{X}{2} + 6\right) \times 28.35\text{ml} > 2\text{ years} \]
\((Y = \text{capacity in ml, } X=\text{age in years})\)

Figure 3: Bladder capacities determined by VCUG in the International Reflux Study.
As in adults, flow rates are clearly dependent upon voided volume, and normal values can only be applied to flow rates that have been registered when voiding at a bladder volume approximating the normal capacity for age [21,24].

B. Evaluation in children who wet

Even with clear definitions, the approach to history-taking and physical examination has to be structured. The child’s complaints at presentation are not synonymous with the signs and symptoms that have to be checked to arrive at a diagnosis. Also, sociocultural aspects and psychomotor development will distort the presentation.

The International Children’s Continence Society has provided two standardization documents on the diagnostic evaluation of children with daytime incontinence as well as on the evaluation of and treatment for monosymptomatic enuresis [1,2].

Standardization reports on urodynamic studies of the lower urinary and on initial diagnostic evaluation, follow-up and therapeutic intervention in congenital neurogenic bladder and bowel dysfunction in children will be available soon.

Validated questionnaires are very helpful in structuring the history-taking; they at least provide checklists [3].

With a structured approach the diagnosis of monosymptomatic nocturnal enuresis can be made with confidence.

When ultrasound imaging of kidneys and bladder, recording of urinary flow, and measurement of post-void residual are added to history and physical examination, the clinical entities caused by functional disturbances of the bladder and sphincter mechanism (non-neurogenic detrusor and pelvic floor dysfunction) can be diagnosed accurately in the majority of cases, and a high level of suspicion can be maintained towards incomplete bladder emptying in both neurogenic pelvic floor dysfunction and structurally caused incontinence. This is important in view of the potential these conditions have to cause irreversible loss of kidney function.

In a minority of incontinent children the non-invasive assessment yields equivocal results, or results suggesting gross deviations from normal function. Only in these situations is there an indication for invasive investigations, such as:

- Voiding cystourethrography.
- Invasive urodynamics (cystometry, pressure/flow/EMG studies, videocystometry).
- Renal scans or intravenous urography.
- Cystourethroscopy.

I. HISTORY TAKING

For the paediatric age group, where the history is jointly obtained from parents and child, and where the failure to develop bladder control generates specific problems, a structured approach is recommended, with a questionnaire [3,4].

Level of evidence: 3.
Grade of recommendation: B

Many signs and symptoms related to voiding and wetting are new to the parents, and they should be specifically asked for, using the questionnaire as checklist. If possible the child should be addressed as the patient and questioned directly, as the symptoms prompting the parents to seek consultation may be different from those are problematic for the child.

A voiding diary is mandatory to determine the child’s voiding frequency and voided volumes. Checklists and frequency volume chart can be filled out at home, and checked at the first visit to the clinics. History-taking should also include assessment of bowel function; a similar pro-active process using a questionnaire should be followed for defecation and faecal soiling [5].

The general history-taking should include questions relevant to familial disorders, neurological and congenital abnormalities, as well as information on previous urinary infections, relevant surgery and menstrual and sexual functions (in prepubertal and older children). Information should be obtained on medication with known or possible effects on the lower urinary tract.

At times it is helpful to more formally evaluate the child’s psychosocial status and the family situation, e.g. using validated question forms such as CBCL (Achenbach) or the Butler forms [6,7].

A short screening instrument for psychological problems in enuresis (SSIPPE) and a disease specific quality of life questionnaire for children with LUTD called PinQ are also validated tools available to the clinician [8,9].

Child abuse is very often signalled first by symptoms of vesico-urethral dysfunction [10].

At present there are no validated questionnaires to diagnose the cause of incontinence in children.

Level of evidence: 4.
Grade of recommendation: C
Apart from a general paediatric examination, the physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 (standing on toes, bulbocavernosus) and anal sphincter tone and control. Special attention should be paid to inspection of the male or female genital region, and of the urethral meatus. Asymmetry of buttocks, legs or feet, as well as other signs of occult neurospinal dysraphism in the lumbosacral area (subcutaneous lipoma, skin discoloration, hair growth and abnormal gait) should be looked for specifically [11].

In examining the abdomen for the presence of a full bladder, full sigmoid or descending colon which is a significant finding with a history of constipation.

Detailed questioning of the parents’ observation of the child’s voiding habits is essential as is direct observation of the voiding, if possible. Children may have their voiding dysfunction ameliorated or even eliminated by correcting anomalies of body position detected when observing the child’s micturition. Children may void in awkward positions, e.g. with their legs crossed or balancing on the toilet without proper support of the legs, thereby preventing the pelvic floor relaxation and obstructing the free flow of urine [12] (Figure 4).

In order to be comprehensive, physical examination should include urinalysis to identify patients with urinary tract infection, diabetes mellitus, diabetes insipidus and hypercalciuria if indicated [13].

The frequency/volume chart is a detailed diary recording each void by time and urine output over 24-hour periods. The chart gives objective information on the number of voidings, the distribution of day and night voids, along with the voided volumes and episodes of urgency and leakage, or dribbling. In order to obtain a complete picture, defecation frequency and/or soiling are often also recorded. Then, this becomes termed as bladder-bowel diary due to its complexity.

From the frequency/volume chart the child’s “functional” bladder capacity may be assessed as the largest voided volume, with the exception of the morning micturition, which actually represents nighttime bladder capacity. Whenever possible, filling out the chart is the responsibility of the child: the parents provide assistance and support. Ideally the chart should cover 3 complete days, but in reality completion over a weekend restricts the record to 2 days.

The frequency volume chart is a reliable non-invasive measure of maximum bladder storage capacity and can be used as an outcome measure in children with bladder dysfunction if care is taken to minimise confounding factors and sources of error during chart completion [14].

The amount of urine voided by a non-supervised child during the day varies considerably since the child’s voidings are dictated more by social circumstances and/or bladder activity rather than by

**Figure 4: Improper position for voiding: the feet are not supported (unbalanced position) and the boy is bent forward. Support of the feet will correct this and will allow the pelvic floor muscles to relax properly.**
bladder capacity. Children with bladder symptoms void smaller volumes of urine than may be expected from traditional estimates [14].

This is unrelated to either gender, type of presenting incontinence or a positive family history of bladder dysfunction. The only significant influence upon voided volumes recorded on a frequency volume chart is the age effect, and voided volumes, even in incontinent children, increase incrementally with age. The frequency volume chart is useful when comparing the mean voided volume and standard deviation by a child’s age [15,16].

Validation and test/retest data on frequency/volume charts whilst scarce indicate that voiding interval is the most variable parameter. Data in normal children and in children with different categories of incontinence are available for comparison [14,17,18].

In order to obtain a complete picture it is better to ask for a bladder diary: fluid intake as well as voiding frequency, voided volumes, incontinence episodes and defecation frequency and/or soiling are recorded.

Test/retest evaluation is not available; trend analyses of frequency/volume charts can be extracted from currently available data.

Level of evidence: 3.
Grade of recommendation: B

2. QUANTIFICATION OF URINE LOSS

Subjective grading of incontinence may not indicate reliably the degree of dysfunction. For objective grading, 12-hour pad test and frequency/volume charts are validated instruments [18-20]. One should be aware that children tend to do their utmost best when filling out diaries and doing padtests: underestimation is more the case than overestimation [21].

In children, the 12-hour pad test should also give information about fluid intake. The pad test is complementary to the bladder diary, which denotes more the frequency of incontinence and the distribution of wetting episodes than the quantities of urine lost.

The amount of urine lost during sleep can be determined by weighing diapers or absorbent pads, before and after sleep. To obtain a measure of the total nocturnal urine output, the volume of the early-morning voiding should be added to the amount lost during sleep.

3 SCORING SYSTEMS

At present three scoring systems, based on validated questionnaires have been described. Specific scores correlated with lower urinary tract dysfunction with a specificity and sensitivity of about 90% [22-24].

The value of these scoring systems to determine the cause of incontinence seems to be of limited value to the individual patient, but can be very useful in studies to determine and compare treatment outcome.

Level of evidence: 3.
Grade of recommendation: C

4. QUANTIFICATION OF CONSTIPATION

Scoring a plain X-ray of the abdomen (Barr score) yields inconsistent results in grading constipation. [17-19] Reproducibility seems to be best using the method described by Leech [28-30].

A better way to match clues from the medical history with signs and symptoms is the measurement of colonic transit time.

As many children with an overactive bladder habitually use their pelvic floor as an “emergency brake”, anomalous defecation frequency and constipation have a high prevalence in this group.

Diagnosing constipation is important: we recommend to use the Rome III criteria listed in the table below [31].

A non-invasive way to determine fecal retention is the estimation of rectal diameter on ultrasound. In children without constipation the mean diameter was 2, 2.1 and 2.4 cm in three different studies respectively [32-34]. In children with constipation the rectal diameter was on average 3.4 cm in the first, 4.9 in the second and 4.2 cm in the third study, significantly different from the non-constipated children. Joensson et al. also re-measured constipated children 4 weeks after treatment with laxatives finding the rectal diameters in the constipation group were significantly reduced (p < 0.001) [34].

Finding a dilated and filled rectum on ultrasound while the child feels no need to defecate probably can replace a digital rectal examination.

Overt constipation should be dealt with before embarking on treatment of incontinence or bladder and pelvic floor dysfunction [35,36].

Level of evidence 3.
Grade of recommendation: B

5. URINARY FLOW

Voiding should be analysed in detail in all incontinent children with the exception of monosymptomatic bedwetting where voiding, as far as we know, is normal.

Graphic registration of the urinary flow rate during voiding is a standard office procedure. Flow
patterns and rates should be repeated to allow for evaluation, and several recordings are needed to obtain consistency.

Approximately 1% of school children have a voiding that can be labelled abnormal with flattened or intermittent flow curves. The remaining 99% have a bell-shaped flow curve [37]. It should be noted that a normal flow does not exclude a voiding disturbance, nor does an abnormal flow pattern automatically mean a bladder or voiding dysfunction, as in asymptomatic normal schoolchildren abnormal patterns were also found [38,39].

Flow recordings with a voided volume of less than 50% of the functional capacity are not consistent: they represent voiding on command, and many children will try to comply by using abdominal pressure. On the other hand, overdistension of the bladder can result in abnormal uroflow recordings also [40].

A helpful tool in this respect is the use of trans-abdominal ultrasound (e.g. bladder scan) before micturition in order to assess the bladder volume [41,42]. If the bladder is still nearly empty the child should be asked to drink some water until the bladder is full enough for a reliable flow.

Urinary flow may be described in terms of rate and pattern and may be continuous, intermittent (in fractions), or staccato (fluctuating). An intermittent flow pattern shows an interrupted flow, whereas in staccato voiding the flow does not stop completely, but fluctuates due to incomplete relaxation of the sphincter.

Measurement of urinary flow is performed as a solitary procedure, with bladder filling by diuresis (spontaneous or forced), or as part of a pressure/flow study, with bladder filling by catheter. Patterns and rates should be consistent to allow for evaluation, and several recordings are needed to obtain consistency [43,44].

The same parameters used to characterise continuous flow may be applicable, if care is exercised, in children with intermittent, or staccato flow patterns (Figure 5-8). In measuring flow time, the time intervals between flow episodes are disregarded. Voiding time is total duration of micturition, including interruptions.

6. ULTRASOUND IMAGING OF UPPER AND LOWER URINARY TRACT

In most clinical settings, ultrasound-imaging techniques are routinely used in children with incontinence. Upper tract abnormalities such as duplex kidney, dilatation of the collecting system, and gross reflux nephropathy can be readily detected, but detection of the more subtle expressions of these abnormalities requires urological expertise on the part of the ultrasound operator [45].

Lower urinary tract abnormalities are even more difficult to assess for the inexperienced, aside from bladder wall thickness: a bladder wall cross-section of more than 3-4 millimetres, measured at 50% of expected bladder capacity, is suspicious of detrusor overactivity [46,47]. Because only a few studies have been conducted to compare bladder wall thickness in normal children without complaints and in children with lower urinary tract dysfunction, more studies need to be performed to validate these non-invasive techniques [48,49].

Another possibility is to assess bladder volume and bladder wall thickness to calculate the Bladder Volume / Bladder Wall Thickness index. In children with nocturnal enuresis this index correlated well with response to treatment [50].

### Functional constipation

Must include ≥ 2 of the following in a child with a developmental age of ≥ 4 years with insufficient criteria for diagnosis of IBS:

- ≤ 2 defecations per week
- ≥ 1 episode of fecal incontinence per week
- History of retentive posturing or excessive volitional stool retention
- History of painful or hard bowel movements
- Presence of a large fecal mass in the rectum
- History of large diameter stools that obstruct the toilet
a) Post-void residual volume

Except in small infants, the normal bladder will empty completely at every micturition [51].

The identification or exclusion of post-void residual is therefore an integral part of the study of micturition. However, an uneasy child voiding in unfamiliar surroundings may yield unrepresentative results, as may voiding on command with a partially filled or overfilled bladder. When estimating residual urine, voided volume and the time interval between voiding and estimation of post-void residual should be recorded. This is of particular importance if the patient is in a diuretic phase. In patients with gross vesi-coureteral reflux, urine from the ureters may enter the bladder immediately after micturition and may falsely be interpreted as residual urine. The absence of residual urine is an observation of clinical value, but does not exclude bladder outlet obstruction or sphincter / pelvic floor overactivity with absolute certainty. An isolated finding of residual urine requires confirmation before being considered significant, especially in infants and young children.

b) Ultrasound-flow-ultrasound

This combination of imaging and non-invasive urodynamics is a standardised procedure used to obtain representative data on flow rate and flow pattern, as well as post-void residual volumes.
With ultrasound, bladder filling is assessed and when the bladder capacity is equal to the function- or expected bladder capacity for age, the child is asked to void into the flowmeter. After recording the flow, post-void residual is assessed again.

This procedure avoids the registration of flow rates at unrealistic bladder volumes.

Alternatively children can be asked to use a flowmeter at home: a special flowmeter has been designed to use at home [52]. For those children who have difficulty voiding in a strange environment, this option can be useful.

7. INVASIVE DIAGNOSTIC TECHNIQUES

The important question (for the incontinent child) "whether invasive diagnostic procedures are necessary" is decided by the results of the non-invasive procedures.

At present there are no studies indicating that a VCUG is useful in children with incontinence, but without urinary tract infections.

In general urodynamic studies will only be done if the outcome will alter the management, and this will also depend on whether the possible treatments being considered are invasive. The diagnostic information needed is that which is necessary to find the correct treatment. Indicators include, straining or manual expression during voiding, a weak urinary stream, previous febrile urinary tract infection, continuous dribbling incontinence or pronounced apparent stress incontinence, or previously identified dilating vesicoureteral reflux.

The finding of genitourinary abnormalities or signs of occult spinal dysraphism at physical examination also indicate the need for further diagnostics. Urinary flow registration will detect the plateau-shaped flow curve typical for structural bladder outlet obstruction, and an intermittent flow suggesting detrusor–sphincter pelvic floor dys-coordination [43].

A clinically significant post-void residual on repeated occasions clearly points to incomplete bladder emptying. The pad test will detect the cases with obvious stress and urgency incontinence, or continuous dribbling. Ultrasound imaging will raise suspicion of an ectopic ureter.

In short, invasive diagnostics are indicated when the non-invasive testing raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (especially posterior urethal valves), genitourinary abnormalities (e.g. epispadias), advanced non-neurogenic detrusor-sphincter pelvic floor dysfunction (as in children with vesicoureteral reflux and upper tract dilatation and/or febrile urinary tract infections), or significant post void residuals.

To diagnose the complex of non-neurogenic detrusor-sphincter dysfunction, recurrent urinary tract infections and vesicoureteral reflux, urodynamic studies are needed in only a minority of all children.

a) Voiding Cystourethrogram

1. TECHNIQUE OF VCUG IN CHILDREN

Cleanse and rinse the external genitalia with lukewarm water: do not use detergents. Use a feeding tube with side holes and a rounded tip (Ch 06-08) or balloon catheter to catheterise the bladder; check the urine for infection. Empty the bladder completely before filling. Use a radio-opaque dye of maximum 30% concentration, at body temperature, and fill the bladder by slow-drip infusion, with a hydrostatic pressure of not more than 40 cm H2O. Note the volume of the contrast medium instilled. Use fluoroscopy during filling at regular intervals.

Take spot-films (70mm or 90mm camera) with the child in supine position, with partial filling and at the end of filling, in AP projection, of the complete urinary tract. Upper and lower tract should be visible.

When voiding is imminent, change the position of the child so that spot films of bladder and urethra in 3/4 projection can be taken during voiding. Also take a spot film of the upper urinary tract during voiding, as the degree of vesicoureteral reflux (VUR) may change with the pressure generated by the detrusor muscle during voiding. Post-void residual volumes vary very considerably with VCUG. The voiding phase is critically important to VCUG, both for reflux detection and for assessment of voiding dynamics. Without a voiding phase the VCUG is incomplete.

Prophylactic antibiotics are indicated in all children, to minimise the risk for post-VCUG urinary tract infection especially in children with an anatomic abnormality.

2. INDICATIONS FOR VCUG

A VCUG is an invasive procedure and should only be done if the outcome will influence the management. It is indicated in children with recurrent urinary tract infections in order to detect reflux, in children with a dilated system on ultrasound and in children with an abnormal flow pattern to detect bladder outlet abnormalities (like valves, strictures or a syringocele).

In children with incontinence the lateral projection during voiding is the most important part of the study. Especially in children with stress incontinence or a neurogenic bladder the position and configuration of the bladder neck during filling and voiding should be noted.
In children with non-neurogenic detrusor-sphincter-pelvic floor dysfunction as well as in children with neurogenic detrusor-sphincter dyssynergia, the proximal urethra may show the so-called 'spinning top' configuration, during filling and during voiding. With detrusor and pelvic floor muscles contracting at the same time, the force of the detrusor contraction will dilate the proximal urethra down to the level of the forcefully closed striated external sphincter. The resulting 'spinning top' configuration used to be seen as a sure sign of distal urethral stenosis, a concept held responsible for recurrent urinary tract infections in girls, with urethral dilatation or blind urethrotomy as the obvious therapy. However, urodynamics made it clear that the 'spinning top' will only appear when detrusor and pelvic floor contract synchronously, which makes it a functional anomaly, not an anatomical one [53,54].

Women often recall their experience with VCUG as young girls in terms bordering on abuse. The use of VCUG in children should be limited to the absolutely necessary.

b) (Video)-Urodynamics

In children urodynamic investigations should only be performed if the outcome will have consequences for treatment [55-57]. Furthermore like VCUG it may be considered when invasive or surgical interventions are planned. The main question is whether the urodynamic study will provide new information that cannot be obtained otherwise and will influence the further management. From the few studies that have addressed this issue it can be concluded that urodynamic studies in the majority of cases do not provide significant additional information to justify this type of investigation as a routine procedure in children [58-60].

Both children and parents need careful preparation and adequate information before the study is done. It is an invasive procedure and artefacts may occur. Because of the invasiveness of the investigations all children are anxious and this may be reflected in the outcome of the study. Especially during the first filling cycle, when the child does not know what to expect, detrusor overactivity may be seen and the voiding phase can be incomplete due to contraction or incomplete relaxation of the pelvic floor muscles during voiding. Once the child knows that filling and voiding are not painful a subsequent filling and voiding cycle may show a completely different pattern. The study should be repeated at least 2 or 3 times. Only if during the first filling cycle, no detrusor contractions are seen and also the voiding phase is in accordance with history and uroflow, it is probably sufficient to do only one complete filling and voiding cycle [61].

Still the results may not always be reproducible and it should be stressed that the primary objective is to treat the child and not a “urodynamic abnormality” per se.

Special attention should be given to a pleasant surrounding for the child: one or both parents should be present and young children may be given a bottle. Older children may be distracted by watching a video movie. The child should be awake, unanaesthetised and neither sedated nor taking any drugs that affect bladder function.

During the study the investigator has the opportunity to observe the child and discuss various findings and correlate them to what the child feels and/or normally would do in such circumstances.

In children, the transition from filling phase to voiding phase is not as marked as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements are performed as one continuous study in paediatric urodynamics.

Electromyography of the pelvic floor muscles is assumed to evaluate the activity of the striated urethral sphincter, in the filling phase and in the voiding phase. Surface skin electrodes are usually used to record the EMG. In children the pelvic floor EMG is probably of much more importance than in adults as it helps to differentiate the different voiding disorders.

Filling the bladder can be achieved by diuresis (natural fill cystometry) or retrograde by catheter. For retrograde filling by catheter, saline 0.9% or contrast medium at body temperature is recommended in children. Especially in young children some urodynamic parameters, such as capacity and detrusor activity are influenced by the temperature of the filling fluid. Although the clinical relevance is as yet unknown, it is recommended to fill the bladder with fluid of body temperature [62].

When filling by catheter, slow fill cystometry (5 – 10 percent of expected bladder capacity per minute (based on the voiding diary), or < 10ml/min) is recommended in children, as certain cystometric parameters, notably compliance, may be significantly altered by the speed of bladder filling.

Involuntary detrusor contractions may be provoked by rapid filling, alterations of posture, coughing, walking, jumping, and other triggering procedures.

The presence of these contractions does not necessarily imply a neurologic disorder. In infants, detrusor contractions often occur throughout the filling phase. (figure 9)

Bladder sensation is difficult to evaluate in children. Only in toilet-trained cooperative children is it a relevant parameter. Normal desire to void
is not relevant in the infant, but can be used as a guideline in children of 4 years and older. Normal desire to void should be considered the volume at which some unrest is noted, e.g. wriggling the toes; this usually indicates voiding is imminent. In the older child, the volume may be small with the first cystometry, for fear of discomfort. Also involuntary detrusor contractions occur more often during the first filling cycle [62]. This is the reason that in paediatric urodynamics at least two cycles of filling are recommended.

*Maximum cystometric capacity (MCC)* is the volume in the bladder at which the infant or child starts voiding. The value for maximum cystometric capacity is derived from volume voided plus residual volume. Values for MCC should be interpreted in relation to normal values for age.

*Compliance* indicates the change in volume for a change in pressure. For children with neurogenic detrusor-sphincter dysfunction, data are available relating poor compliance to the risk of upper urinary tract damage [64].

The urethral closure mechanism during storage may be normal or incompetent. The normal urethral closure mechanism maintains a positive urethral closure pressure during filling, even in the presence of increased abdominal pressure or during detrusor overactivity (guarding reflex) [63].

Immediately prior to micturition the normal closure pressure decreases to allow flow.

Bladder outlet obstruction, recorded with a pressure/flow study, may be anatomical or functional in nature. An *anatomical obstruction* may be present at the bladder neck or in the urethra as a stenosis or a stricture when there is a small and fixed urethral diameter that does not dilate during voiding. As a result, the flow pattern is plateau shaped, with a low and constant maximum flow rate, despite high detrusor pressure and complete relaxation of the urethral sphincter. In a *functional obstruction*, it is the active contraction of the urethral sphincter or pelvic floor during passage of urine, that creates the narrow urethral segment as a constant or intermittent obstruction. To differentiate anatomical from functional obstruction, information is needed about the activity of the urethral sphincter during voiding. This information can be obtained, and recorded together with pressure and flow, by monitoring the urethral pressure at the level of the urethral sphincter, or by recording a continuous electromyogram of the pelvic floor, as in clinical practice the urethral sphincter is not readily accessible, and the electromyogram of the external anal sphincter is often used to monitor activity of the striated urethral sphincter. This corresponds to activity of the pelvic floor muscles. Also the use of video urodynamics can be very helpful in this respect, as contractions of the pelvic floor muscles can actually be seen during the voiding phase (*Figure 9 and 10*).

In infants and small children, pelvic floor muscle overactivity during voiding (with post-void residuals) is not uncommon: in all probability it is a normal developmental feature [65, 66].

c) **Cystoscopy**

In by far the majority of children cystoscopy is not indicated. In boys with therapy resistant incontinence, an abnormal flow pattern, especially in combination with a history of (recurrent) urinary tract infection is suspicious of infra-vesical obstruction such as bladder neck obstruction, urethral valves, syringocele etc. A VCUG may not always show these abnormalities and pressure flow curves may be equivocal [67].

In girls the flow may be directed upward, indicating an abnormal meatal position or stenosis. A dorsal meatotomy generally solves this problem. It has been postulated that in girls the abnormal direction of the stream triggers the bulbocavernous reflex resulting in dysfunctional voiding [68].

**C. Nocturnal enuresis**

### I. DEFINITION

Nocturnal enuresis (NE) is involuntary voiding of urine during sleep, at least three times a week, in children over 5 years of age in the absence of congenital or acquired defects of the central nervous system [1].

Parental concern and child distress affect the clinical significance of the problem [2]. While most children who wet at night after age five are considered nocturnal enuretics, the child’s development level is also important. The age criterion of five is arbitrary but reflects the natural course of achieving bladder control [4]. Verhulst et al argue for flexibility due to different age at which boys develop nighttime continence compared with girls [4]. Extrapolation from Verhulst’s figures suggests that the prevalence of nighttime wetting for 8-year-old boys equals that for girls at 5 years [4].

**Monosymptomatic** NE is bedwetting without day-time symptoms. **Non-monosymptomatic** or polysymptomatic NE describes children with both day and nighttime wetting [5].

### II. SEVERITY

Nocturnal enuretics vary in wetting frequency. Although fifteen percent wet each night, most children wet less frequently [4,6]. In a population survey of nearly 1,800 Irish children aged 4 –14 years, Devlin found the frequency of wetting as
Figure 9: Urodynamic study illustrating involuntary detrusor contractions, counter action of pelvic floor muscles (guarding reflex) and incomplete pelvic floor relaxation during voiding resulting in post void residual urine (detrusor overactivity + dysfunctional voiding) [63]

Figure 10: Classification of urinary incontinence in children

(Over)activity of the urethral sphincter-pelvic floor may occur during the voiding contraction of the detrusor in neurologically normal children; this set of events is termed dysfunctional voiding.

Grade of recommendation: for all diagnostic procedures level B
follows: less than once per week in 33 percent, once per week in 11 percent and 2 to 4 times per month in 25 percent [7]. Some children and parents are concerned about an occasional wet bed, while others accept regular wetting. Clinically severity can be defined as: infrequent (1-2 wetting episodes per week), moderately severe (3 – 5 wetting episodes per week) or severe (6 – 7 wetting episodes per week) [7].

III. PREVALENCE

Bedwetting is common. In the United Kingdom, estimates approximately 750,000 children and young people over 7 years regularly wet the bed. In the United States 5 to 7 million children regularly experience primary NE [8,9,10].

The prevalence of bedwetting varies regionally. In China, where parents take children out of diapers earlier, bedwetting seems to resolve more quickly. For example, in a large survey from Shandon, the proportion of children attaining nocturnal urinary control before age 2 was 7.7%; by age 3, this had increased to 53.1%, and by age 5 to 93%. The overall prevalence of NE was 4.3%, with a significantly higher prevalence in boys than girls. There was no additional decrease in the prevalence of enuresis between 6 and 16 years [11]. This suggests that structured awakening and toileting is effective treatment for monosymptomatic NE, even in small children.

Bedwetting becomes less common with advancing age. In the West, 15 per cent of children each year develop nocturnal bladder control [12]. By adulthood, bedwetting is rare. Hirasing et al sampled over 13,000 adults [18-64 years] and found an overall prevalence rate of NE at 0.5% [13]. Of these, 12 percent of men and 29 percent of women had daytime incontinence. Despite persistence of wetting into adulthood, 50 percent of men and 35 percent of the women never seek help for their problem. The enuresis prevalence of 0.5% in otherwise healthy adults in Hirasing’s study refers to a largely untreated population. Fifty percent of the men had primary enuresis and had never been consistently dry at night. Assuming a prevalence of enuresis of 8 percent in 7-year-old boys, the risk for an enuretic to remain so for the rest of his life is 3 percent. [12,14]. Many believe adult enuretics represent a “hard core” group with worse symptoms. These individuals are likely to have associated diurnal enuresis or voiding symptoms. One study included 18 males and 29 females with a mean age of 20 years with persistent NE. Of these patients 37 (79%) had moderate or severe symptoms and 17 (38%) also had daytime urinary symptoms. Thirty patients had urodynamics including 12 males and 16 females, and 93% had detrusor overactivity. In addition, 73% of patients had urodynamic evidence of functional bladder outflow obstruction, including dysfunctional voiding and detrusor sphincter or detrusor pelvic floor discoordination. Two male patients (6.7%) had an obstructive pattern on urodynamics and subsequent cystoscopic examination confirmed the presence of congenital urethral stricture/valves. Sixteen patients (53%) had significantly reduced bladder capacity of less than 300 ml. [15-18]. These and other studies suggest that persistent NE after childhood is a serious adult problem requiring some investigation and considerable effort to treat.

IV. INHERITANCE

Bedwetting runs in the family of many children who suffer from bedwetting. In one study, A positive family history was found in 94 families (23%) of 411 probands with PNE, including 49% of fathers, 9% of mothers, 6% of both parents, 6% of the siblings and 30% of grandfathers or (and) mothers. Among the probands the ratio of male to female was 1.3:1 excluding sex-linked inheritance. Autosomal dominant inheritance was in 15%, and autosomal recessive inheritance was consistent in 1.46% of families[19]. Thus, the mode of inheritance is usually autosomal dominant; if both parents were nocturnal enuretics as children, the risk for their children is from 65 to 85 % [20]. If only one parent has NE the risk is about 45 percent [21].

Molecular studies have clearly shown that NE is a complex disease with locus heterogeneity and no clear genotype-phenotype association.

Linkage studies to determine the location of the genetic changes have suggested foci on several genes. Linkage studies to markers on chromosomes 8, 12 and 13 demonstrate both clinical, as well as genetic heterogeneity in nocturnal enuresis [22]. But these have not been consistently reported in other studies [23]. So far, there has been no reported association of the genotype with a particular phenotype of enuresis [24].

V. GENDER AND MONOSYMPTOMATIC NE

Boys suffer nocturnal enuresis more frequently. In a population survey of 706 families in London, Weir found a higher prevalence for boys than girls, at age 3 years, with 56 percent of boys and 40 percent of girls being wet at night more than once a week [25]. More recent studies are consistent [26]. Surveys of monosymptomatic NE undertaken in Great Britain, Holland, New Zealand and Ireland suggest that the prevalence for boys is 13-19% at 5 years, 15-22% at 7 years, 9-13% at 9 years and 1-2% at 16 years. For girls the prevalence rates are reported to be about half that rate: 9-16% at 5 years, 7-15% at 7 years, 5-10% at 9 years and 1-2% in the late teenage years [4,7,27,28]. Although
monosymptomatic NE is more common in young boys, by adolescence the incidence in males is the same as in females [16,29]

VI. CLASSIFICATION

1. PRIMARY VERSUS SECONDARY NOCTURNAL ENURESIS

Children who have never been free of bedwetting for 6 months have primary NE. Secondary NE is the re-emergence of wetting after a period of being dry for at least six months. A birth cohort of 1265 New Zealand children studied over 10 years by Ferguson et al found an increased risk of secondary nocturnal enuresis with age [30]. The proportion of children who developed secondary enuresis was 3.3 percent at 5 years, 4.7 percent at 6 years, 6.2 percent at 7 years, 7.0 percent at 8 years, 7.5 percent at 9 years and 7.9 percent at 10 years.

Secondary NE is associated with a higher incidence of stressful events particularly parental separation, disharmony between parents, birth of a sibling, early separation of the child from parents and psychiatric disturbance in a parent [22, 30,31].

Von Gontard and colleagues found children with secondary enuresis had significantly more emotional difficulties compared to those with primary NE. Their evidence also suggests children with secondary enuresis, compared to those with primary enuresis, are more likely to have behavioural problems, a finding which corresponds to that of McGee et al [32].

Both Jarvelin and Ferguson et al argue that primary and secondary enuretics are similar [30,31]. They believe the two share a common etiological basis. The rate the child acquires primary control influences his or her risk of secondary enuresis. The primary form is the consequence of a delay in maturation of the physiological mechanisms. The child's capacity to sustain and maintain nocturnal bladder control is manifest in the rate at which he or she acquires control. On the other hand, this capacity determines the child's susceptibility to lapsing back to night wetting when exposed to stress.

Other sources of secondary enuresis must be excluded prior to proceeding with treatment for enuresis. These include sleep apnea from obstructive airway disease, obesity, constipation and infrequent or dysfunctional voiding. Treatment of sleep apnea from obstructive airway has been shown to improve or eliminate NE in some children following surgery or medical management [34,35]. Obesity has been associated with nocturnal enuresis both independently [36] and in the context of sleep apnea. [37]

2. MONO-SYMPTOMATIC VERSUS NON-MONO-SYMPTOMATIC NE

Mono-symptomatic NE refers to those children who report no other bladder or voiding problems associated with wetting. Non-mono-symptomatic NE refers to bedwetting, that is associated with detrusor overactivity or voiding problems such as urgency and bladder holding during the day [5].

This classification becomes important when considering the most appropriate treatment intervention. Many parents are unaware of daytime symptoms when seeking help for bedwetting and when identified these symptoms should be treated prior to intervention for the NE. Between 10-28% of children with NE have associated daytime wetting. If so, these children should be considered day and night incontinent. In these cases, night time incontinence is not any longer an isolated phenomenon but part of the symptomatology of day and night time incontinence. These children are more resistant to treatment and more vulnerable to relapse [38]. These boys and girls are more appropriately managed in the context of the primary bladder problem.

VII. PATHOPHYSIOLOGY OF MONOSYMPTOMATIC NE

NE stems from a mismatch of bladder capacity, nocturnal urine output and the ability for the child to arouse during sleep. Night wetting is normal until age 5. Delayed maturation in one or more of the following systems results in NE: a lack of stability in bladder function, a lack of arginine vasopressin (AVP) release or response, or relative increased solute excretion during the night [39,40], or an inability to wake from sleep to full bladder sensation [41,42]. Combinations of all three problems may be present.

A unifying and simplistic concept with important clinical implications, is that NE is caused by a mismatch between nocturnal bladder capacity and the amount of urine produced during the night, combined with delayed or incomplete arousal response to the afferent neurological stimulus of the full bladder (Figure 11).

1. INCREASED NOCTURNAL URINE OUTPUT

In normal children, the circadian rhythm of urine production results in a nocturnal reduction in diuresis to approximately 50% of daytime levels [43,44]. In children this is the result of nocturnal release of hormones that regulate free water excretion (arginine vasopressin, (AVP) or solute excretion (angiotensin II and aldosterone) and may result from circadian changes in glomerular filtration [45]. In the normal child, this results in increased urine concentration and reduced urine
volume during sleep. This is why children who are not enuretic sleep through the night without being wet and do not need to rise to void.

Two thirds of patients with mono-symptomatic NE have been found to have a lack of circadian rhythm of vasopressin, resulting in high nocturnal urine production, which exceeds bladder capacity [46,47,48]. Rittig et al and Norgaard et al demonstrated abnormalities in the circadian rhythm of AVP secretion resulting in increased nocturnal urine output that exceeded bladder capacity in children with nocturnal enuresis [46,47]. These children make more urine at night, and often overcome their bladder capacity and wet early in the night. Abnormalities can also be intrinsic, related to reduced nocturnal circadian changes in glomerular filtration rate (GFR) [45] or in sodium and calcium excretion [49].

Detection of low plasma vasopressin levels, GFR assessments or specific sodium and calcium excretion are difficult to measure. Instead, we look for clinical signs of low vasopressin during the assessment interview. Weighing the diapers and adding the first morning void provides the total nocturnal urine output. If this total exceeds the child’s functional bladder capacity this may indicate nocturnal polyuria. Nocturnal urine output varies appreciably from night to night [50], but seems larger in children with NE who respond best to desmopressin (dDAVP).

By the time the child becomes an adolescent, the circadian rhythm is less prominent. In adolescents and adults with nocturnal enuresis, there is no diurnal rhythm of plasma vasopressin concentration. The changes in urine production at night occur from a decrease in the urinary sodium excretion that is not due to differences in concentration of AVP but due to a lack of sensitivity to AVP [51] with resultant increased urine output [39].

There may be a small sub-group of children with impaired renal sensitivity to vasopressin or desmopressin [40,52]. Recent work by Devitt et al suggests that 18 percent of children have ‘normal’ levels of plasma vasopressin release but remain enuretic [48]. These children all failed to respond to a therapeutic dosage of desmopressin. This finding could indicate renal insensitivity to vasopressin but could also be indicative of detrusor overactivity or a small functional bladder capacity. Total urine output during the night could be helpful in differentiating between the two conditions. The subgroup of patients with NE and increased nocturnal urine output generally has a normal func-

---

Figure 11: Basic pathophysiology of NE or nocturia. When the bladder is full because of (relative) polyuria and/or a reduced bladder capacity, the child either wakes up to void (nocturia) or voids while sleeping (NE).
tional bladder capacity and a favourable response to dDAVP [53].

2. DETRUSOR OVERACTIVITY DURING THE NIGHT

The detrusor, in order to function appropriately, needs to be relaxed during filling and allow an appropriate functional capacity. Detrusor overactivity usually causes small voided volumes resulting in a decreased functional bladder capacity [54].

Watanabe and his colleagues, employing EEG and cystometry recording during sleep, discovered that 32 percent of children with NE had involuntary detrusor contractions that resulted in enuresis [60-62]. These children had smaller functional bladder capacities at the point of wetting, than children with enuresis who did not have detrusor overactivity. Functional bladder capacity – defined as the largest daytime void on a frequency-volume (F/V) chart, after excluding the first morning void, may give a reasonably accurate assessment of daytime functional bladder capacity (FBC). Reduced functional bladder capacity, when below 70% of predicted FBC for age, is likely to result in poor response to dDAVP treatment [55]. Daytime bladder capacity is smaller than night time capacity in children without NE [56].

The pattern may be different at night. Yeung et al reported that 44 percent of treatment failures [with desmopressin or the enuresis alarm] have normal daytime bladder function but marked detrusor overactivity during sleep resulting in enuresis [63,64]. Almost none of these children had nocturnal polyuria. Ultrasound studies of the bladder furthermore revealed an increased bladder wall thickness in these children [57].

When further segregated prior to treatment, increased bladder wall thickness and bladder volume predicted the response to therapy in children with their primary nocturnal enuresis (more than three nights weekly). In one study, Yeung, et al, [58] correlated ultrasound measured parameters and urodynamic findings. Of 35 children with frequent NE, bladder wall index was normal in only eight patients. It was less than 70% of predicted in 24, and more than 130% in three. When bladder volume and wall thickness index was correlated with ultrasound, 87% of the patients with a normal index exhibited a normal bladder pattern on imaging and 96% of patients with an index less than 70 exhibited detrusor overactivity on ultrasound. All the children with a normal index either had a complete or good response to conventional treatment for nocturnal enuresis, whereas 62% of those with an index less than 70 % did not respond to treatment. With longer follow-up, bladder dysfunction had resolved in 38% of the children with an initial index of less than 30, all of whom had a good response to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children, prior to management of primary nocturnal enuresis, into groups that have a favorable outcome and those that do not, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regimens in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, et al. [15] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urgency incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component, particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

3. LACK OF AROUSAL FROM SLEEP/CNS FUNCTION

The fundamental mechanism resulting in nocturia or NE is that the bladder fills to its capacity during sleep and needs to empty (figure 11). Bladder fullness is due to nocturnal polyuria and/or a reduction of the bladder capacity due to detrusor overactivity during sleep. These factors do not fully explain why the enuretic child does not wake up during the night to the sensation of a full or contracting bladder. Regardless of whether the child has detrusor overactivity or nocturnal polyuria, the enuresis event results from the child’s inability to awaken from sleep to empty prior to the wetting episode.

There is a widely held belief amongst parents and some clinicians that enuretics are deep sleepers. This is logical, since many of the children exposed to alarm therapy sleep through the alarm while family members awaken. Nevéus reviewed by questionnaire 1413 schoolchildren between the ages of six and ten and noted that enuresis was associated with subjectively high threshold arousal and significant confusion upon awakening from sleep [42]. Wolfish in a study of 15 enuretic and 18 control boys and girls found that enuretics wet most frequently during the first two-thirds of the night and that arousal attempts were less successful in enuretics than in normals[59]. This might explain why the most heavily endorsed view of both children and parents, regarding the aetiology of NE is a belief in deep sleep [60].
More recently Frietag, et al studied brainstem evoked potentials in 37 children with nocturnal enuresis and compared these aged 8 to 14 years, with 40 controls, mean age 10 years, and found that interpeak latencies of the brainstem evoked potentials were increased in children with nocturnal enuresis, suggesting that a maturational deficit of the brainstem was present in children with nocturnal enuresis. Differences in visually evoked potential latencies might point to a reason behind functional cortical differences in children with family history of nocturnal enuresis [61].

Feittag’s study would suggest that a maturational effect is present; however, overnight studies in enuretic children with simultaneous sleep electroencephalographic and cystometry have revealed marked detrusor overactivity, only occuring after sleep at night and not during wakeful periods during the day [62]. Because this pattern has not been observed in normal non-enuretic subjects, even during the newborn period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area in the vicinity of the pontine micturition center, the posterior hypothalamus (responsible for secretion of antidiuretic hormone) or the locus coeruleus which may be the cortical arousal center [63].

Another interesting study by Baeyens et al. [64] showed a convincingly significant difference between children with enuresis and control groups, and the startled eye blink reflex which improved with maturation but did not seem to correlate with resolution of enuresis. Clearly there is considerable work that is required to further unravel the mechanisms behind perceived differences in arousal between enuretic and non-enuretic children.

However a raft of evidence counters such a belief. Sleep patterns of children with NE are no different from children who do not have NE [65].

Enuretic episodes occur during all stages of sleep in proportion to the amount of time spent in that stage and appear to occur independent of sleep stage but occur when the bladder is at a volume equivalent to the maximal daytime functional capacity [66-69].

Bedwetting children sleep normally but are unable to suppress nocturnal detrusor contractions or awaken in response to them or to bladder fullness.

Waking becomes easier as the night progresses. However, several authors have found that children with NE are also more likely to wet in the first third of the night, often in the first two hours following sleep [59,66,67,70,71]. Thus the point of bladder fullness for most enuretic children coincides with a time of night where they find it most difficult to wake from sleep.

Children who do wake up but are afraid to go to the bathroom, and therefore wet their bed should be identified as treatment is completely different for obvious reasons.

VIII. TREATMENT OF NOCTURNAL ENURESIS

The age at which the child and his or her parent begins to be concerned about bedwetting varies. In an important review article, Hjalmas, et al. noted that, “for successful treatment of nocturnal enuresis, the child must be brought to the physician by the parents who are concerned and the physician must have the necessary knowledge about the condition and be motivated to start treatment [43]. In order to fulfill the requirements, parents, teachers, and nurses in primary care need to understand nocturnal enuresis and be ready to treat the child, regardless of age.

Nocturnal enuresis is thought of as a social problem and less of a medical problem; therefore, since the majority of children stop wetting as they mature and since no ill health follows bedwetting in most cases, there is a tendency for many practitioners to take a “wait and see” approach despite the fact that the family and the child in many cases are quite disturbed. In one study, 3803 French school children age five to ten years noted the prevalence of primary nocturnal enuresis to be 9.2%. The majority of the children noted that bedwetting bothered them and hoped that a doctor could help them. In this survey, a questionnaire was addressed to mothers of enuretic children, 100 school teachers and 100 school doctors. The mothers had a relatively tolerant attitude but two-thirds had consulted a doctor. Most of the doctors had proposed no solution or a “wait and see” attitude or treatment with a drug rather than an alarm. From this study, we may conclude that considerable work needs to be done to help educate not only parents but teachers and even physicians about the importance of treatment of nocturnal enuresis as well as supportive care [72].

The actual timing of treatment for nocturnal enuresis may vary depending on the needs of the child and the parent. Toilet training age may be different in different societies. For example, toileting in Asia may begin earlier than in North America or other parts of the world [72,73,74]. Toilet training should be started when both the child and parents are ready. Most studies appear to show that children start training between 24 and 36 months of age with a current trend toward later completion than in previous generations. This is markedly different than noted in some Asian cultures where training
appears to begin much earlier. Toilet training should occur in an environment that is comfortable for the child. Unfortunately, toilets in most household bathrooms are adult sized, making it difficult for the child who needs to climb to the top of the toilet to relax. In these cases, a potty chair to toilet train the child, and once the child is old enough, he or she should be transitioned to an over-the-toilet seat with a footstool to allow optimal posture for voiding. Parents should encourage children to relax and take time to completely empty the bladder [43].

It is essential that both the child and his or her parents understand bedwetting pathophysiology and treatment philosophy. The clinician should give the child general advice such as what to eat and drink and to void regularly during the day, abstain from drinking too much during the late afternoon and evening and have relaxed routines at bedtime. The clinician should stress that NE is common and usually represents a delay in maturation without any psychopathological undertone. Up to 19 percent of children will become dry within the next 8 weeks without any further treatment besides good counselling [43,73,74].

1. EVALUATION

Hjalmas, et al. have recommended a careful history which we will summarize in these next few paragraphs (Figure 12). This approach, which has been recommended by the International Children’s Continence Society, provides an excellent guide toward the taking of a history for a child with nocturnal enuresis [43].

a) The frequency volume chart (FVC). Parents are asked to record a two-day three-night record. This includes recording the child’s fluid intake and urine output, frequency of micturition and the frequency and pattern of voiding. The largest single micturition is considered the functional bladder capacity. This chart can be performed beginning on a Friday evening and concluding on Sunday on any weekend.

b) Symptoms of nocturnal enuresis. A careful history should include questions about the age of onset of nocturnal enuresis, length and circumstances of dry spells, number and time of episodes of nocturnal enuresis or nocturia, presence of daytime voiding symptoms or urinary tract infection, posture while voiding, daytime and evening fluid intake, sleep habits, frequency and consistency of bowel movements and psychosocial situation. One must establish whether or not symptoms represent primary or secondary nocturnal enuresis. It is critical to search for new psychological problems that might cause secondary nocturnal enuresis, particularly when the child presents with nocturnal enuresis after a prolonged period of dryness. The personality of the child, family situation, school environment, and presence of alternate caregivers might have an appreciable impact on voiding habits and will influence management options [43]. Children may drink large volumes of fluid in the hours before sleep and this may result in nocturnal enuresis or nocturia.

It is helpful to determine the number of hours of sleep and to compare this to standard charts of average duration of sleep by age. Morning fatigue may be the result of obstructive sleep apnea. Other symptoms of sleep apnea include mouth breathing, snoring, and restless sleep [43].

It is important to rule out symptoms of anatomical or physiologic urologic conditions that may lead to

---

Figure 12 : Schematic work-up in patients presenting with night-time wetting only
constipation may result in improvement in enuresis. Storage symptoms include increased frequency, urgency, and urgency incontinence including squatting behavior, daytime incontinence and the sensation to need to void again. The clinician must carefully assess daytime wetting, particularly in older children. In many cases, the child may hide these symptoms from the clinician and the family.

Children void four to seven times a day or about every two to three hours [75]. If the child is voiding significantly more frequently than eight or more times a day, this may suggest incomplete emptying or overactive bladder symptoms. Urgency is present in many children and posturing, including squeezing or crossing the legs, squirming while standing or sitting, or physically compressing the genital area with a hand is all suggestive of overactive bladder due to detrusor overactivity which may or may not be associated with dysfunctional voiding. Other causes include urinary tract infection, polyuria from diabetes mellitus or diabetes insipidus, which can also cause more frequent voiding [43]. Treatment for these symptoms is covered in other sections within this chapter.

Additional symptoms during the daytime include continuous dribbling between voids that can come from an ectopic ureter bypassing sphincter mechanisms, or from failing to empty the bladder or sphincter incompetence. Also continuous leakage can result from neurologic causes or anatomical causes such as epispadias, or a closed bladder extrophy or urogenital sinus.

Lastly, children may have incomplete emptying from true dysfunctional voiding which results from the sphincter or pelvis floor contracting at the same time as the detrusor contracts during micturition. In addition, detrusor underactivity may result from neuropathy from diabetes mellitus and in some cases conditions such as the prune belly syndrome will result in detrusor underactivity. Lastly, urethral strictures may result in incontinence due to detrusor overactivity with poor bladder emptying. Boys with posterior urethral valves or Cobb’s collar may also have incomplete emptying. Lastly, the clinician should be alert for symptoms of constipation and faecal incontinence. It is a common misconception that if a child is stooling once per day then he or she is not constipated. In fact, the best symptom of constipation is the infrequent or painful passage of hard small pellet-like stools. Faecal incontinence may also be present, the principal sign of this being faecal material in the underwear. Excessive stool retention may result in bladder dysfunction. In these cases [76], this may result in increased urethral sphincter and pelvic floor activity and explain the association of voiding dysfunction with incomplete voiding. Treatment of constipation may result in improvement in enuresis.

2. PHYSICAL EXAMINATION

Anatomic and behavioral causes for enuresis may be identified through a careful physical examination. Evidence of improper gait, spinal deformities, and foot abnormalities including asymmetry, high-arched feet, or hammer toes are signs of sacral neuropathy. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks and gluteal clefts are also important. A careful abdominal examination with particular emphasis on the left lower quadrant may identify the colon full of firm stool. In most cases, a rectal examination is not performed but in some cases this may also be indicated. Occult feecal impaction, poor perineal sensation and reduced anal sphincter tone can be indicative of neuropathy.

In boys, marked narrowing of the urethral meatus (when the meatal lips are separated and no mucosa is seen), must be identified and carefully noted. If these signs are present, the boy should be asked to void so the clinician can witness and record the flow rate and residual urine. Narrowed or displaced urinary stream is suggestive of meatal stenosis.

In girls, the introitus should be identified for the position of the urethra. Evidence of wetting or irritation of the labia or vagina should be identified, as this could be suggestive of post-void dribbling or incomplete emptying with incontinence due to either detrusor overactivity or sphincter weakness [77].

3. LABORATORY EXAMINATION

There is very little laboratory examination that is required in patients with nocturnal enuresis other than a urinalysis to rule out UTI and evidence of glycosuria and a urine culture if the urinalysis is suggestive of infection.

Urodynamics and imaging are rarely important in the child with monosymptomatic nocturnal enuresis. If there is any suggestion, however, that daytime wetting is occurring, and then a full evaluation of the daytime problem should precede the evaluation for nocturnal enuresis.

4. THE MANAGEMENT of NE depends on:
- the child’s motivation to participate in treatment.
- exclusion of confounding psychosocial factors.
- providing information and instruction about daily habits, underlining the importance of having regular fluid intake, regular voidings, and relaxed routines at bedtime.
- regular review of the new intervention.

The therapist should convey a sense of understanding and compassion to both the child and the
family. Education about the problem and a realistic discussion about the prognosis will help instil competence in the treatment offered which may improve both compliance and outcome [78]. What follows is taken in part from the excellent review article by Hjalmas et al [43].

5. EVIDENCE BASED RECOMMENDATIONS FOR TREATMENT

First line treatment and preliminary steps: primary and secondary forms of nocturnal enuresis are treated the same. If faecal incontinence, constipation or daytime wetting is present, these should be treated first [76].

Although treatment modalities like lifting, fluid restriction, dry-bed training, retention control training, psychotherapy, acupuncture, hypnosis all have been used, there is not sufficient data in the literature to strongly recommend any of these [93-100]. However, non invasive behavioural modifications such as resisting over hydration in the evening are appropriate recommendations at the initiation of therapy. The child must void before bed. Excessive calcium or sodium intake should be avoided as well [79].

During the day the child should be instructed to void regularly, not to hold urine until the last minute, and to relax and take time to completely empty. If deemed important by the parents, a letter should be sent to the school to explain this.

Timing of treatment for the child who wets is dependent on the family's desire and the child's desire. As a good rule of thumb, children should be six to eight years of age. Some children, however, may want to wait until later. Others may be ready closer to age six. It is important for the parents to know that relapses can occur. The successful treatment of children with nocturnal enuresis has a foundation of realistic expectations and a motivated family [43].

Before starting treatment, a "baseline" meeting with counselling, provision of information, positive reinforcement, reassurance that 15% of children resolve each year, and increasing motivation should occur first. Children are asked to fill out a calendar or chart depicting the wet and dry nights. Children became significantly drier in two non-randomized trials associated with fewer wet nights simply by focusing them more on record keeping and true reward charts [80].

6. PHARMACOLOGICAL TREATMENT

Based on the three main causes of enuresis, namely nocturnal polyuria, detrusor overactivity, and disorder of arousal, the pharmacological treatment is designed to address these three areas.

a) Desmopressin.
arginine vasopressin (AVP) or antidiuretic hor-
mone (ADH) is normally produced in the hypothalamus and released in the pituitary in response to hyperosmolality or hypovolemic conditions. Vasopressin acts on the collecting ducts and distal tubules to enhance water absorption. AVP by virtue of an independent vasoconstrictor effect is also a potent vasopressor. Desmopressin (or dDAVP) is an analog of vasopressin created by deaminating the cystine residue at position 1 and substituted D-arginine for L-arginine at position 8. These changes result in significantly increased antidiuretic activity but loss of vasopressor activity. The half-life of Desmopressin is 1.5 to 3.5 hours. In a larger portion of children with monosymptomatic nocturnal enuresis, the normal circadian variation in urine production with nocturnal rise of vasopressin is absent. In these cases, dDAVP would seem to be particularly appropriate. Desmopressin is easy to administer and the clinical effects appear immediately. The usual dose is 0.2 to 0.4 mg orally, or 20-40 micrograms intranasally at bedtime. The intranasal form is no longer recommended for nocturnal enuresis in many places around the world. Some patients have a delayed response and a small group of children who do not respond to desmopressin in ordinary dosage will become dry when the dose is increased [81].

With meal combination desmopressin melt formulation has a superior pharmacodynamic profile to tablets, making it more suitable for the younger age group with a limited interval between meal and drug administration [82].

Desmopressin may be particularly beneficial in the child with limited numbers of wet episodes per month who wants added security on special nights such as a sleepover, etc.

Nocturnal polyuria is a characteristic of children that respond the best to desmopressin [83].

But detrusor overactivity associated enuresis does not easily respond as well to desmopressin treatment. The presence of daytime urgency or daytime incontinence is common in this group, and constipation or faecal incontinence is a regular finding, and these must be treated before offering dDAVP. In the short term, desmopressin is reported to produce more rapid improvement than alarm therapy. The results of various long-term studies which have followed children for six to 24 months after treatment cessation, indicate an annual cure rate in children on long-term treatment of approximately 30% [84,85].

1. TOLERABILITY AND SAFETY

Large amounts of liquid should not be consumed the nights when the drug is taken. There have been several reports that note Desmopressin toxicity [86,87].

This data would suggest that a fairly rigid regimen
of water restriction must be enforced for two hours prior to bedtime and to allow one eight-ounce (300 ml) glass of water at dinner and nothing for the two hours prior to bedtime.

The results of numerous clinical trials have shown that desmopressin is well tolerated even during long-term treatment and associated with a low risk of adverse events. In the SWEET study, only six of 242 children (2.5%) withdrew during the long-term treatment because of very mild adverse events following the administration of intranasal desmopressin. With the exception of water intoxication, which can be serious, this drug seems to be tolerated quite well.

In a survey on hyponatremia in patients with nocturnal enuresis, by Robson and Norgard in 1996, it was found that in the majority of children water intoxication was due to considerable intake of water during the time the child was actually taking the desmopressin.

**2. Predictors of Response:**

The SWEET study found that those who improved or became dry during desmopressin were older (greater than 8 years), had fewer wet nights during baseline, and had only one wet episode during the week and responded initially to the smallest dose of desmopressin used in the study [88,89].

The practical approach, however, is to offer the treatment to enuretic children since it is difficult to absolutely predict those that will respond.

There is considerable evidence that desmopressin works better than placebo. In one study, patients on desmopressin were 4.6 times more likely to achieve 14 consecutive dry nights compared with placebo [90].

However, relapse after short-term treatment is common. Sixty-one percent of 399 patients six to 12 years of age recruited from a primary care in one study responded to desmopressin initially [83]. Using intention to treat analysis 19% (77 of the 399) remained dry off medication and 18% were dry while still on desmopressin, thus not significantly better than the spontaneous cure rate. This suggests that desmopressin, by reducing the urine output over night, reduces nocturnal enuresis but does not significantly affect the resolution rate over time above the spontaneous rate.

Although several studies have shown that dDAVP is a well tolerated and safe drug, even during long-term usage, one has to be aware that dDAVP is a potent antidiuretic drug and that there have been reports of severe water retention with hyponatremia and convulsions, but these are infrequent [91-97].

**b) Antimuscarinic drugs for OAB**

Antimuscarinic drugs should not theoretically be efficacious in children with monosymptomatic nocturnal enuresis. However, because there is considerable misdiagnosis of monosymptomatic nocturnal enuresis, a number of children with mild daytime symptoms of overactive bladder may have symptoms of overactive bladder at night. Moreover, it has been shown that on Urodynamics, 73% of adults with primary nocturnal enuresis have some form of functional bladder outlet outflow obstruction classified as [1] “primary bladder neck dysfunction” or “detrusor sphincter dyssynergia”. [18]. That would suggest then that antimuscarinic drugs might be a useful alternative in some children who are unresponsive to DDAVP. It is also indicated in combined day and nighttime incontinence [52,98,99].

In general, antimuscarinic drugs are well tolerated but there are some side effects, namely dryness of the mouth, constipation and vertigo (rare). Constipation can also pose a problem since antimuscarinics may lead to constipation and the development of constipation may aggravate detrusor overactivity and thus counteract the beneficial effects of the drug. Antimuscarinics may also result in increased residual volumes which may make it difficult for the child to empty prior to bedtime. Antimuscarinic treatment in conjunction with desmopressin may have a role in cases with suspected day and night time detrusor overactivity.

| Level of evidence : 2. |
| Grade of recommendation: B. |

In those children who have NE due to detrusor overactivity during the night, treatment with an antimuscarinic drug should be considered [100]. Because it is difficult to perform a night time cystometry in these children, it may be tried in children who have more than 2 wetting episodes per night and who do not respond to dDAVP or be given in combination with alarm or dDAVP [101,99]. At present no studies have been performed to demonstrate its efficacy in this circumstance.

| Level of evidence: 3. |
| Grade of recommendation: C |

**c) Tricyclic antidepressants**

Although tricyclic antidepressant drugs, imipramine in particular, have worked in a number of children, most of the studies that recommend this drug are relatively old. The major drawbacks to imipramine therapy are cardiotoxic side effects, in some cases even with therapeutic doses, and the possibility of death with overdose.

Because imipramine and other drugs of the same family have potential cardiotoxic side effects they
cannot be generally recommended for treatment of this non-lethal disorder [102].

Although treatment with tricyclic drugs is associated with a decrease of one wet night per week, the lasting cure rate of only 17 percent restricts the use of these drugs [103].

Only in selected cases (like adolescent boys with Attention Deficit Hyperactivity Disorder and persistent NE) it should be considered [104].

In addition to dDAVP and imipramine, other drugs, such as carbamazine and indomethacin have been investigated as well: based on study design as well as study outcomes, these drugs are not recommended at this stage [105-107].

Level of evidence: 1.

Grade of recommendation: C (due to potential cardiotoxicity).

7. ENUREISIS ALARM

The enuresis alarm is the most effective means of facilitating arousal from sleep and remains the most effective way to treat mono-symptomatic NE [107,108]. Intervention with an alarm is associated with nine times less likelihood of relapse than antidiuretic therapy. Relapse rates in the 6 months following treatment are in the order of 15 - 30 %. Alarm therapy has been shown in a meta-analysis to have a 43 percent lasting cure rate [109,110]. Alarm therapy should be considered in every patient. There is an average success rate of nearly 68% with efficacy increasing with the duration of therapy.

Better results occur with optimal motivation of the child and family and higher frequency of wet nights. Reduced efficacy is associated with the lack of concern shown by the child, lack of supervision, inconsistent use, family stress, abnormal scores on behaviour system checklists, psychiatric disorder of the child, failure to awaken in response to the alarm, unsatisfactory housing conditions and more than one wetting episode per night. Enuresis alarms require several months of continuous use and are, therefore, unsuitable for some families [111-112].

For optimal results, alarm therapy requires a motivated family and child with significant commitment to time and effort. The impact on other family members should be considered. In some families, alarm therapy may wake other members of the family and may increase parental annoyance and place a child at increased risk for physical or emotional abuse. Close follow-up is important to sustain motivation, troubleshoot technical problems and otherwise monitor the therapy [43].

The exact mechanisms for alarm treatment are not known. The effects are not due to classical conditioning as stimulus awakening occurs after and not before wetting. Instead it is clearly an operant type of behavioural approach, i.e. a learning program with positive reinforcement that includes aversive elements. Dryness is reached either by waking up leading to “nocturia” in 35% of children or by sleeping through the night with a full bladder in 65%. Body worn (vibrating) alarms are as effective as bedside alarms [113].

The family should continue alarm therapy for at least 14 consecutive dry nights – or a maximum of 16 weeks before discarding it as ineffective [114-116]. Compliance remains a problem: drop-out rates are rarely disclosed in reported studies. Proper guidance and instructions are mandatory.

The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal. Comparison of the different types of alarm did not show significant outcomes.

In general it can be stated that alarm treatment is more effective than other forms of treatment and the lasting cure rate about twice as high [117,118].

Level of evidence 1.

Grade of recommendation A

In some cases, alarm therapy can be enhanced using the alarm in addition to other behavioral components. Overlearning (giving extra fluids at bedtime after successful becoming dry using an alarm) and avoiding penalties may further reduce the relapse rate [108].

8. DRY BED TRAINING

This is a package of behavioural procedures used in conjunction with the enuresis alarm first described by Azrin et al [119]. It incorporates:

- the enuresis alarm
- cleanliness training (encouraging the child to take responsibility for removing of wet night clothes and sheets, re-making the bed and resetting the alarm)
- waking schedules – to ease arousability from sleep as described above and involving:

1 for the first night, waking the child each hour, praising a dry bed, encouraging the child to decide at the toilet door whether he or she needs to void, and on returning to bed the child is encouraged to have a further drink .

2 On the second night the child is awakened and taken to the toilet 3 hours after going to sleep. For each dry night, the waking time is advanced by 30 minutes. If the child is wet on any night, the waking time stays at the time of the previous evening. The waking schedule is restarted if the child begins wetting twice or more in any week, stating again 3 hours after sleep.
High success rates and low drop out have been reported although relapse rates are no different than enuresis alarm treatment alone. Modifications are advocated to remove some of the more punitive elements of the programme but at best, it is a complex, time consuming and a demanding technique [113,120,121].

Hirasing et al found 80% success with group administered dry bed training. Girls responded better than boys [122]. The majority of parents were satisfied with the programme but opinions of the children were divided. Factors not related to success were the child’s age, bedwetting frequency, secondary enuresis or family history.

In another study they found a positive effect on behavioural problems [123].

An important component analysis by Bollard & Nettelbeck found that the enuresis alarm accounted for most of the success achieved through dry bed training. They believe that a large proportion of the components of the procedure can be eliminated without sacrificing much of its overall effectiveness and that the waking schedule coupled with the enuresis alarm is as effective as the complete dry bed-training programme [124].

Level of evidence: 2.
Grade of recommendation D (no more effective than alarm treatment alone)

9. AROUSAL TRAINING

Arousal training entails reinforcing appropriate behaviour [waking and toileting] in response to alarm triggering. The aim is to reinforce the child’s rapid response to the alarm triggering, not on ‘learning to keep the bed dry’.

The instructions involve:
- setting up the alarm before sleep
- when the alarm is triggered the child must respond by turning it off within 3 minutes
- the child completes voiding in the toilet, returns to bed and re-sets the alarm
- when the child reacts in this fashion he is rewarded with 2 stickers
- when the child fails to respond in this way the child pays back one sticker

Van Londen et al first described this procedure with a group of 41 children, aged 6-12 years, with predominantly primary enuresis [125].

They reported 98 percent success [14 consecutive dry nights] compared to 73 percent success with alarm monotherapy. The difference was significant [p<0.001]. Ninety two per cent remained dry after 2 ½ years: a very low relapse rate. An extraordinary aspect of this study was the lack of contact between therapist and parents. All those included were parents who had ordered an alarm from a rental agency and were given the instructions with the alarm. The authors conclude that arousal training is ‘definitely the treatment of choice for enuretic children between 6 and 12 years’. Compared with other studies, and considering experience of daily practice, one may question the very high success rate in this particular group of patients.

Level of evidence: 3.
Recommendation: grade C

The enuresis alarm remains the most effective means of facilitating arousal from sleep. The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal.

10. ACUPUNCTURE:

In one randomised controlled trial that examined acupuncture, 40 children were allocated either to DDAVP or acupuncture, 75% of children were dry after 6 month of therapy (while still on medication), while 65% of patients were completely dry after a mean of 12 sessions. From this study it is concluded that as an alternative, cost-effective and short-term therapy, acupuncture should probably be counted among available treatment options.

Another metaanalysis provides some evidence for the efficacy of acupuncture for the treatment of childhood nocturnal enuresis [126].

Comparison of treatment outcome and cure rates is difficult because of the inconsistent use of definitions, the inclusion of children with daytime symptoms, and the variable follow-up periods in most studies. For a pragmatic approach, see Figure 3.

Level of evidence: 4
Recommendation: grade D

11. COMBINED TREATMENT WITH ALARM AND DESMOPRESSIN

Combined treatment may be superior to alarm alone especially for non-responders of each individual treatment. In this approach, treatments are started at the same time: the rapid action of DDAVP is believed to facilitate the child’s adaptation to the alarm [127,128]. After 6 weeks the DDAVP is discontinued while the alarm treatment is continued until the child becomes completely dry. Compared with either therapy alone, the combination is particularly effective in children with high wetting frequencies and behavioural problems.

Combination with full-spectrum therapy may even yield higher success rates [129-130].

Van Kampen et al reported their results of ‘full-
spectrum’ therapy in 60 patients: they were treated for 6 months with a combination of alarm, bladder training, motivational therapy and pelvic floor muscle training: 52 patients became dry [129].

The combination of alarm with six weeks of 40ug Desmopressin intranasally was better than alarm treatment alone, especially with micturition frequency and comorbid behavioural symptoms [127]. In a Chinese study comparing alarm, Desmopressin and a combined therapy, the latter had the highest rate of sustained response (40.6%). However, there was a high relapse rate after discontinuing medication [131].

In another randomised-controlled, double blind study, the addition of 3 weeks of 40ug and 3 weeks of 20ug Desmopressin to alarm use, lead to temporary, short-term reduction of wet nights compared to controls on alarm and placebo [128]. The long-term success rate did not differ between the two groups and were low (36% and 37%, respectively). In the subgroup of Desmopressin non-responders, the combination of alarm plus Desmopressin was not more successful (51.5% remission) than alarm plus placebo (48.1% remission), so that this cannot be recommended as a routine strategy [132].

Also, theoretically, the combination of alarm and Desmopressin makes little sense: alarm treatment is an operant type of behavioural therapy that requires a certain number of wet nights to be effective: by reducing the number of wet nights through Desmopressin, the child will have less opportunity to ‘practice’ and ‘learn’ continence by the alarm therapy.

Also, the combination of alarm and anticholinergics should be considered if an overactive bladder is suspected. If the alarm is set off several times per night, indicative of overactive bladder, this combination has been proven to be successful. For example, 5 mg of Oxybutinin in the evening combined with alarm could be tried in these cases. If higher levels of anticholinergics are required, several doses should be given over the day.

In conclusion, based on current evidence, alarm treatment alone should be started first. As an adjunct programme, arousal treatment is easy to perform and effective. Also, the combination of alarm and Oxybutinin can be indicated. Alarm and Desmopressin are the two first line alternatives, but their combination cannot be recommended. Other programmes such as ‘full spectrum treatment’ remain treatment forms that are reserved for therapy-resistant cases. In certain cases, alarm treatment will not be possible: this is the prime indication for desmopressin.

12. INHIBITORS OF PROSTAGLANDIN SYNTHESIS

Because nocturnal polyuria in children with NE may not be entirely attributed to a defect in free water excretion, but rather to an increase in nocturnal excretion of sodium, cyclo-oxygenase inhibitors (like diclofenac), which reduce urinary sodium excretion, have been tried and in a randomised double blind placebo controlled study proved to be effective [133]. Further studies need to be done to elucidate the role of these drugs.

13. NON RESPONDERS

About one third of children do not respond to treatment with alarm and/or dDAVP. The majority of these children are likely to have a small nocturnal bladder capacity and suffer from “detrusor dependent NE”. These children may void more frequently than their peers or have urgency and day-time urgency incontinence. They are also often constipated. Prescription of dDAVP plus antimuscarinics should be considered, although evidence from the literature is lacking. Most likely, the reduced urinary output during the night leads to a lower filling rate which may reduce the nocturnal involuntary detrusor contractions and enhance the action of antimuscarinic drugs. Treatment success is usually noted between 1-2 months. Treatment should be continued for 6 -12 months, but clinical evidence is lacking.

On the other hand some of these children may have day time incontinence, which was not discovered during the initial workup. They should be given a strict voiding regimen and a combination of dDAVP with the alarm [54].

Some children who remain non-responders to desmopressin in combination with alarm and / or anticholinergic drugs, may have absorptive nocturnal hypercalciuria which may be responsible for the NE in some of these patients. With an appropriate (low calcium) diet these patients can become desmopressin responders [134].

NE is a symptom, not a homogeneous disorder. A really efficient treatment will never become possible until we have clarified all the different pathophysiological subgroups that go under the heading of NE.

14. CONCLUSION

- Gaining the confidence of the child and the family is paramount. The development of structure in the child’s life, early bedtime, careful diary keeping,
avoidance of fluids late in the day, are critical.

Secondly, identifying compounding psychological or physiologic factors of the child such as constipation and diurnal enuresis are critical.

Third, alarm treatment should probably be recommended as the first choice of treatment with the modifications listed above. Single parents have a difficult time with the effort that is required to awaken the child for the alarm management, and, in some cases, when children are not frequently wet, DDAVP may provide effective therapy for the last few years that they are at risk. In general, those that do the best with the alarm therapy are those with frequent bedwetting, normal estimated bladder volume, parents who are willing to participate, and true monosymptomatic nocturnal enuresis.

Desmopressin seems to work best in children who are unable to participate in alarm therapy, who have truly monosymptomatic nocturnal enuresis, who are wetting only once on a wet night and are relatively devoid of OAB symptoms.

If the initial treatment does not provide satisfactory results in two months, the child can switch to another. In some cases, using both the alarm and Desmopressin can be effective [127,135].

Lastly, combinations of therapy including Desmopressin plus an antimuscarinic can be used in some cases, if detrusor overactivity at night is suspected.

### D. Children with both day and night time incontinence

Urinary incontinence in children may be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder extrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the incontinence and they are referred to as having “functional incontinence.”

Becoming continent is a complicated process: there is a progressive development towards normal storage and emptying of the bladder at a socially accepted place and time, mostly achieved by age 3-4.

Bowel control is believed to be under the influence of the central nervous system. The pontine region is considered to be responsible for detrusor sphincter coordination while the cortical area is responsible for inhibition of the micturition reflex and voluntary initiation of micturition (detrusor overactivity control). Formerly it was believed that bladder maturation followed maturation of cortical inhibition processes. However, recent work of CK Yeung suggests bi-directional maturation of both the coordinating influence on the bladder and the pons may be implicated. This implies that a condition such as detrusor overactivity would be the result of loss of cortical control or of deficiency in cortical control, while dysfunctional voiding would be the result of non maturation of the coordination.

---

**Figure 13. Pragmatic approach to the diagnosis and treatment of nocturnal enuresis**
With the emergence of functional MRI, future studies will be able to illuminate this enigma.[1] This opens an era of corticocentric thinking on lower urinary tract dysfunction, moving away from the current trend of vesicocentric thinking. Detrusor overactivity may be a symptom of a centrally located dysfunction affecting bladder, bowel, sexual function and even mood and behaviour.[2] Indeed many studies indicate that there exists a link between lower urinary tract dysfunction and ADHD (attention deficit and hyperkinesia) [3-5].

The desire to void is a sensation which, in the developing child, is incorporated into daily life so that voiding takes place at an appropriate time and place. Problems with training or psychological difficulties possibly have a great impact on the results of training: some parents send their child to the toilet many times, though his/her bladder may be empty [6]. Voiding in these circumstances can only be achieved by abdominal straining. The positive reinforcement that the child receives by voiding even a small amount may lead to the development of an abnormal voiding pattern. The same is true when children receive negative feedback related to voiding [7]. Urinary incontinence in children may be due to disturbances of the filling phase, the voiding phase or a combination of both. In the ICCS terminology document, these conditions are termed functional bladder disorders or Lower Urinary tract (LUT) conditions. They are divided into either overactive bladder (OAB) or dysfunctional voiding [8]. While the former condition is a filling disorder the latter is considered an emptying disorder. They can of course coincide and one may even be causative of the other.

Detrusor overactivity may lead to disturbances in the filling phase characterized by urgency, frequency and at times urgency incontinence. Girls present with OAB symptoms more often than boys. In addition to the urinary symptoms, children with functional urinary incontinence may also have recurrent urinary tract infections (UTI) and constipation.

Incomplete relaxation or tightening of the sphincter mechanism and pelvic floor muscles during voiding results in an interrupted or staccato voiding pattern, that may be associated with elevated bladder pressures and post-void residuals. Such individuals with dysfunctional voiding are also prone to constipation and recurrent UTIs [9]. Bladder function during the filling phase in these children may be essentially normal, alternatively OAB may be present. In children with a underactive detrusor, voiding occurs with reduced or minimal detrusor contractions with post-void residuals, and incontinence is a characteristic symptom.

### I. PREVELANCE

For more detailed information on the prevalence of daytime incontinence the Chapter on Epidemiology should be consulted, where an overview is presented on the currently available data. The main problem is that it is impossible to draw any conclusions from the presented data as different studies have used definitions and criteria that differ from others. Furthermore, it is virtually impossible to identify the prevalence of detrusor overactivity or dysfunctional voiding as the studies tended to look primarily at daytime versus nighttime incontinence and made no effort to evaluate the type of daytime incontinence.

Daytime or combined daytime and nighttime incontinence at least once a week seems to occur in about 2-4 percent of 7-year old children and is more common in girls than in boys [10]. Overall the rates of prevalence vary from 1 to 10 percent, but in general for 6 to 7 year old children the prevalence is somewhere between 2 and 4 percent, and rapidly decreases during the following years [11-17]. Suresh-kumar et al in a population based survey of over 2000 new entrant primary school children [age 4-6 years] in Sydney, Australia noted an overall prevalence of daytime wetting of 19.2% defined as at least one daytime wetting episode in the prior 6 months with 16.5% having experienced more than one wetting episode and only 0.7% experiencing wetting on a daily basis [17,18]. Multivariate analysis showed that recent stress, a history of daytime wetting along the paternal line, and a history of wetting among male siblings were independent risk factors for moderate to severe daytime wetting. Because this was a cross-sectional study recall bias may have resulted in an overestimate of risk of daytime wetting being caused by such factors as emotional stress and family history. In addition, urine cultures were not obtained so occult UTIs could not be identified.

Chung comes to the same percentage of OAB (16.6%) in 19,240 Korean children. In this study OAB was differentiated in 'dry' OAB and 'wet' OAB: children with OAB do not always have incontinence [19].

In a questionnaire based study, supplemented by telephone calls, Hellstrom assessed the prevalence of urinary incontinence in 7 year old Swedish school entrants [20]. Diurnal incontinence was more frequent in girls than boys, 6.7% vs 3.8%, respectively. Wetting every week was reported in 3.1% girls and 2.1% of boys. The majority of children with diurnal incontinence had concomitant symptoms: urgency was reported in 4.7% girls and 1.3% boys. Nocturnal incontinence combined with daytime wetting was equally common in males versus females, 2.2% versus 2%, respectively. At the age of 17 years daytime wetting, at least once a week, was found in 0.2 % of boys and 0.7% of girls. A limitation of this study is its dependency on recall. Children with daytime or mixed wetting were found to suffer from urgency in 50.7 %, with 79.1 % wetting themselves at least once in 10 days [21]. Urgency symptoms seem to peak at age 6–9 years and diminish towards puberty, with an assumed spontaneous cure rate for daytime wetting of about 14% per year [21,22].
Most children are toilet-trained by the age of 3 years, although the mean age may range from 0.75 to 5.25 years, with girls being trained earlier [2.25 years] than boys (2.56 years) [23]. A Turkish study, in 2008, reported day dryness at a mean age of 28 months [24]. The age of commencing toilet training has increased [25].

This is thought to be associated with higher education levels in parents and the popularity of the child-oriented approach rather than parent-initiated methods [26]. Children who exhibited elimination signals for voiding became dry sooner than those who did not show such signs. There is huge social and cultural variation in toilet training practices with some of the implicated issues being, availability of inside toilet, washable versus disposable diapers, working or home-based mothers, rural or urban location and use or not of punishment methods [23].

It appears that initiating toilet training after 24 months of age may be associated with problems attaining and maintaining bladder control and that early training is not associated with bladder dysfunction [25,26].

Da Fonseca found no such association between children with combined bladder and bowel dysfunction and the time of toilet training compared to healthy children [27].

Swithinbank et al have found a prevalence of daytime wetting [including also “occasional” wetting] in 12.5% in children age 10-11 years which decreases to 3.0% at age 15-16 years [28]. Based on these findings, it seems that the prevalence of all kinds of daytime incontinence diminishes by 1-2% per year from age 10-11 to age 15-16 years, while daytime incontinence, at least once a week, seems to diminish by 0.2% per year from age 7 to age 17 years. Because of treatment interventions the studies may not recount the true natural history.

A more recent cohort study of all school children in the first and fourth grades in the city of Eskilstuna (Sweden), daytime urinary incontinence (at least once a month) was reported in 6.3% of the first graders and 4.3% of the fourth graders, while bedwetting (at least once a month) was reported in 7.1% and 2.7% and faecal incontinence in 9.8% and 5.6%, respectively. This study demonstrates that soiling and daytime urinary incontinence often coexist [29].

The natural history of detrusor overactivity in children is not well understood. It is no longer held that detrusor overactivity in children is idiopathic or due to a maturational delay but more likely to be associated with feed forward loops from the generation of a high pressure system during voiding or filling. Both the interplay of neural drive with motor control and the dynamic nature of the growing bladder could be causative. This is in contrast to the adult population, where detrusor overactivity is considered a chronic condition whose origin is unrelated to functional use. There is no long-term data to determine if childhood detrusor overactivity predicts detrusor overactivity as an adult.

There is evidence that genetic influences affect adult urinary symptoms and that suffering lower urinary tract conditions in childhood increases the risk for these conditions in adult woman [30-33]. Recent research points to a link between deficits in the brain and functional urinary problems [5].

By the age of 5 years, unless organic causes are present, the child is normally able to void at will and to postpone voiding in a socially acceptable manner. After this age, night-time and daytime involuntary wetting become a social problem and a cause for therapeutic intervention. In children who present with a change in voiding habits, such as a new onset of voiding dysfunction, one should consider the possibility of child sexual abuse [37]. A more recent study found no significant differences in the presence of lower urinary tract symptoms between children and adolescents who had experienced sexual abuse and controls [33]. Nevertheless this should be kept in mind, especially when invasive diagnostic and therapeutic procedures are contemplated. One may want to simply ask the parent or caregiver if there were any precipitating events or concerns that they feel may have led to the changes in the child’s voiding habits. The appropriate individuals should be contacted if there is a high index of suspicion. Of adult women with complex urinary symptoms, a significant proportion report sexual abuse as a child.

II. INTRODUCTION TO CLINICAL ASSESSMENT

The International Children’s Continence Society has published standardisation documents on the diagnostic evaluation of children with daytime incontinence as well as on the management of dysfunctional voiding in children. They also assessed psychological and psychiatric issues in urinary and fecal incontinence [34-36].

The evaluation of daytime wetting is based on the medical and voiding history, a physical examination, a urinalysis, bladder diaries and uroflowmetry with post void residual. The upper urinary tract should be evaluated in children with recurrent infections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyography to demonstrate overactivity of the pelvic floor muscles. Urodynamic studies are usually reserved for patients with therapy resistant dysfunctional voiding and those not responding to treatment who are being considered for invasive treatment [38-41].

Treatment is usually a combination of ‘standard therapy’ (see below), behaviour therapy, bladder training, physiotherapy and medical treatment. Surgery is rarely needed for the management of daytime
wetting in the absence of a structural abnormality. The roles of neuromodulation, botulinum toxin and intravesical therapies in the management of pediatric urinary incontinence are less well-defined. Clean intermittent self-catheterization is sometimes necessary in children with poor bladder emptying, due to underactivity of the detrusor and subsequent large residuals, who do not respond to a more conservative approach. The importance of treatment during childhood was pointed out in a general population study of 1333 adult women. Fifty percent reported symptoms of stress incontinence and 22 percent reported symptoms of urgency incontinence. Eight percent noted severe symptoms. Women who at age six years had wet episodes during the day or were wet several nights per week, were more likely to suffer from severe incontinence and report urgency symptoms: occasional bedwetting was not associated with an increased risk in adult life [42].

III. CONFOUNDING FACTORS: LOWER URINARY TRACT DYSFUNCTION, RECURRENT URINARY TRACT INFECTION AND VESICOURETERIC REFLUX (VUR)

The relationship between detrusor dysfunction and VUR associated with a urodynamic anomaly was first described by Allen and Koff and has been confirmed by several authors [43-46]. Koff demonstrated that treatment of detrusor overactivity reduced the incidence of infection and resulted in a 3 fold increase in the rate of reflux resolution. In a study by Sillen of children with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux did not show the same degree of detrusor overactivity [46]. Other investigators assessing high grade VUR in newborns noted similar findings. Van Gool et al noted that 40% of 93 girls and boys evaluated for urgency incontinence and recurrent UTIs had reflux [47].

These studies in infants and the association of combined bladder and bowel dysfunction with reflux and infection in older children support the suggestion that, in some individuals, vesicoureteral reflux is a secondary disorder related more to abnormal detrusor function than to a primary anatomic defect at the ureterovesical junction. It has been shown that increased intravesical pressure, without reflux, may be detrimental for the upper tracts: renal scarring without reflux was described by Vega et al recently [48].

In support of this concept is the common finding of vesicoureteral reflux in children with neuropathic bladders and detrusor-sphincter dysynergia. In such children, the institution of clean intermittent catheterization and anticholinergic therapy leads to the resolution of VUR in a large number of cases. It is believed that the decrease of detrusor overactivity and restoration of functional capacity in combination with regular and complete emptying of the bladder are the responsible co-factors [49].

Koff et al. evaluated the effects of antimuscarinic therapy in 62 children with a history of recurrent UTIs, VUR and detrusor overactivity, and compared these children with an age-matched control group with a normal urodynamic study [50]. The overall small sample size and the small number of compliant patients limit the study, however, it did demonstrate a statistically significant difference in the resolution rate of VUR between the treated group and the control group. The overall infection rate was lower in the treated group [16%] compared to the non-medically treated group [63%] and the age-matched control group [71%]. Several authors have documented the relationship between detrusor overactivity and dysfunctional voiding with recurrent UTIs.

Proposed etiologies for the increased incidence of UTIs in these patient populations include a milk back phenomenon whereby bacteria in the proximal urethra are “milked back” into the bladder during contraction of the pelvic floor muscles. Alternatively, decreased blood flow and relative hypoxia during periods of increased detrusor pressure such as during involuntary detrusor contractions and voiding against functional obstruction, may induce transient bladder mucosal injury.

Constipation is prevalent among children with bladder symptoms, but often poorly identified by parents [51]. It is a risk factor for recurrent UTIs. Contrary to expectations, findings from the European Bladder Dysfunction Study suggested that symptoms of disordered defecation did not influence the cure rate of treatment for bladder symptoms [52]. In a prospective non-randomized clinical series of day wetting children, a strong correlation was found between recurrent urinary tract infections, detrusor overactivity and detrusor-sphincter dysfunction [53]. In a study by Hansson et al, symptoms of detrusor overactivity, such as urgency and daytime incontinence were found in a high percentage of girls with asymptomatic bacteriuria [54].

In the majority of children with dysfunctional voiding the recurrent infections disappeared following successful treatment of the voiding dysfunction. This finding confirms the hypothesis that dysfunctional voiding is the main factor responsible for the infections [and to a lesser extent vice versa] [55,56]. Additionally, since such children typically have coexistent constipation, attempts at restoring normal bowel habits will also contribute to decreasing the risk of UTIs. At present, current opinion is that vesicoureteral reflux as such does not predispose to UTI: however it may facilitate renal involvement [causing pyelonephritis] once bacteriuria has been established in the bladder. This concept has not been scientifically validated and the incidence of renal scars as a consequence of pyelonephritis is reportedly the same, regardless of whether reflux has been documented.
or not [57]. Those children with VUR in association with detrusor overactivity and/or voiding dysfunction may be at increased risk for upper tract damage given their increased risk of developing UTIs. With this in mind, aggressive treatment of the underlying filling/voiding disorder, the addition of prophylactic antibiotics, and attention to their bowel habits should be given in an effort to decrease the risk of UTIs in this higher risk group [58-61].

In a recent study evaluating retrospectively a large group of children with LUT conditions it was shown that in patients who had urinary tract infection the presence of reflux increased the rate of renal cortical abnormalities. [62]

### IV. CLASSIFICATION

Numerous classifications have been used for children who present with varying degrees of 'functional' urinary symptoms, unrelated to apparent disease, injury or congenital malformation. In 2006, the International Children’s Continence Society (ICCS) released a standardized terminology to provide guidelines for the classification and communication about LUTS in children [8]. Symptoms are classified according to their relation to the voiding and or storage phase of bladder function.

In addition to gaining a comprehensive history, observing micturition and examining the child forms the basis of assessment: the information derived from a 48-72 hour bladder diary, stool record, voiding uroflowmetry and lower urinary tract ultrasonography is also essential in making the initial diagnostic classification [34]. Urodynamic investigations elucidate the basis of clinical findings but are first line evaluation techniques only in tertiary referral centers where children have not responded to previous treatment or have symptoms suggestive of neural involvement or anatomical anomalies.

The ICCS has classified daytime LUT conditions into groups that currently align with understanding of underlying pathophysiology. The groups commonly overlap and allocation is based on the 4 symptoms of urinary incontinence, frequency of volitional voiding, micturition volumes and fluid intake.

- Over active bladder (OAB) including urgency incontinence
- Dysfunctional voiding
- Underactive bladder
- The symptom-specific conditions of
  - Voiding postponement
  - Vaginal reflux
  - Giggle incontinence
  - Extraordinary daytime urinary frequency
  - Elimination syndrome

The term 'non-neurogenic dysfunction' is commonly encountered in the literature and describes the whole spectrum, from simple bladder overactivity to severe cases with deterioration of the upper tracts. The fact that a neurologic deficit is not demonstrated at the time of evaluation, does not, however exclude the possibility that a neurologic abnormality was present at the onset of the problem. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [63].

#### 1. OVERACTIVE BLADDER IN CHILDREN

The term bladder overactivity is used to describe the symptom complex of urgency, which may or may not be associated with urgency incontinence and is not a direct result of known neurological damage. Recent suggestions describe OAB as a symptom of corticocentral dysfunction that affects multiple systems rather than a dysfunction isolated to the urinary bladder [64]. Urgency syndrome is characterized clinically by frequent episodes of an urgent need to void, countered by contraction of the pelvic floor muscles (guarding reflex) and holding manoeuvres, such as squatting and the Vincent curtsey sign. The term urgency refers to a sudden compelling desire to void that is often difficult to defer, unlike the need to void which is experienced by all individuals and may be intense if one holds one’s urine for a prolonged period of time. The symptoms arise from detrusor overactivity during the filling phase, causing urgency. These detrusor contractions are countered by voluntary contraction of the pelvic floor muscles to postpone voiding and minimize wetting. The detrusor contractions can be demonstrated urodynamically, as can the increased activity of the pelvic floor muscles during each contraction.

The voiding phase is essentially normal, but detrusor contraction during voiding may be extremely powerful. The flow rate reaches its maximum quickly and may level off (‘tower shape’). Such strong bladder and pelvic floor muscle contractions have been postulated to result in damage to the bladder mucosa increasing the risk of UTIs. In addition, these children may note suprapubic or perineal pain. A cohort of patients presenting with nighttime pain syndromes based on pelvic floor spasms was described by Hoebeke et al. Good response to pelvic floor relaxation biofeedback is described in this study [65].

Overactive bladder (OAB) should also be considered in “continent” children with recurrent UTI and vesicoureteral reflux. Depending on fluid intake and
urine production, the complaints of incontinence be-
- come worse towards the end of the day, due to loss of concentration and fatigue and may also occur during the night. Children usually diminish their fluid intake to minimize wetting, and therefore incontinence may not be the main complaint or symptom, but on careful questioning urgency becomes apparent.

Frequent voluntary contractions of the pelvic floor muscles may also lead to postponement of defeca-
tion. Constipation and fecal incontinence (soiling) are often found in children with detrusor overac-
tivity [66]. The constipation is aggravated by the decreased fluid intake. Constipation contributes to an increased risk of UTIs and may exacerbate the detrusor overactivity. An investigation of the natural history of combined emptying dysfunction of bladder and bowel, using an elimination score in women with and without urogynaecological problems, demonstrated that childhood lower urinary tract dysfunction may have a negative impact on bladder and bowel function in later life [67].

A careful history, physical examination and scrutiny of the child’s bladder diary will identify symptoms of detrusor overactivity. Urine flow rate registration and post-void residual urine measurement help to identify co-existing dysfunctional voiding. Thus in the majority of children, invasive studies such as urodynamic studies are not indicated as part of the initial evaluation. Such studies are reserved for those children with a question of an underlying neurologic defect and those who fail to improve with medical and behavioral therapy, if invasive ther-
- apies are being considered. Those children with a his-
tory of recurrent UTIs should undergo assessment with a renal/bladder ultrasound and depending on the age of the child, and the severity of the UTI(s), a voiding cystourethrogram (VCUG) to assess reflux is occasionally performed [68,69]. By adopting a structured approach to history and physical exami-
nation, the diagnosis of urgency syndrome can be made in the majority of children without the need for invasive diagnostic procedures.

**Treatment:**

The treatment of urgency syndrome involves a multimodal approach, involving strategies such as behavioral modification, antimuscarinic medi-
cation, adjunctive biofeedback and neuromodula-
tion. Underlying and potentially complicating conditions such as constipation and UTIs are managed prior to intervention.

2. DYSFUNCTIONAL VOIDING

Dysfunctional voiding refers to an inability to fully re-
x- lax the urinary sphincter or pelvic floor muscles during voiding. There is no identified underlying neurologic abnormality. Children with dysfunctional voiding usu-
ally present with incontinence, urinary tract infections and constipation and demonstrate a intermittent, or fluctuating pattern referred ot as staccato flow (by ICCS definition) during repeated uroflowmetry.

No clear data are available on the possible causes of dysfunctional voiding. It may be that detrusor overac-
tivity eventually leads to overactivity of the pelvic floor muscles, with subsequent insufficient relaxation during voiding [70]. Alternatively, poor relaxation of the pelvic floor muscles during voiding may be a learned condition during the toilet training years, adopted following episodes of dysuria due to UTI, or consti-
pation or occurring secondary to sexual abuse [71]. The child’s environment, in particular toilet conditions and privacy issues, can trigger or exacerbate voiding anomalies [72]. In some girls, anatomical anomalies of the external urethral meatus seem to be associated with a higher incidence of dysfunctional voiding. The urine stream may be deflected anteriorly and cause stimulation of the clitoris with subsequent reflex activity of the bulbocavemosus muscle causing intermittent voiding [73]. Since no true structural ob-
struction can be identified the intermittent incomplete pelvic floor relaxation that occurs during abnormal voiding is termed a functional disorder.

Abnormal flow patterns seen in children with dys-
functional voiding:

- **Fluctuating (Staccato) voiding:** continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity. Voids are commonly prolonged and incomplete.

- **Interrupted voiding:** characterized by unsustained detrusor contractions resulting in infrequent and incomplete voiding, with micturition in separate fractions. Bladder volume is usually larger than age-
expected capacity. Residual urine is often present. Detrusor overactivity may be seen but it may also be absent [56, 68, 74].

Sustained alteration of voiding is associated with subsequent filling phase anomalies such as pha-
sic detrusor overactivity and inappropriate urethral relaxation [75]. Urinary tract infections and kidney damage are common sequelae[76]. Over time, rou-
tine incomplete bladder emptying can progress to detrusor over-distension associated with chronic urinary retention. The child with this presentation is often classified as having poor bladder emptying due to detrusor underactivity.

Urinary symptoms associated with dysfunctional voiding range from urgency to complex incontinence patterns during the day and night [77]. Children with dysfunctional voiding have a higher rate of recurrent urinary tract infections than children with no voiding abnormality and also demonstrate increased incidence of higher grades of VUR [63, 78]. Symptoms are significantly more common in children with Attention Deficit Disorder than in ‘normal’ children [79].
Signs of dysfunctional voiding reflect initial “compensatory” overactivity of the detrusor along with poor emptying ability. They may include small bladder capacity, increased detrusor thickness, decreased detrusor contractility, impaired relaxation of the external urinary sphincter/pelvic floor during voiding, weak or interrupted urinary stream and large post-void residual volumes of urine. There may also be ultrasound abnormalities, secondary vesicoureteric reflux, fecal incontinence or constipation [63, 80,81].

Treatment:

Symptoms are often refractory to standard therapy of hydration, bowel management, timed voiding and basic relaxed voiding education. Effective intervention requires combination therapy, generally with a sizeable investment of time over a long period. Treatment is aimed at optimizing bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.

Specific goals are:

- consistent relaxation of the pelvic floor throughout voiding,
- normal flow pattern,
- no residual urine and
- resolution of both storage and voiding symptoms.

Strategies to achieve these goals include pelvic floor muscle awareness and timing training, repeated sessions of biofeedback visualization of pelvic floor activity and relaxation, clean intermittent self-catheterization for large post-void residual volumes of urine, and antimuscarinic drug therapy if detrusor overactivity is present. If the bladder neck is implicated in increased resistance to voiding, alpha-blocker drugs may be introduced. Recurrent urinary infections and constipation should be treated and prevented during the treatment period.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms [82]. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dysfunctional voiding is not well delineated and optimum duration of therapy is poorly described.

Level of evidence: 4.
Grade of recommendation: C

3. DETRUSOR UNDERACTIVITY

Children with detrusor underactivity may demonstrate low voiding frequency and an inability to void to completion using detrusor pressure alone. Voiding is of long duration, low pressure, intermittent and often augmented with abdominal straining.

Children with this condition usually present with urinary tract infections and incontinence. Urodynamically, the bladder has a larger than normal capacity, a normal compliance and reduced or no detrusor contractility during voiding. Abdominal pressure is the driving force for voiding. The previously used term ‘lazy bladder’ is incorrect and is no longer used.

A correct diagnosis can only be made by urodynamic evaluation. Renal function studies, renal ultrasound and VCUG should be performed to assess the extent of renal damage and reflux. Long-standing overactivity of the pelvic floor may in some children be responsible for decompensation of the detrusor, leading to a non-contractile detrusor. However, no data are available to support this theory.

Treatment:

Treatment is aimed at optimizing bladder emptying after each void. Clean intermittent (self) catheterization is the procedure of choice to promote complete bladder emptying, in combination with treatment of infections and constipation [which may be extreme in these patients]. Intravesical electrostimulation has been described, but at this time it is still not recommended as a routine procedure for children.

Level of evidence 4
Grade of recommendation C

4. VOIDING POSTPONEMENT

Voiding postponement is a condition in which children postpone imminent micturition until overwhelmed by urgency, resulting in urgency incontinence [83]. A recent study comparing children with typical OAB to those with voiding postponement revealed a significantly higher frequency of clinically relevant behavioral symptoms in postponers than in children with OAB, suggesting that voiding postponement is an acquired or behavioral disorder [83]. In the children with voiding postponement only 20% exhibit a fluctuating voiding pattern. It remains to be determined whether or not voiding postponement can develop in the setting of a perfectly normal urinary tract or whether OAB is a necessary precursor.

Level of evidence 4
Grade of recommendation C

5. GIGGLE INCONTINENCE

In some children giggling can trigger partial to complete bladder emptying well into their teenage years, and intermittently into adulthood [84]. The condition occurs in girls and occasionally in boys and is generally self-limiting. The etiology of giggle incontinence is not defined. Urodynamic studies fail to demonstrate any abnormalities, there is no anatomic dysfunction, the upper tracts appear normal on ultrasound, the urinalysis is normal and there are no neurologic abnormalities [85,86]. It is postulated that laughter induces a generalized hypotonic state with urethral relaxation, thus predisposing an individual to incontinence, however the effect has not been
demonstrated on either smooth or skeletal muscle. It has also been suggested that giggle incontinence is due to laughter triggering the micturition reflex and overriding central inhibitory mechanisms. One small study hinted at an association with cataplexy (a state of excessive daytime sleepiness), suggesting involvement of central nervous structures, however with only 7 subjects further evidence is needed [87]. Since the etiology of giggle incontinence is not known it is difficult to determine the appropriate form of treatment. Positive results have been reported with conditioning training, methylphenidate and imipramine [85-91]. Others have tried antimuscarinic agents and alpha-sympathomimetics. There is no acceptable evidence that any form of treatment is superior to no intervention.

Level of evidence 3
Grade of recommendation D

6. VESICOVAGINAL ENTRAPMENT

Urinary leakage that occurs in girls a short time after voiding to completion, that is not associated with any strong desire to void, may be the result of vesicovaginal reflux [92]. Urine may become entrapped in the vagina during voiding due to labial adhesions, a funnel shaped hymen, or an inappropriate position on the toilet. The classic presentation is that of a girl who does not spread her legs apart during voiding and who is not sitting all the way back on the toilet seat, but who is rather sitting near the end of the toilet seat tilting forward. Obesity may be an associated risk factor. Changes in voiding position and treatment of labial adhesions will lead usually to resolution of the urine leakage.

Level of evidence 4. Grade of recommendation C

7. ELIMINATION SYNDROME

This is a term used to describe dysfunctional emptying of bowel and/or bladder presenting with symptoms of OAB, constipation and sometimes infrequent voiding.

The term is misleading as the combined bladder and bowel dysfunction involves dysfunction of both emptying and storage.

The genitourinary tract and the gastrointestinal system are interdependent, sharing the same embryologic origin, pelvic region and sacral innervation. Although children with voiding disturbances often present with bowel dysfunction, until recently this co-existence was considered coincidental. However, it is now accepted that dysfunction of emptying of both systems, in the absence of anatomical abnormality or neurological disease, is inter-related. The common neural pathways, or the mutual passage through the pelvic floor musculature, may provide a theoretical basis for this relationship, as may the acquisition of environmental and developmental learning. The latter can be influenced by episodes of urinary tract infection, constipation, anal pain or trauma, childhood stressors, reluctance to toilet and poor toilet facilities [66,72,93].

There is also evidence to suggest that in severe cases symptoms may have a neurological basis.

The Elimination Syndrome [ES] is seen more frequently in girls than boys and is significantly associated with the presence of both VUR and UTI [94]. VUR is slower to resolve and breakthrough urinary tract infections are significantly more common in children with ES when compared to those without the diagnosis. Infections do not ameliorate with antibacterial prophylaxis. Age of first febrile UTI does not appear to be an etiological factor [84], however, recurrence of UTI in children older than 5 years is associated with the presence of ES [95,96].

Abnormal recruitment of the external anal sphincter during defecation or at call to stool is considered causative, in that it elicits concomitant urethral sphincter and pelvic floor co-contractions. Thus in both systems a functional obstruction to emptying is generated. In the case of the urinary system, high pressures generated by the detrusor muscle to overcome a decrease in urethral diameter can stimulate detrusor hypertrophy, detrusor overactivity, and lead to incompetence of the vesicoureteric junctions. In the early stages of defecation disorders, bowel emptying is incomplete, infrequent and poorly executed. As the dysfunction progresses stool quality becomes abnormal, the child develops distension of the rectum and descending colon, seems to lose normal sensation and develops fecal retentive incontinence. If constipation was not present as a predisposing factor, it rapidly develops [93].

Children with elimination syndrome commonly complain of urinary incontinence, non-monosymptomatic nocturnal enuresis, recurrent urinary tract infections, imperative urgency to void (OAB) and exceptionally urinary frequency. On investigation, they are often noted to have poor voiding efficiency, vesicoureteric reflux, constipation, fecal incontinence, no regular bowel routine and infrequent toileting. The incidence of children with elimination syndrome and sub-clinical signs and symptoms is unknown.

Assessment follows the same process as for other aspects of pediatric bladder dysfunction, with the addition of a 2 week bowel diary and relevant symptom score. The inclusion of an ultrasound rectal diameter measure, either via the perineum or when assessing the bladder, has been shown to be discriminative for children with elimination syndrome. Urinary flow curve, perineal EMG and post void residual urine estimate, when considered in isolation, are not conclusive for the diagnosis of elimination syndrome. There is no evidence to suggest that anorectal manometry is warranted as a first line investigation in these children. Recently a symptom scale for ES has been developed providing objective assessment for diagnosis and quantification of severity [97].

**Treatment:**

Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching dynamic elimination skills. As bowel dysfunction is more socially isolating than urinary incontinence, and in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, most clinicians begin with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool reaccumulation, and post-prandial efforts to empty the bowel while maintaining optimal defecation dynamics. Once stools are being passed regularly, treatment focuses on teaching awareness of age appropriate fullness in the bladder, and training unopposed emptying (without straining or pelvic floor muscle recruitment), at pre-scheduled times. Pelvic floor awareness training and biofeedback therapy are integral.

There are few studies of the efficacy of treatment in children with elimination syndrome. Several authors have evaluated the outcome of constipation management on bladder symptoms, however the baseline characteristics of subjects were not described adequately enough to allow clear diagnosis of elimination syndromes [66, 97].

A review on the effectiveness of biofeedback for dysfunctional elimination syndrome reports that 80% of children benefited from biofeedback but that the level of evidence was low due to poor study designs [99].

Grade of recommendation C

**V. PRINCIPLES OF NON PHARMACOLOGICAL TREATMENT FOR ALL DIFFERENT STATES**

Treatment of the over active bladder focuses on both the involuntary detrusor contractions and the child’s response to these. The initial treatment of daytime urinary incontinence involves a behavioral and cognitive approach. The child and parent(s)/caregiver(s) are educated about normal bladder function and responses to urgency. Voiding regimens are instituted and UTIs and any constipation are managed. Additional treatment involves pharmacotherapy, pelvic floor muscle relaxation techniques and biofeedback, either alone or in combination.

Although there are many studies reported in the literature assessing the effects of various forms of therapy on daytime incontinence and urinary symptoms, many of these are case series rather than being randomized or controlled trials. The paucity of studies evaluating basic standard therapy initiatives has precluded double-blinded trials of novel and multimodal interventions. Whilst clinically important benefits are commonly described, patient numbers, objective outcome measures and length of follow-up are sub-optimal.

The main objectives of treatment are to normalise the micturition pattern, normalize bladder and pelvic floor overactivity and cure the incontinence, infections and constipation. Traditional therapy for day-wetting children is cognitive and behavioural. Children learn to recognize the desire to void and to suppress this by normal central inhibition instead of resorting to holding manoeuvres [i.e. immediate voiding without postponement] to generate urethral compression. Children with dysfunctional voiding learn to initiate voiding with a completely relaxed pelvic floor and to pass urine in association with a detrusor contraction rather than via generation of abdominal pressure. Dietary changes and bowel regimens are used to treat the constipation [98]. Antibiotic prophylaxis may prevent recurrent UTIs, however, data to support this is limited.

“Bladder training” is used widely, but the evidence that it works is variable [50, 88]. Some authors contend that in less severely affected children a thorough explanation of the underlying causes and the expected progress of resolution is sufficient treatment in itself [47]. More active conventional management involves a combination of cognitive, behavioral, physical and pharmacological therapy methods. Common modes of treatment include parent and child reassurance, bladder retraining (including timed toileting), pharmacotherapy, pelvic floor muscle relaxation and the use of biofeedback to inhibit rises in detrusor pressure associated with urinary incontinence [29, 100-102]. Further treatment options include suggestive or hypnotic therapy and acupuncture. A combination of bladder training programs and pharmacological treatment, aimed specifically at reducing detrusor contractions, is often useful and sometimes necessary.

1. **BLADDER REHABILITATION AND URO-ThERAPY**

Initial intervention for OAB and dysfunctional voiding uses a non-pharmacologic approach. This is often termed Urotherapy. Despite its use for many years there is no set format to urotherapy and many clinical studies utilize differing combinations of therapies, which makes it difficult to evaluate the results [29, 60, 101]. The aim of urotherapy is to normalize the micturition pattern and to prevent further functional disturbances. This is achieved through a combination of patient education, cognitive, behavioral and physical therapy methods.

A Danish report of the outcome of standard urotherapy in 240 children with daytime incontinence noted achievement of dryness in 126 children (55%). Alarm therapy has traditionally been used for the treatment of nocturnal enuresis but was recently used in management of daytime wetting. When a time watch was utilized as a reminder to void at regular intervals 70%
Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the patient as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. Biofeedback may be utilized for the management of both filling phase (detrusor overactivity) and voiding phase (dysfunctional voiding due to pelvic floor muscle overactivity) abnormalities.

Biofeedback can help children to identify how to relax their pelvic floor muscles or recognize involuntary detrusor contractions.

Training with biofeedback can be used as a single treatment [110,111], or in conjunction with a comprehensive rehabilitation program [112,113]. It may be performed by a cystometrogram during which the child is taught to recognize and inhibit involuntary detrusor contractions by watching the pressure curve during cystometry. This is invasive and a time consuming process with limited application as a routine treatment.

More commonly pelvic floor muscle relaxation is taught through the use of EMG biofeedback and real-time uroflow. The child sits on a toilet with a flow transducer, watching both the flow curve and EMG on a computer display, and attempts to empty completely in one relaxed void. Ultrasound may be used to determine the post void residual and demonstrate complete emptying. Interactive computer games are commonly used to make biofeedback training more attractive to children [114,115], however care should be taken that posture and muscle recruitment approximates that of the voiding position.

The results of biofeedback are commonly reported as case series rather than RCTs. Results are generally positive but overall may not be superior to high quality standard urotherapy. The group receiving adjunctive biofeedback in the Vasconcelos study [106] did not achieve greater continence rates at the study end point, although a greater proportion of subjects achieved earlier dryness. Furthermore, the post void residual volumes were significantly reduced in the biofeedback group compared to the standard therapy only group.

Long duration follow-up, whilst desirable, confounds results of intervention in children who are continually growing and maturing. Hellstrom et al report results of a 6 week bladder rehabilitation program inclusive of biofeedback [101] and note that at 3 years, 71% of the children with detrusor overactivity, 70% of those with dysfunctional voiding and 73% of those with a combined disturbance had a normal micturition pattern. The potential for bias from intercurrent events and interventions precludes statements about the efficacy of biofeedback alone.

Level of evidence: 3
Grade of recommendation C

2. ADJUNCTIVE BIOFEEDBACK

Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the patient as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. Biofeedback may be utilized for the management of both filling phase (detrusor overactivity) and voiding phase (dysfunctional voiding due to pelvic floor muscle overactivity) abnormalities.

Biofeedback can help children to identify how to relax their pelvic floor muscles or recognize involuntary detrusor contractions.

Level of evidence 3.
Grade of recommendation C

3. CLEAN INTERMITTENT (SELF) CATHETERIZATION

In children with an underactive detrusor, bladder emptying can be achieved with timed and double voiding. If this does not adequately empty the bladder clean intermittent self-catheterization (CISC) may be tried [116-118]. This requires careful guidance for both the child and the parents. Sometimes it is necessary to give the child a suprapubic catheter for a while and gradually prepare him/her to accept CISC. Once the infections have cleared and the child is continent it will become easier for both the parents and the child to accept. The frequency of CISC depends on the
Neuromodulation has been used in adults for a variety of lower urinary tract symptoms and has been applied in children. The use of transcutaneous stimulation with surface electrodes stimulating the sacral root (S3) has shown promising results, especially when tested as part of a randomized controlled trial [119]. Transcutaneous and percutaneous neuromodulation delivered either the sacral outflow or peroneal region of the ankle at a frequency between 10-25 Hz, has proven a useful adjunctive treatment in children with detrusor overactivity. Intravesical stimulation can impact function of an underactive detrusor and potentially improve detrusor contractility and enhance bladder emptying [120,121].

Electrical current directly affects the central nervous system by artificially activating neural structures; facilitating both neural plasticity and normative afferent and efferent activity of the lower urinary tract. For children with structural abnormalities, for example imperforate anus, electrostimulation is one method of facilitating strength gains in the skeletal muscle and its fascial attachments. Treatment is particularly useful in patients with very little pelvic floor awareness to stimulate muscle recruitment. Once neural efficiency has improved, training is augmented by active pelvic floor contractions.

In 2011, three papers were published reviewing the use of neuromodulation in children [122-124]. This highlights the level of interest in this modality for treating LUTD and also bowel dysfunction. A literature search revealed 18 reports of the use of neuromodulation in children with non-neurogenic bladder dysfunction. Only three of these studies were randomized and controlled, one a randomised crossover study whilst the rest were case series. However parasacral TENS has been shown to be more effective than sham in randomized trials in treating OAB. Use of neuromodulation in children with neurogenic LUT dysfunction has been reported in 9 studies, 3 of which were randomized controlled trials.

Of note is the fact that most studies have looked at the use of electrical neuromodulation in children whose symptoms have been refractory to all other interventions, whereas using it as first-line treatment may prove beneficial. Also studies using intravesical, transcutaneous and implantable electrodes have noted improved bowel function. One randomised placebo-controlled trial using interferential current transcutaneously showed significant improvements in colonic transit times, decreased soiling and abdominal pain and increased quality of life in children with severe constipation [125].

From Table 1 and 2 it is clear that different modes of application have been trialed in mostly small series of children. There is minimal standardization of populations, application parameters or outcome measures. Thus evidence is largely drawn from low quality studies. Clearly neuromodulation in children warrants larger, controlled and randomized studies, including its use as first-line intervention and in children with combined bladder and bowel dysfunction. Despite the slow pace of research the reviewers of the articles mentioned above agree that there is a positive role for neuromodulation in children with LUTD, and that it is adjunctive to other interventions, with no known predictors of efficacy at the present time, but also rare and minor adverse events. Neuromodulation of the bowel shows promise.

</table>
Reported changes on bladder function with neuro-modulation include: significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased frequency of urinary tract infection. Significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction have also been noted.

More recently the first reports on sacral nerve stimulation with implantable electrodes have been published. In a group of 20 patients between 8 and 17 years old followed prospectively. Urinary incontinence, urgency and frequency, nocturnal enuresis and constipation were improved or resolved in 88% (14 of 16), 69% (9 of 13), 89% (8 of 9), 69% (11 of 16) and 71% (12 of 17) of subjects, respectively. Complications were seen in 20% of patients [126]. Due to the uncontrolled design the level of evidence is low. Experience from adults offered this treatment modality suggests future positive development in children to be likely.

**Level of evidence: 3.**

**Grade of recommendation C**

5. **ALARM TREATMENT**

Alarm therapy has traditionally been used for the treatment of nocturnal enuresis and has rarely been used for daytime wetting. Only one randomised clinical trial has been published to establish the efficacy of this form of treatment. Halliday et al compared a contingent alarm which sounded when the child wets with a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) [103]. Forty-four children participated in the study, 50% were assigned to each form of therapy for a 3 month period. Success was measured as 6 consecutive weeks without daytime wetting. Nine children in the non-contingent group and 6 children in the contingent group had persistent wetting. Although the risk of persistent wetting with the contingent alarm was 67% of the risk of persistent wetting with the noncontingent alarm, the difference in the reduction in wetting between the groups was not significant (RR 0.67, 95% CI 0.29 to 1.56). In a more recent retrospective review by Van Laecke et al, a cure rate of 35% after the use of a daytime alarm was described[127]. Due to the retrospective design of the study the level of evidence is low.

**Level of evidence: 3**

**Grade of recommendation C**

6. **CONCLUSION**

Most clinical studies describe combinations of therapies rather than single interventions, which makes it difficult to evaluate the results. Physiotherapy and biofeedback both focus on the pelvic floor. Relaxation of the pelvic floor during voiding is essential for normal voiding and most of these patients are unable to relax their pelvic floor muscles. Biofeedback is important for showing the children the effect of their relaxation efforts. Most studies only state the clinical responses, and do not provide information on urodynamic parameters before and after treatment. A 'normal' flow curve may not mean normal voiding if no information is provided on post-void residual urine. In most papers the inclusion and exclusion criteria are not clearly documented, and it may very well be that the more difficult patients with both storage and voiding dysfunction were included in the study population. Furthermore, different series may describe different groups of patients due to poor definitions and an inadequate classification system. In children with a suspected bladder outlet obstruction, endoscopic investigations should be performed. Most often the anatomic abnormality causing obstruction can be treated at the same time. In girls, a meatal web may cause a deflection of the stream upwards [causing stimulation of the clitoris and bulbocavernous reflex. A meatomy may cure this problem, though no information on the long-term effects is available [73].

VI. **PHARMACOLOGICAL TREATMENT**

1. **ANTIMUSCARINIC THERAPY**

Antimuscarinic therapy remains one of the common forms of therapy for detrusor overactivity. Its use is predicated on the concept that parasympathetic mediated stimulation of muscarinic receptors in the bladder causes detrusor overactivity, which is responsible for the symptoms of detrusor overactivity. Antimuscarinic agents have been demonstrated to increase bladder capacity, increase bladder compliance and decrease detrusor contractions in neurogenic detrusor overactivity. Detrusor overactivity is believed to play a role in many children with functional incontinence, vesicoureteral reflux and urinary tract infections [128]. More commonly, pharmacotherapy is instituted when behavioral therapy has failed to achieve a satisfactory outcome. Some clinicians use pharmacologic therapy as a first line therapy in children with moderate to severe daytime incontinence [60].

Despite the frequent use of anticholinergic therapy, often in conjunction with a behavioral therapy regimen, the outcome of pharmacologic therapy for daytime urinary incontinence is “unpredictable and inconsistent” and there are few randomized studies available to assess drug safety and efficacy.

a) **Oxybutynin**

Currently the pharmacologic therapy most widely used in children with detrusor overactivity is oxybutynin [129]. More recently, a long-acting formulation, Oxybutynin- XL, has been approved by the FDA for use in children [130]. Historically, oxybutynin use has been limited by its adverse effect profile with such
side effects as dry mouth, constipation, facial flushing and CNS effects. The incidence of side effects seems to be dose-related, both for oral and intravesical administration [131]. The CNS effects are related to the ability for oxybutynin to cross the blood brain barrier. Oxybutynin- XL utilizes a novel delivery system, which results in absorption in the large intestine, thereby bypassing the first pass metabolism in the liver. This leads to a decrease in the amount of active metabolite [produced in the liver]: resulting in a more favorable tolerability profile. The delivery system requires an intact tablet and thus it cannot be cut or crushed to facilitate swallowing. Another method of delivery of oxybutynin is intravesical therapy. This method of delivery also avoids the first pass effect and leads to increased amounts of oxybutynin available compared to immediate release oxybutynin. Its use in the neurologically intact patient is limited by the need for catheterization [132].

There are only a few studies, none randomized and double blinded, assessing the efficacy of oxybutynin in detrusor overactivity in children. Curran et al, in a retrospective review assessed the efficacy of several agents, primarily oxybutynin in children with non-neurogenic detrusor overactivity, confirmed by urodynamics, who were refractory to behavioral therapy. Some children were treated with combination therapy. Eighty percent had complete resolution or a significant improvement in their urinary symptoms. The authors noted an average time to resolution of symptoms of 2.7 years [range 0.2 to 6.6], however patients were not followed frequently [133]. In a study by Van Hoec et al, holding exercises with and without oxybutynin showed no beneficial effect on bladder volume of adding oxybutynin.[134].

Level of evidence: 3.
Grade of recommendation C

b) Tolterodine

Tolterodine, a nonselective antimuscarinic is currently being used for the treatment of detrusor overactivity in adults. It is the first antimuscarinic agent designed specifically for use in detrusor overactivity and is felt to be “bladder selective”. It’s affinity for the bladder compared to other organ systems leads to an improved tolerability profile. The chemical nature of tolterodine makes it less likely to penetrate the blood brain barrier, which is supported by EEG studies [135]. The delivery system of the long acting preparation is such that the capsule may be cracked and “sprinkled” on food. Tolterodine has not been approved for use in children but there are several studies, which evaluate its safety and efficacy in children with detrusor overactivity. Hjålmas reported the results of an open label, dose escalation study using immediate release tolterodine in 33 children [136]. Doses ranged from 0.5 mg po BID to 2 mg po BID for 14 days. The results demonstrated a 21% (23% with 2 mg po BID) mean decrease from baseline in mic-

Level of evidence: 3.
Grade of recommendation C
c) Terodiline

One of the drugs which has been investigated in a randomized placebo controlled trial was terodiline [141,142]. Because of serious cardiac side effects terodiline has been withdrawn from the market. Trospium chloride is another agent, which has been used in small series in children. It is currently available in a twice a day dosing formulation. In the adult population, there is a 16% intra-individual variability in bioavailability and 36% inter-individual variability. Absorption is affected by food intake. Trospium’s chemical structure make it unlikely to penetrate the blood brain barrier as supported by EEG studies [135]. Lopez Periera et al evaluated the use of trospium in 62 children with documented detrusor overactivity and absence of ‘detrusor sphincter dyssynergia’ [143]. Children were randomly assigned to 10, 15, 20 or 25 mg of trospium administered in 2 divided doses or placebo. Fifty-eight children were evaluated. Response rates were assessed by incontinence episodes and urodynamic parameters. Overall, 32% had an excellent response, 42% a good response and 8% a fair response. Detrusor overactivity completely resolved in 35%. Four children had medication related adverse effects including headache, dizziness, abdominal cramps and dry mouth.

Level of evidence: 3.
Grade of recommendation C

**d) Trospium and propiverine**

Like trospium, propiverine has been used in children, but results are variable and inclusion and outcome criteria were not in accordance with ICCS definitions making comparison with other studies difficult. Recently a randomized, double-blind, placebo-controlled phase 3 trial with propiverine in children aged 5-10 yr was performed. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. The primary efficacy parameter showed a decrease in voiding frequency (-2.0 episodes for propiverine versus -1.2 for placebo; p=0.0007). Superiority could also be demonstrated for increase in voided volume (31.4 vs. 5.1ml; p<0.0001) and reduction in incontinence episodes (-0.5 vs. -0.2 episodes per d; p=0.0005. This clinical trial showed superior efficacy of propiverine over placebo and good tolerability for the treatment of children suffering from DO and urinary incontinence.[144,145] This is the first study with level of evidence 1 that shows beneficial effect of anticholinergic therapy.

Level of evidence: 1.
Grade of recommendation B/C (only single study)

**e) Solifenacin**

Solifenacin is the last antimuscarinic agent recently used in children with OAB: Hoebeke et al treated 139 children with therapy resistant OAB, with favourable results, and few side effects [146].

Some authors try combinations of anticholinergics for refractory OAB: Bolduc et al treated 33 children with a combination of oxybutinin and solifenacin or tolterodine with good success [147].

f) Botulinum toxin

Botulinum toxin is currently being used in children, mainly with neurogenic detrusor overactivity. Initial results seem promising, but more studies need to be done. In children. 300 Units on average, are injected in 30-40 spots [148]. The trigone should not be injected, as there is an increased risk of reflux developing. The results last about 6-9 months. Botulinum toxin is not registered for injection in the detrusor or the sphincter in children. It is off label used and further prospective studies are needed before a general recommendation can be made [149].

One prospective uncontrolled study by Hoebeke et al shows beneficial effects of botulinum toxin in 70% of children with therapy resistant detrusor overactivity [150]. Injection of botulinum toxin is also possible into the external sphincter, but the results are more variable and last only 3-4 months [151] Radojici et al describe excellent results in the treatment of dysfunctional voiding. In 20 children good results are described for 17 patients. [152] In a retrospective study by Franco et al, similar results are described in 16 children, however using a higher dosage. [153]

Less invasively, botulinum toxin can be administered electromotively: a small study in 15 children shows the administration is feasible, safe, and results in considerable improvement on urinary incontinence [154].

Level of evidence: 3
Grade of recommendation C

**g) Alpha-adrenergic blockade**

Treatment of the overactive pelvic floor and sphincter is much more difficult. Treatment with alpha-adrenergic blockade seems promising, but from the presented studies it is difficult to draw firm conclusions: as most series are small, not randomized and describe a mixed patient population [155-157].

In a more recent uncontrolled study by Donohoe et al a total of 26 patients with Primary Bladder Neck Dysfunction (20 males, 6 females, mean age 12.8 years) were treated with alpha-blockers. Mean average and maximum uroflow rates improved from 5.5 to 12.6 cc per second and from 10.3 to 19.7 cc per second, respectively, while mean EMG lag time decreased from 24.4 to 5.7 seconds and post-void residual urine volume from 98.9 to 8.9 cc (all p <0.001). Mean follow-up was 31 months and no major adverse side effects were observed.[158]

Further randomized controlled studies are needed to define the place of alpha-blockers.

Level of evidence: 3.
Grade of recommendation C
Because there is much variability in presenting symptoms as well as the underlying pathology an individual approach is advisable: a step by step algorithm has been developed by Marschall-Kehrel, which seems to deal with many of these variables [159].

Level of evidence 3.
Grade of recommendation B/C

The limited number of identified randomized controlled trials does not allow a reliable assessment of the benefits and harms of different methods of management in children. Further work is required in this difficult clinical area. The establishment of outcome measures is needed, to facilitate randomized controlled trials of routine therapy. Interventions that would benefit from further investigations include: bladder and voiding education, bladder retention training, bowel management, hypnotherapy and alternative therapies, psychology, prophylactic antibiotic medication, neuromodulation, biofeedback therapy and pelvic floor muscle awareness and specific relaxation. Only then can the efficacy of new interventions be measured in children with detrusor overactivity or dysfunctional voiding.

In summary, while there is a wide therapeutic choice available to clinicians, many of the commonly used treatments are of dubious value and have not been rigorously evaluated in careful clinical trials with an appropriate study design. Children who suffer this distressing condition, and their families, and those who care for them clinically, need clear guidance as to which treatments are of proven value. They need access to treatments which work, and they need protection from treatments which do not work.

Children who present with urinary symptoms may have been victims of sexual abuse. In these cases, the use of invasive diagnostic procedures (VCUG and urodynamic studies) must be regarded as contraindicated, as must the use of invasive intra-anal treatment devices. Development of less invasive methods of diagnosis and treatment should therefore be encouraged.

VII. CONCLUSION CHILDREN WITH BOTH DAY AND NIGHT TIME INCONTINENCE

In this difficult clinical area. The establishment of outcome measures is needed, to facilitate randomized controlled trials of routine therapy. Interventions that would benefit from further investigations include: bladder and voiding education, bladder retention training, bowel management, hypnotherapy and alternative therapies, psychology, prophylactic antibiotic medication, neuromodulation, biofeedback therapy and pelvic floor muscle awareness and specific relaxation. Only then can the efficacy of new interventions be measured in children with detrusor overactivity or dysfunctional voiding.

In summary, while there is a wide therapeutic choice available to clinicians, many of the commonly used treatments are of dubious value and have not been rigorously evaluated in careful clinical trials with an appropriate study design. Children who suffer this distressing condition, and their families, and those who care for them clinically, need clear guidance as to which treatments are of proven value. They need access to treatments which work, and they need protection from treatments which do not work.

Children who present with urinary symptoms may have been victims of sexual abuse. Development of less invasive methods of diagnosis and treatment should therefore be encouraged.

E. NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION

I. INTRODUCTION

Neurogenic detrusor-sphincter dysfunction (NDSD) can develop as a result of a lesion at any level in the nervous system. This condition contributes to various forms of lower urinary tract dysfunction which may lead to incontinence, urinary tract infections (UTIs), vesicoureteral reflux (VUR), and renal scarring. Surgery may be required to establish adequate bladder drainage, and potentially, if not managed properly, NDSD can cause renal failure, requiring dialysis or transplantation.

Management of neurogenic detrusor sphincter dysfunction in children has undergone major changes over the years. While the use of diapers, permanent catheters, external appliances and various forms of urinary diversion were acceptable treatment modalities; these are now reserved for only a small number of resistant patients [1]. Initially, long term renal preservation was the only aim of therapy and early diversion had the best long term results for preserving renal function. Despite some of the complications of ileal conduits and cutaneous urostomies requiring secondary surgery, this form of treatment offered the best outcome for renal preservation with socially acceptable continence [2].

Introduction of clean (self) intermittent catheterization revolutionized the management of children with NDSD. It, not only made conservative management a very successful treatment option, but also made surgical creation of continent reservoirs a very effective alternative with a good quality of life [3].

The most common cause of NDSD in children is neurospinal dysraphism and this condition presents with various patterns of detrusor-sphincter dysfunction within a wide range of severity. About 15% of neonates with myelodysplasia have no signs of lower urinary tract dysfunction (LUTD) when initially studied [4]. However there is a high chance of progressive changes in the dynamics of the neurological lesion in time and even babies with normal LUT function at birth have a 1 in 3 risk of developing either detrusor sphincter dyssynergia or acontractile detrusors by the time they reach puberty [5]. Nearly 60% of the neonates with neurospinal dysraphism may develop upper tract deterioration due to increased detrusor filling pressures and infections, with or without reflux [6,7].

As our understanding of urodynamic studies has evolved it allowed us to understand the nature and severity of the problems and administer management in a more rational manner differing according to the functional characteristics of each detrusor sphincter unit. Although the last quarter century has witnessed a remarkable progress in understanding pathophysiology, pathogenesis and the management of these children, the main goals of treatment remained the same i.e. the prevention of urinary tract deterioration and the achievement of continence at an appropriate age.

II. PRESENTATION OF NEUROGENIC DETRUSOR SPHINCTER DYSFUNCTION IN CHILDREN

Neurogenic detrusor sphincter dysfunction can develop as a result of a lesion at any level in the ner-
vorous system, including the cerebral cortex, spinal cord or the peripheral nervous system. The type and degree of detrusor sphincter dysfunction is poorly correlated with the type and spinal level of the neurologic lesion.

The closure of spinal canal in utero takes place in caudal direction from cephalic end and is completed at around 35 days of gestation. The failure of mesodermal in-growth over the developing spinal canal results in an open lesion most commonly seen in the lumbosacral area. The degree of this closure deficiency contributes to a variable presentation of neural injury with varying degrees of LUTD and lower extremity problems. Developmental anomalies that result from defects in neural tube closure are termed as myelodysplasia. This term includes a group of lesions like spina bifida occulta, meningocele, lipomyelomeningocele, or myelomeningocele. Myelomeningocele is by far the most common defect seen and the most detrimental. Traumatic and neoplastic spinal lesions of the cord are less frequent in children. [8]

The neurologic lesions produced by myelodysplasia are variable and contingent on the neural elements that protrude within the meningocele sac. The bony vertebral level correlates poorly with the neurologic lesions produced. Additionally, different growth rates between the vertebral bodies and the elongating spinal cord can introduce a dynamic factor to the lesion, and scar tissue surrounding the cord at the site of meningocele closure can tether the cord during growth [9-10].

In occult myelodysplasia, the lesions are not overt and often with no obvious signs of neurologic lesion. The diagnosis of this condition has increased since the advent of spinal ultrasonography and magnetic resonance imaging. Yet, in nearly 90% of patients, a cutaneous abnormality overlies the lower spine and this condition can easily be suspected by simple inspection of the lower back. These cutaneous lesions can vary from a dimple or a skin tag to a tuft of hair, a dermal vascular malformation, or an obvious subdermal lipoma. [8] Alterations may be found in the arrangement or configuration of the toes, along with discrepancies in lower extremity muscle size and strength with weakness or abnormal gait. Back pain and an absence of perineal sensation are common symptoms in older children.

Incidence of abnormal lower urinary tract function in patients with spina bifida occulta is as high as 40%. Occult lesions may also become manifest with tethering of the cord later in life. This can lead to changes in bowel, bladder, sexual and lower extremity function.

Sacral agenesis is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. Perineal sensation is usually intact and lower extremity function is usually normal and the diagnosis is made when a flattened buttock and a short gluteal cleft is seen on physical examination. This lesion may produce variable degrees and patterns of LUTD.

Cerebral palsy patients may also present with varying degrees of LUTD usually in the form of overactive detrusor and wetting.

Imperforate anus is a rare anomaly and presents with a closed rectum that does not open onto anal skin verge. These children may present with accompanying spinal cord pathology. This is more common when the rectum ends above the pelvic floor muscles and they should undergo a MR imaging for detection. Early detection of this problem in imperforate anus patients is important to improve the child’s chance of maintaining healthy kidneys and becoming continent.

### III. CLASSIFICATION: PATTERN RECOGNITION

The purpose of any classification system is to facilitate the understanding and management of the underlying pathology. There are various systems of classification of the neurogenic bladder.

Most systems of classification were formulated primarily to describe those types of dysfunction secondary to neurologic disease or injury. Such systems are based on the localization of the neurologic lesion and findings of the neuro-urologic examination. These classifications have been of more value in adults as neurogenic lesions are usually due to trauma and more readily identified.

In children, the spinal level and extent of congenital lesion is poorly correlated with the clinical outcome. Indeed, severe detrusor sphincter dysfunction has been associated with minimal bony defects. Various possible neuropathologic lesions of the spinal cord including syringomyelia, hydromyelia, tethering of the cord and dysplasia of the spinal cord are the causes of these disparities and they may actually extend several segments above and below the actual site of the myelomeningocele. Therefore urodynamic and functional classifications have been more practical for defining the extent of the pathology and planning treatment in children.

The detrusor and sphincter are two units working in harmony to make a single functional unit. The initial approach should be to evaluate the state of each unit and define the pattern of bladder and sphincter dysfunction. Determined by the nature of the neurologic deficit, they may be either in an overactive or an inactive state. The detrusor may be overactive with increased contractions during filling, with a diminished bladder capacity.
and compliance or be underactive with no effective contractions during voiding; the bladder outlet (urethra and sphincter) may be independently overactive causing functional obstruction or paralyzed with no resistance to urinary flow leading stress incontinence.

These conditions may exist in any combination [9-14].

Urodynamic evaluation (preferably in combination with fluoroscopy) makes pattern recognition possible. Four major types are usually used to describe the detrusor-sphincter dysfunction:

1. Detrusor overactivity with overactivity of the sphincter (mostly dyssynergia),
2. Detrusor overactivity with normal or underactivity of the sphincter,
3. Detrusor underactivity with sphincter overactivity and
4. Detrusor underactivity with sphincter underactivity.

Besides these 4 patterns, one can use the ICS classification: overactive detrusor, underactive detrusor, overactive sphincter and underactive sphincter. Sometimes this is more helpful, as the detrusor may be overactive during filling, but underactive during 'voiding'.

The urodynamic investigation is considered normal when there is suitable age appropriate capacity, good compliant bladder with no overactivity and normal innervation of the sphincter with normal sacral reflexes and an increase in pelvic floor activity during filling and no activity during voiding. Presence of detrusor overactivity during filling with or without decreased capacity and compliance, is usually seen when there is upper motor neuron lesion and this is usually accompanied by overactivity of the sphincter and failure to relax during voiding. A lower motor neuron lesion is considered when the voiding detrusor contractions are weak or lost and the sphincter is underactive. Urodynamic investigations make it possible to establish a management plan for each individual patient.

**Evidence level 3**

**Grade of recommendation B**

For the very young child the combination of an overactive detrusor and sphincter is potentially dangerous because of the high intravesical filling pressures, which will put the upper tract at risk (vesicoureteral reflux and hydronephrosis), whereas an underactive detrusor and a paralysed sphincter is relatively safe, providing a low-pressure reservoir [15-17].

**Level of evidence: 2**

**IV. MANAGEMENT**

The main aim in management of NDSD in children is to ensure and maintain a reservoir with normal age-matched capacity and good compliance that can be emptied completely at low pressures and at regular intervals.

1. **ASSESSMENT**

In the first years of life, the kidneys are highly susceptible to backpressure and infection. In this period, emphasis will be on documenting the pattern of neurogenic detrusor-sphincter dysfunction and assessing the potential for functional obstruction and whether or not there is vesicoureteral reflux [17,18]. Ultrasound studies and a VCUG or video-urodynamics to exclude reflux have to be performed soon after birth. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydronephrosis or vesicoureteral reflux, and can help identify children at risk for upper urinary tract deterioration and impairment of renal function.

A urodynamic evaluation can be done after some weeks and needs to be repeated at regular intervals, in combination with evaluation of the upper tracts [19].

**Level of evidence 3.**

**Grade of recommendation: B**

2. **TREATMENT**

Overwhelming experience gained over the years with early management of neurogenic bladder in infants has lead to a consensus that children do not develop upper tract deterioration when managed early with CIC and antimuscarinic medication [19-22]. Therefore initial treatment should consist of oral or intravesical antimuscarinic drugs in combination with clean intermittent catheterisation, to start soon after birth in all babies and especially in those with signs of possible outlet obstruction [23-27].

**Level of evidence 2.**

**Grade of recommendation: B**

The early initiation of intermittent catheterization in the newborn period, makes it easier for parents to master it and for children to accept it as they grow older [28,29].

With early management not only are upper tract changes less, but also bladders are better protected and incontinence rates are much lower.

It has been suggested that increased bladder pressures due to detrusor sphincter dyssynergia cause
secondary changes of the bladder wall. These fibroproliferative changes in the bladder wall may cause further loss of elasticity and compliance: resulting in a small non-compliant bladder with progressively elevated pressures. It is believed that early institution of intermittent catheterization and anticholinergic drugs may prevent this in some patients [30-32].

Level of evidence 3.

Retrospective evaluation of patients has also shown that significantly fewer bladder augmentations were required in patients with early start of CIC [23,24].

Level of evidence 4

The main disadvantage of CIC is bacteriuria which is found in 60% of the patients, but symptomatic UTIs are less common (20%) with CIC when compared to the group without CIC (40%). Since the risk of reflux is similarly lower with CIC the renal scar rates are lower. CIC alone, when begun in infancy can achieve continence at a rate of 60%. When combined with newer and more potent antimuscarinic drugs continence rates approach 75-80%. [33-36]

At present oxybutynin, tolterodine, trosipran and propiverine are the most frequently used anticholinergic drugs to treat detrusor overactivity in children. Some clinical studies are available, but no randomised placebo controlled studies have been performed [31,37-41].

A prospective controlled trial evaluating trosiupran in children reports that trosiupran is effective and safe in correcting detrusor overactivity in children but this study does not include patients with a neurogenic bladder [42].

Two different forms of tolterodine have been investigated in children with neurogenic bladder and extended release formulation of tolterodine is found to be as efficient as the instant release form with the advantages of being single dosage and less expensive [43].

Level of evidence 3. Grade of recommendation: B

Use of medication in children with neurogenic bladder to facilitate emptying has not been studied well in the literature. Few studies investigating the use of alpha-adrenergic blockade in children with neurogenic bladder report good response rates but they are non-controlled studies and long-term follow-up is lacking [44-46].

Level of evidence 4.

Use of intravesical oxybutynin in children with poorly compliant neurogenic bladder has been investigated in some studies and incontinence has been shown to be improved significantly in most studies, with “dry and improved” rates ranging from 61% to 83% [47]. Use of lidocain intravesically also has been shown to be effective to improve bladder capacity and compliance and decrease overactivity in children with neurogenic bladder [48]. None of these studies are randomized controlled trials and evidence available is insufficient to strongly recommend this therapy. There are no data available on long term use.

Level of evidence 3.

In neurogenic bladders that are refractory to antimuscarinics and still remain to be in a small capacity and high-pressure state, injection of botulinum toxin into the detrusor has been introduced to be a new treatment alternative [49-50]. Initial promising results in adults have also initiated its use in children. So far pediatric studies have been open-label studies and prospective controlled trials are lacking [51-53]. Injection of botulinum toxin in therapy resistant bladders seems to be an effective and safe treatment alternative. This treatment seems to be more effective in bladders with evidence of detrusor overactivity, while non-compliant bladders without obvious detrusor contractions are unlikely to respond to this treatment. Dosage in children should be determined by body weight, with caution regarding total dose if also being used for treatment of spasticity, and minimum age [54-57].

Level of evidence 3.

In a single study urethral sphincter botulinum-A toxin injection has been shown to be effective in decreasing urethral resistance and improve voiding. The evidence is still too low to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases [58].

Intravesical electrical stimulation of the bladder was introduced more than four decades ago and it has been tested in some open clinical trials in children since 1984. Its practice is limited to a few centres who have reported varying results. The nature of this type of treatment (time consuming and very dedicated personal) does not make it attractive for the majority of treatment centres [59].

Level of evidence 3.

Children with neurogenic bladder also have disturbances of bowel function. Fecal incontinence in these children is frequently unpredictable; it is related to the loss of lower bowel sensation and function, altered reflex activity of the external sphincter and the consequent failure to fully empty the rectum [60].

The majority of children with a neurogenic bladder also have constipation and this is managed most commonly with laxatives, such as mineral oil, combined with enemas to facilitate removal of bowel...
contents. A regular and efficient bowel emptying regimen is often necessary to maintain fecal continence and this may have to be started even at a very young age. With antegrade or retrograde enemas, the majority of these children’s constipation can be managed and they may attain some degree of fecal continence [61-65].

Level of evidence 3.
Grade of recommendation C

Biofeedback training programs to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management program in achieving fecal continence [66]. Electrostimulation of the bowel may also offer a variable improvement in some patients [67].

Level of evidence 3.
Grade of recommendation D

Urinary tract infections are common in children with neuropenic bladders. In the absence of reflux, patients with urinary tract infections should be treated if symptomatic. There is strong evidence not to prescribe antibiotics to patients with bacteriuria without clinical symptoms [68-71]. Bacteriuria is seen in more than half of the children on clean intermittent catheterization (CIC), but patients who are asymptomatic do not need treatment.

Level of evidence 3.
Grade of recommendation B

Patients with vesicoureteral reflux and urinary tract infection often should be placed on prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage [72].

Sexuality, while not an issue in childhood, becomes progressively more important as the patient gets older. This issue has historically been overlooked in individuals with myelodysplasia. Patients with myelodysplasia have sexual encounters, and studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. Therefore counseling patients regarding sexual development is important in early adolescence.

Children with a good response to antimuscarinic treatment and an overactive sphincter may be continent in between catheterizations. Bladder pressure and (normal) development of the upper tracts will determine whether additional treatment is necessary.

Children with therapy resistant overactivity of the detrusor, or small capacity and poor compliance will usually need additional surgical treatment such as bladder augmentation.

Children with detrusor overactivity but with underactive sphincters will be in a better shape in terms of protecting their upper tracts, but they may be severely handicapped because of their incontinence. Initial treatment will be intermittent catheterization (as it may reduce the degree of incontinence and offers a much better control over urinary infections) in combination with antimuscarinic drugs. At a later age the outlet resistance has to be increased in order to render them continent [73]. There is no medical treatment of proven efficacy that increases bladder outlet resistance. Alpha-receptor stimulation of the bladder neck has not been very effective. Surgical procedures need to be considered for maintaining continence [75-77].

It is important to establish adequate bowel emptying before attempting to correct bladder dysfunction surgically or medically.

Patients with a neurogenic bladder require lifelong supervision and monitoring of renal function is extremely important. Periodic investigation for upper tract changes, renal function and bladder status is mandatory. Therefore repeat urodynamic studies are needed more frequently at younger ages and less frequently at later ages. A repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure. In case of any apparent changes both in the upper and lower urinary tract or any changes of neurological symptoms, a more detailed examination including urodynamics and MRI of the spine is indicated. Renal failure usually progresses slowly but may occur with startling rapidity in these children.

F. Surgical management of urinary incontinence in children

Intermittent catheterization and drug therapy are usually sufficient in the majority of cases for maintaining continence and preserving upper tracts. Surgical procedures should be considered if conservative measures fail to achieve continence between catheterizations or preserve upper tracts.

Surgical intervention is required for congenital and acquired diseases interfering with the function of the storage function of the bladder, the sphincter mechanisms or which bypass normal sphincter mechanisms. A plethora of different surgical procedures has been proposed to maintain continence by using different mechanisms. Various procedures using different mechanisms for maintaining continence may be used in the same patient.

In many cases measures such as intermittent catheterization and drug therapy are needed in addition to surgery since most of the surgical procedures can achieve ‘dry- ness’, but rarely restore normal voiding.

Patients with bladder neck incompetence pose a real challenge and require a different approach. All surgical procedures to “reconstruct” the bladder neck have one thing in common; an obstruction is created
to enhance bladder outlet resistance. Even if successful, normal spontaneous voiding with low pressures without external help is not possible in most patients. Considering the long-term outcome, it may be better not to void spontaneously when bladder outlet resistance is increased because longstanding outlet resistance may cause secondary changes of the bladder wall.

The rarity and complexity of the conditions associated with congenital incontinence in children precludes the establishment of higher levels of evidence because of the rarity and spectrum of the pathology. Results are highly dependent on the skills of the individual surgeon. Therefore graded recommendations for specific procedures cannot be provided. There are no randomized controlled trials (level 1 and 2 evidence). Based on the available literature most studies have a level of evidence 3-4 and grade of recommendation C or D.

I. ABNORMALITIES OF STORAGE

Bladder Exstrophy: The incidence of bladder exstrophy is 1 per 30,000 live births. (male to female ratio 2:3.1-6.1). Closure of the bladder is generally performed within the first days of life; pelvic osteotomies facilitate reconstruction of the abdominal wall and may improve ultimate continence [1,2,3]. Some children will develop more or less normal capacities. Even after successful closure there will be some children who end up with a poorly compliant small bladders, requiring later bladder enlargement or urinary diversion (ureterosigmoidostomy) [4,5,6,7]. Patients with a good bladder template who develop sufficient bladder capacity after successful primary closure and epispadias repair can achieve acceptable continence without bladder augmentation and intermittent catheterization [8,9,10].

Reconstruction of the bladder neck can either be done at the time of bladder closure or at a later stage. Early reconstruction may facilitate normal bladder function, but should be attempted only at centers experienced with such surgery [11,12]. Continence rates vary from center to center and may range between 43 to 87% [13,14].

Cloacal Exstrophy: The incidence of cloacal exstrophy is 1 per 200,000 live births. This is a much more complex deformity that requires an individual approach. Most of these children have anomalies of the nervous system, upper urinary tract and gastrointestinal tract that can adversely affect urinary tract reconstruction. Before reconstructive procedures are considered, an extensive evaluation has to be carried out.

Agenesis and duplication of the bladder are both extremely rare. Agenesis is rarely compatible with life. In bladder duplication other associated congenital anomalies are often observed such as duplication of external genitalia or lower gastrointestinal tract.

Abnormal storage function in combination with other anomalies is usually caused by a neurologic deficit or is secondary to bladder outlet obstruction. Sacral anomalies are frequently seen with cloacal malformations and imperforate anus [15,16,17,18].

Posterior urethral valves may cause severe hypertrophy of the detrusor with a small poorly compliant bladder [19,20].

Unfortunately, following valve ablation, these bladders may not return to normal function [21,22].

II. ABNORMALITIES OF SPHINCTERIC FUNCTION

Epispadias (without exstrophy): incidence 1 in 60,000 live births, male to female ratio: 3-5:1. All patients with bladder exstrophy also have complete epispadias.

In male patients with complete epispadias and all females, the sphincteric mechanism is deficient and the child has complete incontinence. Reconstruction of the bladder neck is either performed at the time of epispadias repair or at a later stage. The bladder function may or may not be normal in these patients [23,24].

Malformation of the Urogenital Sinus occurs exclusively in phenotypic females. The incidence is 1 in 50,000 live births. In patients with classical urogenital sinus or cloaca, the sphincteric mechanism is insufficient and due to associated neurological abnormalities the bladder function may be abnormal.

Ectopic ureteroceles protruding into the urethra may be responsible for a partial defect of the bladder neck. In these rare cases, sphincteric incontinence may be the result.

Sphincter abnormalities secondary to spina bifida and other neurologic disorders are of particular importance. The sphincter may be overactive (like in detrusor sphincter dyssynergia) or underactive. Overactivity of the sphincter causes secondary changes of the bladder wall (increased collagen type III with decreased elasticity and compliance). Continence is usually achieved with antimuscarinic drug treatment or bladder augmentation (using the overactivity of the sphincter for continence). In cases of incompetence of the sphincter, different types of surgical intervention are possible to enhance the sphincteric mechanism. In general all patients with a neurogenic bladder need Clean Intermittent Catherization (CIC). In patients bound
to a wheelchair a suprapubic channel can be created (Mitrofanoff) to facilitate CIC.

III. BYPASS OF SPHINCTERIC MECHANISM

Ectopic Ureter is an abnormally located terminal portion of the ureter. Instead of the ureter opening in the bladder, it opens in the urethra, vagina, or uterus. Ectopic ureters occur more frequently in girls and are commonly part of a duplex system: in girls the ectopic orifice of the upper pole moiety drains into the urethra below sphincteric level or vaginal vestibule, thus causing incontinence [25]. When the ectopic ureter represents a single system, the trigone is usually asymmetrical and not well developed. These children may suffer from continuous incontinence as well as a deficient sphincteric mechanism; this is particularly true in bilateral ectopia of single systems. In these patients the trigone and bladder neck are functionally abnormal and treatment includes surgical reconstruction of the bladder neck. When the upper pole ureter opens in the mid or distal female urethra or outside the urinary tract (i.e. vulva or vagina) incontinence results. Upper pole nephrectomy or ipsilateral uretero-ureterostomy solves the problem.

A rare and a challenging condition is when there are bilateral ectopic ureters. Since the bladder is hypoplastic, in these children achieving normal bladder capacity and function may require additional procedures to ureteric reimplantation [26,27,28].

Urethral duplications. Most patients with urethral duplication will leak urine from the abnormal meatus during voiding. In rare cases, when the urethra bypasses the sphincteric mechanisms, continuous leakage may be present [29].

Vesicovaginal fistulas. Acquired fistulas may be traumatic or iatrogenic, following procedures on the bladder neck.

IV. EVALUATION AND DIAGNOSIS

A detailed history and physical examination in combination with imaging studies and urodynamic evaluation are the corner stones for successful management. Imaging studies are essential to define the anatomical abnormalities responsible for and associated with incontinence. Ultrasonography of bladder and kidneys as well as a voiding cystourethrogram are the basic studies. In infants and small children sacral ultrasonography can demonstrate normal position and mobility of the spinal cord. The scout film of the contrast voiding cystourethrogram (VCUG) assesses the lower spine and sacrum, intersymphyseal distance, and fecal retention. The contrast films will show bladder configuration, presence of vesicoureteral reflux, incomplete voiding, bladder neck competence, urethral anatomy, and vaginal reflux. Occasionally, an intravenous urogram will provide the clearest assessment of the urinary tract. MRI and CT scanning can be helpful in defining spinal abnormalities as well as congenital abnormalities in the urinary tract.

In addition to imaging studies, urodynamic studies (cystometrography, and when needed, electromyography of the sphincters and urinary flow studies) are useful for all patients with neurogenic incontinence, and after surgery in some cases of bladder exstrophy and after posterior urethral valves resection to help define the mechanism of any continued incontinence. However in many patients much useful information on the function of the lower urinary tract can be obtained with very basic studies including ultrasound and cystometry.

V. INDICATIONS FOR SURGICAL PROCEDURES TO CORRECT URINARY INCONTINENCE

1. STORAGE FUNCTION

Reduced bladder capacity is the main indication for simple bladder augmentation. Reduced capacity can be congenital (bilateral single ectopic ureters, bladder exstrophy) or caused by previous surgery e.g. bladder neck reconstruction in exstrophy patients, where a part of the bladder is used to create an outlet resistance. Other indications are low functional bladder capacity as it may be present in neurogenic detrusor overactivity, or poor bladder compliance (meningomyeleocele), or bladder scarring from previous surgery or obstruction. Bladder scarring from bilharzia remains common in endemic areas and is increasingly common with immigration to the developed world. In all such cases surgery is indicated when conservative treatment has failed.

Several studies suggest that aggressive early intervention with CIC and anticholinergic therapy improves bladder compliance and may protect children from augmentation surgery [30,31]. Yet in a recent survey has reported that there has been no change in augmentation rates during the last 5 years: they demonstrated significant interinstitutional variability [32].

2. SPHINCTER FUNCTION DURING STORAGE

Most of the diseases in childhood requiring surgical repair for incontinence not only have an influence on bladder capacity but also on sphincter function.
Conservative measures to improve sphincter function have limited value and surgery is required in many cases. There are different surgical options; either to increase outlet resistance or to create or implant a new sphincter mechanism. In neurologically normal patients such as classic extrophy patients, early anatomic reconstruction may allow ‘normal’ bladder and sphincter function. Sling procedures are indicated when the residual sphincter function is not sufficient to avoid incontinence. This may be the case in patients with neurogenic bladder disturbances and urethral incontinence. If there is no residual sphincter function or outlet resistance, an autologous tape or colposuspension in girls, and an artificial sphincter in boys, may be required. Primary urinary diversion (rectal reservoirs / continent stoma) offers an alternative solution to this problem.

3. PROCEDURES TO BYPASS THE SPHINCTER

If bladder outlet surgery fails or urethral catheterization is not possible, a continent stoma may be constructed. Some patients prefer catheterizing through a continent stoma rather than through the sensate urethra. The continent stoma (Mitrofanoff principle) may be combined with bladder augmentation and/or bladder neck reconstruction or closure. An alternative to such procedures would be the use of the anal sphincter for urinary continence with the use of colon as the storage reservoir.

VI. BLADDER RESERVOIR CONSTRUCTION

1. URETEROSIGMOIDOSTOMY

This type of continent urinary reconstruction may be utilized in reconstruction for bladder exstrophy, an incontinent urogenital sinus or the traumatic loss of the urethral sphincter. As this reconstruction is totally dependent on the normal function of the anal sphincter, contraindications include incompetence of the anal sphincter, anal prolapse, previous anal surgery, and irradiation. Because of the potential for electrolyte resorption, renal insufficiency is also a contraindication.

Low pressure rectal reservoirs are superior to simple ureterosigmoidostomy because the augmented or reconfigured rectal bladder achieves lower pressure storage and accordingly, enhances continence.

There are two techniques which have been utilized:

a) The augmented rectal bladder in which the rectosigmoid is opened on its antimesenteric border and augmented by an ileal segment. The sigmoid may be invaginated to form a nipple valve to avoid reflux of urine into the descending colon and thus to minimize metabolic complications.

b) The sigma-rectum pouch (Mainz pouch II) in which there is an antimesenteric opening of the recto-sigmoid and a side to side detubularization anastomosis. Ureteral reimplantation of normal sized ureters is by a standard submucosal tunnel (Goodwin, Leadbetter). If the ureter is dilated the technique utilizing a serosa lined extramural tunnel may be more appropriate [33,34].

As reported by D’elia et al, the results of these low-pressure rectal reservoirs are excellent with day and night continence better than 95% and complications related to the surgical procedure range from 0 -10% with the sigma-rectum pouch to 34% for the augmented rectal bladder [35]. Late complications for the sigma-rectum pouch range from 6-12.5% and the late complications for the augmented rectal bladder are 17%. Early complications include pouch leakage while late complications are mainly related to the ureteral implantation into the bowel and pyelonephritis. Metabolic acidosis also occurs (69% of the patients had a capillary base excess of –2.5 mmol/L and used oral alkalinizing drugs to prevent hyperchloremic acidosis).

Periodic follow-up studies are important to check the upper urinary tract and prevent metabolic acidosis. Due to the risk of malignancy at the ureterointestinal anastomosis, colonoscopy should be performed annually beginning at postoperative year 10 [30,36,37,38,39].

Grade of recommendation: B

2. BLADDER AUGMENTATION, BLADDER REPLACEMENT AND CONTINENT URINARY DIVERSION, USING INTESTINE

The indication for bladder augmentation, replacement of the bladder, or the creation of a continent urinary diversion, is either the morphological or functional loss of normal bladder function. The main goal of this surgery is to relieve high pressure and low capacity of the urinary bladder and create a new reservoir with low storage pressures that can be emptied periodically. It is particularly important that the patients understand that spontaneous voiding will not be possible after such surgery and life long intermittent catheterization will be required.

Before deciding on what type of procedure can be performed some significant factors must be addressed. These are:

1. Physical and mental capacity of the patient to do intermittent catheterization.
2. Previous surgery (on urinary tract and bowel)
3. Renal function status (including acid base state)
4. Absence or presence of reflux
5. Outlet resistance

6. The need for a catheterizable channel

The different technical approaches to bladder augmentation or replacement are dependent on the clinical presentation of the patient:

- a simple bladder augmentation using intestine may be carried out if there is any bladder tissue, a competent sphincter and/or bladder neck, and a catheterizable urethra,

- an augmentation with additional bladder outlet procedures such as bladder neck reconstruction or other forms of urethral reconstruction are required when both the bladder and outlet are deficient. This occurs most commonly in spina bifida or bladder exstrophy. It must be appreciated that bladder outlet procedures may complicate transurethral catheterization.

- augmentation with surgical closure of the bladder neck may be required primarily, or as a secondary procedure in certain rare clinical situations. In this situation a continent stoma will be required. Most urologists however prefer to leave the bladder neck and urethra patent as a safety precaution: when the bladder is very full leakage will occur and it allows transurethral manipulations such as catheterization if the continent reservoir cannot be emptied through the suprapubic catheterizable channel.

- an augmentation with additional continent stoma is utilized primarily following failure of previous bladder outlet surgery. It is advisable also when it can be anticipated that there will be an inability to catheterize transurethrally. An abdominal wall continent stoma may be particularly beneficial to the wheelchair bound spina bifida patient who often can have difficulty with urethral catheterization or who is dependent on others to catheterize the bladder. For continence with augmentation and an abdominal wall stoma, it is essential that there be an adequate bladder outlet mechanism to maintain continence.

- total bladder replacement in anticipation of normal voiding in children is very rare, as there are infrequent indications for a total cystectomy, with preservation of the bladder outlet and a competent urethral sphincter. This type of bladder replacement is much more common in adult urologic reconstruction.

The main contraindications are the inability of the patient to be catheterized, or perform CIC him or herself and the anticipation of poor patient compliance. When there is reduced renal function generally with a creatinine above 2 mg/dl or a creatinine clearance below 40 ml/min/1.73 m², there is a relative contraindication to the use of ileum or colon because of metabolic acidosis secondary to reabsorption. The stomach with its excretion of acid may be used with a low creatinine clearance possibly in preparation for transplantation. It is, however, not wise to use stomach in any voiding patient or one with any questions of an incompetent bladder outlet because of the severe skin irritation that the acid urine may produce (hematuria-dysuria syndrome).

3. WHICH INTESTINAL SEGMENT SHOULD BE UTILIZED?

a) Stomach

Stomach has limited indications primarily because of the complications that have been seen. It is the only intestinal segment suitable in patients with significantly reduced renal function [40,41,42].

Additionally, when no other bowel may be available, as after irradiation or there exists the physiology of a short bowel syndrome, as in cloacal exstrophy, this may be the only alternative remaining.

b) Ileum / Colon

Clinically these two intestinal segments appear to be equally useful. In children, sigmoid colon is widely used except in those who have been treated for imperforate anus. Use of the ileocecal region can be associated with transient and sometimes prolonged diarrhea. This segment should be avoided in patients with a neurogenic bowel such as in myelomeningocele or who have been subject to previous pelvic irradiation. If the ileocecal valve must be used, it can easily be reconstructed at the time of performing the ileo-colonic anastomosis. The ileum can be satisfactorily used for bladder augmentation: however because of its smaller diameter a longer segment of ileum is required to create a comparable reservoir to that created from colon. Colon has greater flexibility for ureteral implantation and construction of a continent catheterizable channel.

c) General principles

There are several important principles for bladder augmentation and replacement that should be respected:

- use the minimal amount of bowel and if available use hindgut segments or conduits from previous surgical procedures,

- a low-pressure large capacity reservoir is essential. This requires detubularization of any intestinal segment used.

- for colonic reservoirs a sigmoid segment of 20-30 cm is generally satisfactory. A slightly longer segment of ileum is generally used. The
length of the segments can be scaled down in smaller children. Care should be taken not to use more than 50 to 60 cm of ileum in adolescents and comparable lengths in younger children because of reduction of the intestinal resorptive surface.

- the jejunum is contraindicated in intestinal reconstruction of the urinary tract because of its metabolic consequences (hyponatremia, hypercalcemia, and acidosis).
- it is wise to strive to achieve an anti-reflux ureteral anastomosis into the reservoir to avoid the potential for reflux and consequently ascending infection: in high pressure bladders with reflux the reflux usually disappears spontaneously following augmentation [43,44].
- a reliable continence mechanism (continent urinary outlet) must be assured.
- because of the risk of stone formation only resorbable sutures and staples should be used in bladder augmentation and reservoir construction.

d) Bladder augmentation techniques

1. In gastric augmentation a 10-15 cm wedge-shaped segment of stomach is resected. Most commonly this is based on the right gastroepiploic artery but can be based on the left one as an alternative. The segment is brought down to the bladder easily in the retroperitoneal space along the great vessels.

2. When using large or small bowel the segment to be utilized is opened on the antimesenteric border and detubularized prior to anastomosis to the bladder remnant. The anastomosis of the intestinal segment to the bladder remnant and to itself is usually carried out in one running layer of inverting absorbable sutures.

3. The techniques for urinary diversion with continent stoma (Mainz pouch, Indiana pouch, Kock pouch) are covered in the chapter on urinary diversion in adults [45,46,47].

Currently, augmentation cystoplasty is the standard treatment for low capacity and/or low compliance bladders secondary to neurogenic, congenital and inflammatory disorders. Due to the relatively high morbidity of conventional augmentation there is renewed interest in alternative methods [48, 49,50,51,52,53]. These alternative techniques try to avoid the contact between urine and intestinal mucosa and include gastrocystoplasty, bladder auto-augmentation, seromuscular augmentation, alloplastic or biodegradable scaffolds grafted with autologous urothelium developed in cell culture, and ureterocystoplasty.

e) Auto-augmentation

The principle of auto-augmentation of the bladder is the excision of a great portion of the detrusor while leaving the urothelium intact, creating a large diverticulum for the storage of urine at lower pressures. This urine stored at a low pressure can be drained by intermittent catheterization. The theoretical advantages of this procedure are the low complication rates of the surgery, reduced operative morbidity with shorter stay in the hospital, absence of urine salt resorption, less mucous production in the urine and possibly absence of carcinogenic potential. Although some series showed good results with this procedure [54,55,56,57], most authors have been unable to achieve previously reported success [58].

Long-term results have been rather disappointing: MacNeilly et al concluded that of 17 patients with neurogenic bladder following auto-augmentation, 71% were clinical failures and 14 out of 15 were urodynamic failures [59]. Similar findings have been reported by others [60,61]. The inability of this procedure to achieve long-term good results may be due to the regeneration of nerve fibers divided during the surgery as well as the ischemic atrophy of the mucosa.

Although there are many potential advantages to this approach to a small poorly compliant bladder the inconsistency of success make it a less favorable option at this time. It is generally felt that pressures can be lowered but that capacity remains unchanged.

More recently, some authors have proposed the laparoscopic auto-augmentation as a minimally invasive procedure for the treatment of low capacity/low compliance bladder. [62,63]. Despite the indifferent results some still suggest its consideration before a standard augmentation because of the reasons listed above [64,65,66].

Level of evidence 4.
Grade of recommendation C

f) Seromuscular patch

To overcome one of the major disadvantages of a conventional augmentation that is mucus formation several techniques have been developed to use intestinal segments free of mucosa. The first attempts at using intestinal segments free of mucosa to improve bladder capacity resulted in viable seromuscular segments covered with urothelial mucosa [67,68]. The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans [69]. Further attempts consisted of using the association between demucosalized intestinal segments and auto-augmentation. In the
the animals sacrificed within one month. In addition, colonic mucosa regrowth occurred in one third of the animals [70]. Follow-up studies in a dog model with previously reduced bladder capacity suggested that the contraction of the intestinal patch in seromuscular enterocystoplasty can be avoided by the preservation of both the bladder urothelium and lamina propria, together with the submucosa and muscularis mucosa of the intestinal patch [71,72]. This form of bladder augmentation was shown to prevent absorption of toxic substances like ammonium chloride [73]. Other authors using the same technique to line de-epithelialized gastric patches in the mini-pig model found it useless due to the fibrotic changes and decreased surface of the patch [74].

The initial experience in treating humans with colocystoplasty lined with urothelium were reported by Gonzales and Lima who developed a slightly different technique independently [75,76]. Bladder capacity increased significantly while bladder pressures decreased. Biopsies demonstrated urothelium covering the augmented portion of the bladder in the majority of cases.

Longer term follow-up is now available and although the results are very encouraging, the results seem to be highly operator dependent and the way the mucosa is removed seems to be a crucial factor. Lima et al. do no longer preserve the bladder urothelium and use a silicone balloon to prevent the augmented segment from contracting (they remove the balloon after 2 weeks: urine is diverted using ureteral stents): in 123 patients no ruptures were found and only 10% were regarded as failures [77].

Gonzalez et al. found seromuscular colocystoplasty in combination with an artificial urinary sphincter successful in 89% of their patients and that it effectively achieves continence with no upper tract deterioration, and concludes that this is their preferred method of augmentation when adverse bladder changes occur after implanting the AUS [78].

Although more authors have now reported their results it still remains a more complex form of augmenting the bladder. This procedure has not receive a general acceptance among the paediatric urological community but is being done in some designated centres [79,80,81,82]. A recent comparison of the long term outcome of this technique with standard intestinocystoplasty has indicated that most of the risks and benefits of augmentation cystoplasty performed using intestine and seromuscular patch appear similar.

g) Ureteral bladder augmentation

Another alternative to avoid the morbidity of intestinal bladder augmentation is the use of ureteral segments to improve bladder capacity and/or compliance. Megaureters associated with poorly or nonfunctioning kidneys provide an excellent augmentation material with urothelium and muscular backing, free of potential electrolyte and acid base disturbance, and mucus production [83,84].

Another alternative in patients with ureteral dilation and good ipsilateral renal function, is to combine transureteroureterostomy with ureterocystoplasty [85]. Another alternative in bilateral dilated ureters with preserved renal function is bilateral reimplantation and the use of bilateral distal ends for detubularized bladder augmentation [86,87].

Bladder augmentation with ureter may be effective in a small sub group of patients with ureteral dilatation and poor bladder capacity. Overall long-term results are good and remain so over a longer period of time [88,89,90,91,92,93].

In a recent evaluation of the long term functional outcome of this technique it is reported that ureterocystoplasty provides durable functional urodynamic improvement, yet some patients (4 out of 17 in this series) would eventually need a standard intestinal cystoplasty [94].

Level of evidence 3.

Grade of recommendation B

It has been shown that this type of augmentation can also be employed in children who require a kidney transplantation [95,96,97].

h) Experimental Methods

The artificial bladder has been the topic of speculation and experiment that remains still outside the bounds of clinical application. Somewhat nearer to clinical application may be the concept of tissue engineering using autologous urothelium and bladder muscle cells. These cells may be grown on biodegradable scaffolds—both naturally derived and synthetic—for the temporary support of growing tissues and then can be used for augmenting the bladder. A number of synthetic materials and natural matrices have been used in experimental and clinical settings and major improvement have been gained in techniques of cell harvest, culture, and expansion as well as polymer design.

A range of applications of engineered bladder tissues are at different stages of development. There have been a few in preclinical trials, recent progress suggests that engineered bladder tissues may have an expanded clinical applicability in the future.
Clinical trials with these methods are not far away [98-110].

Although this field of research may represent the future of bladder reconstructive surgery, currently only few experimental studies are available and it may be some time before all this knowledge can be used clinically. We strongly encourage further research in this field.

**VII. BLADDER OUTLET SURGERY**

1. **URETHRAL ENHANCEMENT**

In those children where sphincteric incompetence is the only cause of incontinence or plays a mayor role in association with decreased bladder capacity or compliance, surgical procedures to enhance outlet resistance should be considered. In many cases bladder outlet surgery needs to be combined with other procedures aimed at creating a large low pressure storage reservoir.

2. **BULKING AGENTS**

The injection of bulking substances in the tissues around the urethra and bladder neck to increase outlet resistance in children dates back to at least 1985. However, concern about distant migration of the injected substance and risk of granuloma formation prevented this technique from gaining widespread acceptance [111,112].

The search for safer, biocompatible substances to create periurethral compression has first led to the use of cross-linked bovine collagen, with initially reported success in about 20-50% of children [113,114,115].

Collagen injection appeared to effectively improve urethral resistance, but this did not always translate into satisfactory dryness, besides, the effect of the injection is of short duration and repeated injections were often necessary [116,117]. Because of this collagen is no longer recommended for this indication.

At present the following substances are available and have been tested in children with incontinence: dextranomer / hyaluronic acid copolymer (a nontoxic, nonimmunogenic, non-migrant synthetic substance) and polydimethylsiloxane.

Usually the substance is injected endoscopically in the bladder neck area (finding the best spot is often the most difficult part of the procedure): more than one procedure may be necessary. On average 2.8 – 3.9 ml is injected. More than 50% of patients need more than one injection. Initial results of 75% success have been reported, but after 7 years there is a gradual decrease and only 40% remained dry [118,119,120].

Others have reported success rates of 0 - 70% [121-128].

Despite limited success it remains an option for all patients who are poor surgical candidates and those who want to avoid extensive BN reconstruction.

An alternate route may be the injection around the urethra using laparoscopy [129].

**3. ARTIFICIAL URINARY SPHINCTION**

Since its introduction in 1973 the AUS has undergone major transformations over the years. Different devices are currently in use: one of the most frequently used devices is the AS800-T that has been in use for almost 20 years [130]. It consists of an inflatable cuff, a pressure regulating balloon and a unit containing a pump and control mechanisms. The inflatable cuff can only be implanted around the bladder neck in females and pre-pubertal males. In post-pubertal males the bulbar urethral placement is possible but not recommended for wheelchair patients or those who perform intermittent catheterization [131]. In patients who have had extensive urethral surgery (exstrophy and epispadias) it may also not be technically feasible.

Implantation of an AUS requires special training and difficulties may be encountered in the dissection of the space around the bladder neck in obese, post-pubertal males or in patients with a history of previous bladder neck procedures. A 61-70 cm H2O pressure balloon is used exclusively when the cuff is around the bladder neck and a lower pressure balloon when it is around the bulbar urethra. Although high in cost, the artificial sphincter remains the most effective means of increasing urethral resistance and preserving the potential for voiding.

The ideal candidate for AUS implantation is a patient with pure sphincteric incompetence who voids spontaneously and has good bladder capacity and compliance. Unfortunately only a small proportion of children with sphincteric incontinence meet the criteria. The AUS may also be used in patients dependent on clean intermittent catheterization. The compatibility of the AUS with intermittent catheterization and enterocystoplasty is well documented [132,133,134].

The ability to empty the bladder spontaneously or by Valsalva maneuver may be preserved after AUS implantation. In series reporting children with AUS, the majority having neurogenic incontinence, 25% void spontaneously [135]. When the AUS is implanted before puberty, the ability to void spontaneously may be lost after puberty.
Overall, 40 to 50% of neurogenic patients require a bladder augmentation concomitantly or subsequently to the AUS implantation [133,136,137,138].

The continence rate ranges from 63 to 97% [139-146].

Herndon et al reported a success rate of 86% (of 134 patients): 22% voided, 11% had to perform CIC after voiding, 48% only performed CIC through the urethra, 16% performed CIC through a continent channel and 3% used diversion [147]. Mechanical problems occurred in 30% of patients who had an 800 model implanted (versus 64% in the old model). Revisions (in 16%) were significantly less in the 800 model. Erosion occurred in both groups (16%). A major complication was perforation of the augmented bladder in this group (it occurred in 10 patients). In 28% a secondary bladder augmentation was necessary.

Another interesting aspect of the AUS is that in some children the device is either deactivated or no longer functions but they remain dry: others have reported that placing a cuff only without activation is all that is required to make them dry [148].

The complications most commonly encountered in patients with AUS are mechanical failures. The longevity of the present devices is expected to exceed 10 years, although Spiess et al reported a mean lifetime of only 4.7 years [149].

The second most common problem is the development of reduced bladder compliance with time. This may result from an error in the preoperative evaluation or the reaction of the detrusor to obstruction (a reaction noted in some patients with spina bifida). These changes can be seen after many years of follow-up. The results of decreased capacity and compliance may be incontinence, upper tract deterioration, or the development of vesicoureteral reflux. Therefore long term follow-up with ultrasound, renal scintigraphy and if indicated urodynamics is mandatory in all patients with an AUS.

Infection of the prosthesis should occur in no more than 15% of all cases. Erosions of the tissues in contact with the prosthesis are rather infrequent. Bladder neck erosions are practically non-existent when the sphincter is implanted around a "virgin" bladder neck. When the AUS is used as a salvage procedure following bladder neck reconstruction, the erosion rate may be as high as 30% [137]. Despite the high complication and revision rate, AUS results show that acceptable continence rates can be achieved in the long-term. For this reason AUS implantation may be better considered as the initial treatment in selected cases [150].

4. FASCIAL SLINGS

Fascial slings constructed with the fascia of the anterior rectus muscle have been used to increase outlet resistance in incontinent children, particularly those with neurogenic dysfunction since 1982 [151]. The sling is used to elevate and compress the bladder neck and proximal urethra. The dissection around the urethra may be facilitated by a combined vaginal and abdominal approach, however, this option is limited to post-pubertal females [152].

Several technical variations of the sling have been reported. The fascial strip may be a graft or a flap based on the rectus sheath on one side. The fascial strip can be crossed anteriorly or wrapped around the bladder neck to enhance urethral compression.

Although the short-term success rate reported by most authors is encouraging, there are no series reporting detailed results at 5 years [153-154]. Most authors report a greater success when fascial slings are used in conjunction with bladder augmentation and success seems more likely in females than in males [155-158]. In patients with neurogenic incontinence postoperative CIC is recommended.

The pubovaginal sling in girls may also be placed through the vagina: in 24 girls with spina bifida this procedure was successful in 19, while another 3 became dry following additional injections with bulking agent around the bladder neck via a suprapubic needle introduction. CIC was possible in all patients. One patient developed a vesicovaginal fistula [159].

Complications of sling procedures include difficulties with intermittent transurethral catheterization, erosion of the urethra and persistent incontinence. Overall, the increase in outlet resistance provided by slings seems less than that provided by the artificial sphincter. Experience with these procedures suggests an overall success between 50 and 80% in females.

Numerous alternatives are being used nowadays: small intestinal submucosa has been used in 20 children and showed equivalent rates of continence. The advantage being that it is available off-the-shelf. Results were better in girls than in boys (85 vs 43% being dry) [160,161,162].

When combining bladder augmentation with a Gore-tex sling in 19 children the results were bad: because of erosion the sling had to be removed in 14 patients, all except one also had a bladder stone. In this respect this type of sling should not be used [163].

From the data published it presently seems that the AUS provides more consistent results in boys and for girls capable of spontaneous voiding who have not had previous bladder neck surgery. Bladder neck slings may be used for the enhancement of bladder outlet resistance in the
majority of patients with neurogenic bladder who need augmentation cystoplasty and whom we do not expect will be capable of voiding spontaneously. Sling procedures are probably equally effective for girls dependant on intermittent catheterization and in conjunction with bladder augmentation. At present, given the cost and lack of effectiveness of injection procedures, their use does not appear justified in incontinent children. The cost of the AUS may restrict its use.

Level of evidence 2.
Grade of recommendation B

It is important that one should be aware of the fact that these patients who undergo bladder outlet surgery need long-term follow-up not only because of the complications but also because their bladder behavior may undergo unexpected clinically asymptomatic changes that could negatively affect their upper tracts if augmentation is not performed at the same time[164].

5. BLADDER NECK CLOSURE

In ‘desperate’ cases the bladder neck may be closed, the indication being persistent leakage despite several attempts to enhance outlet resistance by bulking agents or other surgical procedures. Although initial results are acceptable, long-term results are usually disappointing; persistent urinary leakage, stomal stenosis and leakage or stone formation (in up to 40%) [165,166]. One of the most important factors seems to be compliance with intermittent catheterization and bladder irrigation.

6. BLADDER OUTLET RECONSTRUCTION

Surgical procedures to achieve urinary continence are dictated by functional and anatomic deficiencies and by the ultimate goal of either continence (with normal voiding) or dryness (dependent on intermittent catheterization).

Construction of a functional urethra for continence usually implies an anatomic defect without a neurogenic component (epispadias / exstrophy) and includes urethral and bladder neck narrowing and urethral lengthening [167-172].

Such procedures may initially require intermittent catheterization or occasional post voiding catheterization, but bladder emptying by voiding is anticipated.

Urethral reconstruction for dryness, however, mandates intermittent catheterization. The goal in surgery to achieve dryness is to create a urethra suited to catheterization, which has closure such that intra-luminal pressures always exceed intra-vesical pressure. The most dependable procedures for dryness utilize a flap valve or tunnel to achieve urethral closure, although urethral slings, wraps and injections have also been used [173].

Level of evidence 3.
Grade of recommendation C

Reconstruction to achieve continence is based on the principle that proximal reduction of the caliber of the urethra supports the inherent proximal sphincteric mechanism of the bladder neck and proximal urethra. The narrowing must be dynamic to permit closure for continence and yet permit opening with funneling during voiding. Several techniques have been described to achieve this goal [3, 166-176]. Young [1922] performed a “double sphincter technique” that involved the excision of a wedge of tissue at the anterior bladder neck, as well as removal of a wedge of tissue just proximal to the epispadiac meatus (external sphincter). Dees [1949] added the concept of lengthening the urethral tube to that of narrowing. In his procedure parallel incisions were made through the existing bladder neck area which created a posterior urethral plate from what had previously been the trigone of the bladder. This is tubularized to give added length to the proximal urethra. The added length provides increased potential for urethral closure and moves the bladder neck and proximal urethra into the abdominal cavity. Leadbetter [1964] modified the Young-Dees procedure by creating muscular flaps from the area of the bladder neck and proximal urethra which were used to wrap the newly created proximal tube. This procedure was popularized by Jeffs [1983] who applied it to a staged repair of exstrophy. He supported a lengthened urethra by a suspension. They report their long term continence rate with this procedure as greater than 80%, without the need for CIC or augmentation [177].

Presently, this represents the gold standard for reconstruction for continence, however, modifications of the technique have reported similar or improved results. Most urethral lengthening procedures utilizing the posterior urethra and bladder neck require ureteral reimplantation and preservation of the posterior urethral plate. Because part of the bladder is used to create the functional lengthening of the urethra, bladder capacity decreases following the procedure. It also remains to be seen whether the created urethra is actually a functioning urethra: in many patients fibrosis around the urethra prevent it from being really ‘functional’: in these patients it may act as an anatomic obstruction and long-term follow-up is necessary to follow not only the bladder but also the upper tract.

Surgery for dryness is dependent on the effectiveness of intermittent catheterization and is usually reserved for patients with neurogenic dysfunction or multiple previous surgeries. Procedures to
Achieve dryness usually create a urethral closure pressure that exceeds bladder pressure.

A flap valve can be constructed by using an anterior or posterior bladder flap (full thickness) to construct a tube that is placed in a submucosal tunnel [171,175,176].

The major disadvantage of these procedures (flap valves) is that the valve will not allow leakage with high intravesical pressures, potentiating renal damage. Therefore, these procedures can be dangerous to the patient who is not totally committed to follow catheterization recommendations.

Unfortunately, the ideal procedure for surgical reconstruction of the bladder neck does not exist. The surgical approach to urinary incontinence in the child must be multifaceted because of the inherent complex and varied nature of the problem.

Recent data would support the concept that very early reconstruction in the exstrophy/epispadias group may result in physiologic bladder cycling which facilitates normal bladder and urethral development. This results in higher potential for continence without the need for bladder augmentation and bladder neck reconstruction (Level 3). More work and clinical experience in this area is strongly recommended. (Grade A)

7. ALTERNATIVE CONTINENCE CHANNELS

In the surgical treatment of incontinence in children every effort must be made to preserve the natural upper and lower urinary tract. The bladder is the best urinary reservoir, the urethra the best outlet and the urethral sphincters the best control mechanism. If the bladder is partly or wholly unusable it may be augmented or replaced by a variety of techniques.

Urethral failure may occur either because the sphincters are incompetent or because it is overactive and does not allow spontaneous voiding. It would be preferable for the former to be treated by one of the techniques described above and the latter by intermittent catheterization (CIC). If all of these fail, continent suprapubic diversion is indicated.

a) The Mitrofanoff principle.

Mitrofanoff’s name is given to the principle of burying a narrow tube within the wall of the bladder or urinary reservoir whose distal end is brought to the abdominal wall to form a catheterizable stoma suitable for intermittent catheterization [178]. The technique is simple and familiar to all urologists who are accustomed to re-implanting ureters. Several narrow tubes are available for the Mitrofanoff conduit [179,180]. In the original description, the appendix was used. However, even if the appendix is still present, it may be unusable in 31% of patients [181].

If no suitable tube is found, a good tube can be formed by tailoring ileum transversely so that only 2-3cm of ileum can be made into a 7-8 cm conduit. This modification was originally described by Yang in humans and by Monti in experimental animals[182,183]. It is increasingly used though great care must be taken in its construction to avoid an internal fistula [184].

The ureter may be used but there may be some difficulty in achieving sufficient calibre with a previously normal ureter. Earlier reports that the Fallopian tube could be used have not stood the test of time.

The Mitrofanoff system achieves reliable continence which is maintained in long term follow-up, for a high proportion of patients. Long-term follow-up data shows that in the original series of Paul Mitrofanoff of 23 patients after a mean follow-up of 20 years, 1 patient had died, but in the other 22 patients no metabolic changes were noted. The bladder neck was closed in 21 patients. Secondary bladder augmentation had to be performed in 8, while in 4 children a non-continent diversion was created. With time the need for additional surgery decreased and after 20 years 16 patients had a good and stable continent diversion [185].

The pressure generated within the lumen of the conduit is 2 to 3 times higher than that within the reservoir so that continence is preserved even when the intra abdominal pressure is raised by straining. Conversely, the pressure in the lumen of a Kock nipple is only slightly higher than that in the reservoir so that continence is less reliable[186,187].

The conduit may be buried either between the mucosal and muscle layers of the reservoir, or may be completely imbrocated in the full thickness of the reservoir wall. Any well supported tunnel of about 2-4 cm will suffice. The choice depends both on the nature of the reservoir and on the conduit [188].

Continence rates of 90-100% with the Mitrofanoff Principle are reported, regardless of diagnosis, reservoir or conduit type [188,189]. Follow-up for at least ten years has shown that the system is resilient [190,191,192].

A modified technique of vesicostomy is described using a gastrostomy button, which could be used as a continent urinary stoma in children with incomplete voiding. Button vesicostomy is a useful addition to the options available for a catheterizable continent urinary stoma in children in the short or medium term [193].

Although perfect continence seems attractive, it may not be in the child’s best interests. A ‘pop-off’ valve may be in the interest of the child if catheterization is impossible or forgotten.
b) The Ileo--cecal valve.

The ileo-cecal valve is an obvious sphincter to combine with cecum and ascending colon as the reservoir and the terminal ileum as the conduit. The early continence rate of 94% was not sustained because of high pressures in the tubular reservoir and weakness of the valve [194,195,196].

The Indiana system is based on the competence of the ileo-caecal valve but with a detubularized reservoir [197]. The valve itself is reinforced with non-absorbable plicating sutures and the terminal ileum which forms the conduit is tailored. The best reported continence rate is 96% with a 2% rate of catheterization difficulties.

In the complete Mainz I pouch a length of terminal ileum is intussuscepted through the ileo-cecal valve as a Kock nipple [198]. It is impossible to say whether the nipple or the ileocecal valve (or both) produce the continence which is reported in 96% of patients.

Both these systems work well as complete reconstructions and are widely used as bladder replacements in children. The sacrifice of the ileo-cecal valve may cause gastro-intestinal complications.

c) Kock pouch

The first workable continent diversion was the Kock pouch [42]. The reservoir is made from 40cm ileum reconfigured to reduce the intrinsic pressure. The continence mechanism is formed by intussusception of 12cm of ileum. In a complete form it requires 72cm of ileum which may be more than can be spared from the gastro-intestinal tract.

Although first described as a mechanism for a continent ileostomy in children the Kock pouch is now not commonly used in children because of the problem with large amount of bowel needed, stone formation and mediocre success with dryness of the catheterizable stoma [199,200].

d) Artificial Sphincter

As a last resort, the AUS may be considered to give continence to a reconstructed outlet. Experimental evidence suggests that AUS cuffs can be placed safely around intestine providing the cuff pressure is low [201]. The AUS has been used successfully around large bowel, in three of four children with follow-up to 11 years [202].

e) Where to place the cutaneous stoma

In patients with spina bifida, particularly non-walkers, the site must be chosen with particular care. The natural tendency is for the spine to collapse with time so that the lower half of the abdomen becomes more pendulous and beyond the range of vision. A low site may seem appropriate in the child, but will become unusable in the adult. It is best to use a high, midline site, preferably hidden in the umbilicus. The site should be determined in a sitting position and marked before surgery because in the supine position the position will change dramatically. In some patients the best position may not be in the midline at all: special care must be taken that the patient can manage bladder emptying and irrigation himself/herself.

For most other patients, the site of the stoma should be chosen by cosmetic criteria. The umbilicus can be made into a very discrete stoma; the risk of stenosis is low and it is a readily identifiable landmark. Otherwise, the stoma should be as low on the abdominal wall as possible and certainly below the top of the underpants. However, many surgeons find the best results by placing the catheterizable stoma in the umbilicus.

The problem of stomal stenosis remains ever present. It can occur at any time so that only follow up of many years could determine whether any system of anastomosis to the skin is better than any other. The published rate of stomal stenosis is between 10 and 20%. The multi-flap V.Q.Z. stoma is claimed to have the lowest rate but follow up is short and it may well not pass the test of time [203].
The principal complications arise because the reservoir is usually made from intestine. Ideally, urothelium should be used and preservation of the bladder epithelium gives fewer complications than enterocystoplasty [207].

Combinations of detrusor myomectomy and augmentation with de-mucosalised colon have given promising results in the short term. The surgery is difficult as the bladder epithelium must not be damaged and the intestinal mucosa must be removed completely. When achieved there are no metabolic problems and many patients can void [207].

When augmentation can be done with a dilated ureter, the results are good and the complication rate low even in children with compromised renal function or transplantation [208].

All intestinal reservoirs produce mucus. The amount is difficult to measure and most estimates are subjective. No regime has been shown to dependably reduce mucus production [209].

2. RESERVOIR RUPTURE

The incidence of spontaneous rupture varies between different units. There may be delay in diagnosis although the history of sudden abdominal pain and diminished or absent urine drainage should make it obvious. The patient rapidly becomes very ill with symptoms of generalized peritonitis [210,211]. A ‘pouchogram’ may not be sensitive enough to demonstrate a leak. Diagnosis is best made by history, physical examination, ultrasonography and a CT cystogram. If diagnosed early, catheterization and broad spectrum antibiotics may sometimes lead to recovery. If the patient fails to respond within 12 hours on this regime or if the patient is ill, laparotomy should be performed at once. If there is any instability of the patient laparotomy should be considered as an immediate necessity as bladder rupture in this clinical situation can be lethal.

Level of evidence 2.

Grade of recommendation A

Figures are not available on the incidence of this complication in reservoirs made only of bowel but come from patients with intestinal segments in the urinary tract. Most papers report small numbers. In a multicentre review from Scandinavia an incidence of 1.5% was noted. There were eight patients with neurogenic bladder which was said to be disproportionately high [210]. In a series of 264 children with any sort of bowel reservoir or enterocystoplasty, 23 perforations occurred in 18 patients with one death [211]. Therefore, as this complication is more common in children it becomes a very important consideration [212].

A review of 500 bladder augmentation procedures performed during the preceding 25 years, spontaneous perforations occurred in 43 patients (8.6%), for a total of 54 events. The calculated risk was 0.0066 perforations per augmentation-year [213].

Patients and their families should be warned of this possible complication and advised to return to hospital at once for any symptoms of acute abdomen, especially if the reservoir stops draining its usual volume of urine. All young patients with urinary reconstructions including enterocystoplasty should carry suitable information to warn attending physicians of their urinary diversion in case of emergency.

3. METABOLIC COMPLICATIONS

Metabolic changes are common when urine is stored in intestinal reservoirs and must be carefully monitored. It is uncertain whether they are commoner in children or whether they just live longer and are more closely monitored.

Nurse et al found that all patients absorbed sodium and potassium from the reservoirs but the extent was variable [214]. A third of all patients (but 50% of those with an ileocecal reservoir) had hyperchloremia. All patients had abnormal blood gases, the majority having metabolic acidosis with respiratory compensation. The findings were unrelated to renal function or the time since the reservoir was constructed.

In 183 patients of all ages at St Peter’s Hospitals who had any form of enterocystoplasty, hyperchloremic acidosis was found in 25 (14%) and borderline hyperchloremic acidosis in an additional 40 (22%) patients. The incidence was lower in reservoirs with ileum as the only bowel segment compared to those containing some colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found [215].

In a series of 23 patients, Ditonno et al found that 52% of patients with a reservoir of right colon had hyperchloremic acidosis [216]. In ileal reservoirs, Poulsen et al found mild acidosis but no patients with bicarbonate results outside the reference range [217].

Many authors do not distinguish between patients with normal and abnormal renal function. All of 12 patients in one series with a pre-operative serum creatinine above 2.0mg% developed hyperchloraeic acidosis within 6 months of enterocystoplasty[218]. It is prudent to monitor patients for metabolic abnormalities, especially hyperchloremic acidosis, and to treat them when found [219].

With increasing experience, it has become clear that there is a risk of developing vitamin B12 defi-
ciency, sometimes after many years of follow up. It is likely that resection of ileum in children leads to an incomplete absorption defect. Stores of B12 may last for several years before the serum level becomes abnormal. At a mean follow up of six years, low levels of B12 have been found in 14% of children. There was a corresponding rise in the serum methyl malonic acid which is a metabolite that accumulates in B12 deficiency suggesting that the finding was clinically significant. Similarly, in adults, 18.7% have B12 deficiency at five years. In the adults the mean B12 level was significantly lower when the ileo caecal segment as opposed to ileum alone had been used (413 ng/ml compared to 257 ng/ml) [220,221]. In order to avoid the serious neurological complications, regular monitoring of B12 levels is essential.

In a review of 500 augmentations starting at 7 years postoperatively, 6 of 29 patients (21%) had low B12 values, while 12 of 29 (41%) had low normal values [222].

Pediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B12 deficiency. These patients are at the highest risk beginning at 7 years postoperatively, and the risk increases with time. An annual serum B12 value in children beginning at 5 years following bladder augmentation is recommended.

Level of evidence 2.
Grade of recommendation B

The stomach has had a checkered career as a urinary reservoir. Its non-absorptive role in the gastrointestinal tract has made it particularly useful in reconstruction of children with inadequate intestine, such as those with cloacal exstrophy. There is little effect on gastrointestinal function. Metabolically, the acid production leading to hypoclorhaemic alkalosis may be positively beneficial in children with renal failure. It produces no mucus and the acidic urine is less easily infected and seldom grows stones. However about a third of children have had serious long term complications, often multiple. The quite severe dysuria / haematuria and the skin complications from the acid urine, particularly, have limited its use [223,224].

4. EFFECTS ON THE GASTROINTESTINAL TRACT

Little attention has been paid to the effects on gastrointestinal motility of removing segments of ileum or cecum for urinary reconstruction in children. In adults, disturbance of intestinal function has been found to be more frequent and more debilitating than might be expected.

Disturbance of bowel habit does not mean diarrhoea alone. It also includes urgency, leakage and nocturnal bowel actions. It is clear that quality of life may be seriously undermined by changes in bowel habit [225].

It is known that the bowel has a considerable ability to adapt, especially in young animals, when parts are removed. Nonetheless, reconstruction should be undertaken with the smallest length of bowel possible. Particular care should be taken in children with neurologic abnormality in whom rectal control is already poor. Poorly controlled fecal incontinence may occur in a third of patients [226,227].

5. RENAL FUNCTION

Obstruction and high pressures in the bladder during storage have devastating effects on the upper urinary tract. Bladder augmentation eliminates these high pressures. Urinary diversion with recurrent urinary tract infections and stone formation also may have deleterious effects on renal function. It is therefore of utmost importance to evaluate renal function in young children who have undergone undiversion or continent diversion. In the follow-up so far available, these procedures do not seem to affect renal function. When function has improved after such surgery it is likely to be the result of eliminating obstruction or high bladder storage pressure.

In rats with near complete nephrectomy the rate of progression of renal failure is no worse in those with ileocystoplasty compared to those with normal bladder [228]. This suggests, experimentally, that storage of urine in small intestine is not, on its own, harmful to renal function.

Clinically, in the longer term, renal deterioration has been related to obstruction, reflux and stone formation. In one long-term study of Kock pouch patients, these complications occurred at the same rate as that found in patients with ileal conduits: 29% at five to 11 years [229]. Similarly, in a prospective follow-up to a minimum of 10 years, it was found that the deterioration in glomerular filtration rate (GFR), that was found in 10 of 53 patients, was due to a ‘surgical’ cause in all but one [230].

Although a more complicated procedure, a renal transplant can be anastomosed to an intestinal reservoir with similar long term results as those using an ileal conduit [231,232].

6. INFECTIONS AND STONES

The incidence of bladder reservoir stones varies between 12 and 25%. This is higher in children compared to adults. Palmer et al reported an incidence of 52.5% during a follow-up of four years[233]. Renal stones are uncommon, occurring in about 1.6% of patients, an incidence which would be expected in a group with congenital urinary tract anomalies.
In a series comparing the Kock pouch with the Indiana pouch (which does not have staples), 43.1% of 72 Kock reservoirs formed stones compared to 12.9% of 54 Indiana reservoirs [234]. Furthermore, no patient with an Indiana pouch formed a stone after 4 years, but patients with Kock pouches continued to do so at a steady rate up to eight years.

Apart from the presence of a foreign body, several factors have been blamed for the high stone risk. Almost all reservoir stones are triple phosphate on analysis, though Terai et al found carbonate apatite, urate and calcium oxalate in up to 50% of stones from patients with an Indiana pouch [235]. This suggests that infection rendering the urine alkaline is a key factor. Micro-organisms that produce urease and split urea to form ammonia are the main culprits. The incidence of infection in reservoirs is high, 95% in one series, and yet the majority of patients do not form stones, suggesting that there are predisposing factors other than infection and the anatomical abnormality of the urine reservoirs [236].

It has been suggested that the immobility associated with spina bifida may be responsible, but this seems to have been in series with a predominance of such patients and was not confirmed in other studies [237].

The production of excess mucus has also been blamed. The problem is that the measurement of mucus is difficult.

The finding of a spectrum of stone formation from mucus, through calcification to frank stone lends some support to this aetiology. However, it could be a secondary event, with mucus becoming adherent to a stone that has already formed. Many surgeons encourage patients to wash out their reservoirs vigorously with water two or three times a week. There seem to be fewer stones in those that claim to practice regular washing. In a prospective study a regime of weekly washouts did not improve the incidence of stones in 30 children compared to historical controls [238].

Mathoera et al found an incidence of 16% during a follow-up of 4.9 years in 90 patients: girls were more frequently affected than boys and concomitant bladder neck reconstruction, recurrent infections and difficulties with CIC were other risk factors identified, while the frequency of irrigation did not appear to be a risk factor [239].

Mucins are an important component of the epithelial barrier and protect the epithelium from mechanical and chemical erosion. Mucins are known to act as important adhesion molecules for bacteria. Mucins may also enhance the formation of crystals [240]. Mucin expression changes after incorporating the intestinal segment in the bladder. Upregulation of MUC1 and MUC4 expression occurs in transposed ileal segments resembling normal epithelium, whereas ileal segments in enterocystoplasty showed an upregulation of MUC2,3,4 and 5AC expression towards the site of anastomosis with the ileal segment. These changes which may be due to exposure to urine coincide with a change from ileal sialomucins to colonic sulfomucins by a change in glycosylation. The mucins bind calcium and may form a template resembling the crystal structure on which crystals are formed and grow. From these studies it is concluded that inhibition of bacterial adhesion (by using different irrigation fluids based on sugars) could be of eminent importance in the prevention of certain types of infection stones.

An interesting comparison has been made between children with a native bladder alone and those with an augmentation, all of whom were emptying by self catheterization. There was no significant difference in the incidence of stones with or without an augmentation [241].

Stones are associated with inadequate drainage in the sense that CIC through the urethra, the most dependent possible drainage, has the lowest stone rate. Patients with the most ‘up hill’ drainage, that is with a Mitrofanoff channel entering the upper part of an orthotopic reservoir have a higher incidence of stones [239].

Kronner et al made the observation, that the incidence of stones was statistically associated with abdominal wall stomas and a bladder outlet tightening procedure (21.1% compared to 6% in patients with augmentation alone) [236].

Once a bladder stone has been diagnosed it has to be removed: several methods are available, but ESWL should be avoided as it is difficult to remove all fragments (and small particles may get trapped in mucus and the pouch wall), which may form the focus of a new calculus. Because of the recurrent nature of these stones the least invasive method should be recommended [242,243].

Because of the high incidence of stones following enterocystoplasty several measures should be recommended to the patients and their parents. Regular CIC under hygienic circumstances with adequate fluid intake and irrigation seem to be the most important [244]. It is unclear whether prophylactic antibiotics are useful, but a clinical infection should be treated adequately. Maybe in the future different types of irrigation fluid may prove helpful.

7. GROWTH

The suggestion that enterocystoplasty delayed growth in height seems to have been ill founded. In a group of 60 children reported in 1992 it was stated that 20% had delayed growth [245]. Current follow up of the same group has shown that all have caught up and achieved their final predicted height. Furthermore, measurements in a group of
123 children from the same unit have shown no significant delay in linear growth [246].

Enterocystoplasty may have an effect on bone metabolism even if growth is not impaired. At least in rats with enterocystoplasty there is significant loss of bone mineral density especially in the cortical compartment where there is endostal resorption. These changes are not associated with HCA and are lessened by continuous antibiotic administration [247,248].

More recent follow-up data shows either no effect on growth or a decreased linear growth [249-252].

8. PREGNANCY

When reconstructing girls it is essential to have a future pregnancy in mind. The reservoir and pedicles should be fixed on one side to allow enlargement of the uterus on the other.

Pregnancy may be complicated and requires the joint care of obstetrician and urologist [253]. Particular problems include upper tract obstruction and changes in continence as the uterus enlarges.

Pregnancy with an orthotopic reconstruction appears to have a good outcome but chronic urinary infection is almost inevitable and occasionally an indwelling catheter is needed in the third trimester [254]. With a suprapubic diversion, catheter drainage for incontinence or retention may be needed in the third trimester [255].

Except in patients with an artificial urethral sphincter and extensive bladder outlet reconstruction, vaginal delivery is usual and caesarean section should generally be reserved for purely obstetric indications (distorted pelvis in spina bifida patients). During the delivery the bladder reservoir should be empty and an artificial sphincter deactivated. The urologist should be present during Caesarean section to ensure protection for the reservoir, the continent channel and its pedicles.

9. MALIGNANCY

The possibility of cancer occurring as a complication of enterocystoplasty is a constant source of worry. Currently cancer following augmentation cystoplasty is a recognized risk factor. It is known to be a frequent complication of ureterosigmoidostomy after 20 to 30 years of follow up. Animal evidence suggests that faecal and urinary streams must be mixed in bowel for neoplasia to occur. However, if it is chronic mixed bacterial infection, rather than the faeces per se, then all bowel urinary reservoirs are at risk.

In patients with colonic and ileal cystoplasties high levels of nitrosamines have been found in the urine of most patients examined [256]. Clinically significant levels probably only occur in chronically infected reservoirs [257]. Biopsies of the ileal and colonic segments showed changes similar to those that have been found in ileal and colonic conduits and in ureterosigmoidostomies. More severe histological changes and higher levels of nitrosamines correlated with heavy mixed bacterial growth on urine culture [258].

In a review by Filmer et al, 14 cases of pouch neoplasm were identified [259]. Special features could be found in nearly all the cases. Ten patients had been reconstructed for tuberculosis; four tumors were not adenocarcinomas; one patient had a pre-existing carcinoma; six patients were over 50 years old. Cancer was found in bowel reservoirs at a mean of 18 years from formation. This is a few years earlier than the mean time at which malignant neoplasms are seen in ureterosigmoidostomies.

In a review of 260 patients with a follow-up of more than 10 years, Soergel et al found 3 malignancies (all transitional cell carcinoma): 2 following ileocecal and 1 after cecal augmentation. The age at augmentation was 8, 20 and 24 years respectively: the tumors were found when they were 29, 37 and 44 years old. All had metastatic disease and died. The incidence of malignancy in this group was 1.2%; considering that the development of tumors usually takes 20-25 years the probable incidence of malignancy following enterocystoplasty may be as high as 3.8 % [260].

Hussmann et studied a group of 153 patients with a mean follow-up of 27 years (10-52 yrs) after augmentation cystoplasty. In those with a Neurogenic bladder (n=97) they found 2 patients with transitional cell carcinoma (both smokers), in 38 patients with bladder exstrophy 3 multifocal adenocarcinomas in the augmented segment were found and in 2 of 18 patients with urethral valves an adenocarcinoma was discovered. The overall risk of cancer was 4.5% after a median period of 32 years. Of the 7 patients 5 died suggesting that these tumors are very aggressive and metastasise early [261].

This was also confirmed by Sung [262].

Patients who undergo bladder augmentation with a gastric remnant are at increased risk for malignancy, probably similar to that in patients with enterocystoplasty. In a review of 119 patients underwent augmentation cystoplasty with stomach in 2 institutions, three patients had gastric adenocarcinoma, while the other had poorly differentiated transitional cell carcinoma. Each case progressed to malignancy more than 10 years after augmentation (263-265).

If cancer is going to be a common problem, there will be some difficulty in monitoring the patients at risk [266]. Endoscopy with a small instrument through a stoma may not be sufficient. Ultrasound may not be able to distinguish between tumors and folds of mucosa. Three dimensional reconstruction of computerised tomography may be helpful, though the equipment is expensive and not widely
available at present [267]. At present it is advised to perform an annual endoscopic evaluation in all patients following enterocystoplasty starting 10 years after surgery.

10. PSYCHOLOGICAL CONSEQUENCES AND QUALITY OF LIFE

The main justification for performing a bladder reconstruction or continent diversion is to improve the individual’s Quality of Life (QoL).

It would seem logical that continent urinary diversion would be better than a bag. This is not always the case. In adults the only sure advantage is cosmetic. Validated QoL surveys in children have not been reported, primarily because of the lack of suitable instruments [268]. Our prejudice is that reconstruction does, indeed, improve the lives of children. Supporting evidence is very thin and based on experience in adults.

The ileal conduit has been a standard part of urological surgery for over 50 years. It has well known complications but few would seriously suggest that they were more troublesome than those of the complex operations for bladder replacement. In an early investigation into quality of life issues, Boyd et al investigated 200 patients, half with an ileal conduit and half with a Kock pouch; there was little difference between the groups except that those with a Kock pouch engaged in more physical and sexual contact. The only patients that were consistently ‘happier’ were those who had had a conduit and subsequently were converted to a Kock pouch [269].

In a recent QoL survey in adults, a wide range of complications were considered to be acceptable, although an ordinary urological clinic would be full of patients trying to get rid of such symptoms: mild incontinence (50%), nocturia (37%), bladder stones (12%), urinary infections (9%), hydronephrosis (5%). Nonetheless, their QOL was judged to be good, primarily because 70% had experienced no adverse effect on their normal daily lives [270].

Quality of life does not mean absence of disease or a level of complications acceptable to the reviewing clinician. It is a difficult concept to measure because lack of validated instruments, difficulties in translating from one culture or language to another, and the difficulties in selecting control groups and variations in clinical situations. Gerharz et al have constructed their own 102 item instrument and compared 61 patients with a continent diversion and 131 with an ileal conduit. Patients with a continent diversion did better in all stoma related items indicating that containment of urine within the body and voluntary emptying is of major importance. In addition they had better physical strength, mental capacity, social competence and used their leisure time more actively. There was little difference in satisfaction with professional life, financial circumstances and in all interactions within the family including sexual activity [271].

IX. CONSENSUS STATEMENT ON SURGICAL TREATMENT OF URINARY INCONTINENCE IN CHILDREN

Forms of urinary incontinence in children are widely diverse, however, a detailed history and physical and voiding diary obviate the need for further studies. These should identify that limited group that may require surgery. Many patients in this group will have obvious severe congenital abnormalities.

Because of the spectrum of problems the specific treatment is usually dictated by the expertise and training of the treating physician. The rarity of many of these problems precludes the likelihood of any surgeon having expertise in all areas. Furthermore, nuances in surgical procedures develop gradually and often are tested without rigorous statistics.

Nevertheless it may be that newer forms of very early aggressive surgical approach to severe complex anomalies such as exstrophy, myelodysplasia and urethral valves may provide a successful model for significant impact on the ultimate continence in such patients. Ultimately this may provide a basis for randomized studies to determine the most specific and effective mode of therapy.

The committee would encourage vigorous research in the molecular basis of bladder development and also support the development of surgical and treatment strategies which would utilize the natural ability of the bladder to transform in the early months of development and immediately after birth. Furthermore efforts to promote bladder healing, and protecting and achieving normal bladder function should be supported. Such studies and research may lead to earlier and more aggressive treatment of many of the complex anomalies now treated by the surgical procedures outlined in this report.

Since the publication of the ICI report in 2009 [1], an increasing body of studies has been published on psychological factors of incontinence in children including some comprehensive reviews [2-7]. This part includes an update based on the recent literature and especially the ICCS standardisation document on psychological aspects in urinary and faecal incontinence [8].

I. INTRODUCTION

Children with urinary incontinence, enuresis and faecal incontinence carry a higher risk for manifest behavioural disorders, as well as for subclinical emotional and behavioural symptoms. It is important to assess and integrate psychological factors in treatment for two reasons:

1. As can be seen in table 3, the rate of comorbid behavioural and emotional disorders is much higher than possible organic causes [7,8]. The same care used to exclude organic causes should be applied to the assessment of behavioural aspects. Therefore, even paediatricians and urologists should have a basic understanding of psychological principles in order to treat their young patients adequately.

2. In functional elimination disorders, provision of information, cognitive therapy and behavioural modification are the most effective, first-line approaches to treatment. Medication can be helpful in many cases, but are usually not the mainstay of treatment. Surgery is rarely indicated. As most of the techniques used in “urotherapy” are based on cognitive-behavioural psychotherapy, it is essential to be acquainted with the basic psychological principles.

This chapter provides information on comorbid manifest clinical disorders, as well as symptoms which might be emotionally distressing for children and parents, but do fulfil the criteria for a disorder. Often, these will resolve upon attaining continence, while manifest disorders usually do not. In addition, children with psychological disorders are less compliant, and this explains why the failure rate of children’s incontinence treatment is much higher. It is recommended that both incontinence and any comorbid psychological disorder are treated separately to ensure effective therapy.

Also, the relevance of psychological factors for the different subtypes of incontinence will be considered. The terminology of the ICCS for enuresis and urinary incontinence as well as of the Rome-III classification for faecal incontinence will be used [9,10].

II. CLINICAL BEHAVIOURAL DISORDERS

The rate of clinically relevant behavioural disorders in children and adolescents lies between 12.0% (ICD-10 criteria) and 14.3% (DSM-IV) [11-13]. The rate of comorbid behavioural disorders is increased in children with all types of incontinence. Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The focus on comorbidity allows a descriptive approach without making reference to possible causal associations. Basically, four combinations are possible:

- A behavioural disorder can be a consequence of the wetting problem,
- A behavioural disorder can precede and induce a relapse when a genetic disposition for enuresis is present, for example in secondary nocturnal enuresis,

• Wetting and a behavioural disorder can both be due to a common neurobiological dysfunction (such as in nocturnal enuresis and ADHD).

• With such common disorders, no causal relationship can be present and the two may co-exist by chance.

Psychological disorders (synonyms: psychiatric, psychic, mental disturbances) indicate that there is “a clinically significant behavioural or psychological syndrome or pattern (not a variant of normal behaviour) that occurs in an individual, that it is associated with present distress, disability or impairment and carries a risk for the future development of the individual" (DSM-IV)[12].

Clinically relevant disorders can be assessed by two basic methods: the categorical and the dimensional approach. The categorical method is based on a detailed diagnostic process (including: history, observation, exploration, mental state examination, questionnaires, testing, physical examination and other procedures) and are professional diagnoses according to standardised classification schemes: ICD-10 [11] or DSM-IV [12]. Dimensional assessment is based on symptom scores by questionnaires, but do not represent diagnoses. Cut-offs are defined to delineate a clinical (and sub-clinical) range.

One can differentiate:

- externalising or behavioural disorders with outwardly-directed, visible behaviour (examples: conduct disorders and ADHD),

- internalising, i.e. inwardly-directed, intrapsychic disorders such as emotional disorders (examples: separation anxiety, social anxiety, phobias, sibling rivalry and depressive disorders),

- and other disorders that do not fit into the two categories, such as anorexia nervosa, tic disorders and autistic syndromes.

III. CLINICAL BEHAVIORAL DISORDERS IN CHILDREN WITH ENURESIS AND URINARY INCONTINENCE

Children with urinary incontinence show a higher rate of comorbid behavioural and emotional problems than non-wetting children, in both epidemiological and in clinical studies. The overall relative risk is 1.4 – 4.5 times higher (table 2) [7].

1. EPIDEMIOLOGICAL STUDIES

Epidemiological studies have the advantage of revealing representative associations. They often cannot differentiate well between subgroups.

Not all epidemiological studies on enuresis actually assess behavioural problems in a standardised form [14]. Only those studies that clearly define the group of clinically deviant children are reported in table 4. If a control group is reported, the relative risk for a behavioural problem can be calculated; otherwise the normative data is used.

a) Nocturnal Enuresis

In the Isle-of-Wight study, 25%-28% of enuretics were seen by their parents to show problematic behaviour according to the Rutter Child Scale, 3-4 times more often than the controls [15]. Using the same instrument, the longitudinal Study from Christchurch (New Zealand) came to similar rates for the primary children with nocturnal enuresis, while the children with secondary nocturnal enuresis showed a much higher rate of 52% [16]. The same study assessed rates of DSM-III diagnoses at a later age, with marked differences between the primary and the secondary children with nocturnal enuresis [17].

In the Dutch study by Hirasing et al [19], 23% of children with enuresis scored in the clinical range of the CBCL total problem scale. In the cross-sectional Chinese study by Liu et al [18], a third of all wetting children were in the clinical range, 3.6-4.5 more often than controls. The US-Study by Byrd et al [13] used the 32-item-BPI (Behavior Problem Index), which is modelled after CBCL. The rates are lower than in the other studies, but included infrequent wetters, with as few as one wetting episode per year.

In a British population-based study of 8242 children at the age of 7½ years, children with enuresis were affected by: separation anxiety (8.0%), social anxiety (70%), specific phobia (14.1%), generalised anxiety (10.5%), depression (14.2%), ODD (8.8%), conduct disorders (8.5%) and ADHD (17.6%) [21,22].

In summary, the epidemiological studies show clearly that, depending on definitions and instruments used, 20-30% of all nocturnal enuretic children show clinically relevant behavioural problems, 2 to 4 times higher than non-wetting children.

Children with primary nocturnal enuresis were not different from controls in epidemiological studies [17]. Secondary nocturnal enuresis was preceded by a higher rate of weighted life-events [23] and was significantly associated with a higher rate of DSM-III psychiatric disorders, which can persist into adolescence [17]. By adolescence, the attainment of dryness after the age of 10 years increased the risk for behavioural problems, independently of the primary or secondary status [14].

The only epidemiological study addressing monosymptomatic nocturnal enuresis included 8242 children aged 7½ years [24]. Though not adhering to the ICCS criteria, children with monosymptomatic nocturnal enuresis showed fewer behavioural symptoms than those with daytime problems (i.e. the non-monosymptomatic forms), although the differences did not reach significance.

b) Urinary Incontinence (Daytime Wetting)

Daytime wetting has been neglected in epidemiological research. Only recently, the first study was published based on a cohort of 8213 children aged 7 ½ to 9 years [20]. Children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behaviour (10.9%) and conduct problems (11.8%). Externalising disorders predominate in daytime wetting children which, in turn, will interfere with treatment. In the same cohort, 10,000 children aged 4 to 9 years were analysed. Delayed development, difficult temperament and maternal depression / anxiety were associated with daytime wetting and soiling [25]. In another population-based study, 36.7% of children with urinary incontinence had ADHD symptoms, in comparison to 3.4% of dry children [22].

2. CLINICAL STUDIES

Clinical studies are limited by selection biases, but allow a much more detailed assessment of patients. Overall, children with nocturnal enuresis have lower rates of comorbid disorders (33.6%) than children with daytime wetting (52.6%) [26]. In another study, the rates were 29% and 46%, respectively [27]. Van Hoecke et al could also show that children with daytime wetting (or combined DW/NW) had significantly higher CBCL total problem scores than pure nocturnal enuretics or controls [28].

</table>

According to the ICCS terminology, four subgroups of nocturnal enuresis can be differentiated:

- primary monosymptomatic nocturnal enuresis
- primary non-monosymptomatic nocturnal enuresis
- secondary monosymptomatic nocturnal enuresis
- secondary non-monosymptomatic nocturnal enuresis

Regarding the subtypes of nocturnal enuresis, children with primary nocturnal enuresis showed behavioural problems less frequently (19.5%) than those with the secondary type (75.0%) [26]. The group with the lowest comorbidity – no higher than in the normative population – were those with monosymptomatic nocturnal enuresis (10.0%) without any daytime symptoms such as urgency, postponement or dysfunctional voiding. In a replication study, 29% of children with nocturnal enuresis had at least one ICD-10 diagnosis, 24% of those with monosymptomatic and 33% of those with non-monosymptomatic nocturnal enuresis [27].

Regarding the types of behavioural and emotional disorders, externalising disorders predominate [26]. The most specific comorbid disorders with enuresis identical to our own studies in a child psychiatric setting using the same instruments [26]. The rates of a selected group of treatment-resistant children with nocturnal enuresis undergoing Dry Bed Training were 2.2 times higher [31]. In the study of Van Hoecke et al [32], internalizing symptoms predominated in a mixed group of day and night wetting children with significantly higher scores for withdrawal, physical complaints, anxious / depressed, social problems and internalising behaviour scales compared to controls.
are ADHD (DSM-IV) or the Hyperkinetic Syndrome (ICD-10). In our own studies, the rates ranged from 9.3% (HKS) to 13.5% (HKS and ADHD) [26, 34]. ADHD is not associated with any specific type of nocturnal enuresis [33].

In a retrospective study of patients with ADHD, 20.9% wetted at night and 6.5% during the day. The odds-ratios were 2.7 and 4.5 times higher, respectively, which means that there is a nonspecific association of ADHD and both night and daytime wetting [35]. 25% of 140 children with ADHD were affected by nocturnal enuresis compared to 10.8% of 120 controls [36]. The highest comorbidity rates of 40% for ADHD and nocturnal enuresis were reported by Baeyens et al. [33], possibly due to selection bias: 15% had a combined, 22.5% an inattentive and only 2.5% a hyperactive type of ADHD. In a community based sample, the prevalence rate was much lower [37]. ADHD continued to be present in 72.5% of children in a two-year follow-up indicating a high stability [37]. Children with ADHD continued to wet at follow-up much more often (65%) than controls (37%) (Odds-ratio 3.17) [37]. At a 4-year follow-up, 64% still had ADHD: of these, 42% continued to wet at night (compared to 37% of the controls) [38].

In clinical practice, children with ADHD are more difficult to treat. In a retrospective study, 113 children with ADHD and nocturnal enuresis had a worse outcome on alarm treatment than controls (with nocturnal enuresis only): 43% (vs. 69%) were dry at 6 months and 19% (vs. 66%) at 12 months. There was no difference if they were treated with medication, which does not require active cooperation. Non-compliance was reported in 38% of children with ADHD, but only in 22% of the controls [39]. This means that children with both enuresis and ADHD require special attention – and both need to be treated separately.

b) Urinary Incontinence (Daytime Wetting)

Only a few studies have addressed the specific problems of children with daytime wetting. In a study of 418 children aged 5 – 17 years, day wetting children were described as being more stubborn, oppositional and secretive than nocturnal enuretic children[40]. In a subgroup of 58 children, those with and without urinary tract infections were compared: 11% of day wetting children with urinary tract infections had a CBCL total score in the clinical range, 35% of day wetting children without urinary tract infections and 16% of nocturnal wetters. This indicates that children with a higher risk for behavioural problems were day wetting children without urinary tract infections [40]. In another study, 90 girls with recurrent UTI's had significantly more behavioural abnormalities than controls [41], so the issue of behavioural problems in children with and without UTI's remains to be settled.

ADHD is a common problem among day wetting children, as well. Compared to controls, children with ADHD had more symptoms of incontinence, constipation, infrequent voiding and dysuria [42]. With ADHD, treatment outcome is worse. In a retrospective analysis, 68% of day wetting children with ADHD became dry compared to 91% of controls. Non-compliance was much higher for timed voiding [39].

Daytime wetting is a heterogeneous group of disorders. According to the ICCS terminology, following subgroups can be differentiated [9]:

- Over-active bladder including urgency incontinence
- Voiding postponement
- Underactive detrusor
- Dysfunctional voiding
- Obstructive voiding
- Stress urinary incontinence
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency

Only some of these subgroups have been studied regarding comorbid psychological disorders.

Children with urgency incontinence have previously been considered to have few behavioural problems [43]. 29% of children with urgency incontinence had an ICD-10 diagnosis and 14% had an internalizing disorder. 13.5% had a clinical total problem score in the CBCL, again mainly internalizing problems [44, 45]. The children are distressed by their wetting and family functioning is intact [45]. In a new study, 35% of children with urgency incontinence fulfilled the criteria for an ICD-10 diagnosis [27]. Children with urgency incontinence have lower rates of comorbid disorders than those with voiding postponement (36% vs. 59%), but higher than controls (9%) [46]. Children with urgency incontinence predominantly have emotional, introverted disorders, while the most typical disorder in voiding postponement is ODD [46]. Comorbid disorders are usually a consequence of wetting in urge incontinence, while ODD seems to be the underlying disorder in voiding postponement in many children. In summary, children with urgency incontinence have only a slightly increased rate of comorbid psychiatric disorders. If they are affected, emotional, introverted symptoms predominate.

Children with voiding postponement, on the other hand, fall into two groups: in some it represents an acquired habit, in others, it is associated with externalising psychological disorders, especially oppositional defiant disorder (ODD). In a systematic study of children with voiding postponement in a paediatric and child psychiatric setting, 53.8 % fulfilled the criteria for at least one ICD-10 diagnosis [44]. These were mainly externalizing disorders in a third of all children such as Oppositional Defiant Disorder (ODD). Also, 37.3% of children had a CBCL total score in the clinical range, again, with externalizing
symptoms predominating. In addition, family functioning was impaired [44,45]. In a new sample, 53% of children with voiding postponement had at least one ICD-10 diagnosis [27]. In summary, children with voiding postponement have highly increased psychiatric risks.

Systematic studies on comorbid behavioural problems in children with underactive bladder have not been performed, although by clinical impression the rate of associated problems is high. In the original article, the “lazy bladder syndrome” was described as an acquired habit; it has “developed from the habitual neglect of the patient to empty the bladder on getting the urge to micturate” [47].

Systematic investigations of psychological aspects of dysfunctional voiding are rare. Again, in some children it represents an acquired habit, in others severe psychological disturbances are present [48]. Dysfunctional voiding following severe sexual abuse and deprivation as well as other familial stressors such as migration has been described in case reports [49].

There have been no systematic investigations of children with giggle incontinence. From clinical experience, they are highly distressed by the symptom and try to avoid situations in which they might be forced to laugh. Social withdrawal, not going to parties and meeting with friends has been observed. It is not known if the rate of behavioural disorders is increased.

Regarding the other subtypes of urinary incontinence, not even anecdotal data is available.

IV. CLINICAL BEHAVIORAL DISORDERS IN CHILDREN WITH FAECAL INCONTINENCE

According to the Rome-III classification, two subtypes of faecal incontinence can be differentiated [11]:

- Functional constipation (with or without incontinence)
- Non-retentive faecal incontinence.

1. EPIDEMIOLOGICAL STUDIES

In the large ALSPAC study of 8242 children aged 7-8 years, children with faecal incontinence had significantly increased rates of separation anxiety, specific phobias, generalised anxiety, ADHD and ODD (table 6) [50]. In other words, soiling children show a completely heterogeneous pattern of both internalising and externalising disorders. Again, these will require assessment in the individual child, as they will interfere with treatment of the incontinence.

2. CLINICAL STUDIES

As many studies have used the Child Behaviour Check List (CBCL) [51], the results can be compared easily. As shown in table 4, 35% to 50% of all children with faecal incontinence had a total behavioural score in the clinical range in this parental questionnaire. Compared to the normative population (10%), 3.5 to 5 times more children with faecal incontinence have total behaviour scores in the clinical range. As all studies were conducted in a paediatric setting, this rate cannot be due to selection effects of mental health clinics. Children with behavioural maladjustment are less compliant than children without psychological disorders (71% vs. 38% non-compliant) – so if these behavioural problems are not addressed treatment will be less successful [52].

Children with faecal incontinence and constipation have the same rate of behavioural scores in the clinical range as children without constipation (39% vs. 44%, [52] and 37% vs. 39%, [53]). This means that the two major types of faecal incontinence cannot be differentiated according to the behavioural comorbidity. More importantly, regarding the aetiology, there is no evidence that one type (i.e. with constipation) has more somatic aetiology, while the other type (i.e. without constipation) has a more psychogenic aetiology. There is no specific psychopathology typical for faecal incontinence: all types of behavioural and emotional disorders can co-exist.

Internalising clinical behavioural scores (32%) were twice as common as externalizing ones (17%) in one study [58]. In others, single behavioural items, denoting oppositional behaviour and attentional problems predominate [53, 59]. Compared to controls, children with faecal incontinence rated significantly higher regarding anxious/depressed behaviour, attentional difficulties and disruptive behaviour on the CBCL subscales. For example, the rate of children with attentional problems in the clinical and borderline range was 6 - 7 times higher than in controls (20% vs. 3%; norms 5%) [60]. Again, the heterogeneity of behavioural symptoms is apparent.

Only few studies have assessed behavioural and emotional disorders according to standardized child psychiatric criteria. They also show a high general rate and heterogeneity of comorbid disorders. Thus, 34% of 41 children with faecal incontinence had an emotional disorder, 12% a conduct disorder and 10% a hyperkinetic syndrome according to ICD-criteria [61]. In another study of 85 highly selected child psychiatric inpatients with faecal incontinence, 83 % fulfilled the criteria for at least one ICD-10-diagnosis. 32% had a hyperkinetic syndrome, 21% an emotional disorder and 9% a conduct disorder [62]. Children with faecal incontinence and urinary incontinence have an even higher rate of behavioural and emotional disorders than children with wetting problems alone [63].

The co-occurrence of faecal incontinence and sexual abuse has been described by several authors [64]. In one study, 36% of abused boys had faecal incontinence [65], but other symptoms

</table>
can co-exist [66,67]. However, in a retrospective analysis of 466 children having experienced sexual abuse, 429 children with externalising disorders and 641 controls, the occurrence of faecal incontinence did not differ between groups (faecal incontinence in 10.3%, 10.5% and 2%, respectively) [68].

V. SUBCLINICAL SIGNS AND SYMPTOMS OF WETTING CHILDREN

Subclinical behavioural signs and symptoms are common, understandable, adequate reactions towards the wetting problem and not disorders. Many studies have addressed the impact of wetting on children.

1. IMPACT ON CHILDREN

Most children are distressed by enuresis. For example, 35% said that they felt unhappy, 25% even very unhappy about wetting at night in one study (40 children aged 5-15 years)[69]. In a Finnish population-based study, 156 day and night wetting children (from 3375 7-year olds) showed significant differences compared to 170 controls regarding following personality traits [70]: they were more fitful (vs. peaceful), more fearful (vs. courageous), more impatient (vs. calm), more anxious (vs. does not worry) and had more inferiority feelings (vs. feels equal). In a large population-based British study of 8209 children aged 9 years, 36.7% of children consider bed-wetting to be "really difficult" — ranking 8th behind other stressful life-events [71].

In a clinical study, 70.3% of day and night wetting children aged 5 to 11 years could clearly indicate that the wetting was of disadvantage [72]. The types of disadvantages or negative consequences were: social (I can't sleep at friends' house, friends can't stay over night – in 32.1%), affective (I feel sad, ashamed, annoyed – in 16.4%), of isolation (I feel like a baby, nobody is allowed to know about it, I feel different from other children – in 6.7%), of sensation (it feels unpleasant, cold, wet, itchy, nasty – in 32.1%) or referred to direct consequences (I have to take a shower, sleep in pampers, won't get a bicycle – in 17.6%). Only 4.9% reported any advantages of the wetting at all (I like the wet feeling, I get more attention from mother).

One construct of special importance is that of self-esteem. In one study, lower self-esteem in children with enuresis disappeared upon attaining dryness [73]. In another, global self-esteem was significantly lower in children with nocturnal enuresis than in controls [74] and in yet another, the self-esteem total score was higher among enuretics than norms [75]. Therefore, it was concluded that there is no clear evidence that bedwetting leads to lower self-esteem [76] – but there can be no doubt that self-esteem can improve upon attaining dryness [75]. Self-esteem increases even if treatment of enuresis is not successful [77], showing that care and “good doctoring” for children and parents is of great help – regardless of outcome. Recently, a focus has been on quality of life, which is reduced in children with urinary incontinence [78].

In a population-based study of 75 boys with faecal incontinence were compared to 73 matched controls [79]. Specifically, encopretic boys showed higher rates of food refusal, general negativism, strong anxiety reactions, lack of self-insurance, poor tolerance to stress, both inhibited and aggressive behaviour, a strong fixation to their mothers and difficulties in relationships. Also, children with faecal incontinence tended to feel less in control of positive life events and had a lower sense of self-esteem than children with other chronic conditions [80]. However, in a more recent study, self-esteem did not differ between children with faecal incontinence and controls on the Piers-Harris questionnaire [81]. Although some of these subclinical symptoms will diminish under successful treatment [57,58], it is not known which ones will persist and become chronic.

2. IMPACT ON PARENTS

Enuresis and urinary incontinence may be just as distressing for parents as for children. Generally, parents are very concerned about the welfare of their child. In a population based study, 17% worried a great deal and 46% some or a little [82]. In one study, the greatest maternal concerns were: emotional impact, social relationships, smell, extra washing and financial aspects [83]. Mothers of children with nocturnal enuresis had a reduced quality of life scores (bodily pain and emotional role) and more depressive symptoms [84].

Parents also believe that their child should be dry at a very early age, which can induce anxiety and stress: the mean anticipated age of dryness was 3.18 years in one study [85] and 2.75 years in another [86]. Also, many parents think that emotional factors are the cause of nocturnal enuresis and forget that they might be the effect of the wetting problem instead [85,86].

A minority of parents show an attitude that was described as “maternal intolerance” by Butler et al [83]. Convinced that their child is wetting on purpose, the risk for punishment is increased. The reported rates of punishment varied from 37% [89], 35.8% [85], 23% [86] to 5.6% [87]. In other cultures, punishment is even more common: 42% of Turkish children were spanked and 13% beaten [89]. Chinese parents show a high level of parenting stress associated with externalising behavioural problems or their child [90]. These parental attributions and experiences have to be taken into account in all treatment plans for enuresis, as they can decisively influence the outcome.
Parents of children with faecal incontinence are also stressed and worried the problem [91]. In one study, children with faecal incontinence had family environments with less expressiveness and poorer organisation than controls [81]. In another study of 104 families, nearly half (51%) had no unusual family problems; 23 had severe and widespread difficulties including sexual abuse; 11 families described moderate difficulties and 18 a single traumatic event [92]. In other words, the atmosphere was warm and supportive without major difficulties in at least half of the families.

VI. GENERAL PRINCIPLES

1. ASSESSMENT

a) Screening Questionnaires

Due to this high comorbidity of psychological symptoms as well as disturbances, every child should be screened as part of the routine assessment. The best screening instrument is still a good history and careful clinical observation, which requires some training and experience in addition to a screening questionnaire, such as the Child Behavior Check List (CBCL) [51], which contains 113 empirically derived behavioural items. These are checked on a three-point scale and are formulated in simple wording. From these items, eight specific syndrome scales and three general scales can be calculated.

Recently, even shorter screening instruments have been derived from the CBCL. Thus, Van Hoecke et al. [93] validated a short questionnaire consisting of 7 items for emotional problems, 3 for attention problems and 3 for hyperactivity/impulsivity. This is an extremely useful short questionnaire both for clinical and research uses.

In the recent ICCS document, a general screening for emotional and behavioural problems in all settings (paediatric, urologic, child psychiatric, etc.) with a validated and standardised parental behavioural questionnaire is recommended because of the high rate of comorbid disorders in 30-50% of children [8]. This can be done in two steps (short screening questionnaire such as the SSIPPE [93] first, long questionnaire next) or in one step (validated, long questionnaires such as the CBCL only). If many problem items are checked, a child psychological or psychiatric assessment should follow. If comorbid disorders are present, counselling or treatment, if necessary, is recommended (see figure 14).

Also, other useful questionnaires addressing specific aspects of enuresis have been developed [94]. These assess the subjective views and attributions of parents and children, such as parental intolerance. Another potentially useful questionnaire addresses aspects of everyday burden of enuresis on children and their families [95]. Other non-validated questionnaires for the assessment of children with all types of incontinence can be found in von Gontard and Neveus [9]. For children with faecal incontinence, the Virginia-Faecal incontinence-Constipation-Apperception Test (VECAT), a validated, picture-based questionnaire for children and parents was shown to be good at differentiating bowel-specific problems [96].

One construct of special interest in children with elimination disorders is that of self esteem. Well-known self-esteem questionnaires include the Piers-Harris Children’s self – concept scale [97] as well as others [98]. Another important construct is that of health related quality of life (HQOL). This is a complex construct that tries to assess health related wellbeing in different domains of daily life. Generic HQOL questionnaires allow comparison between children with different medical disorders [99]. These range from short screening to longer, more detailed questionnaires (such as the KINDL-questionnaire)[101]. Recently, the first specific quality of life questionnaire for children with wetting problems was developed by Bower et al. [102]. This has the advantage that the specific, elimination-related effects on daily life can be assessed. For children with faecal incontinence, a health-related quality of life questionnaire with good psychometric properties was described: the Defecation Disorder List (DDL) consists of 37 items and can be used in children with all types of faecal incontinence and/or constipation [103].

b) Child Psychiatric Assessment

A child psychiatric assessment is a professional procedure with the goal of to coming to a categori- cal decision: to see if a diagnosis, according to the standardised classification schemes (ICD-10 or DSM-IV) is present in the child or not.

The first step is a detailed developmental, behavioural and family history in much greater detail than provided in the outline in the appendix. The next step is to observe the child as well as the parent-child-interaction, followed by an active exploration of the child. The information gained from history, observation and exploration forms the basis of the mental state examination. This is a descriptive, phenomenological assessment of mental and behavioural signs and symptoms (for example: CASCAP-D)[104].

Questionnaires are always an essential part of child psychiatric assessment. They are a time-economical way to gather information from different informants. They can contribute towards but do not provide a diagnosis. Behavioural questionnaires can again be divided into general and specific questionnaires. The best known, most widely used general parental questionnaire is the Child Behavior Check List, which has been translated into many languages (CBCL/4-18)[51]. In the meantime, Achenbach and co-workers have pro-
duced a whole “family” of questionnaires for different age groups (infants, children – adolescents, young adults) and different informants (parents, teachers and for children themselves starting from age 11). In addition, other specific questionnaires address circumscribed areas such as depressive symptoms or ADHD problems.

An intelligence test is not routinely indicated in the assessment of children with elimination disorders, as the IQ is in the normal range for most children with wetting, as well as soiling problems. However, the rate of elimination disorders is clearly increased in children with general developmental disorders, including those with mental and physical handicap [105-107]. If a lower intelligence is suspected, one-dimensional tests (such as the CFT or CPM/SPM tests) or multidimensional tests such as the Kaufman or the Wechsler tests can be performed. If specific developmental disorders such as dyslexia or dyscalculia are suspected, specific tests for these circumscribed disorders are indicated. Disorders of speech or language (such as articulation, expressive and receptive speech disorders) require a detailed assessment by an audiologist and speech therapist.
Motor disorders can be assessed clinically by including soft neurological signs in the physical examination of children or by standardized tests such as the Zurich Motor Tests [108,109]. After the diagnostic process has been completed, the child's disorder is diagnosed according to standardized classification schemes. The two standard classification systems are the ICD-10 [11], which is widely used in Europe and in other parts of the world and the DSM-IV [12] employed in the United States.

In child psychiatry, a multi-axial classification is used. Six different axes denoting different domains are used, including:

1. Axis: clinical psychiatric diagnosis (such as anorexia nervosa, depressive episodes, etc.)
2. Axis: specific developmental disorders (such as dyslexia)
3. Axis: intelligence (such as dyslexia, speech and motor disorders)
4. Axis: somatic diagnosis (such as epilepsy and other paediatric diagnoses)
5. Axis: psychosocial risks occurring within the last six months (such as distorted intra-familial interaction, isolated family and other stressful life events)
6. Axis: the global severity of a disorder (ranging from mild incapacitation to disorders requiring constant supervision and guidance)

Only after the diagnostic process has been completed and discussed with parents and children, should therapeutic interventions be planned.

2. OF PSYCHOLOGICAL DISORDER

For most children with elimination disorders, a symptom-oriented approach is sufficient. If, however, another, co-occurring child psychiatric disorder is present, additional types of treatment will be necessary. In these cases, a differential indication for therapy is mandatory. The question is: which treatment is most effective for this child in this family at this moment?

For some disorders (such as ADHD), medication plays a major role. For most others, psycho-therapeutic interventions are the first-line treatment. There can be no doubt that psychotherapy in children is effective. In one of the best and largest meta-analysis of 150 studies, Weizs et al. [110] conclude that “psychotherapy with young people produces positive effects of respectable magnitude” (i.e. effect sizes in the medium to large range - 0.5 to 0.8). It has been estimated that over 500 different types of psychotherapies exist in the USA for children and adolescents alone [111]. Of those which have been evaluated, four basic schools of psychotherapy can be differentiated:

1. Depth psychology (or psycho-analysis), which addresses and works with unconscious aspects of the psyche;
2. Client-(or child-) centred-psychotherapy, which focuses on the current conscious experience of the child and the healing aspects of their therapeutic relationship;
3. Family therapy, which focuses on the interaction between family members but not the individual person;

Before initiating any psychotherapy, a differential indication for therapy as to be made. The first basic question should be: is treatment needed at all? In many cases counselling of parents and child is all that is required. In other cases, changes in the child's environment (such as changing school) or help from social services can be more useful than psychological treatment in the narrower sense.

The modality has to be considered. Although parents are nearly always included, the focus can be on an individual, group or family therapy. The intensity and duration have to be addressed: is a short focal therapy focussed on one specific problem needed, or a longer more general treatment? The age of the patient plays an important role: while older children and adolescents can be reached verbally, younger children require play or other non-verbal media in their therapy.

Psychotherapies can be combined with other methods, such as pharmacotherapy, but also by using speech, occupational, physiotherapy, music and other types of therapies – if indicated. The decision should no longer be based on personal inclinations. Instead, empirically based “practice parameters” or “guidelines” have been developed in many countries. These interventions are usually performed on an out-patient basis. Day clinic treatment can be indicated in more severe disorders, which require a more intense approach and management. Finally, in-patient child psychiatric treatment is indicated in severe disorders, in which a more intense type of treatment is possible.

3. UROTHERAPY

A major part of therapy of incontinence in children is non-pharmacological and non-surgical. The term urotherapy is used in some countries. It is an umbrella term which has been defined as a “type of training which makes use of cortical control of the bladder, teaching children to recognize and employ conscious command over their lower urinary tract. Its main ingredients are information about normal lower urinary tract function and the specific dysfunction in the child, instruction about what to
do about it and support and encouragement to go through with the training program” [112].

Although not a psychotherapy in a narrow sense, it employs many psycho-therapeutical techniques borrowed especially from counselling and cognitive-behavioural therapies. As these approaches have been shown to be most effective, basic principles and findings shall be outlined.

4. NON-SPECIFIC APPROACHES

The first step in any diagnostic and therapeutic process is to create a good relationship with both the child and the parent. One should enquire and talk about all relevant facts, signs and symptoms openly. It is also important to ask about the subjective meanings and connotations. Next, the provision of information is essential, because many facts are not known. It is often forgotten that not only parents but each child needs information, as well. This should be provided in words and concepts that a child understands and in a format that is attractive. Increasing motivation and alleviation of stress and guilt feelings are also part of all patient contacts.

5. COUNSELLING

Counselling is already part of the treatment process, which has been defined as the provision of assistance and guidance in resolving personal, social, or psychological difficulties. For many children, even with psychological disorders, counselling is, in fact, sufficient. Sometimes, it can be helpful to enhance the verbal counselling by other techniques. One simple technique is that of “demonstration”, e.g. actively showing how an alarm works. In “coaching”, parents and children take an even more active role, e.g. they set and activate an alarm themselves. They can be observed and corrected. Other techniques might include “modeling” and “role-playing”. The learning effect is much greater in these active forms of teaching than in solely verbal counselling.

6. COGNITIVE-BEHAVIOURAL THERAPY

Cognitive-behavioural therapy (CBT) is a subtype of psychotherapy that has shown to be effective for many disorders. Cognitive therapy focuses on irrational, dysfunctional conditions, thoughts and beliefs. Cognitive therapy encompasses a whole variety of techniques such as “self-monitoring” (observation and registration), “activity scheduling” (organisation of activities) and “labelling” (using positive suggestive statements). Behavioural therapy concentrates on observable behaviour, which it aims to modify with a variety of techniques. These include “classical conditioning” and “operant conditioning”, which basically means learning by success, which can be achieved by different strategies using positive or negative reinforcement.

7. BASELINE AND OBSERVATION

Baseline and observation are effective techniques used in cognitive-behavioural therapy. Children (and parents) are advised to observe a defined symptom. Different parameters such as frequency (how often it occurs), severity (how marked it is), symptomatology (in what form it occurs) and in which situation (associated factors) can be registered, e.g. in an observation chart. The mere observation and registration actually has a therapeutic effect and many symptoms actually diminish if they are simply observed.

In nocturnal enuresis, children are asked to fill out a calendar or chart depicting the wet and dry nights symbolically for two to four weeks [113,114]. These non-specific measures have been shown to be successful and are associated with fewer wet nights [3,115]. In one clinical trial, for example, 18% became dry after an 8-week baseline [116]. The authors of the recent Cochrane Review conclude that “simple methods could be tried as first line therapy before considering alarms or drugs, because these alternative treatments may be more demanding and may have adverse effects” [3,5].

In urgency incontinence, the cognitive aspects are stressed in treatment: children are asked to register feelings of urgency, refrain from using holding manoeuvres, to void and register the voiding (or any wetting) in a chart [117,118]. For children with voiding postponement, timed voiding 7 times a day and registration in a chart is recommended [118].

For all children with faecal incontinence, stool regulation is an essential part of treatment. Children are asked to sit on the toilet three times a day after meal-times in a relaxed mode for five to ten minutes [119]. This is documented in a chart and can be reinforced positively. In one study, 15 % of children were cured within six weeks by simple methods such as these [57]. If constipation is present and the large amount of faecal masses has accumulated, disimpaction has to be performed at the beginning of treatment. To avoid re-accumulation of faecal masses, maintenance therapy with oral laxatives, such as polyethylenglycol (PEG) is recommended for at least six, and up to twenty-four months [120]. The preferred oral laxatives are osmotic laxatives such as PEG. “These behaviour interventions when used together with laxative therapy may improve continence” according to a Cochrane review of 18 RCT’s and 1168 children [6] and other reviews [121].

8. BIOFEEDBACK

Biofeedback has been shown to be effective in some elimination disorders such as dysfunctional
voiding [122]. It is defined as a variety of techniques, by which physiological activity is registered, enhanced and presented to the patient in real time by visual and acoustical signals [122]. In faecal incontinence, biofeedback is no more effective than standard behavioural techniques in faecal incontinence both with [123] and without constipation [124] and is not recommended in a systematic Cochrane Review [6].

9. ALARM TREATMENT

Alarm treatment for nocturnal enuresis is also a type of cognitive behavioural therapy. It works by positive reinforcement, as well as aversive, negative experiences and has been shown to be highly effective and was introduced by Mowrer and Mowrer [125].

It is the most effective form of treatment of nocturnal enuresis with the best long-term results (grade I level of evidence according to reviews and meta-analyses). Houts et al. [126] compiled a systematic review and meta-analysis on 78 randomised studies on nocturnal enuresis. 62% were dry at the end of treatment and 47% at follow-up. The authors conclude that “urine alarm treatments should not only be considered the treatment of choice, but the evidence from this review suggests that cure rather than management is a realistic goal for the majority of children suffering from nocturnal enuresis”.

Lister-Sharp et al [115] provided a systematic review, including only RCT’s on nocturnal enuresis. The likelihood for 14 consecutive dry nights was 13.3 times higher than without treatment. The authors conclude that “in the long term, alarm treatment would appear to be the most clinically effective, and because the cost of drug therapy, also the most cost effective intervention”. Melton and McGrath’s [127] compiled a systematic review on 70 well-controlled outcome studies. With a dryness rate of 77.9%, alarm treatment is deemed clearly efficacious. A comprehensive narrative review was written by Moffat [128] concluding that “all the current evidence suggests that conditioning gives the best long-term outcomes for bed wetters”. Finally, a Cochrane review of 50 RCT’s involving 3257 children concluded: “Alarm interventions are an effective treatment for nocturnal enuresis. Alarms appear more effective than Desmopressin or tricyclics because around half of the children remain dry after alarm treatment stops” [2].

Therefore, when indicated, alarm has been endorsed as a first line treatment by multidisciplinary European [129], world-wide [130], German [114] and American child psychiatric guidelines [113], as well as various individual authors [131].

The effect of alarm treatment can be enhanced by adding additional behavioural components to the treatment. Programmes that include alarm in addition to other behavioural components showed following general effects: 72% of children became dry at the end of treatment, and 56% remained so at follow-up (meta-analysis)[126], so that combinations were considered as “probably effective” [127].

These specific programmes including alarm are all essentially cognitive-behavioural techniques. Arousal training is a simply and easily performed [132,133]. Children are instructed to turn off the alarm within three minutes, go to the toilet and reset the alarm. This goal is reinforced positively with two tokens. If the goal is not reached, one token has to be returned. The initial success rate (89 %) and the rate of dryness after 2 ½ years (92 %) were higher than with alarm treatment alone (73 % and 72 % respectively) [132].

Dry Bed Training is a complicated program starting with an intensive night and maintenance treatment and using positive, as well as negative reinforcers [134]. Despite high success rates reported in early studies [134], recent meta-analyses have shown that DBT is no more effective than alarm treatment alone [115]. The likelihood to attain 14 consecutive dry nights was 10 times higher than in controls without treatment – but not different from alarm treatment alone. Also, alarm is the most important component of DBT. DBT without alarm showed only a 2.5 times higher likelihood of attaining dryness than controls. The relapse rates were not improved by DBT compared to alarm treatment alone [115]. As it is a cumbersome treatment, it nowadays it is reserved for children and especially adolescents with therapy-resistant nocturnal enuresis, as it “may augment the effect of an alarm” and “might reduce the relapse rate” [3]. Thus, Hirasing et al. [30] could show that behavioural problems were reduced in children with persistent nocturnal enuresis treated with DBT.

Other programmes include the Full spectrum home treatment. This is a combination package including a written contract, full arousal, over-learning and bladder retention exercises [126]. 78.5% of children became dry in 2 studies [127], but the alarm exerts the main effect [3]. Over-learning is a relapse prevention programme: after attaining dryness, increasing fluids are given before sleep to stabilise the achieved effects [135]. The relapse rate could be reduced from 20-40% to 10% through this “provocation method”.

Finally, alarm treatment can be combined with pharmacotherapy, although the evidence for combination treatment is conflicting. The combination of desmopressin and alarm treatment has been reported in several studies [136-139]. The combination with anticholinergics plays an important part in clinical practice, but has not been investigated systematically.
This review summarised the most important psychological aspects in children with enuresis, urinary incontinence and faecal incontinence.

The rate of comorbid clinical behavioural disorders is increased. Children with urinary incontinence are more affected than those with nocturnal enuresis. Children with secondary and non-monosymptomatic nocturnal enuresis have especially high rates of comorbid psychological disorders. The most common single diagnosis is ADHD.

Children with daytime wetting have mainly externalising behavioural disorders. Children with urgency incontinence have a low comorbidity, those with voiding postponement are characterised by oppositional behaviour. Children with faecal incontinence have the highest rate of associated disorders – both internalising and externalising.

These disorders will not disappear upon attaining dryness. They have to be addressed, as they will interfere with the incontinence therapy due to low compliance.

Even if comorbid disorders are not present, children and parents are highly stressed by the incontinence. These subclinical symptoms will often recede upon successful treatment.

Questionnaires are useful as screening instruments in the assessment process. It is recommended that questionnaires are used as a general screening procedure for emotional and behavioural problems routinely in all settings [8]. If a psychological disorder is suspected, a full child psychiatric assessment and subsequent treatment is needed. The basic principles, including those of psychotherapy, are outlined. Psychotherapeutic techniques are used in urotherapy, especially cognitive-behavioural elements. Non-pharmacological and non-surgical techniques are most effective for most forms of incontinence based on systematic reviews. Therefore, it is important that psychological aspects are integrated into the treatment of children with incontinence problems.

This chapter deals with neurologic urinary and faecal incontinence; it draws on previous ICI reports, and complements information in other ICI chapters. In developing the content, literature searches were undertaken with the keywords; “neurologic”, “neurogenic”, “bladder”, “bowel”, “lower urinary tract”, “anorectal”, “incontinence “, “continence”, “urinary”, “faecal”, “paralysis”, “dysfunction”, “retention”, “constipation”. Searches for specific neurologic diseases (section E) were undertaken, looking into selected neurologic diseases of particular relevance to neurourology, comprising the more prevalent or more challenging in terms of incontinence diagnosis and treatment.

A. Introduction

Continence relates to reservoir functions of the bladder and rectum, and closure of their respective outlets by contraction of smooth muscle (bladder neck and internal bowel sphincter) and striated muscle urethral and anal sphincters. Expulsion requires relaxation of these latter structures, and contraction of the musculature of the respective reservoirs, to permit a physiological reflex evacuation of urine or faeces.

The lower urinary tract (LUT) and the lower bowel tract (LBT) are interrelated structures. Embryologically, bladder and rectum originate from the same basic structure, the cloaca [1]. Anatomically both viscera lie in close proximity to each other, and to the muscular structures of the pelvic floor. Both are innervated by autonomic and somatic nerves, (Table 1) and have similar principles of central control [2, 3]. The LBT differs from the bladder in having an enteric nervous system [4]. Interactions between the two organ systems are increasingly recognised, and their activity is co-ordinated. Voiding can occur without defecation [5], and the initiation of micturition often precedes that of defecation, even if both organs are considered equally full [6]. The filling status of the bladder influences sensation in the rectum and vice versa [7], and the potential for mutual influence in pathology is emerging [8]. Nonetheless, little information is available on co-ordination of both functions in patients with neurological pathology.

The evidence base

Neurogenic lower urinary tract dysfunction (NLUTD) is a term that applies to an extraordinarily diverse spectrum of clinical conditions. This heterogeneity can be appreciated by considering the different challenges faced by the infant born with myelomeningocele and the elderly patient with dementia-associated incontinence. Some order can be imposed by grouping conditions based on their cause and site of impact on the neuraxis (see Table 2) [9].

Historical data demonstrates that the management of NLUTD has made huge advances over the last century, largely based on a trial and error approach and the dissemination of expert opinion [10]. Improved outcomes for patients were the result of the development of a urodynamic-based understanding of pathophysiology, the introduction of effective treatments to allow safe and reliable urine storage and intermittent catheterisation, the advent of more effective antibiotics and the development of better catheters and appliances. However, the historical approach is accompanied by significant problems. Dangerous or ineffective treatments can be trialled out-with an appropriate ethical framework and successful therapies can be slow to be introduced because their proponents may not convince their peers of the merits of the new treatment.

There is an inherent risk when an area of clinical practice has not been accompanied by a culture of high quality scientific research, and where the data which is available is used uncritically. For example, there has long been concern that management of NLUTD by indwelling catheter drainage results in excessive morbidity and, at first glance, published data on complication rates between different bladder management systems would appear to confirm that catheters are damaging to upper urinary tract function. However, this is based on cross-sectional data; such studies do not effectively take into account the preceding bladder management methods, the inability to randomise to different management approaches, and that catheters are typically used as a last resort in patients who have already developed problems with their urinary tracts [11]. Prospective longitudinal evaluation accounting for
The antecedent bladder management actually indicates that indwelling catheterisation is protective for the upper urinary tract [12].

The extensive evidence base concerning NLUTD is clearly demonstrated by the content of this chapter, but much of the evidence is contained in reports of studies which fail to meet contemporary standards for high quality evidence. How then should the clinical community respond to the challenge of improving the scientific foundations of our care for patients with NLUTD?

There are many aspects of modern management of NLUTD which will never be tested in definitive clinical trials because they appear to be of self-evident value. As a result, no trial could be conducted because the hypothesis that was to be tested would lack equipoise. For example, it would be impossible to conduct a trial that randomised spinal cord-injured patients between urodynamic-led and clinical-led treatment planning. However, that does not preclude the need to question these standard approaches. For example, such a study could be conducted in the context of multiple sclerosis where different approaches have been advocated [13, 14].

Despite the difficulties of conducting high quality trials in the field of NLUTD, there are an increasing number of studies that demonstrate the feasibility of such studies. Large, industry-sponsored studies have been conducted and are capable of providing near-definitive data on important clinical questions [15, 16]. However, even where high-quality data exists for some patient groups, there may be little or no data for others; spinal cord-injured and multiple sclerosis patients have been shown to respond to intra-detrusor injections of botulinum neurotoxin A but there is a dearth of data on patients with neurogenic detrusor overactivity (DO) due to intracranial conditions. Extrapolation from one condition to another is inevitably going to be needed but would be aided by even small, well-conceived trials that looked at patients with less common conditions.

There are a large number of interventions that have only been assessed by low quality methodologies, typically uncontrolled case-series. In some cases, such as that of the artificial urinary sphincter, there is sufficient data on which to base an evaluation, whereas other procedures still await a more complete assessment; the majority of alternative operations used to treat neurogenic stress incontinence fall in this category.

Finally, there is the question of how to evaluate new investigative and treatment techniques. Drug therapies are tightly controlled by regulatory authorities but

it is common for drugs to be extensively investigated in the non-neurogenic population but not in patients with NLUTD. It is to be hoped that tighter regulation and the demonstration that NLUTD trials are feasible will encourage drug evaluation in this patient group. For devices and surgical procedures, regulation is less tight and it is therefore for the clinical body to resist the premature introduction of techniques that lack an appropriate evidence base. There is a need for multi-centre cooperation in clinical trials that are designed to look, not only at short-term clinical efficacy, but also at long term results, complications and cost-effectiveness of new interventions.

I. SUPRAPONTINE LESIONS

Patients with lesions above the pons usually continue to have reflex contractions of the detrusor. However, they may lose one or more of the cerebral contributions to LUT and bowel function, such as volitional control over timing of emptying, inhibition of reservoir (bladder, rectum) contractility, conscious filling and emptying sensations and some integration functions with other organ systems. This is the case in brain lesions, such as stroke, head injury, etc., which mostly continue to have a normal synergic LUT function. However these patients may purposely increase sphincter activity during an overactive detrusor contraction [1] to prevent urinary incontinence which would otherwise occur. This has been termed “pseudo-dyssynergia” because it is difficult to distinguish from true detrusor sphincter dyssynergia (DSD) on a urodynamic record. Nonetheless, in suprapontine lesions, sphincter activity is synergic with the bladder. Urinary incontinence in suprapontine lesions is due to bladder overactivity [2], or due to disinhibition of the micturition reflex (enuresis).

II. PONTINE LESIONS

Isolated pontine lesions are rare and most often occur in the setting of a neoplasm or vascular event. Urinary retention was described in children with pontine tumours [3] and case histories have been described of patients with retention and focal pontine lesions [4-7]. Amongst patients with brainstem stroke, it was dorsally situated lesions that resulted in lower urinary tract dysfunction [8]. Proximity of the medial longitudinal fasciculus to the pontine micturition centre means that a disorder of eye movements, such as internuclear ophthalmoplegia, is highly likely in patients with pontine pathology causing voiding disorders [9].

III. SUPRASACRAL SPINAL CORD LESIONS

When a lesion is located below the pons in the spinal cord (or medulla oblongata), DSD is a common finding. Incontinence may still be caused by detrusor overactivity, but can be accompanied by retention due to the DSD. For lesions above T6 where the isolated spinal cord below the injury level remains viable, an additional feature can be autonomic dysreflexia. This is a severe, potentially life-threatening, rise in blood pressure precipitated by stimulation in the part of the body supplied by the autonomous distal spinal cord [10]. Clinically, it is characterised by headache, bрадycardia, hypertension, and altered cutaneous bloodflow (vasoconstriction in the skin below the level of SCI, vasodilation above).

A spinal cord lesion above the lumbosacral cord level eliminates voluntary and supraspinal control of micturition, leading to DO mediated by spinal reflex pathways. The reflex bladder function is thus very different from normal; (1) it involves different afferent fibres (experiments in cat indicate the relevant afferents are the C-fibres) [11], (2) bladder contractions are poorly sustained, (3) the urethra and bladder become dyssynergic, and (4) previously irrelevant stimuli influence the bladder and/or external sphincter activity. Voluntary inhibition of the micturition reflex is lost, though some consciousness of bladder sensation may be still present. Of the 269 patients with suprasacral spinal cord injuries investigated by Weld et al., 12.3 % had no dyssynergia, 7.4 % had intermittent and 80.3 % continuous DSD. There was no significant association between the specific level of lesion and the DSD type. Blaiwas found that 64.9% of patients with suprasacral lesions demonstrated detrusor overactivity and/or DSD, 41.8 % had low bladder compliance and 40 % had high detrusor leak point pressure. DSD causes a functional outflow obstruction; the clinical impact is impaired voiding, with elevated residual urine, sometimes also prolonged detrusor contractions, structural bladder damage and vesico-ureteric reflux. When combined with recurrent urinary tract infections, renal failure may result. This is more common with continuous than intermittent DSD. More than half of men develop urological complication.

After spinal cord injury, mechano-sensitive C-fibre afferents mediate the abnormal sacral segmental
bladder reflex. The mechanism of this change from chemo-sensitivity to mechano-sensitivity of C-fibres is unclear. In animal models, afferent neurons innervating the bladder increase in size, a change prevented by urinary diversion, perhaps mediated by nerve growth factor (NGF). There is also a change in excitability, mediated by a shift in expression of sodium channels from high threshold to low threshold sensitive channels.

IV. SACRAL (CONUS MEDULLARIS) LESIONS

The intermediolateral nucleus is the part of the spinal cord containing the nuclei of the autonomic nervous system (ANS). In the sacral spinal cord, the intermediolateral nucleus is parasympathetic, and damage to the nucleus renders the detrusor areflexic. Resulting retention of urine can cause incontinence (formerly termed overflow incontinence). Sensation can be impaired as well, affecting LUT filling sensations, and urethral sensation of urine flow during voiding. Constipation occurs due to loss of spinal-cord mediated, though the myenteric plexuses of the enteric nervous system can continue to generate segmental colonic peristalsis.

Onuf's nucleus, located medially in the ventral horn of the sacral spinal cord, is a mixed autonomic/somatic nucleus containing the motor nuclei for the external sphincters of the LUT and LBT. Damage to this structure affects sphincters (and some pelvic floor musculature), and thus stress incontinence may result. If the pudendal nerve is also impaired, there is an increased risk for incontinence. Loss of function of the puborectalis muscles leads to reduction of the rectal angle.

V. SUBSACRAL LESIONS (CAUDA EQUINA OR PERIPHERAL NERVES)

The same effects as seen with lesions of the conus medullaris can result from lesions of the subsacral nerves (the cauda equina, or the peripheral nerves-including the pudendal nerves). Both parasympathetic and somatic motor function will potentially be impaired; the detrusor can be underactive or flaccid and the external sphincter can be paralyzed. These lesions can also cause a variety of sensory deficits. Some pain sensation can be retained because of intact sympathetic hypogastric nerves [3], which enter the spinal cord in thoracic roots. The bladder neck normally can function independently of the external sphincter, for example closing the sphincter is open at the time of ejaculation in men, while the bladder neck should be closed. Since it is predominantly innervated by sympathetic pathways, it can retain some function in sacral injury. If there is extensive autonomic damage, the bladder neck remains open; this will lead to retrograde ejaculation if ejaculatory function is preserved.

C. Neurological urinary incontinence

NLUTD may be caused by a variety of neurological diseases and/or events affecting the various parts of the nervous systems controlling the LUT. The resultant dysfunction depends grossly on the location, extent, and nature of the causative neurological lesion or lesions. Overall prevalence estimates for NLUTD in the general population are scarce, but data are available on the prevalence of the underlying conditions and, in some cases, the relative risk for the development of NLUTD. It is important to realise that most of these data show a very wide range of prevalence figures, due to low level of evidence in most published data and smaller sample sizes.

A Pubmed search was conducted, using the publication range from 2008 until 2011 with search words—epidemiology, neurogenic bladder, neurologic incontinence, neurologic patients, and prevalence, as well as using the specific neurological conditions noted in the discussion below. In general, specific disease states were reported in retrospective analyses, with the prevalence of symptoms and/or abnormal physiological findings in those populations typically highlighted. Only rarely were multi-centre studies conducted and/or prospective analyses performed. Thus, in general, the cohorts studied are small, and the prevalence estimates are typically based on patients referred for the assessment of LUTS. Applying the prevalence estimates to an affected group of neurological patients (who may or may not have NLUTD) therefore may not always be appropriate due to the manner in which most of the data are reported, and due to the possible coexistence of other anatomical or functional abnormalities unrelated to the neurological lesion.

1. NEUROLOGICAL LESION BY DISEASE LOCATION

a) Diseases Affecting Brain/Brainstem

Brain tumours Brain tumours can cause NLUTD in up to 24% of the patients [1]. Case reports and small series note the development of urinary retention and other LUTS in patients with pontine glioma, metastatic oligodendroglia, as well as other lesions [2-5]. In a series of patients with brain tumours voiding difficulty was reported in 46/152 (30 %) of patients with tumours in the posterior fossa, while urinary incontinence occurred only in 3 (1.9 %), though urodynamic data are largely lacking.

Dementia One cannot easily distinguish LUTS caused by age-related changes of the bladder or other lower urinary tract pathology from that due
to dementia [6]. Therefore the true prevalence of LUTS caused by dementia is difficult to estimate. It has been shown that in geriatric patients with dementia, incontinence is much more frequent than in non-dementia patients [7-8]. Additionally, Lewy body dementia (LBD), Binswanger, Nasu-Hakola and Pick diseases have all been associated with NLUTD [9-13]. One recent study found that patients with LBD were much more likely to have urge incontinence (53%) compared to Parkinson’s disease (PD; 27%) and Alzheimer’s disease (AD; 12%). With the exception of detrusor overactivity, which was much higher in patients with LBD (92%), all other urodynamic parameters were similar between groups and similar to expected findings for this age group [14].

With regard to AD, the occurrence of incontinence is reported to be between 23% and 48% [15-16]. The onset of incontinence usually correlates with disease progression, and a male to female ratio of dementia-related incontinence was reported to be 1:15 [17].

**Mental Retardation Assessing** LUTS in the setting of mental retardation is often difficult due to significant cognitive impairment. A NLUTD prevalence of 12% -65% has been described, which has been shown to vary with the severity of mental retardation [18-19]. A recent case control study of children with mental retardation noted a much higher prevalence of voiding dysfunction (35.2%) when compared to age matched controls (8.3%), and similarly, a higher prevalence of incontinence [20]. Similarly, adults with severe intellectual disability due to mental retardation appear to be at greater risk for carrying a PVR > 150 ml than those with lesser disability [21].

**Cerebral Palsy** A study of 97 children (mean age 8) with cerebral palsy, who were not necessarily referred for urological evaluation, found a prevalence of NLUTD of 61% and incontinence of 44%. In other populations, LUTD has been reported in 30 – 40% of patients [22-24].

**Normal pressure hydrocephalus (NPH)** Case reports have indicated the presence of NLUTD in patients with NPH [25-27] A recent study of 42 patients with idiopathic NPH reported urinary symptoms in 93% of patients (storage symptoms more common than voiding), and detrusor overactivity was noted urodynamically in 95% [28].

**Basal Ganglia Pathology – Parkinson’s Disease (PD), Huntington, Shy-Drager, Multiple System Atrophy Parkinson’s disease** is accompanied by NLUTD in 37.9-70% [29-31]. Progressive neurological disability has been associated with greater voiding dysfunction in patients with PD [32]. While there is some disagreement as to whether NLUTD is independently associated with PD progression versus expected age-related pathology, consensus indicates a higher prevalence of symptoms and urodynamic disturbances in patients with PD. Control based studies noted a prevalence of LUTS of 27-63.9% using LUT symptom questionnaires [33-38].

NLUTD is extremely common in patients with Shy-Drager syndrome (one form of Multiple System Atrophy) [31] while incontinence is present in up to 73% [34]. LUTS appear to occur earlier in the course of MSA when compared to PD [39]. Indolent LUTS may arise in young men with PD, even with relatively minor neurological impairment [37]. Urethral dysfunction appears to be common in patients with MSA, with an open bladder neck at rest noted on VUDS, and external sphincter denervation.

**Cerebrovascular Accident (CVA)** CVA causes NLUTD in 20-50% of patients [40-41] with decreasing prevalence in the post-insult period [42]. Over half of patients report persistent LUTS at 3 months following a CVA [43] and, without proper treatment, symptoms such as incontinence remain in 20-30% at 6 months [44]. The most common urodynamic finding is detrusor overactivity, with sphincteric dysfunction relatively uncommon [45-50].

Location of the CVA may impact the likelihood of LUTD. Sakakibara et al. [51] reported the urinary symptoms of 39 patients who had brainstem strokes. Almost half the patients had urinary symptoms; nocturia and voiding difficulty were seen in 28%, urinary retention in 21% and urinary incontinence in 8%. The side of the stroke (dominant hemisphere, non-dominant, bilateral) does not appear to affect the likelihood of developing NLUTD [52].

**Traumatic Brain Injury** Traumatic brain injury can cause significant NLUTD. In a study of 57 patients, the majority [30] had symptoms of overactive bladder. Urodynamically, 49% were found to have DO, while 32% had detrusor underactivity. DO was found to be associated with the presence of right hemispheric damage, while impaired contractility was associated with left hemispheric damage [53].

**b) Diseases of the spinal cord**

Demyelinating lesions - multiple sclerosis (ms), transverse myelitis (tm) Multiple sclerosis causes NLUTD in 50-90% of the patients [54-57]. DO (mean 65%), DSD (35%), and detrusor underactivity (25%) are the most common urodynamic findings [58]. There is a very high likelihood of NLUTD when pyramidal dysfunction has been diagnosed neurologically (and progressive gait abnormalities noted on exam). With regard to symptoms, urgency, urgency incontinence, and impaired bladder emptying/voiding dysfunction are the most common reported. Though controversial, MS severity based on EDSS (extended disability symptom score) does appear to correlate with LUTS overall [59]. It is uncommon for LUTS to be the presenting symptom in MS (2-12% of the patients), though this may be as high as 34% depending on the method of symptom assessment [60]. Upper tract impairment is relatively uncommon in MS, perhaps ow-
Disc disease, such as prolapsed intervertebral disc, may cause NLUTD in 28-87% of the patients [71-72]. Importantly, data suggesting that NLUTD is clearly reversed following surgical intervention for disc disease is lacking, in most cases, with the exception of patients who develop cauda equina syndrome. Cauda equina due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [73-80]. In this instance, surgical intervention is frequently effective at restoring normal voiding and eliminating incontinence [81].

Disc Disease Disc disease, such as prolapsed intervertebral disc, may cause NLUTD in 28-87% of the patients [71-72]. Importantly, data suggesting that NLUTD is clearly reversed following surgical intervention for disc disease is lacking, in most cases, with the exception of patients who develop cauda equina syndrome. Cauda equina due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [73-80]. In this instance, surgical intervention is frequently effective at restoring normal voiding and eliminating incontinence [81].

Spinal Stenosis And Spine Surgery About 50 % of the patients seeking help for intractable leg pain due to spinal stenosis report LUTS, such as sense of incomplete bladder emptying, urinary hesitancy, incontinence, nocturia or urinary tract infections [82]. When evaluated urodynamically, nearly 75% of patients may be found to have LUTD, though this is often an older population with coexisting anatomical abnormalities that could contribute [83-85]. Surgical intervention for stenosis has been shown to improve certain urodynamic parameters (capacity, flow rate, residual volume) while not affecting others (detrusor pressure at maximum flow, compliance) [86].

Spinal surgery itself has been associated with the development of LUTD (most commonly retention) in 38%-60% of patients, depending on the complexity of the surgical intervention [87-88].

c) Peripheral nerve problems

Diabetes Diabetes mellitus has a prevalence of 1-6% in the United States, depending on the specific criteria utilized to identify the disease. Overall, up to 59% of diabetic patients will report urinary symptoms, while 75-100% of those with evidence of peripheral neuropathy will develop NLUTD [89,90]. The classic “diabetic cystopathy” (impaired bladder sensation, increased capacity, ultimately increased post void residual) has been estimated to occur in 43% to 87% of insulin-dependent diabetics, with no sex or age differences, [91], though typically, severely impaired bladder emptying is thought to occur in patients with more long-standing poorly controlled diabetes. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment [92]. More recent urodynamic studies have noted a spectrum of findings in DM; those presenting relatively late with severe LUTS have a higher likelihood of impaired bladder sensation, detrusor underactivity and impaired emptying, while those investigated earlier are more likely to have detrusor overactivity and urgency incontinence [93].

Alcohol Abuse Chronic alcohol use may cause peripheral neuropathy, though its reported prevalence varies from 5% to 64% [94]. No recent studies have confirmed a prevalence estimate of LUTD, though impaired sensation and emptying have been previously noted in patients with chronic alcohol use.

Herpes Virus Infections The incidence of LUT dysfunction is as high as 28 % if only patients with lumbosacral dermatome-involvement are considered. The overall prevalence of NLUTD may be as low as 4% [95,96], and is transient in most patients, typically with symptoms resolving within 2 months.

Guillaine-Barre Syndrome This demyelinating disorder often results in severe autonomic dysfunction [97]. The prevalence of micturition disorders varies from 25% to over 80% [98-99] with severely impaired emptying or frank urinary retention being the most common finding.
**d) Other**

**Systemic Lupus Erythematos (SLE)**. Though nervous system involvement occurs in about half of patients with SLE, overt LUTS appear to be only rarely attributable to the disease (1%) [100-101]. An interstitial cystitis syndrome has been described in the setting of SLE, which has been reported to result in asymptomatic hydronephrosis in at least one instance [102].

**HIV** Voiding dysfunction occurs in 12% of HIV-infected patients, mostly in an advanced stage of the disease [103, 104]. Urinary retention associated with other viral-induced neuropathies has also been reported [105].

**Iatrogenic** Abdominoperineal resection for rectal cancer has been described to cause NLUTD in up to 50% [106-108], which results in chronic voiding dysfunction in at least 10%. Surgical prevention with nerve preservation was shown to be important to try to minimize the risk of urinary retention [109,110]. Simple [111] and radical [112-116] hysterectomy, as well as pelvic radiation have been associated with NLUTD (voiding dysfunction, altered compliance) in 8 to 57%. Nerve-sparing procedures have been shown to reduce the risk of altered compliance and improve LUT-associated QOL following radical hysterectomy [117,118].

**Conclusions**

- Dysfunction of the LUT occurs in patients with a variety of neurologic diseases but precise epidemiological data is seldom available.
- Common manifestations of NLUTD include urinary incontinence, voiding difficulties, and urinary retention.
- Because neurological disease is often present in elderly populations, it is frequently difficult to discriminate if LUTS are due to aging alone, or due to the presence of neurological disease. This difficulty is reflected in widely varying prevalence estimates.

**Recommendations**

- Patients with neurologic disease known to be associated with NLUTD should be evaluated for the presence of lower urinary tract symptoms.
- In certain neurologic disease states, NLUTD may be relatively asymptomatic, yet represent a risk of upper urinary tract impairment.
- In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idopathic severe LUTS after proper office evaluation for common etiologies.

---

**II. SPECIFIC DIAGNOSTICS**

Before any functional investigation is planned, all “basic” data should be gathered and used for further interpretation of the NLUTD. Relevant investigations include; voiding diary, urodynamic studies (cystometry, electromyography (EMG), video-urodynamics, uroflowmetry, pressure-flow study), diagnostic imaging with voiding cystourethrography and ultrasonography. In this chapter are highlighted some data specially related to NLUTD. Some tests developed for the diagnosis of neurologic dysfunction are considered specifically; the bethanechol supersensitivity test, and the ice water or bladder cooling test. Neurophysiologic studies are discussed in the chapter “Clinical Neurophysiological testing”, and only some data for NLUTD is given here.

**1. HISTORY**

The general history aims at gathering information on the neurological and congenital abnormalities, previous urinary complications or treatments. The use of medication with known or possible effects on the LUT, menstrual, sexual and bowel function, and obstetric history are also important. Hereditary or familial risk factors, metabolic diseases and other must be known. Lifestyle factors such as smoking, alcohol, or addictive drug use should be assessed as well as an evaluation of Quality of Life. Patients with a spinal cord lesion above Th6 may develop autonomic dysreflexia, so a history of severe headaches should be explored.

The signs and symptoms that bring the patient to consultation must be documented. Symptoms related to storage and voiding, continence and/or retention, as well as onset and nature of the NLUTD (acute or insidious) should be determined. If appropriate this information should be compared with the patient’s condition before the NLUTD developed. Bladder sensation and mode and type of voiding (catheterization) should be considered. Warning signs and symptoms that warrant early further investigation include; fever, pain, hematuria, catheterization problems, clinical infections and signs of autonomic dysreflexia. Individuals with NLUTD may not be accurate at determining whether they have a UTI based on their symptoms [3]. UTI management is not standardised and clinical practice suffers from a weak evidence base [4].

A urinary diary can be used to capture information on the number of voids (frequency and nocturia), the sensation at each void, volumes voided, incontinence, and volume/time of fluid intake. Little information is available on optimal diary duration in NLUTD, considering information captured balanced against...
inconvenience to the patient [5]. Nonetheless, such diaries deliver useful assessment for evaluating treatment outcomes [6].

2. PHYSICAL EXAMINATION

A general impression of patient’s physical and mental possibilities is relevant to the choice of investigations and treatment. Severely impaired mobility, extreme spasticity, severe mental disorder or general weakness are all important in this respect. The physical examination evaluates the lower abdomen, external genital organs and perineal skin. Palpation per vagina or per rectum is done in search of pelvic organ descent, or cervix-uterus/ prostate disease. The strength of the pelvic floor muscles should be assessed. Cardiovascular function should be considered. Patients with very high neurological lesions may suffer from a significant drop in blood pressure when changing position.

Specific examination of the lumbo-sacral innervation includes: sensation of fine touch and pin-prick in the different perineal dermatomes (figure 1 and 2), evaluation of bulbocavernous/ anal/ cremaster reflexes, tone of anal sphincter and voluntary contraction of the anal sphincter / pelvic floor muscles. Clinical neurological findings correlate well with NLUTD in some types of neuropathy such as single level traumatic spinal cord lesions [7] but less in other types like meningo(myelo)coele or combined traumatic spinal cord lesions [8,9]. Urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment in infantile cerebral palsy [10].

3. URODYNAMIC TESTS

Urodynamic techniques evaluate multiple functional parameters in NLUTD [11]. The International Urodynamic Basic Spinal Cord Injury (SCI) Data Set sets out data to be included in the urodynamic evaluation of patients with spinal cord injury. Variables included are; bladder sensation during filling cystometry, detrusor function and compliance during filling cystometry, detrusor function during voiding, detrusor leak point pressure, maximum detrusor pressure, cystometric bladder capacity and post-void residual [12].

Often, the nature of NLUTD is impossible to anticipate from clinical assessment alone, exemplified by CNS tumours in children [13]. Likewise, severity of NLUTD does not necessarily correspond with severity of neurological lesion.

a) Electromyography (EMG) during cystogram

The basis of EMG has long been a question of debate [13a]. Sundin and Petersen [14] used cystometry (EMG) investigation in NLUTD for patients with an active detrusor contraction associated with
Simultaneous recording of intravesical pressure, sphincter electromyography and uroflowmetry was compared by Aoki et al. [22] with cystometry EMG. They found some influence of the catheter in the urethra. Micturition pressure and opening pressure were larger with cystometry EMG, and incidence of DSD was greater. The authors also found that the Credé manoeuvre exaggerated the DSD. Urodynamics with EMG permitted Kirby [23] to differentiate between patients with pelvic nerve injury, distal autonomic neuropathy, progressive autonomic failure - multiple system atrophy, and idiopathic Parkinson's disease. This influenced the selection of patients for transurethral surgery. Pavlakis et al. [24] studied cystometry concomitant with perineal floor and rectus abdominis EMG and were able to improve the recognition of intravesical pressure elevation owing to voluntary contraction of the abdominal musculature. EAS motor unit potential (MUP) analysis and EMG cystometry were used to differentiate multiple system atrophy (MSA) from Parkinson's disease in the first five years after disease onset. It showed that involvement of Onuf's nucleus in MSA is time-dependent; before the fifth year of illness, the prevalence of neurogenic change does not seem to be high, so a negative result cannot exclude the diagnosis of MSA [25]. Rapidi et al. used combined urodynamics and electrophysiological study of diabetic cystopathy [26].

b) Filling parameters

The importance of detrusor pressure has been acknowledged for many years. Filling rate is important in NLUTD, and slow filling is recommended by the International Continence Society to minimise artefactually affecting compliance [27].

Bruschini et al. [28] undertook clinical, urodynamic and imaging evaluation of the upper and lower urinary tract in inadequately managed myelomeningocele patients. The urodynamic data correlated with the status of the upper urinary tract (UUT). The cystometry showed detrusor overactivity (DO), poor compliance, increased bladder capacity and normal cystometry in 48, 49, 2 and 1% of the patients, respectively. Detrusor leak point pressure (DLPP) over 40 cm H2O was associated with UUT damage. Patients with decrease of functional bladder capacity (FBC) had more renal scars than their counterparts. Incomplete SCI patients with neurogenic DO should be evaluated with the same caution as complete SCI patients, as there can be little difference in cystometric capacity and leak point pressure between complete and incomplete spinal cord injury patients [29].

The importance of urodynamic tests for diagnosis and follow up was demonstrated in the study by Abrahamsson et al. [30] on urodynamic changes with untethering in myelomeningocele children. After untethering, 35% experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward,
and 90% of those who were stable preoperatively continued to be stable postoperatively. Regular evaluation of bladder function in children with myelomeningocele is recommended. Kang et al. [31] used urodynamic tests to determine prognostic factors affecting urological outcome after untethering surgery for lumbosacral lipoma.

Perkash and Friedland [32] found simultaneous transrectal ultrasonography helpful. They recommended not to irritate the bladder when introducing the urodynamic catheter, and to examine the entire curve of the CMG, not simply the initial rise [33].

c) Filling technique

In SCI patients with neurogenic LUT dysfunction, Ko et al. [34] determined whether cystometry performed by filling using diuretics (FMCG) reveals different findings compared with conventional CMG. Significant differences between the two techniques were found in pressures and compliance in neurogenic DO, but not in hyporeflexic or areflexic bladders. Natural filling by the production of urine can change the results of cystometry considerably, and should be considered when performing urodynamic investigations and interpreting the results.

De Gennaro et al. [35] performed continuous urodynamic monitoring over six hours in children and compared this with standard urodynamics. They found continuous monitoring feasible, permitting a better diagnosis than standard cystometry in some cases. Zermann et al. [36] investigated the diagnostic value of natural fill cystometry (NFC) in children with neurologic bladder in comparison to conventional videocystometry. In 45%, NFC detected additional findings. The extra value of ambulatory urodynamics as compared to conventional urodynamics in spinal cord injury patients was investigated by Martens et al. They concluded that ambulatory urodynamics do not seem necessary for diagnosis and risk assessment in SCI patients suspected for DO when conventional urodynamics are done properly [37].

d) The outlet during voiding

Pressure-flow study can demonstrate an obstructive pattern (high pressure voiding) in neurologic patients due to urethral relaxation failure [38,39]. Videourodynamic (VUDS) offers visualisation of bladder neck and urethral sphincter activity during filling and voiding [40,41]. Accordingly, VUDS is a test that can determine the site of obstruction. Zerin et al. [42] found that the urographic position of the bladder neck in relation to the pubic symphysis was correlated with lower motor neuron (LMN) denervation of the urethral sphincter as detected with electromyography in infants and children with myelodysplasia. They concluded that, although not as precise as urodynamic testing, significant descent of the bladder neck is a reliable urographic finding of complete LMN denervation of the external urethral sphincter in infants and children with myelodysplasia. In men with SCI, some cystometric variables and detrusor overactivity may remain consistent over sequential studies [43].

e) Bladder sensation

In a large cohort study it was shown that impaired perception of bladder filling during CMG is a sign of neuropathy [44]. Nonetheless, despite spinal abnormality, patients can experience bladder filling sensation, signifying the presence of afferent pathways joining the spinal cord at higher levels. In 52 SCI patients, 26 % of those with a supposed complete lesion had sensation of bladder filling during cystometry [45]. In 41 patients with myelodysplasia the perception of bladder filling was present in a majority [46]. In a study of 26 SCI patients, bladder sensation was reported by 73% of patients in daily life. However, only 41% of patients had analyzable bladder sensation concomitant with detrusor overactivity during ambulatory Urodynamics [47].

Ersoz and Akyuz [48] investigated bladder filling sensation in 73 SCI patients with complete lesions above T11 and below T10 and with incomplete lesions. Bladder filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and in 38.9% of the patients with complete lesions above T11. Bladder-filling sensation investigations were reproducible in terms of bladder filling sensation category in 36 SCI patients who had a second CMG. The authors concluded that presence of bladder-filling sensation in many SCI patients reveal the potential for sensation-dependent bladder emptying, especially in the ones with complete lesions below T10 and the ones with incomplete lesions. The safe use of sensation-dependent bladder emptying was shown to be dependent on the urodynamic situation [49].

The amplitude of the first overactive contraction and the maximal detrusor contraction were found to be statistically greater in female patients with multiple sclerosis and neurogenic detrusor overactivity compared to women with idiopathic overactivity. The threshold volume for detrusor overactivity was greater, likely secondary to the elevated post void residual urine volume in the MS patients. In this study using a cut off value of 30 cm H2O for amplitude of the first overactive contraction achieved a positive predictive value of 88% for identifying multiple sclerosis [50].

f) Complications of urodynamic testing

Complications of cystometry include hematuria due to the urethral catheter, the development of oedema in the urinary bladder wall and urinary bladder spasm as a result of catheter irritation. One case report of twist and knot formation in the double lumen urethral catheter after cystometry of a patient with a hypocompliant bladder has been published [51]. Another case report describes bladder rupture during filling cystometry many years after bladder augmentation in a girl with meningomyelocele [52].
Symptomatic urinary tract infections after cystometry are not infrequent and antibiotic prophylaxis has been advocated [53]. Randomised controlled trials (RCTs) comparing effectiveness of prophylactic antibiotics with placebo or nothing in reducing bacteriologically proven UTI after invasive cystometry for all patients, including NLUTD [54]. The use of prophylactic antibiotics in urodynamics reduced the risk of significant bacteriuria.

Conclusions

- Findings of Urodynamic tests can be difficult to anticipate from clinical assessment alone in NLUTD (LOE 2).
- A combination with EMG and/or imaging adds to the diagnostic possibilities (LOE 2).
- Filling rate can influence the outcome of several urodynamic parameters (LOE 2).
- Pressure development in the bladder is one of the important parameters to be studied and high leak point pressure is a risk factor for renal deterioration (LOE 2).
- Sensation of filling may be preserved despite spinal abnormality (LOE 2).
- Complications of urodynamic testing are rare, but antibiotic prophylaxis can be advocated (LOE 2).

Recommendations

- Urodynamic tests should selectively be employed to supplement clinical assessment in determining management in NLUTD.
- Methods of Urodynamic testing in NLUTD should follow International Continence Society recommendations.

4. SPECIAL TESTS

a) Bladder-cooling reflex; the ice water test (IWT)

The ice water test (IWT) is a C-fiber mediated reflex, first described as a way to differentiate upper from lower motor neuron lesions. It is based on the principle that mucosal temperature receptors can elicit a spinal reflex contraction of the detrusor, a reflex that is normally inhibited by supraspinal centers. An upper motor neuron lesion interrupts these inhibitory pathways, resulting in manifestation of the reflex, whereas a lower motor neuron lesion does not. A positive test should therefore theoretically occur in patients with upper motor neuron lesions, whereas those with lower motor neuron lesions and neurologically normal patients should have a negative test. Simultaneous measurement of intravesical pressure with cold fluid instillation enables evaluation of the response. Patients without neurogenic disease have a greater perception of cold during the IWT than neurogenic patients; this must be consid-
finding in patients with idiopathic DO. In multiple sclerosis it may have pathophysiological value, indicating a spinal rather than cerebral mechanism of overactive bladder, and diagnostic value, indicating multifocal demyelination [63].

Conclusions:

- The literature results from IWT show value in the diagnosis of NLUTD and in the differentiation between reflexic and areflexic neurologic bladder (LOE 2).

Recommendation:

- The ice water test is an optional test which should be interpreted in the context of all data from the diagnostic evaluation (B).

b) Bethanechol supersensitivity test (BST)

Bethanechol is a muscarinic agonist which may improve bladder emptying in some non neurologic patients, and correspondingly increase bladder sensitivity [64]. The BST was developed by Lapides et al. in 1962 [65] to try to distinguish between a neurologic and a myogenic etiology in an accontractile bladder. It is based on the observation that after an organ is deprived of its nerve supply, it develops hypersensitivity to the normal excitatory neurotransmitters. A neurologically intact bladder should have a pressure increase of less than 15 cm H2O above the control value, whereas a denervated bladder shows a response greater than 15 cm H2O. The clinical utility has not been studied in detail recently.

The test is considered unreliable by some [66]. Pend- ers [67] considered the test reliable when the indications are good (large capacity, hypotonic bladder, clinical suspicion of lower neuron lesion) and when the interpretation is based on a right understanding of its mechanism. Pavlakis et al. [68] suggest that the BST is more sensitive and more specific than perineal floor electromyography in corroborating bladder neuropathy. Sidi et al. [69] studied patients with neurologic or non-neurologic detrusor areflexia with the BST, EMG of the urethral rhabdosphincter and bulbocavernosus reflex latency and found the sensitivity of these tests in detecting neurologic mechanisms to be 90, 87.5 and 78.1%, and the specificity 96, 76 and 80%, respectively. When all three tests were performed together, the combined accuracy approached 100 %. They conclude that these combined tests are useful in the diagnosis of patients with equivocal bladder neurologic conditions and in those with subtle neurological lesions. Denervation supersensitivity to bethanechol was demonstrated in acute idiopathic autonomic neuropathy [70].

Wheeler et al. [71] found the positive BST not diagnostic of neurologic detrusor areflexia because of the many variables that can influence the test. In a later study, the same group [72] suggested that flow rate, surface electromyography, and bethanechol supersensitivity test cannot help differentiate neurologic from non-neurologic detrusor failure. Although no test can accurately differentiate neurologic from non-neurologic female urinary retention, careful neurologic evaluation will help guide to more appropriate management.

Conclusion:

- The literature on the value of the bethanechol test for the diagnosis of neurologic pathology is contradictory. The test may contribute to overall evaluation of neurologic LUT dysfunction. (LOE 2)

Recommendation:

- The bethanechol supersensitivity test has limitations, and result should be interpreted in conjunction with established diagnostic results. (B)

c) Electrodiagnostic tests

1. EMG of the Urethral Sphincter

EMG of the urethral sphincter has been used for decades in the diagnosis of NLUTD; its value in practice remains uncertain. Use of needle or surface electrodes is debated. Urethral concentric needle electrodes were found to be superior to surface patch electrodes for evaluating relaxation of the muscle during voiding in neurologically intact women [73]. Nordling and Meyhoff [74] used cystometry in combination with urethral and anal sphincter EMG in patients with suspected NLUTD and found anal sphincter EMG to be highly unreliable. Koyanagi et al. [75] also found discordant activities between the anal and the external urethral sphincters in 39 % of male patients with SCI. The degree of bladder dysfunction was related more to the degree of dyssynergia of the urethral than the anal sphincter. Nevertheless, Podnar states that anal sphincter EMG is the most useful diagnostic test, particularly for focal sacral lesions, and atypical Parkinsonism [76]. Fowler et al. [77] introduced a technique of recording EMG activity of striated muscle in the urethral sphincter by using a concentric needle electrode and an oscilloscope with a delay line and trigger. Individual motor units were isolated and measured. Vodusek also studied individual motor units [78]. Both conclude that quantitative EMG may be a helpful technique in the investigation of patients with disorders of micturition.

Ziemann and Reimers [79] found the sphincter EMG the most sensitive technique in the diagnosis of chronic pudendal lesions. However, pure afferent lesions cannot be detected by the sphincter EMG. In this case, the BCR, using unilateral stimulation of the dorsal nerves of the penis, provides the opportunity to distinguish between afferent and efferent lesions of the sacral innervation. Fowler [80] concluded that sphincter electromyography (EMG) has is valuable for identifying patients with Parkinsonism who have multiple system atrophy.
Tests which examine aspects of nerve conduction velocity have proved to be of lesser value both because such investigations test conduction of nerve fibres rather than levels of innervation. Furthermore, they examine large myelinated fibre conduction, rather than the unmyelinated fibres which comprise the autonomic innervation. Sphincter EMG is a diagnostic test of Fowler’s syndrome in young women with urinary retention [81]. Sphincter EMG can be used in gauging timing of stimulation for suppressing DO [82].

De E J et al. [83] found a significant disagreement between needle EMG and voiding cystourethrogram (VCUG) for diagnosis of DSD. A combination of EMG and VCUG may identify more cases of DSD than either modality alone and underscores the need for more strict criteria when defining this entity from a urodynamic standpoint.

Anal sphincter EMG as well as external urethral sphincter EMG can be used to detect the onset of detrusor contractions in patients with both neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD) opening a door for the use of triggered devices to inhibit unwanted contractions through continuous electrical stimulation of sensory nerves [84, 85]. Light et al. [86] found in patients with detrusor areflexia and a high spinal cord lesion, EMG of the pelvic floor muscles is the neurophysiological test which best predicts detrusor contractility.

EMG of the urethral sphincter has been used to investigate retention in multiple-system atrophy [87], LUT function in Machado-Joseph disease [88], the impact of pregnancy and delivery on vesico-urethral disorders in patients with multiple sclerosis [89] and children with cerebral palsy [90].

2. EMG of Detrusor Muscle

Detrusor EMG has not been widely studied in neurologic patients. La Joie et al. [91] recorded simultaneous EMG recordings from the bladder detrusor muscle and the inferior rectus abdominis muscle in 6 normal subjects, in 4 patients with LMN bladder disease and in 2 patients with an UMN type of bladder lesion. The bladder electrodes did not appear to record muscle activity remote from the abdominal muscles so that any increased detrusor electrical activity with abdominal contraction must have some other explanation. Kaplan and Nanninga [92] analysed detrusor EMG in upper motor neuron type NLUTD. Kinder et al. did not advocate detrusor EMG [93]. Recent data are lacking and so the technique cannot be considered a standard diagnostic test.

Conclusion

- Sphincter EMG can be valuable in the diagnosis of neurologic bladder dysfunction (LOE 2).
- Detrusor EMG is not established as a diagnostic test.

Recommendation:

- EMG of the urethral sphincter can be considered as a diagnostic method in patients with neurologic LUT dysfunction and neurologic urinary incontinence (B B).

3. Dynamic Bulbocavernous Reflex (BCR).

Walter et al. [94] studied dynamic BCR during micturition induced by using periodic dorsal penile nerve stimulation; the evoked reflex response was recorded with an anal sphincter pressure sensing balloon. Results indicate that an enhanced BCR is a factor contributing to increased urethral resistance during micturition.

Kaiho et al. [95] recorded the evoked potential of the BCR (BCR-EP) with a concentric needle electrode at the periurethral striated muscle. They found was BCR-EP suppressed during voluntary voiding in normal subjects, but it was insufficiently suppressed in the patients with NLUTD. It was suggested that the measurement of BCR-EP could distinguish voluntary voiding caused by pathological urethral sphincter relaxation from voluntary voiding. The same group [96] investigated the change of sacral reflex activity of the striated urethral sphincter in the urine storage phase with BCR-EP in normal male subjects and male patients with NLUTD due to suprasacral spinal cord injury. Sacral reflex activity was accelerated by bladder filling in both the normal subjects and SCI patients, particularly in the latter.

In addition to the conventional evaluation of the integrity of sacral reflex arc by BCR examination, the observation of changes of BCR affected by bladder filling may provide information on the continuity of sacral segment and supraspinal micturition center. Niu et al. showed that in 8% of patients with SCI and in 70% of patients with peripheral nerve lesions the BCR was abnormal [97].

4. Motor Evoked Potentials

Motor evoked potentials (MEP) has been used to assess neurogenic lesions affecting the urethral compressive musculature with simultaneous recording of evoked pressure curves [98]. MEP recording is an accurate and easily applicable test for the diagnosis of lumbosacral spinal cord lesions [99].

5. Nerve Conduction Studies

In patients with diabetes mellitus, conduction velocities are decreased [100]. Vereecken et al. [101] found urethral and anal responses produced by electrical stimulation of penis, bladder neck and anus were delayed and the duration reduced. Carbone et al. [102] assessed the effect of urinary bladder filling on the excitability of somatic spinal motor neurones in patients affected by neurogenic and non-neurogenic DO and proposed that H-reflex modulation may be considered a tool in the differential diagnosis of voiding dysfunctions.
6. Somatosensory Evoked Potentials

In the committee’s literature search, no recent publications were found on somatosensory evoked potentials (SSEP). Badr et al. [103] described techniques of recording evoked potentials in humans in response to stimulation of the urinary bladder. Galloway et al. [104] described a method of sacral evoked response to measure the integrity and function of the lower sacral segments by stimulation at the urethral and anal sphincters.

Mochida et al. [105] studied evoked spinal cord potentials (ESCP) in surgical patients with cervical myelopathy. The presence of NLUTD was closely correlated with severe limb symptoms and relatively slow ESCP velocity. However, for 47% of the patients with urinary complaints, findings of urodynamic examinations were negative; these patients may have had pathologic or psychosomatic factors other than neurogenic bladder due to cervical myelopathy.

Curt et al. [106] studied the significance of SSEP recordings in predicting the recovery of bladder function in acute, traumatic spinal cord injury (SCI). They found a good correlation with the recovery of the external urethral sphincter function, but not with the urodynamic impairment. SSEP in response to stimulation of the tibial nerve have been studied in patients with hyperactive urinary bladder to clarify their role in prognosis of tibial neuromodulation efficacy [107].

7. Afferent Nerve Recording on Sacral Roots

Afferent nerve activity from the sacral dermatome, bladder and rectum can be recorded using cuff electrodes placed on the extradural S3 sacral root in humans, but improvements in recording quality and sophisticated signal processing methods are needed for chronic application. The applicability in clinical practice is very limited [108,109].

Conclusions:

- Detrusor EMG, BCR-EP and MEP are techniques of experimental interest, but with insufficient basis for use as standard clinical diagnostic tests.
- There are some arguments that nerve conduction studies can be useful in the further differentiation of the nerve deficits in cases of neurologic pathology of the bladder (C).
- Direct measurement of sacral afferent nerve activity is still experimental.

Recommendation:

- Somatosensory evoked potentials can be of use in the further diagnosis of nervous deficits related to LUT dysfunction (C).

8) Electroosensation in the LUT

Measurement of the sensory threshold of the LUT towards electrical stimulation was attempted as early as 1899 [110]. After re-introduction of the technique by Markland et al. [111] several authors have studied its value in neurologic bladder dysfunction. Kieswetter [112], and Powell and Feneley [113] demonstrated abnormal electroosensation in patients with NLUTD. Frimodt- Möller [114] described pathological electroosensation in patients with Parkinson’s disease, multiple sclerosis and meningomyelocoele. He also found abnormal electroosensation in half of patients with diabetes and generalized sensory neuropathy, but only in 10% of the diabetic patients with a neurologic bladder. Electro sensation was present in many meningomyelocoele patients with absent skin sensation and absent reflexes, and in many patients with suspected complete spinal cord injury on clinical evaluation [44, 46].

Wyndaele [115] determined the threshold of sensitivity to electrical stimulation in several parts of the LUT in 436 consecutive patients. In the groups with different patterns of disturbed sensation a higher incidence of neuropathy was found than in the group with a normal sensation. Further neurological investigation revealed abnormal innervation in 29% of patients who lacked electroosensitivity in one or more parts of the LUT but who had no previous evidence of neuropathy.

Standardization is necessary to develop the technique and achieve reproducible results [116]. While it is a constructive concept to be able to determine threshold of different fibre types selectively [117], so far no such fibre selectivity has been demonstrated in the bladder [118]. In the committee’s literature search, no recent publications were found.

Conclusion:

- To determine the electroosensation in the LUT might be valuable to evaluate the afferent innervation in cases of neurologic bladder.
- Absent electroosensitivity might guide further neurologic tests in patients with LUT dysfunction (LOE 2).
- Further development and standardisation is needed for the use of electroosensation test to become established as a clinical test.

9. Sympathetic Skin Response

Schurch et al. [119] assessed the descending sympathetic spinal tract and correlated these findings with bladder neck function in SCI patients. Evidence was presented that the integrity of the descending sympathetic spinal tract is necessary for a synergic function of the vesicourethral complex and that sympathetic skin responses (SSR) are of value in the diagnosis of bladder neck dyssynergia. SSR’s
are absent in case of bladder neck dyssynergia. For lesions below the T12 level, other investigative methods to exclude bladder neck dyssynergia are necessary. Rodic et al. [120] found that recording the perineal SSR in addition to that of the hand and foot represents a sensitive diagnostic tool for assessing sympathetic nerve function within the thoracolumbar spinal cord, representing a reliable and accurate diagnostic tool for assessing bladder neck competence and incompetence.

SSR recordings above a spinal lesion level after urethral electrostimulation might provide a useful and technically simple objective diagnostic tool to assess integrity of autonomic (visceral) afferent nerves from the LUT. Somatosensory deficits are not always paralleled by viscerosensory loss and vice versa. SSR may be superior to visceral sensory evoked potentials, which are more difficult to record. The clinical utility needs to be further studied.

Conclusion

- Sympathetic skin responses may help evaluate the integrity of LUT-related sympathetic function, including bladder neck competence and synergia (LOE 2)

III. CONSERVATIVE TREATMENT

Therapeutic principles in different patterns of NLUTD depend on the underlying processes: dysfunction of the detrusor, dysfunction of the sphincter or a combination of both. Neurogenic detrusor overactivity leads to reflex-incontinence, detrusor areflexia to incontinence with retention (overflow incontinence). An areflexic (incompetent) sphincter causes neurogenic stress-incontinence, a hyperreflexic (spastic) sphincter overflow-incontinence.

Quite often detrusor and sphincter are affected simultaneously by the neurogenic lesions. In most patients the storage problem, leading to incontinence, is associated with an emptying problem; therefore both aspects have to be considered at the same time. Therapy of neurogenic incontinence is primarily a conservative one. Timed bladder emptying, by whatever means, controlled fluid-intake and avoidance of urinary tract infections are the prerequisites for successful treatment.

If incontinence persists, and if operative procedures are not indicated or possible, containment products will be needed. The indwelling catheter remains an option for conservative therapy, and can offer acceptable quality of life outcomes [1] and long-term protection of the upper urinary tract [2, 3]. Most experts regard indwelling catheterisation as being associated with significant problems [4]. While suprapubic catheters are generally preferred over urethral, there is little evidence on which to base practice [5]. Urethral leakage can persist despite continuous drainage with a SPC, so additional steps such as bladder neck closure may need to be considered [6].

1. OVERVIEW ACCORDING TO TYPE OF LESION

a) Supraspinal lesions

In supraspinal lesions, neurogenic DO is mostly combined with normal sphincter function; overactivity incontinence is the main symptom and antimuscarinic therapy together with behavioural treatment is the method of choice, especially in patients with cognitive impairment.

b) Suprasacral lesions

Spinal lesions mostly cause simultaneous dysfunction of the detrusor and the sphincter. In suprasacral lesions, the spinal reflex bladder manifests the combination of DO with an overactive/dyssynergic sphincter. For these patients, spontaneous reflex voiding may be possible. However, detrusor contractions may be inadequate, and detrusor striated sphincter dyssynergia is present, both potentially leading to inefficient voiding. Triggered reflex voiding is recommended only if it is urodynamically safe and reflex incontinence is manageable; accordingly, careful support is needed to achieve adequate symptom control [7] and long-term renal safety [3]. Treatment to lower tone and spasticity of the urethral sphincter can be used to aid emptying, such as sphincterotony [8], stenting [9] or botulinum toxin injections into the sphincter [10]. Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia. Sphincterotony may help in reducing episodes of autonomic dysreflexia [11a].

The mainstay of treatment in current practice is intermittent catheterization (IC) [12], undertaken by the patient or carer. However, to achieve low pressure LUT urine storage and continence between catheterisations, additional pharmacotherapy may be necessary. If bladder relaxing agents fail or are not tolerable, electrotherapy is an alternative in incomplete lesions: anogenital electrostimulation (penile, clitoral, vaginal and anal) can inhibit neurogenic detrusor overactivity by stimulating pudendal nerve afferents.

c) Lower motor neuron lesions

For complete conus lesions, areflexia of the detrusor and sphincter is characteristic. Sphincter incompetence causes neurogenic urinary stress incontinence and may be combined with dribbling incontinence if adequate emptying is not achieved. Conservative treatment to achieve continence is often unsuccessful. Bladder expression is potentially dangerous, and pharmacotherapy is not helpful in this situation. Accordingly, appliances and condom catheters are often necessary, and consideration of suitability of surgery may be needed [10].
 retention. With this combination, overflow incontinence can be controlled by intermittent catheterization—mostly without adjunctive additional pharmacotherapy. If intermittent catheterization is not possible, an indwelling catheter, preferable supra-pubic, may be needed. If overactivity of the detrusor is combined with areflexia of the sphincter, reflex incontinence is combined with neurogenic stress incontinence. This pattern is sometimes found in epiconal lesions, especially in myelomeningoceles. Bladder relaxant agents may diminish neurogenic detrusor overactivity. In incomplete lesions, electrical stimulation of the pelvic floor musculature may improve sphincter function. However, with this type of neurogenic LUT dysfunction, conservative treatment alone is generally unable to restore continence; therefore either appliances or operative treatment must be considered.

Cauda equina and peripheral nerve lesions are often incomplete. Hypoactivity or areflexia of the detrusor may be combined with a normally functioning external striated sphincter, a combination which can be seen after intrapelvic surgery, when the pudendal nerves remain intact. Conversely, pudendal nerve lesions in which the pelvic plexus remains intact, a combination of a normally functioning detrusor with a hypo- or areflexic external sphincter may be present. If there is DO, pharmacotherapy is the first choice treatment. For some lesions, intravesical electrotherapy has been reported to increase detrusor contractility [13]. Injection of botulinum toxin in the striated sphincter has created a potential new treatment option, but more research is needed.

2. SPECIFIC INTERVENTIONS

During the acute period of spinal or cerebral shock, bladder management comprises proper bladder drainage. For the post shock period, or for non-acute neurogenic dysfunctions, several conservative treatments are in use [14, 15]:

a) Behavioral therapy

1. Triggered Reflex Voiding

“Automatic” or “reflex” bladder behavior can occur following recovery from spinal shock in spinal cord lesions not involving the conus or cauda equina. This can be used as a means to empty the bladder, using voluntary approaches to provoking a bladder contraction by stimulation of the sacral and lumbar dermatomes. The most commonly used manoeuvres are suprapubic “tapping”, thigh scratching and anal/rectal manipulation. A quadriplegic patient who is unable to perform ISC may choose this option because it gives more independence. If the efferent branches of the pelvic nerve are impaired, reflex emptying is much less complete, and considerable voluntary straining is additionally required to empty the bladder to a satisfactory degree. Integrity of the sacral reflexes predicts the potential to use this approach. The aims of regular triggered reflex voiding are to achieve “balanced voiding”, decreasing incontinence but ensuring safe (low pressure) urodynamic function. The possibility of collecting the urine in a socially acceptable way and a reasonable time period for bladder emptying are needed. Frequency of emptying has to be specified for each patient. Whether bladder outlet obstruction is present also has to be considered; this is not often considered in published literature. To improve emptying, control autonomic dysreflexia related to bladder filling and contraction, and avoid upper tract damage, alpha-blockers or botulinum toxin sphincteric injections should be tried; sphincterotomy and/or bladder neck incision may sometimes be needed. Regular follow-up is essential, though the frequency of check-up appointments is not validated.

Triggered voiding should not be recommended as first line management; in current practice, IC is the accepted standard for continence, upper urinary tract protection and improvement of quality of life.

Conclusions

- Reflex voiding is based on an unphysiological sacral reflex. It is potentially dangerous and has a limited role in managing the reflex bladder (LOE3).
- Costs of appliances and of adjuvant therapies (pharmacotherapy, surgery, urethral prosthesis etc) have to be evaluated (LOE 2).
- Treatment of co-existing sphincteric spasticity/ bladder neck obstruction and co-morbidity should be taken into consideration (LOE 1 and 2)

Recommendations

- Triggered voiding could be recommended only for patients whose situation has proven to be urodynamically safe and stable, and who can manage reflex incontinence.
- Triggered voiding can be considered for patients after sphincterotomy and/or bladder neck incision and/or alpha-blockers and/or intravesical botulinum toxin injections, in order to improve spontaneous reflex voiding (C).
- Reflex voiding can be recommended only if an adequate follow-up is guaranteed (C)
- Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia.

2. Bladder Expression (Crédé and Valsalva)

Bladder expression comprises various techniques aimed at increasing intravesical pressure in order
to facilitate bladder emptying. The most commonly used are the Valsalva (abdominal straining) and the Crédé (manual compression of the lower abdomen). It has been recommended for a long time for patients with a combination of an areflexic detrusor with an areflexic sphincter or with an incompetent urethral closure mechanism of other origin (e.g. after sphincterotomy). Difficulties in emptying the bladder by expression may be due to an inability to open the bladder neck. However, especially in men, these techniques may induce a functional obstruction at the level of the striated external sphincter despite complete paralysis of the musculature of the pelvic floor. Over time, a high proportion of patients manifest problems such as reflux into the prostate and seminal vesicles, or epididymo-orchitis. Moreover, the high pressures could cause reflux into the upper urinary tract. The stress to the pelvic floor with these techniques several times a day also can make incontinence worse, and causes additional genital-rectal prolapse and haemorrhoids.

Adjunctive therapy to decrease outflow assistance includes alpha-blockers, sphincterotomy or botulinum toxin injections. If effective, they usually cause or increase neurogenic urinary stress incontinence. Expression of the bladder for voiding by Crédé and Valsalva can be effective. To empty the bladder, the pressures measured may be high and potentially dangerous for the upper urinary tract. Bladder expression is often not safe. Sphincter-hyperreflexia and detrusor-sphincter dyssynergia are contra-indications for bladder expression.

Conclusions

- Bladder expression by Valsalva or Crédé is potentially hazardous for the urinary tract due to functional obstruction at the level of the pelvic floor (LOE 3).
- It is contraindicated if it creates a high intravesical pressure, particularly in association with reflux into the ureters or seminal vesicles. Hernias, pelvic organ prolapse, haemorrhoids and urethral pathology (strictures) are relative contraindications (LOE 3).
- Bladder expression may adversely affect a flaccid pelvic floor, potentially exacerbating incontinence (LOE 3).
- Alpha-blockers, sphincterotomy or botulinum toxin may reduce the outflow resistance, but may also induce or increase urinary stress incontinence (LOE 3).

Recommendations

- Before recommending bladder expression by Valsalva or Crédé, it must be proven that the LUT is urodynamically safe. (B)
- Exclude contraindications, such as vesico-

ureteric reflux, pelvic organ prolapse, hernias, urethral pathology and symptomatic UTIs before recommending this type of bladder emptying. (B)
- In general, bladder expression should be replaced by CIC in most patients with neurogenic bladder-sphincter dysfunction. (B)
- Adjunctive therapy of outflow obstruction can be considered. (B).

3. TOILETING ASSISTANCE: TIMED VOIDING, HABIT RETRAINING, PROMPTED VOIDING.

See also the chapters on adult conservative treatment and frail elderly.

Adaptation of the drinking and voiding regimen requires education and can be implemented by the patient and/or caregivers. The aim of the behavioural process in adults is to re-establish the control of urinary continence. The goals include correcting faulty habit patterns of frequent urination, improving ability to control bladder urgency, prolonging voiding intervals, increasing bladder capacity, reducing incontinent episodes, and building a patient’s confidence in controlling his/her bladder. In dependent patients all these techniques can be proposed and tried, provided that caregivers (physiotherapist, nurse, family members, etc.) are supportive.

Timed voiding is characterized by a fixed interval between toileting. It is a passive toileting assistance program, initiated and maintained by caregivers. It is considered appropriate for patients who cannot participate in independent toileting. It has been used where incontinence is associated with cognitive and/or motor deficits. Its aim is more to avoid incontinence than to restore a normal bladder function. For neurologic patients it has also been considered as an adjunct to tapping and/or Crédé manoeuvre and/or intermittent catheterisation. Timed voiding can be recommended in management of patients with excessive bladder volumes, exemplified by diabetic patients with impaired bladder filling sensation.

Habit retraining and prompted voiding have to be initiated and maintained by caregivers. They are more suited to patients with brain diseases than spinal cord diseases, and for patients with cognitive and/or motor deficits. The aim of habit retraining is to help patients to avoid incontinence by decreasing voiding intervals. Such program has to be adapted to each patient and needs a specific analysis of voiding patterns to select a good individual schedule for voiding. Such a program is very useful for institutionalised patients. Prompted voiding is used to teach people to initiate their own toileting through requests for help and positive reinforcement from caregivers. There are no specific evaluations on neurologic patients in the literature.
Conclusions

- Behavioural techniques should be used in conjunction with other therapies (pharmacological treatment, catheterisation) (LOE 2).
- When appropriate, toileting assistance should be used to improve continence of neurologic impaired patients (LOE 3).
- Prompted voiding may be able to decrease incontinence episodes. Patients likely to benefit from the technique are those with less cognitive impairment and higher dependency (LOE 2/3).

Recommendations

- Behavioural techniques are a suitable component of the rehabilitation program for each individual. (C)
- There are no guidelines or consensus on suitable intervals for bladder emptying. They should ideally be derived from the voiding diary and other related factors (bladder volume, fluid intake, post-void residual urine volume, urodynamic parameters). (C)
- The mental status of a patient must be taken into consideration, and a rehabilitation program realistically tailored to the patient’s possibilities. (B/C).

b) Catheters and appliances

1. Intermittent Catheterization

Intermittent catheterization (IC), including intermittent self-catheterization (ISC), aims to resume normal bladder storage and regularly complete urine evacuation. They avoid some of the complications of indwelling catheterization (IDC). IC can improve incontinence, or make patients with neurogenic bladder continent, if; bladder capacity is sufficient, bladder pressure is kept low, urethral resistance is adequate, and fluid intake is balanced with frequency of catheterization. In children with SCI, IC used with anticholinergic drugs appears to minimise upper urinary tract deterioration, improve continence and decrease infections; safe increase in capacity appears to increase with growth [16, 17]. Post-void residual signifying the need to institute IC remains to be clarified. However, Dromerick et al. [18] (LOE 2) demonstrated in a series of stroke patients that a post-void residual greater than 150ml is an independent risk factor for development of UTI.

Most appropriate technique and catheter depend on individual anatomic, social and economic possibilities [19] (LOE 1). Two main techniques have been adopted, sterile IC (SIC) and clean IC (CIC). The sterile non-touch technique involves the use of sterile materials handled with sterile gloves and forceps. In an intensive care unit, some advocate wearing a mask and a sterile gown as well [20]. De Ridder et al. [21] compared SpeediCath hydrophilic-coated catheters versus uncoated polyvinyl chloride (PVC) catheters, in SCI patients. This 1-year, prospective, open, parallel, comparative, randomised, multi centre study included 123 male patients injured within the preceding 6 months. Primary endpoints were occurrence of symptomatic UTI and hematuria. Secondary endpoints were development of urethral strictures and convenience of use. The results indicate a beneficial effect regarding UTI when using hydrophilic-coated catheters. Bjerklund-Johansen et al. evaluated patient willingness to change and satisfaction with catheters for IC in neurogenic bladder dysfunction. They also compared patient response to conventional catheters and a packaged hydrophilic catheter: LoFric Primo [22]. 409 neurogenic patients were recruited and 378 (283 males, 95 females; mean age 43.5 years) completed a short-term trial. Patient satisfaction was expressed on a Visual Analogue Scale for seven topics covering use and general satisfaction. Differences regarding satisfaction, handling, time spent, and ability to cope with daily life were reported. Kovindah and Madersbacher investigated whether a silicone catheter reused over years for clean IC was safe for men with SCI [23]. Reused silicone catheter appeared to function as well as disposable. However, to reuse urinary catheters, one should consider the increased risk of infection. The authors suggest that for SCI patients in developing countries, CIC with a reusable silicone catheter may be a suitable and safe choice if one cleans and applies it. In the same way, Getliffe performed a systematic Cochrane review summarizing current evidence on the relationship between sterile single-use catheters or clean reused catheters and the incidence of UTIs [24]. 13 trials met the inclusion criteria. There was considerable variation in length of follow-up, definitions of UTI, and numbers of subjects. Attrition was a problem for several studies, and all were underpowered. Several studies were more than 10 years old, and outcome measures were imprecise, making it difficult to draw conclusions on the benefit of one catheterization method over another. They concluded that there are no definitive studies illustrating that incidence of UTIs is affected by sterile single-use or coated catheters compared to clean reused catheters. However the current research base is weak and design issues are significant. Based on the current data, it is not possible to state that one catheter method is better than another and further research is needed (LEO1). Research to evaluate clean vs. sterile PVC catheter use, and hydrophilic vs PVC use (both sterile and reused), is needed.

Frequency of catheterization depends on many factors, e.g. bladder volume, fluid intake, post void residual, and urodynamic parameters (compliance, detrusor pressure). Usually it is recommended to catheterize 4–6 times a day during the early stage after spinal cord lesion. Some will need to keep this frequency if IC is the only way of bladder emptying. Others will
catheterize 1 – 3 times a day to check and evacuate residual urine after voiding. To overcome high detrusor pressure, adjunctive therapy with antimuscarinic drugs or other bladder relaxants can be indicated. For those who develop a low compliance bladder, upper tract deterioration or severe incontinence, injection of Botulinum toxin in the bladder wall or surgery, such as bladder augmentation, may be necessary.

If catheterization is begun by patients with recurrent or chronic UTI and urinary retention, the incidence of infection usually decreases. If symptomatic infections occur, improper CIC or misuse should be considered. Chronic infection persists if the cause of the chronicity remains. Treatment of UTI is necessary if the infection becomes symptomatic. Lindehall et al. evaluated the rate of complications associated with catheterization and the risk of urethral lesions in myelomeningocele treated with clean IC for a minimum of 10 years. They found that there were remarkably few problems [25]. The incidence of major urethral lesions did not increase during puberty. Larger catheters seemed to be protective against major lesions [26] (LOE3). In contrast, Chen et al. found that the incidence of urethral strictures increases with a longer follow-up, and bladder stone formation is associated with long-term use of CIC in SCI patients [27] (LOE3).

Oh et al. evaluated health-related quality of life (HRQOL) with IC in neurogenic bladder. They conducted a prospective trial involving 132 patients (81 men and 51 women, mean age 41.8 years, range 18 to 80 years) with SCI [28]. Patients using IC have a reduced quality of life in all health domains, as assessed by the SF-36 (LOE2) [29].

Conclusions

- IC in the neurogenic bladder is effective and safe in short- and long-term use. (LOE 1)
- Complications such as UTI are regularly seen and seem to be related to both the catheterization itself and the pre-existing LUT condition (LOE 2).
- Urethral and bladder complications seem to increase in the long-term (LOE 3).
- In order to reduce and prevent complications, appropriate materials and correct techniques should be taught and performed (LOE 3).
- Adequate frequency of CIC, a non-traumatizing technique and suitable materials are the key factors for a successful outcome (LOE 2).

Recommendations

- IC is the first choice treatment for those with inability to empty the bladder adequately and safely in neurogenic voiding dysfunction. It is a valuable tool for achieving continence. (A)
- Proper education and teaching are necessary to achieve a good outcome. (B)
- To prevent and reduce complications, a non-traumatizing technique (external lubricant or lubricant coated catheters) with adequate frequency of catheterization and complete emptying should be achieved. (B)
- Annual follow-up is needed. (B/C)
- It is not currently possible to state whether any IC method is advantageous (Grade D) and further research on the topic is strongly recommended.

2. Indwelling Catheter (IDC)

The Foley catheter was developed in the early 20th century. After the World War I, most SCI and other neurologic patients were treated with indwelling urethral catheterization (IDUC) or suprapubic catheterization (SPC) due to difficulty in voiding or urinary incontinence. While IC is nowadays recommended for neurologic patients, many still choose IDC due to difficulty in performing IC, or persistent leakage between catheterizations. In developing countries, IDC can still be the method of choice for those with urinary retention or incontinence.

IDUC placement requires meticulous technique. More frequent catheter changes may be needed in patients with recurrent UTIs. IDC can cause various complications, such as: urethral trauma and bleeding, urethritis, bladder stones, cystitis, acute and chronic UTI, bladder neck incompetence, meatus and urethral sphincter erosion, and bladder carcinoma. Fistulas can result from pressure effects, caused by improper catheter size and inadequate securing technique, particularly with long-term use. Therefore many experts advocate removal of an IDUC as soon as possible, and usage of other methods such as IC or SPC. Nowadays the complications of IDC seem less, presumed due to better materials, judicious size selection and a proper technique of securing the catheter. For CIC wet patients, overnight IDUC self-placement seems to decrease risk of febrile episode due to UTI, as compared to CIC alone [30]. In the morning, the catheter was removed, washed with tap water and stored in disinfectant (LOE3).

The study by Pannek (LOE 3) reported an incidence 0.11% for bladder cancer in catheterised SCI individuals (48 out of 43,561 patients), similar to that observed in the general population [31]. However, more than 60% of the patients with SCI initially presented with muscle-infiltrating bladder cancer. Hypothetically, the expression of inducible nitric oxide synthase with IDC [32] might predispose to formation of potentially carcinogenic nitrosamines in the bladder. Hamid et al. [33] did not find bladder cancer on bladder biopsies in patients with SCI and a mean IDC use of 12.1 years.
Routine antibiotic prophylaxis for patients with IDC is not recommended. Attempts at eliminating bacteriuria associated with indwelling or intermittent catheters are generally unsuccessful [34, 35] (LOE 4). For prevention of UTI, general cleanliness and local hygiene should be encouraged. In symptomatic UTI, it is important to consider catheter blockage and problems such as urinary stones. Symptomatic UTIs have to be treated with the most specific, narrowest spectrum antibiotics available for the shortest possible time. Guidelines for selecting antimicrobial agents in SCI patients are similar to guidelines for the treatment of complicated UTIs in the general population. Characteristics of the quinolones make them well suited for treating UTI in SCI patients [36] (LOE 4). Recommendations of the local microbiology department should be sought.

The benefit and risks of SPC are similar to IDUC, including the risk for UTI, stone formation and maintenance cost of catheter and bag. Advantages include: minimized risk of urethral trauma and pain-in neurologically impaired women with even relatively short-term IDUC, urethral destruction is a significant risk. The key disadvantage is that SPC placement requires a minor ‘surgical’ produce to insert the suprapubic catheter, with potential to injure nearby organs [37]. While most centres favour SPC use, complications are well-recognised and literature is limited. Most publications are old, there are no prospective studies and no RCTs on SPC.

Conclusions:

- Long-term IDUC use in neurologic patients can predispose to complications. (LOE 2)
- Catheters should have as large a lumen as possible to maximise time to blockage by encrustation, and 5-10 ml self-retaining balloons to minimise the pressure effect on the bladder neck. (LOE 4)
- Closed drainage systems are associated with lower infection risk. (LOE 1)
- Frequency of change largely depends on time to blockage, which is influenced by catheter materials and lumen, patient factors and infection. (LOE 3)
- SPC is a reasonable alternative to IDUC, but IC is the first line intervention (LOE 3).
- SPC is a safe and effective short-term management of urinary retention. (LOE 3)

Recommendations:

- Silicone or hydrogel-coated catheters are preferable. (A/B)
- Use sterile materials and aseptic technique, and routine catheter care in the context of a closed drainage system. (C/D)
- Catheters should be changed regularly, to try to pre-empt obstruction or infection. (C/D)
- Bladder irrigation and antibiotic prophylaxis are not recommended as a routine infection-control measure. Symptomatic UTI should be treated with narrowest spectrum antibiotic possible, according to local microbiology practice. (B)
- Patient education on daily cleanliness and hygiene care are mandatory. (C)
- Short-term IDC during the acute phase of neurological injury is a safe management for neurologic patients. (B)
- Long-term IDC may be safe only if a careful check-up of urodynamic, renal function, and upper and lower tract imaging are performed. (B)
- Bladder screening for bladder cancer is strongly recommended, especially those with IDC more than 5-10 years. (C)
- Annual cystoscopy and biopsy may be necessary for those with gross hematuria, or chronic symptomatic UTI refractory to therapy. (C)
- Consider the use of antimuscarinic drugs in individuals with suprasacral lesions using chronic indwelling catheters. (C)
- Patient comfort, convenience, sexuality and quality of life need to be considered. (C)

3. CONDOM CATHETERS AND EXTERNAL APPLIANCES

Male patients with neurogenic bladder and chronic urinary incontinence can be candidates for a condom catheter connected to a collection bag. However, some men have difficulty in applying condom catheters, e.g. due to obesity, penile atrophy or retraction.

Conclusions

- Condom catheters facilitate urinary containment in neurologic male patients (LOE 3).
- Long-term use does not increase the risk of UTI when compared to other methods of bladder management. (LOE 3)
- Complications may be less if technique, hygiene, replacement and maintenance of low bladder pressures are optimised. (LOE 3)

Recommendations

- Size selection should consider control of leakage, and prevention of penile compressive effects. (B)
- Regular bladder emptying with low bladder pressures and low post void residual should be confirmed (B).
IV. PHARMACOTHERAPY

This chapter deals only with specific issues of continence pharmacotherapy in neurologic patients. For a fuller description of the drugs in use, see chapter 8. The principal causes of urinary incontinence in this subpopulation are neurogenic DO and/or incompetence of urethral closing function. Accordingly, treatment aims to decrease storage-phase detrusor activity, increase bladder capacity and/or increase bladder outlet resistance. This picture is blurred by the occurrence of DSD, which can be present concomitantly with DO. Pharmacologic therapy is particularly helpful in relatively mild degrees of neurogenic bladder dysfunction. Patients with more profound neurogenic bladder disturbances may require pharmacologic treatment to improve results of other forms of management, such as IC.

The two most commonly used classes of agents are antimuscarinics and alpha-adrenergic antagonists. However most drugs have not been evaluated specifically in neurogenic bladder dysfunction.

1. DRUGS FOR NEUROGENIC STORAGE DYSFUNCTION

a) Bladder relaxants

General indications of pharmacological treatment in neurogenic DO are to improve reflex incontinence, ameliorate high intravesical pressure and support other interventions e.g. IC and IDC. Antimuscarinic therapy is a symptomatic treatment. In neurogenic DO, antimuscarinics may increase post void residual urine.

The evidence base for the use of antimuscarinics in patients with a neurogenic bladder is limited. In fact, in a recent Cochrane review performed on all current literature regarding anticholinergic therapy for MS-related incontinence, only five usable studies were found, and no conclusion supporting benefit could be drawn from the analysis [1].

1. Oxybutynin

Oxybutynin hydrochloride is a moderately potent antimuscarinic agent with a pronounced muscle relaxant activity and local anesthetic activity as well-the clinical relevance of the latter is debatable. In a prospective, 12-week dose titration trial of controlled release oxybutynin (OXY-XL), Bennett et al. [2] evaluated the efficacy and tolerability of higher dose oxybutynin chloride in patients with neurogenic bladder and multiple sclerosis, spinal cord injury or Parkinson’s disease. A 7-day washout period was used before initiation of the starting dose of 10 mg OXY-XL. Doses of OXY-XL were increased by 5 mg at weekly intervals to a maximum dose of 30 mg per day guided by patient perception of efficacy versus side effect. At the end of the study statistically significant decreases in the number of voids in 24 hours, episodes of nocturia and incontinence episodes were observed. Residual urine remained unchanged. No patient experienced serious adverse events (LOE2). In a prospective, open label trial of 3 formulations of oxybutynin (tablets, syrup and extended release tablets), Franco et al. [3] evaluated the efficacy and safety of oxybutynin in children with neurogenic DO. The effect of treatment on average urine volume per catheterization and on secondary urodynamic outcomes was evaluated. Maximal cystometric capacities increased, and mean detrusor and intravesical pressures were significantly decreased at week 24. Improvements in bladder function were consistent across all oxybutynin formulations (LOE 2). Gajewski et al. demonstrated in a prospective randomized study that oxybutynin was more effective than propantheline in the treatment of DO in patients with multiple sclerosis (LOE 1) [4].

2. Propiverine

In a randomized, double-blind, prospective multicenter clinical study, Stöhrer et al. [5] compared the efficacy and tolerability of propiverine and oxybutynin in patients with neurogenic detrusor overactivity. Propiverine and oxybutynin were equally effective in increasing bladder capacity and lowering bladder pressure. The trend for better tolerability of propiverine compared to oxybutynin achieved significance for dryness of the mouth (LOE1). Propiverine hydrochloride has also been shown to be effective in neurogenic detrusor overactivity in children and adolescents, even in some of those cases unresponsive to other anticholinergics [6, 7]. The low incidence rate of adverse events evidenced a favourable risk-benefit profile of propiverine hydrochloride (LOE3).

3. Trospium

Trospium is a quaternary ammonium derivative with mainly antimuscarinic actions. Trospium has been shown to significantly reduce the number of urinations, increase cystometric capacity and mean effective volume of the bladder, and reduce the incidence of urgent voids in neurogenic patients [8, 9] (LOE1).

4. Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist. Tolterodine has a high selectivity in vitro and exhibits selectivity for the urinary bladder over the salivary glands in vivo. Several phase II studies have demonstrated the efficacy and safety of tolterodine in patients with overactive bladder [10]. Ethans conducted a prospective, randomized, double-blind, crossover trial plus open-label comparative stage, aiming at comparing tolterodine with oxybutynin and placebo in people with neurogenic DO. Tolterodine, when used at self-selected doses (SSDs) was comparable with oxybutynin at SSDs in enhancing bladder volume and improving continence, but with less dry mouth. It seems that larger
doses of tolterodine are needed to achieve best effect on neurogenic bladder [11, 12] (LOE3).

5. SOLIFENACIN SUCCINATE
Solifenacin has been extensively studied in OAB [13, 14] (LOE1). In a prospective, open-label study of solifenacin for the treatment of OAB in MS patients, van Rey et al. demonstrated a significant improvement in number of micturitions, number of pads used per day and severity of urgency compared to baseline following eight weeks of treatment [15] (LOE 2).

6. DARIFENACIN
Dariferacin has a higher relative selectivity for the M3 receptor compared with other anticholinergics. Dariferacin has been extensively studied in OAB, but not in neurogenic bladder dysfunction.

7. FESOTERODINE
Fesoterodine acts functionally as a prodrug, hydrolysed by nonspecific esterases to 5-hydroxymethyl tolterodine (5-HMT). This active metabolite, responsible for the antimuscarinic activity of fesoterodine is also an active metabolite of tolterodine. Phase 3 trials have evaluated fesoterodine in OAB, but there is no current data on the effect of fesoterodine in neurogenic LUT dysfunction.

8. DUAL THERAPY WITH ANTIMUSCARINICS
Dual therapy (between combinations of oxybutynin, tolterodine and trospium) has been shown to be effective and well tolerated in a few patients with neurogenic bladder dysfunction [16] (LOE 2).

9. ANTIMUSCARINICS IN NEUROLOGICAL PATIENTS WITH COGNITIVE IMPAIRMENT
In the cognitively impaired, antimuscarinics should be prescribed with a warning about possible deterioration in memory or the onset of confusion. It would appear sensible to recommend the use of antimuscarinics that are likely to have less impact on cognition, either by lower propensity to cross the blood–brain barrier (e.g. trospium chloride) or by relative selectivity for the M3 receptor (e.g. darifenacin) which is not known to be involved in cognition; evidence affirming these considerations is limited. No studies have specifically evaluated patients with neurological disease. In a randomised, double-blind, parallel group, multicentre study of 3 weeks treatment with darifenacin in the healthy elderly, no significant effects on memory compared to placebo was observed, in comparison to oxybutynin ER which caused significant memory deterioration [17] (LOE 1). In a single-centre, non-comparative, pre-post dose intervention phase IV study of healthy elderly that was primarily designed to evaluate CSF trospium levels after orally dosed trospium, no decline in performance on tests of learning and memory was observed following ten days [18] (LOE 2).

Recommendations
- The evidence demonstrating the efficacy of antimuscarinics in the management of overactive bladder symptoms in patients with a neurogenic bladder is limited. Randomised control studies are needed to evaluate this further.

b) Intravesical bladder relaxants
1. ANTIMUSCARINICS.

Since the first use of the intravesical application by Brendler et al. 1989 [19], there have been several articles reporting successes of intravesical oxybutynin to treat OAB and neurogenic DO. The main findings were, at least at short term follow up; improved LUTS, fewer incontinence episodes, an increase of maximum bladder capacity and decreased DO. George et al. 2007 compared the therapeutic response of intravesical oxybutynin, propantheline, and capsaicin in the treatment of neurogenic DO [20]. Oxybutynin 5 mg in solution or propantheline 15 mg in solution and capsaicin were instilled intravesically in each patient. Urodynamic studies were done before and after the intravesical instillation of each drug. There was a significant difference in therapeutic response between intravesical oxybutynin, propantheline, and capsaicin in the treatment of detrusor overactivity for leak volume (LV) and leak frequency at 2nd week. When comparing responses of oxybutynin and propantheline, more subjects demonstrated improvement with intravesical propantheline than oxybutynin for reflex volume, detrusor leak point pressure, clean intermittent catheterization volume, and LV (LOE3). However, there is no standard instillation protocol concerning the use of intravesical oxybutynin; doses used range between 5-30 mg, diluted in 30-40 ml saline [20, 21]. Also the instillation frequency is not standardized and varies between 1 to 3 times /d. Small case series report on long-term success of intravesical oxybutynin (up to 3 years in adults, up to one year in children with NDO (LOE4) [22, 23]. Despite favourable results on urodynamic parameters, there is also a low level of evidence for the use of intravesical oxybutin in low-compliance neurogenic bladders [24]. Modulation of the ice-water test and suppression of the electrical perception threshold by oxybutynin has been studied [25]. An animal experiment suggested that early administration of oxybutynin might have a protective effect on structural bladder alterations, at least in obstructed animals [26].

Fader et al. 2007 [27] tested the efficacy and side effect profiles of intravesical atropine compared to oxybutynin immediate release (IR) in MS. They performed a study to determine the most effective dose of atropine. Eight participants used increasing doses of intravesical atropine (2 to 6 mg in 20 ml saline) during a 12-day period. Bladder diary data
showed that the instillation of 6 mg atropine 4 times daily was most effective for increasing bladder capacity (voided/catheter volumes). Afterwards they performed a randomized, double-blind crossover trial. Participants received 14 days of treatment with oral oxybutynin IR 5 mg twice daily (range 2.5 twice to 5 mg 4 times daily) or with intravesical atropine, followed by 14 days of alternative treatment. Participants recorded a bladder diary and rated side effects and quality of life. The primary outcome variable was bladder capacity. 57 participants with MS completed the study. Average change in bladder capacity was higher in the atropine arm. Changes in incontinence events and voiding frequency were not statistically different between the arms. Changes in total side effect and dry mouth scores were significantly better in the atropine treatment arm. These findings suggest that intravesical atropine is as effective as oxybutynin IR for increasing bladder capacity and has less antimuscarinic side effects (LOE2). However, no further results of clinical trials with intravesical atropine have been published since.

2. NOCICEPTIN/ORPHANIN FQ (N/OFQ)

Nociceptin is a peptide that exerts several physiological actions at both the central and the peripheral level by activating a specific G-protein-coupled receptor named nociceptin orphan peptide (NOP) receptor. Animal studies have demonstrated that N/OFQ inhibits the micturition reflex in the rat [28]. Lazzeri et al. recently studied the feasibility, safety and efficacy of daily intravesical instillation of 1 mg of the endogenous peptide N/OFQ in a selected group of patients who performed CIC for neurogenic DO [29]. A total of 18 patients were randomized to receive 1 mg nociceptin/orphanin FQ in 10 ml saline or placebo (saline) at the first catheterization for 10 days. Mean daily urine leakage episodes significantly decreased from 2.18 at baseline to 0.94 during nociceptin/orphanin FQ treatment, while no significant changes were reported in the placebo group. The bladder capacity significantly increased in patients receiving nociceptin/orphanin FQ. The urodynamic parameters showed an increase in cystometric capacity and a decrease in maximum bladder pressure. Although these findings supported the use of nociceptin/orphanin FQ peptide receptor agonist as an alternative approach for controlling NDO incontinence (LOE2), no further study results have been published in five years.

3. COMPOUNDS ACTING VIA THE TRANSIENT RECEPTOR POTENTIAL (TRP) CHANNELS

The vanilloids, capsaicin (CAP) and resiniferatoxin (RTX), desensitize afferent nerves by binding TRPV1 receptors. CAP has been the subject of small, short-lasting placebo-controlled trials in patients with SCI or MS [30] (LOE1-2). Thus, the use of CAP is still largely experimental and limited by the fact of prolonged and painful excitation of the sensory c-fibers. The alcoholic solvent may be a major factor in the poor tolerability of alcoholic CAP instillation, as suggested by the result of one placebo controlled study showing that side effects appeared to be the same after intravesical instillation of CAP diluted in 30% ethanol as after instillation of ethanol alone (LOE2).

RTX acts without the potent neuronal excitatory effect of capsaicin, and therefore elicits less discomfort. The difference in tolerability of the 2 vanilloids (CAP vs. RTX) was usually attributed to the differential pungency of the 2 agents. Nevertheless, because we know the role of the solvent in the irritative effect on bladder mucosa, it is reasonable to assume that differential effects could be related to the use of different vectors. From a technical point of view the choice of the solvent is limited because of the poor hydrosolubility of CAP, imposing the use of an alcoholic, lipidic or glucidic vector. The safety of the lipidic solution could be imperfect because of difficulty of achieving complete elimination of lipidic solution from the bladder. On the contrary, a glucidic solution may represent a safe and valuable alternative to the alcoholic vector. De Seze et al. [31] compared the efficacy and tolerance of intravesical instillations of CAP and RTX using a glucidic solvent for CAP and the 10% ethanol solvent for RTX in a controlled randomized, double blind study in patients with severe urinary incontinence due to spinal cord injury. On day 30, improvement was found clinically and urodynamically in 78% and 83% respectively of patients treated with CAP vs. 80% and 60% treated with RTX. No significant difference between the 2 groups was observed. The benefit remained in two-thirds of the 2 groups on day 90. There were no differences in regard to incidence, nature or duration of side effects in CAP vs. RTX treated patients. These results once more strongly argue for the importance of accounting the role of vanilloid solute when interpreting efficacy and tolerance of vesical vanilloid instillation in neurogenic DO cases. They suggest that a glucidic solution is a valuable solvent for CAP instillation (LOE2).

RTX seems to have a beneficial effect on neurogenic DO (LOE 2). However, good randomized controlled studies are needed to determine its place in the treatment of NDO. Also the optimum doses (concentration) as well as the inter treatment intervals need to be determined. Moreover, the long-term safety of vanilloid agents, particularly concerning mutagenic and carcinogenic effects on the bladder wall is not perfectly known. RTX belongs to the family of tumor promoting phorbol esters, strengthening the need to ensure the safety of RTX before extending its therapeutic applications.

Initial interest in RTX has declined following the introduction of intradetrusor Botulinum toxin injections in the treatment of intractable neurogenic DO. In a randomized trial comparing onabotulinumtoxinA injection to resiniferatoxin intravesical instillation in 25 patients with spinal neurogenic DO [32] there was
Transient receptor potential channels are being increasingly investigated as targets for the treatment of detrusor overactivity. Piperine, a novel vanillic fatty acid nitroalkene derivative which modulates gene transcription and protein function via post-translational protein modification demonstrated TRP-agonist actions affecting both the TRPV1 and the TRPA1 receptors in rat bladders [36].

4. Botulinum Neurotoxin Type A

**Efficacy:** The past decade saw the emergence of the most successful intravesical treatment for refractory neurogenic DO to date, namely Botulinum neurotoxin (BoNT) intradetrusor injections. Following several publications from increasing numbers of centres worldwide and multicentre registration studies, BoNT type A (BoNT/A) in the OnabotulinumtoxinA (BOTOX™) format has become the newest approved treatment for urinary incontinence in adult neurological patients with inadequate response to (or reduced tolerance of) an anticholinergic medication (U.S. Food and Drug Administration approval). Similar approval has been granted or is awaited in a number of European countries. Several systematic reviews [37-40], a number of randomized, placebo-controlled trials (LOE1, four fully published studies [41-44], one active comparator-controlled trial (LOE1-2) [32], three LOE2 studies [45-47], and several LOE3 studies have confirmed the efficacy of BoNT/A in the treatment of refractory neurogenic DO incontinence. Clinical improvement is accompanied by significant ameliorations in bladder function, as urodynamic parameters that matter in the management of NDO, namely maximum cystometric capacity, maximum detrusor pressure and reflex volume, appear to gain substantial benefits in most published patient series [37-39]. Almost all studies have published on two BoNT/A preparations, onabotulinumtoxinA (Botox) and abobotulinumtoxinA (Dysport) [39]. The two formats are not interchangeable and there are no direct comparisons for dose, efficacy and safety, at least in urological indications. Although both products appear to be efficacious in NDO, onabotulinumtoxinA has been more comprehensively studied than abobotulinumtoxinA [39]. An LOE1 study has been published reporting abobotulinumtoxinA [46]. An LOE3 study suggests that onabotulinumtoxinA may be more efficacious than a novel BoNT/A preparation, Prosigne, in the treatment of refractory NDO [48].

The mean duration of efficacy of a single injection is 6-16 months for onabotulinumtoxinA and 5-12 months for abobotulinumtoxinA [39]. The FDA regulatory trials (275 and 416 patients, respectively) demonstrated a mean duration of effect of 37-42 weeks for onabotulinumtoxinA compared to 13 weeks for placebo [43, 49]. Complete continence was achieved in 36-38% and 40-41% respectively with the 200U and 300U doses of onabotulinumtoxinA as opposed to 7.6-10% with placebo. Interestingly, significantly higher post-treatment continence rates have been reported in single-centre studies with both preparations (a mean 71% with onabotulinumtoxinA and 65% with abobotulinumtoxinA) [39]. The concomitant use of anticholinergics did not appear to provide additional benefit, although this needs to be confirmed in specifically-designed studies. Several retrospective studies now attest to the sustained efficacy of repeat treatment sessions with either of the two formulations [50-58].

Reported failure rates range was 5-25% for onabotulinumtoxinA and 10-32% for abobotulinumtoxinA [39]. Clinical predictors of success/failure in NDO have not been studied. A study of patients with MS proposed that longer duration of MS may be a predicting factor for treatment failure [59] (LOE3). To date there is no robust evidence to link treatment failure with the formation of neutralizing BoNT/A antibodies, but a wide range of antibody formation rates following treatment has been reported (0-35%) [60-63] and its clinical significance needs further investigation. A small, controlled study in children (LOE1-2) found no association between antibody formation and treatment failure, but reported an increased rate of antibody formation in those receiving repeat versus single injections (71% versus 38%) [64] in the mid-term (up to 4 months post treatment). In the long-term, antibody titers returned to control levels.

**Patient populations:** The majority of the studies involved participants with neurogenic bladder due to SCI or MS, often mixed, while only small case series investigated efficacy in patients with Parkinson's disease, multiple system atrophy or cerebrovascular accident (CVA) [65-68]. Comparisons of efficacy between neurological subpopulations are generally lacking, although a small LOE3 study suggested better continence outcomes and more significant improvements in maximum detrusor pressures in SCI patients compared to those with CVA [68]. The largest RCTs which involved MS and SCI patients conclude that the toxin is highly efficacious in both subpopulations [43, 49]. A lower placebo effect
in the SCI subpopulation could be noted, although the studies were not designed for head-to-head comparisons. The same studies demonstrated a similar efficacy and adverse event profile for the 200U and 300U onabotulinumtoxinA (BOTOX) doses, suggesting a plateau in the efficacy of the toxin. Similar conclusions had been drawn by the results of an earlier study in the IDO population (plateau dose 150U onabotulinumtoxinA) [69]. Providing the best benefit/risk ratio, the 200U onabotulinumtoxinA dose was recommended for the treatment of refractory NDO incontinence [43, 49]. A LOE2 study suggested a trend towards better clinical and urodynamic improvements with 750U as opposed to 500U abobotulinumtoxinA [46]. Other, non-randomised and inadequately powered studies (LOE3) [45, 56, 70] could not identify a clear dose-response for higher doses of abobotulinumtoxinA, although 1000U abobotulinumtoxinA might produce a beneficial effect of greater duration than that with 500U [45].

Little data exists on lower doses. A pilot LOE3-4 study suggests that 100U onabotulinumtoxinA could be effective in MS patients and minimize unfavourable side-effects, particularly the need for IC [71], while a LOE1 dose-response study still in abstract format confirms a more significant clinical benefit of the 200U dose as opposed to the 50U and 100U doses of onabotulinumtoxinA in patients with SCI [72].

**Effect on quality of life (QOL):** Both preparations have been shown to improve patients’ QOL in RCTs. A single injection of 500 units abobotulinumtoxinA, diluted in 25 ml saline and injected into 25 injection sites, was compared to placebo in 31 patients with NDO-associated incontinence. At 26 weeks follow-up, patients in the abobotulinumtoxinA group had a more significant change in clinical QOL and urodynamic parameters, and anticholinergic use [42]. Similarly, 200U and 300U onabotulinumtoxinA administered into 30 injection sites improved QOL scores significantly more than placebo in all LOE1 studies [43, 44, 49, 73]. The I-QOL questionnaire has been used in the majority of LOE1 studies.

**Administration technique:** A large variance in the number and volume of injections has been described. However, in the majority of studies onabotulinumtoxinA was given at 30 injection sites (range 10–40) at a dilution of 10U/ml per injection site (total volume of 30 ml, range 3–30 ml), as described in the original publication by Schurch et al. [74]. The same dilution and number of injection sites was used when administering either 300U or 200U onabotulinumA in the regulatory trials. Administration of abobotulinumtoxinA is less standardized (10–30 injection sites, total volume of 5–30 ml), but a total 30 ml given at 30 injection sites appears to be the most common again [39]. The effect of these variables on outcomes has little been studied. In a LOE3 study, Karsenty et al. compared 10 versus 30 injection sites (300 U Botox) [75]. They reported no significant difference in efficacy measured by number of incontinence episodes or cystometric capacity, but a significant reduction in post-procedure pain was noted in the 10 injection-sites group.

The majority of studies reported injections into the detrusor muscle sparing the trigone, as in the original technique [74]. There is, however, LOE2 evidence to suggest that trigonal injections may produce better continence rates than detrusor injections alone; urodynamic parameters were affected to a lesser extent, as only reflex volume was improved more significantly in patients who received trigonal injections [47].

Alternative delivery techniques are being investigated in preclinical studies and include intravesical instillation of BoNT/A encapsulated in liposomes [76] or via electromotive drug administration (EMDA) [77]. The latter method has also been tested in a pilot LOE3-4 study in children with myelomeningocele and significant improvements were reported in maximum cystometric capacity, detrusor pressure, urinary incontinence, vesicoureteric reflux and even fecal incontinence [78], but these conclusions need to be confirmed in controlled trials.

**Safety:** The treatment appears to be overall safe in currently used doses and techniques. The most common adverse event is the significant increase in postvoid residual in patients not using CIC prior to treatment. In onabotulinumA placebo-controlled trials, 12-22%, 30-47%, and 42-49% of patients in the placebo, 200U, and 300U groups, respectively, initiated CIC post-treatment. Although earlier studies had reported a reduced incidence of UTIs in NDO patients treated with BoNT/A [55, 79, 80], recent large RCTs suggest a higher incidence of UTIs in those treated with onabotulinumtoxinA as opposed to placebo-treated patients [43, 49]. This might be associated with the increased rate of de novo CIC in the Botox-treated population. Prospective, long-term trials are needed to clarify this apparent discrepancy.

Haematuria, constipation and flu-like symptoms have also been described [39, 43, 49], while inclusion of trigonal injections does not appear to produce vesicoureteral reflux (LOE2-3) [47, 81, 82]. A study in SCI male patients found a post-treatment decrease in the volume of ejaculate accompanied by improvements in semen quality, sperm mobility and vitality, as well as semen culture [83]. Further research is needed to confirm these results and explore whether they are due to a local re-organisation of autonomic function which also affects the reproductive system.

The most serious adverse event is generalised paraparesis/ fatigue, which has been described in 0.005% of patients receiving onabotulinumtoxinA and in 0.026% of patients receiving abobotulinumtoxinA [39]. The effect resolves spontaneously after 4-6 weeks and appears to be dose-related, with
most cases reported in those patients injected with 750-1000U abobotulinumtoxinA or 300U onabotulinumtoxinA [49, 53, 84].

As BoNT/A studies in skeletal muscles have identified autonomic, histological and other secondary effects [85, 86], further investigation is needed on safety issues, especially after repeat injections [38]. A single study to-date prospectively examined distant effects post-BoNT/A bladder injection using single-fibre EMG; one-third of the patients had findings of neuromuscular jitter post-treatment, but there was no placebo arm or pre-treatment data for comparison [87] (LOE3). Other studies produced histological evidence of reduced or no additional fibrosis after one or multiple injections, including in children [88-90].

Future research should highlight the gaps in our knowledge of long-term treatment, overall safety and different techniques of application.

5. POTENTIAL INTRAVESICAL TREATMENTS WITH CANNABINOID MODULATORS

While orally administered cannabinoid modulators appear to improve neurogenic OAB symptoms, particularly in MS patients [91], the identification of functional cannabinoid receptors (CBs) in the human bladder urothelium [92, 93] has intensified research in intravesical cannabinoid agonists for bladder dysfunctions. To date, only preclinical studies exist, and in non-neurogenic bladder models. Cannabinor, a selective CB2 receptor agonist, was found to affect bladder function in both normal rats as well as rats with bladder outlet obstruction, by increasing intervals between bladder contractions as well as flow pressures [94, 95]. In rats, but not humans, a Cannabis sativa extract enriched in cannabidiol drug substance reduced cholinergic-mediated bladder contractility in vitro [96]. Intravesical application of a non-selective cannabinoid agonist suppressed afferent activity via activation of CB1 receptors [97]. Finally, intravesical administration of the fatty acid amide hydrolase, the enzyme responsible for the degradation of the endocannabinoid anandamide, altered afferent-related urodynamic parameters in normal rats [98]. In a single study using a spinal cord injury model, systemic administration of a CB2-selective agonist could improve spontaneous voiding, possibly via a positive effect on inflammatory responses in the spinal cord [99].

c) Drugs for sphincter deficiency

Several drugs, including alpha-adrenergic agonists, estrogens, beta-adrenergic agonists and tricyclic antidepressants, and duloxetine have been used in an effort to increase outlet resistance. No adequately designed controlled studies of any of these drugs for treating neurogenic sphincter deficiency have been published.

2. DRUGS FOR TREATING VOIDING DYSFUNCTION

a) Alpha-adrenergic antagonists

Alpha-adrenoceptors are present in the bladder base, posterior urethra and prostate. Alpha-blockers have been already reported to be useful in neurogenic bladder by decreasing urethral resistance during voiding. Tamsulosin has been shown to improve bladder storage and emptying in MS and SCI [100]. Abrams et al. [101] evaluated the efficacy and safety of tamsulosin in patients with neurogenic lower urinary tract dysfunction secondary to suprasacral spinal cord lesions in a 4-week randomized controlled trial (RCT) followed by a 1-year, open label, long-term study. A total of 263 patients were randomized to 4-week double-blind therapy with placebo, or 0.4 or 0.8 mg tamsulosin once daily. The primary efficacy parameter was maximum urethral pressure (MUP). In the long-term study, but not in the RCT trial, there was a statistically significant mean decrease in MUP from baseline to end point. In the long-term study tamsulosin also improved several cystometry parameters related to bladder storage and emptying, e.g. decreased maximum urethral closure pressure. It also increased mean voided volume based on the micturition diary. There was statistically significant improvement for the International Prostate Symptom Score Quality of Life. Both doses were effective and well tolerated. (LOE1).

b) Botulinum toxin

Sphincter injections were historically the first application of BoNT/A in the lower urinary tract [102], but there is still inadequate evidence to support its use. The most commonly injected volume is 4ml of either the onabotulinumtoxinA or the abobotulinumtoxinA preparations. Usually 100U onabotulinumtoxinA or 150U abobotulinumtoxinA have been delivered transperineally or transurethrally [103, 104]. There exists no direct comparison of injection techniques; there is LOE4 to suggest the two delivery approaches are equally effective [105].

In a LOE1 study, the effects on DSD of botulinum toxin versus placebo was studied in 86 multiple sclerosis (MS) patients [106]. The study employed a single transperineal injection of onabotulinumtoxinA, 100 U in 4 ml normal saline, or placebo, into the striated sphincter with EMG guidance. The primary endpoint was post void residual volume at 30 days. The secondary endpoints included voiding and urodynamic variables. OnabotulinumtoxinA failed to decrease post-void residual volume in this group of MS patients, although it increased voided volume and reduced pre-voiding and maximum detrusor pressures. These findings differ from those in patients with spinal cord injury and may be due to lower detrusor pressures in MS patients. A small LOE1 study showed a superior effect of onabotulinumtoxinA over lidocaine 0.5% injected in the urethral sphincter in MS patients [104]. In MS patients
BoNT/A is probably safe and effective for the treatment of DSD in spinal cord injury patients (LOE2). However, on the basis of one LOE1 study, BoNT/A does not provide significant benefit for the treatment of DSD in MS patients.

- There is no adequately designed controlled study of any drug for neurogenic sphincter deficiency.

### Recommendations

- Antimuscarinic drugs should be recommended for the treatment of neurogenic detrusor overactivity (A). Titration of the dosage of these drugs individually should be done to optimal balance of therapeutic and adverse effects. If one drug is not tolerated, another drug should be tried (C/D).
- BoNT/A should be offered as a treatment option for incontinence associated with neurogenic detrusor overactivity (A).
- Further research is needed on long-term outcomes and safety, administration techniques, the bio-equivalence of the various preparations, the concomitant use of anticholinergic drugs, mechanisms of action, and wider effects (A).
- Vanilloid intravesical therapy still remains experimental and therefore is not recommended except within clinical trials (C/D).
- For decreasing outlet resistance in neurogenic bladder a-adrenergic antagonists may be used (B/C).
- BoNT/A may be considered for DSD in spinal cord injury patients (B).
- For neurogenic sphincter deficiency, no effective drugs are available up to now; further research is needed (D).
- For detrusor areflexia no effective drugs are available up to now; further research is needed.

### V. ELECTROSTIMULATION

#### 1. ELECTRICAL NEUROMODULATION

In the last decade, sacral nerve neuromodulation (discussed in the Surgical Treatment section of this chapter) has been established as a treatment option for patients with OAB. The success with sacral neuromodulation has increased the interest in other neuromodulation techniques. Additional methods include; (a) anogenital stimulation (b) pudendal nerve stimulation, (c) dorsal genital nerve stimulation (d) percutaneous tibial nerve stimulation, (e) magnetic stimulation and (f) deep brain stimulation. It is not really known how neuromodulation works, but there is evidence that sites of action are spinal and supraspinal [1]. Firstly the non-surgical ways of neuromodulation will be presented, followed by the surgical techniques.

- Conclusions

  - Antimuscarinic drugs improve storage function (LOE 1).
  - Antimuscarinic drugs have a high incidence of side effects (dry mouth, constipation, urinary retention, etc.). Tolterodine, propiverine, tros-pium and controlled-release oxybutynin have significantly less side effects compared to immediate-release oxybutynin (LOE 1).
  - High doses of oxybutynin have been used to treat patients with neurogenic bladder dysfunction (LOE 3).
  - Intravesical instillation of oxybutynin may be an alternative route of administration (LOE 4).
  - Intravesical instillation of capsaicin/resiniferatox-in has been reported to improve spinal reflex incontinence. Resiniferatoxin is preferable (LOE 3).
  - Recent results supporting their use are lacking.
  - Botulinum neurotoxin A (BoNT/A) injection into the detrusor muscle improves clinical and urodynamic parameters (LOE1), and has been approved as second-line treatment for urinary incontinence associated with neurogenic detrusor overactivity in patients with inadequate response to or intolerance of an anticholinergic.
  - Repeat intradetrusor injections of BoNT/A provide sustained clinical benefits (LOE3).
  - Treatment with intradetrusor BoNT/A is considered overall safe, with increased post-void residual and need for post-treatment CIC being the most common adverse event (LOE1).
  - Long-term alpha adrenergic antagonists are effective and well tolerated in patients with MS and suprasacral spinal cord lesion with neurogenic lower urinary tract dysfunction (LOE1).
  - BoNT/A is probably safe and effective for the

- Treatment with intradetrusor BoNT/A is considered overall safe, with increased post-void residual and need for post-treatment CIC being the most common adverse event (LOE1).
- Long-term alpha adrenergic antagonists are effective and well tolerated in patients with MS and suprasacral spinal cord lesion with neurogenic lower urinary tract dysfunction (LOE1).
- BoNT/A is probably safe and effective for the
a) Anogenital Stimulation

This has been applied in children with OAB complaints. Gladh et al. found a response for anogenital stimulation in 53% of the children [2]. Trsinar and Kralj used an endoanal electrode and reported a complete or partial response to the treatment in 75% of the patients [3]. In a control group of patients who had the endoanal electrode introduced but not activated, no patient had the symptoms resolved completely. No recent publications could be found.

b) Pudendal Nerve Stimulation

Pudendal nerve stimulation and electrode positioning can be carried out under neurophysiological monitoring (using a St. Mark’s electrode) in order to guide the electrode in Alcock’s Canal as close as possible to the pudendal nerve [4]. Electrode implantation can also be carried out by a rear approach under local anesthesia according to the method described by the same team [5, 6]. On the other hand, an anatomical study demonstrated that the technique for implanting electrodes at the pudendal level may carry some risk [7].

Direct pudendal nerve stimulation has beneficial effects on numerous pelvic floor function impairments such as urinary and/or fecal incontinence, retention, and constipation. In preceding literature the implant technique required a fairly complex and invasive procedure, although recent advances with percutaneous placement of the lead through an introducer have made the procedure much less invasive. Electrical stimulation of pudendal nerve afferents can inhibit bladder contractions in patients with SCI, and bladder capacity can be increased [8] (LOE3). Implants such as the InterStim system have made this treatment modality commercially available (see sacral nerve stimulation). Common to these implantable systems is that they use continuous stimulation. Detrusor inhibition is in principal only necessary during an involuntary contraction and, thus, stimulation could be turned off between contractions (i.e. conditional stimulation) [9]. Such a stimulation scheme could have a number of advantages. Power consumption may be decreased and, thus, extend battery lifetime. Furthermore, continuous stimulation of a reflex may lead to habituation, which would be minimized or prevented by conditional stimulation. Hansen et al. [10] examined the effect of the automatic, event-driven electrical stimulation of pudendal nerve afferents on bladder capacity in patients with SCI. The study included two women and 14 men older than 18 years with NDO, bladder capacity below 500 ml and complete or incomplete suprasacral SCI. Detrusor pressure (Pdet) was recorded during natural bladder filling. In a similar subsequent recording Pdet was used to trigger electrical stimulation when pressure exceeded 10 cm H2O. Of the 16 patients enrolled in this study, 13 had increased bladder capacity and reduced storage pressure decrease achieved by event-driven electrical stimulation. During stimulated filling, Pdet never exceeded 55 cm H2O. An average bladder capacity increase of 53% was achieved (LOE 3). Ohlson et al. treated eight patients with NDO in whom vaginal/rectal stimulation failed, with acute pudendal nerve stimulation. Five achieved a decrease in urinary frequency and four had an increase in cystometric capacity [11]. Spinelli et al. [5] performed a staged procedure similar to that of sacral neuromodulation (SNM) to place a tined lead near the pudendal nerve, using neurophysiological guidance. They named this approach chronic pudendal nerve stimulation (CPNS). Fifteen neurogenic patients (eight male, seven female) with urgency incontinence underwent CPNS. All patients had complete neurophysiological and urodynamic evaluation at baseline and follow-up and were asked to complete a voiding and bowel diary for 7 days. During screening, the average number of incontinent episodes per day decreased from 7+/-3.3 to 2.6+/-3.3 (P<0.02, paired t-test). Eight patients became continent, two improved by more than 88% (from 9 to 1 daily incontinence episodes) and two patients reduced the number of incontinence episodes by 50%. The implantable pulse generator (IPG) was subsequently implanted in those 12 patients. Three patients without improvement did not continue to second stage. In implanted patients with 6 months follow-up, urodynamic evaluation showed an objective improvement in the maximum cystometric capacity which increased from 153.3+/49.9 to 331.4+/110.7 ml (P<0.01, paired t-test). The maximum pressure decreased from 66+/24.3 to 36.8+/35.9 cmH2O (P=0.059, paired t-test). Eight patients reported significant improvement in bowel function (LOE3).

c) Dorsal Genital Nerve (DGN) stimulation

DGN stimulation can be continuous or conditional. Goldman et al. used continuous stimulation for one week [12]. They found a 55% increase in cystometric capacity. In 47% there was >50% reduction in incontinence episodes, and in 81% there was >50% reduction in number of urgency events. Increases in cystometric capacity vary significantly between studies using continuous stimulation (range 11-177%) and also conditional stimulation (range 37-144%). Horvath et al. and Oppisso et al. showed that DO was suppressed conditionally, with a subsequent increase in bladder volume and postpone ment of incontinence [13, 14]. Martens et al. found with conditional stimulation that increase in stimulation current results in a more pronounced detrusor inhibition [15]. Besides DO suppression, increases of the pressure at the bladder neck and the urethral sphincter contribute to continence [16]. In general, patients tolerate conditional stimulation well and they adapt to the sensation in long-term use [17]. Stimulation effectively suppresses urgency and decreases urgency episodes. Suppression of urgency
during stimulation might contribute to tolerance of stimulation. This might enable stimulation at higher current to increase effectiveness when stimulation is applied conditionally.

**d) Posterior tibial nerve stimulation**

Percutaneous posterior tibial nerve stimulation (PTNS) was described 20 years ago as a minimally invasive treatment for urge incontinence due to neurogenic detrusor overactivity (NDO) in spinal cord injury (SCI) patients. Interestingly, the location where the tibial nerve is stimulated is in the same area as the Sanyinjiao (SP6) point used in Chinese acupuncture to treat pelvic floor organ dysfunctions. The PTN is derived from the L4-S3 nerve roots and therefore shares common roots with those serving bladder functions. SCI and Parkinson’s patients with neurogenic DO have been treated with PTNS. PTN seems to increase cystometric bladder capacity and bladder volume at which DO and associated leakage occurs [18, 19] (LOE3). Gobbit et al. looked at the effect in 21 MS patients. Eighty-nine percent of patients reported a treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King’s Health QoL questionnaire [20]. Kabay et al. looked at the clinical and urodynamic effects in MS and Parkinson’s disease [21, 22]. They found significant clinical and urodynamic improvements, although it was impossible to completely suppress DO. De Seze et al. looked at transcutaneous PTNS in 70 MS patients [23]. With daily stimulation sessions, they showed clinical improvement in urgency and frequency in more than 80% of patients at three months. They also observed an initial acute cystometric response in > 50% of the patients without correlation with clinical efficiency. There is still debate about the possibilities to really influence voiding behavior via the posterior tibial nerve [24]. PTNS is a stimulation technique that allows for sham comparison. It should therefore be tested in this fashion.

**e) Repetitive transcranial magnetic stimulation**

Repetitive transcranial magnetic stimulation (rTMS) of the motor cortex induces a long-lasting modulation of spinal cord excitability [25]. Thus, it represents a potentially useful tool for the treatment of neurogenic urinary disturbances. Centonze et al. [26] investigated the effects of high frequency (5 Hz) excitatory rTMS over the motor cortex on LUT dysfunction in a population of 10 MS patients complaining of urinary symptoms. All but one of the patients reported an improvement of voiding phase LUT symptoms and a significant reduction of post void residual volume. In patients with pure detrusor underactivity, there was increase of PdetQmax and Qmax. In patients with DSD, on the other hand, rTMS produced negligible effects, although the observation of a reduction of PdetQmax in this context seems to suggest a better relaxation of the urethral sphincter (LOE3). Brusa et al. also observed positive effects lasting 2 weeks after rTMS in 8 patients [27].

**f) Deep brain stimulation**

1. **Subthalamic Nucleus Deep Brain Stimulation (ST-N-DBS)**

A large proportion of patients suffering from Parkinson’s disease present with urinary dysfunction including urgency, increased frequency or incontinence [28]. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been established as a surgical treatment of motor symptoms in Parkinson’s disease patients [29]. However, data from experimental urodynamic measures in men [30] and animal models [31] have also demonstrated a significant influence of STN-DBS on urinary bladder function. In these studies, the main effect of STN-DBS appeared to be a normalization of urodynamic parameters in the storage phase with a delayed first desire to void and an increased bladder capacity. Herzog et al. investigated the effect of STN-DBS on the neural mechanisms underlying cerebral bladder control. Using PET to measure changes in regional cerebral blood flow (rCBF), 11 patients with bilateral STN-DBS were studied during urodynamic bladder filling in STN-DBS ON and OFF condition. A filled bladder led to a significant increase of rCBF in the anterior cingulate cortex, which was further enhanced during STN-DBS OFF. A significant interaction between bladder state and STN-DBS was observed in lateral frontal cortex with increased rCBF when the bladder was filled during STN-DBS OFF [32, 33] (LOE3).

2. **Thalamic Deep Brain Stimulation**

The precise mechanisms underlying cerebral regulation of lower urinary tract function are still poorly understood. Essential tremor (ET) is not known to induce lower urinary tract symptoms (LUTS) or neuropathological changes in the thalamus. Consequently, DBS in patients with ET offers the unique opportunity to investigate the role of the thalamic ventral intermediate nucleus (VIM) nucleus in lower urinary tract function. Kessler et al. [34] evaluated the effect of thalamic DBS on urodynamic parameters in patients with ET. Seven patients were examined (two females, five males) with ET 15–85 months after implantation of DBS leads into the VIM. They compared urodynamic parameters during thalamic DBS (ON state) and 30 min after turning the stimulator off (OFF state). In the ON compared with the OFF state, there was a significant decrease in bladder volume at first desire to void (median, 218 ml vs. 365 ml, p = 0.031), at strong desire to void (median, 305 ml vs. 435 ml, p = 0.031), and at maximum cystometric capacity (median, 345 ml vs. 460 ml, p = 0.016). No significant differences between the ON and OFF state were detected for changes in detrusor pressure during filling cystometry, bladder compliance, maximum detrusor pressure, detrusor pressure at maximum flow rate, maximum flow rate, voided volume, and postvoid residual (LOE3).
Conclusions

- Electrical neuromodulation is not first line treatment for neurogenic DO. There are some limited reports showing that it may be beneficial (LOE 3).
- Automatic, event-driven electrical stimulation in the treatment of neurogenic DO is feasible (LOE 3).
- Chronic pudendal nerve stimulation is feasible. Neurophysiological guidance seems to be mandatory to place the lead near the pudendal nerve (LOE 3).
- Percutaneous Tibial Nerve Stimulation gives improved clinical and urodynamic parameters (LOE3), but its role is not established.
- Enhancing corticospinal tract excitability by rTMS might be useful to ameliorate detrusor contraction and/or urethral sphincter relaxation in MS patients with bladder dysfunction (LOE3).
- Thalamic deep brain stimulation resulted in an earlier desire to void and decreased bladder capacity, suggesting a regulatory role of the thalamus in lower urinary tract function (LOE3).
- STN-DBS appeared to tend to normalization of urodynamic parameters in the storage phase, with a delayed first desire to void and an increased bladder capacity (LOE3).

Recommendations

- If pharmacotherapy fails to relax the hyperreflexic detrusor, electrical neuromodulation may be optional in patients with neurogenic DO (C/D).
- Although the setup for conditional, event-driven electrical stimulation is not suitable in a clinical setting, the treatment modality is promising and it warrants further investigation (D).
- Further studies on chronic pudendal nerve stimulation must be carried out to identify the best stimulation parameters and to verify the long term results (D).
- The thalamus may be a promising target for the development of new therapies for lower urinary tract dysfunction. Further investigation on this matter is needed before its potential role can be elaborated.

2. ELECTRICAL STIMULATION OF THE PELVIC FLOOR MUSCULATURE

The aim of electrical stimulation in patients with neurogenic urinary stress incontinence is to improve key functions, namely the strength and/or timing of the pelvic floor muscle contraction. Electrical stimulation is provided nowadays mostly by portable battery powered stimulation, offering a wide combination of wave forms, frequencies, intensities, electrode placements etc.

In patients with incomplete denervation of the pelvic floor muscle and of the striated sphincter, electrical stimulation via anal or vaginal plugs performed over months, may improve pelvic floor function, and may thus improve incontinence. The incompleteness of the lesion should be as such that the patient is able to contract voluntarily the pelvic floor to some extent, even if such contraction is weak.

Conclusions

- There is no study published which deals with electrical stimulation via anal or vaginal plugs could be able to improve the strength of pelvic floor musculature (LOE 4).

Recommendations

- In patients with incomplete denervation and some voluntary contraction of the pelvic floor muscle and the striated sphincter, electrical stimulation may be an option to improve pelvic floor function, thus improve incontinence (C/D).

3. INTRAVESICAL ELECTRICAL STIMULATION (IVES)

The technique involves a catheter with a stimulation electrode, introduced into the bladder and connected to the stimulator. Saline (0.9 %) is used as the current leading medium within the bladder. The neutral electrode is attached to the skin in an area with preserved sensation, usually in the lower upper abdomen. The afferent stimuli induced by IVES travel along afferent pathways from the LUT to the corresponding CNS structures. This “vegetative afferentation” results in sensation of bladder filling/urge to void, with subsequent enhancement of active contractions, and possibly also in voluntary control over the detrusor. Feedback training is mediated by enabling the patient to observe the change of the detrusor pressure on a water manometer, which enables the patient to notice when a detrusor contraction takes place. This also facilitates voluntary control.

Intravesical electrical stimulation of the bladder (IVES) is still not established as a therapy for patients with neurogenic detrusor dysfunction. IVES may help to verify function of afferent pathways, proper indication is crucial and this type of therapy should only be applied in those with afferent fibers between the bladder and the cortex, proved by the evaluation of viscerosensory cortical evoked potentials. Intravesical electrotherapy may be able to improve neurogenic bladder dysfunction. Studies about IVES were reviewed in previous consultations [35].

Conclusions

- Basic research during the last decade supports the underlying working concept of IVES (LOE 3).
• The results reported in the literature are controversial, mainly because of varied inclusion and exclusion criteria (LOE 3).

• In the only sham-controlled study the treatment period was short and the inclusion and exclusion criteria were not fully defined (LOE 3).

Recommendations

• Intravesical electrotherapy may improve neurogenic bladder dysfunction, inducing bladder sensation and the urge to void (B/C).

• IVES is the only available option to induce/improve bladder sensation and the urge to void (B/C).

• Selection of patients is crucial and IVES should be applied only if afferent fibers between the bladder and the cortex are still intact and if the detrusor muscle is still able to contract (B).

• The ideal indication is the neurogenic hypo-sensitive and hypocontractile detrusor (C).

VI. SURGICAL TREATMENT OF URINARY INCONTINENCE

1. SACRAL NEUROMODULATION

Two indications for neuromodulation are clearly valid in urology: overactivity/urgency urinary incontinence and chronic urinary retention (aside from vesicosphincteric dyssynergia) [1], as discussed elsewhere in the consultation. This section focuses on the possible application of sacral neuromodulation in patients with neurological bladder dysfunction. The literature survey was undertaken with the key words: neurogenic bladder; spinal cord injury; spina bifida; meningomyelocele; multiple sclerosis, sacral neuromodulation.

a) Hypotheses on the modes of action of neuromodulation

The first effects of electricity on the bladder were reported during electro stimulation treatment of pelvic floor muscles (with the aid of electrodes situated in the anus, the vagina, on the penis...) during urinary incontinence reeducation [2-5]. Inhibition of bladder contractions by electrostimulation was seen. Tanagho and Schmidt, the pioneers of neuromodulation, attributed the benefits of neuromodulation in urinary incontinence to a hypertrophy of the pelvic muscles, allowing better control [6]. Voluntary contractions of the pelvic floor muscles can cause reflex relaxation of the bladder. However, the most widely held hypothesis currently is that neuromodulation allows a restoration of normal vesical reflexes [7-9] (LOE4). This hypothesis explains that the stimulation can inhibit the guarding reflex pathway and restore normal urination or turn off supraspinally mediated overactivity by blocking ascending sensory pathways. The role of cortico-subcortical structures was recently emphasized in studies of patients with incontinence [10, 11] (LOE4) or retention [12] (LOE4). Somatic afferents as the vectors for neuromodulation mechanism of action is supported by the observation that visceral nerve fibers are not activated by the parameters normally used [13] (LOE4). Despite data obtained in animals [14] (LOE4), it seems that neuromodulation cannot be effective in patients with a non functional peripheral nerve circuit.

b) Treatment of neurogenic detrusor overactivity incontinence

There is little in the literature concerning sacral neuromodulation (SNM) in this specific indication. Many studies recorded results for incontinence and for retention at the same time, without always separating the results. Since the technique’s first stages, Vodusek [5, 6] (LOE4) reported that non-muscular electrical stimulation of the sacral somatic afferents can induce bladder inhibition in patients who present with DO secondary to a medullary lesion, be it due to trauma or to multiple sclerosis (MS).

Two points must be kept in mind when treating patients with neurological bladder:

• The disappearance of wettings between catheterizations can be considered a success by itself in patients using IC. In contrast, in able-bodied patients, treating retention with IC is most often considered a failure.

• On the other hand (contrasting, for example with botulinum toxin injections), neuromodulation does not systematically require the use of IC. Furthermore, reversibility of neuromodulation is a strong point that must be considered when devising a therapeutic plan.

The main published series are summarized in Table 3. Author definitions for neurological pathology differed widely: some authors considered a history of pelvic surgery as a possible etiology while others included only patients with medullary neurological lesions. Despite this, several points considering the neurological etiology of the bladder dysfunction can be discussed;

• MS is not a contra-indication for neuromodulation [10, 15, 16] (LOE3-4). However, it seems important to propose this treatment only in patients who present with a stabilized form of multiple sclerosis. In addition, patients must be clearly informed that the results of neuromodulation may be altered by the evolution of their underlying illness.

• Patients with incomplete medullary lesions, whether of traumatic or other origins, may benefit from neuromodulation [10, 17-22] (LOE3-4). On the other hand, all authors agree on excluding

NP: Not precisely stated, NA: Not applicable; LOE: Level of evidence MS: Multiple sclerosis
patients with complete medullary lesions. Clinical data, especially from the Hohenfellner series [19] (LOE3), support among others those reported by Schurch et al. in 2003 [23] (LOE4). These authors published a study in which they recorded external anal sphincter (EAS) electromyographic activity caused by stimulation of the S3 sacral root during a percutaneous needle evaluation (PNE) test in three patients who presented with neurogenic DO and DSD secondary to a complete traumatic medullary lesion. They describe a reflex response with early and late latency in the three patients. They also demonstrated that the EAS contraction observed during the PNE represented an indirect motor response mediated by the afferent nerves towards the spinal cord. Despite the recording of an EAS motor response in the three patients, they did not obtain any urodynamic or clinical benefit. This suggests the participation of supraspinal neuronal centers—presumably a spino-bulbar spinal pathway—in the SNM mode of action. However, these data are contradicted by an experimental study using bilateral neuromodulation in the cat [24] (LOE4).

- Guys et al. [25] demonstrated significant but limited urodynamic differences in children (LOE3). However, the clinical translation of these modifications has not been reported. It must be emphasized that, in the absence of electrodes adapted to paediatric sizes, the study was carried out without the usual percutaneous evaluation phase.

- Encouraging short term results in neurological bladder dysfunction do not necessarily translate into long-term efficacy [19] (LOE2). Despite a positive test in about half of the patients tested, long term (54 months) results were poor in almost all patients (1/12 had neuromodulation efficacy).

- Sievert et al. [26] performed acute bilateral sacral S3 nerve stimulation in 10 patients with complete spinal cord lesions (SCLs) during the spinal shock phase, with six patients as controls. After a mean follow-up of 26 months, the cystometric capacity increased and IDC were abolished in the stimulation group. Further studies should look into this technique and question the ideas about the working mechanism in sacral nerve stimulation since afferent stimulation effects are unlikely in complete SCI.

- One of the largest and latest series is from Chaabane et al. [27]. They looked at the results of PNE testing and SNM implants with a mean follow-up of 4.3 years in 62 patients (34 with DO, 28 with chronic urinary retention). DSD was present in nine cases. 41 patients (66.1%) had more than 50% improvement on urodynamic evaluation and bladder diary with PNE, and 37 were implanted. At follow-up results remained similar to the evaluation phase in 28 cases (75.7%). In six cases (16.2%), clinical response had been lost; in these six cases, neuromodulation failed on average 12.0 months after implantation.

Scheepens et al. [20] reported two prognostic factors for poor response (the study population was six incomplete medullary injuries, five patients with cauda equina syndrome, six with multiple sclerosis, and one with myelomeningocele) (LOE3): duration of the symptoms (more than seven months in this study) and the existence of a neurological cause for bladder dysfunction. Neurological patients with a very localized and incomplete nervous condition were the most successful. Patients with herniated disc surgery had a greater chance of good response. Patients with complete medullary or large sacral lesions were poor neuromodulation candidates.

Clinical results of neuromodulation do not necessarily correlate to urodynamic results. Bosch indicated in his series [17] that almost half of the patients considered to have had a good outcome clinically in reality retained some overactivity. One publication reported correspondence between urodynamic test data and clinical data [10] (LOE4). In 2001 Chartier-Kastler [28] et al. published the results of a prospective study concerning the evolution of urodynamic parameters during the acute phase of the PNE test in 14 patients with neurogenic DO. The authors concluded that the acute phase of PNE was accompanied by a significant change in urodynamic parameters in more than 2/3 of the patients, and that this should be a possible means for selecting patients.

c) Sacral neuromodulation for urinary retention in neurological bladder dysfunction

The only study which reported specific results for neurogenic urinary retention is from Hohenfellner et al. [19] (LOE3), reporting on 11 patients. Of these patients, three were implanted and there were temporarily satisfactory results in only two. Thus, it seems that neuromodulation has a marginal place in retention patients with neurological bladder. Patients need to be clearly informed of the high risk of failure. In this respect the bladder contractility test can be helpful in order to predict a successful outcome of sacral nerve stimulation in intractable neurogenic bladders [29]. It is also necessary to be especially prudent in patients with cauda equina problems, who may have the illusion of recovering urination, but actually may be enhancing abdominal straining to evacuate their bladder. In reflex incontinence, patients with complete spinal cord or cauda equina lesions are poor candidates (LOE4). While a few studies have reported on SNM in specific contexts [30-33], patients should be informed that IC is the first-line therapeutic option for neurogenic urinary retention.

Recommendations

- Sacral neuromodulation can have an inhibitory effect on neurogenic DO (C).
• While sacral neuromodulation has a place in the care of neurological urinary incontinence or neurological urinary retention, the proportion of patients whose condition is improved is much less than in non-neurological pathologies (B).

• Indications for sacral neuromodulation in the care of DSD in neurological urinary dysfunction are still not established (D).

2. DENERVATION PROCEDURES FOR TREATING REFLEX URINARY INCONTINENCE DUE TO DRETRUSOR OVERACTIVITY

a) Peripheral bladder denervation

Various techniques of peripheral bladder denervation, such as prolonged hydrodistension or bladder trans-section, are no longer used. Some authors have reported transient improvement in certain patients after prolonged hydrodistension, but DO recurs rapidly and the procedure is not straightforward. There are no reports for patients presenting specifically with neurogenic DO [34]. Bladder trans-section was briefly popular at the end of the 70s [35-37]. It involved complete section of the bladder wall from one ureteric orifice to the other. The technique was indicated for urgency incontinence. However, a lack of anatomical and physiological information to support the mechanisms of efficacy of the procedure, and a lack of reproducible results from the initial series, explains why it is no longer used.

Another bladder denervation technique was developed by Ingelman-Sundberg [38, 39], by resection of the inferior hypogastric plexus in contact with the bladder through an inverted U-shaped vaginal incision, dissecting the bladder laterally and posteriorly, as widely as possible. In the most recent paper [39], the authors report up to 54% recovery over a mean follow-up of about three years. Each published series is from the same group, is retrospective and reports only a small sample size (LOE4). It has only occasionally been used in neurogenic DO.

b) Isolated rhizotomy of ventral and/or dorsal sacral roots

Historically, attempts at sacral root surgery first focused on cutting the motor (ventral) sacral roots. It was soon clear that this method failed within six months. With a different objective, Brindley [40] developed a technique involving stimulation of ventral sacral roots to obtain controlled and complete bladder voiding in cases of SCI. He realised that patients only acquired continence if the stimuli causing reflex bladder contractions could be blocked [41]. Early techniques consisted in selective destruction of the dorsal sacral roots that evoke detrusor contractions. These selective rhizotomies did not, however, give the best results. Only after complete de-afferentation of the sacral micturition centre by intradural rhizotomy were better results obtained [42-45] (LOE2-3).

The technique of “selective” dorsal sacral rhizotomy has been studied more extensively. It involves making an extra-dural approach to the sacral roots (S2-5), isolating and stimulating the dorsal (sensory) contingent whilst monitoring changes in urodynamic pressure within the bladder in order to cut only those fibres responsible for overactivity. To retain reflex erection, S2 must be preserved, at least on one side. This treatment may be proposed for patients with neurogenic DO, and also those with urgency incontinence. The literature records only case series without control groups. Preliminary results were promising but were based on a small number of cases with short follow-up times [46-49] (LOE4). The outcome seems to deteriorate over time. Opsomer et al. [50] reported deterioration after one year for all treated patients (n=8)(LOE4). Torrens, one of the first to use the technique, was led to re-evaluate his long-term results [51]. The most recent article by Lucas et al. [52] concerning 22 patients (LOE3), also reported a significant, but less marked, deterioration at four years. At the mean follow-up of 4 years, 39% of patients retained a urodynamically stable bladder with satisfactory clinical response. The authors ascribe these improved results to a more extensive rhizotomy. However, it should be noted that there was a marked heterogeneity of patients in this series, three out of the eight, considered to be “successes”, were IDC patients with leakage due to DO.

Mertens et al. [53] applied a technique previously used for limb spasticity, namely microsurgical DREZotomy, the aim of which is to destroy the dorsal root entry zone (DREZ). This zone, first defined in 1972 by Sindou [54], is a functional anatomical entity that groups together the proximal portion of the dorsal root, the medial portion of the dorso-lateral tract and the superficial layers of the dorsal horn. The technique involves making a micro-surgical lesion (by micro-coagulation) on the ventro-lateral portion of the entry zone, near the apex of the dorsal zone. The effect of DREZotomy is to selectively block nociceptive afferents, and their relays, and myotatic afferents. The benefit of the limited lesion is to avoid complete abolition of tactile and proprioceptive sensitivity and to prevent the development of deafferentation phenomena. To treat neurogenic DO, the lesion must be made on both sides from S2 to S3, or even S4. The results from the first series concerned 38 patients treated for incapacitating lower limb spasticity, treated by extended DREZotomy from L2 to S1. 58% of these patients were permanently catheterized. At six months, DO had disappeared in 82%, with 63% having significantly improved bladder capacity. At 18 months post-surgery, leakage had disappeared in 89% of cases. In the last 8 years, no publications on DREZotomy for neurogenic LUT disorders were found.

Hohenfellner [55] following Brindley’s experience,
proposed “neurogenic bladder augmentation”. This involved completely destroying the ventral and dorsal sacral roots, possibly followed by continent cystotomy and simplified urinary catheterization. The author reported his experience with eight patients retrospectively (LOE3). After surgery in all patients, bladder capacity increased from about 177 ml to 670 ml, with complete disappearance of detrusor overactivity. No updates have been published since 2001 on this technique.

**Percutaneous sacral root block**

Sacral root block is an old technique, since Dogliotti [56] proposed it as early as 1931 to relieve vertebral cancer pain by chemically sectioning several dorsal roots. An injection of alcohol causes denervation due to the fragmentation of myelin in the endoneurium. In the 1950s, Bors [57] applied the technique to the bladder, standardized the procedure and described preliminary results. Later authors reported on a few series (LOE3) [58, 59], but always with the same result; the benefit disappeared after a few months. Phenol, considered to be “selective” for C fibers was then tried but the results were no better [60-62]. Chemical destruction of the sacral nerve roots has proved ineffective and is accompanied by a high rate of minor complications (pain), resulting in significant discomfort and prolonged hospitalization (LOE3) [58, 59]. Mulcahy et al. [63] proposed sacral rhizotomy by percutaneous radiofrequency for neurogenic bladder (LOE4). A recent study was published by Ferreira et al. [64]. In 8 SCI patients they performed a bilateral block of S3 with bupivacaine. These 8 respondents had an increased bladder capacity and for 3 out of 4 patients autonomic dysreflexia (AD) improved.

**c) Rhizotomy of posterior sacral roots and stimulation of the anterior sacral roots**

Electrostimulation to improve micturition in patients with spinal cord injury has been extensively researched since 1954. Direct stimulation of the detrusor, the spinal cone, the splanchnic and sacral nerves have not produced reliable results. Since 1969, G.S. Brindley has developed a set of electrodes for stimulating the spinal roots in the cauda equina. The technique, first tested in baboons, led to the development of an implanted stimulator to induce micturition in paraplegic patients. Sacral rhizotomy performed during implant surgery makes it possible to control bladder hyperactivity and ensure continence. The energy source and the microprocessor for adjusting the stimulation parameters are not implanted. The transmitter transforms the electric current from the energy source into electromagnetic waves, which are picked up by the implanted receptor and re-transformed into an electric current that circulates to the electrodes in contact with the nerve. Depending on the surgeon’s decision, the implant is placed within the membranes of the dura mater or outside them, so as to stimulate the sacral roots from S2 to S4. At the same time, it is essential to perform posterior rhizotomy from S2 to S4 to remove any detrusor overactivity, though this is difficult to perform [65] (LOE4). This technique can only be performed in those with spinal damage who are para- or tetraplegic. The sacral reflex arc must be preserved.

Micturition is not continuous: the detrusor cannot be stimulated without also stimulating the sphincter. The parasympathetic fibers and the fibers destined for striated muscles are stimulated together. The response of detrusor smooth muscle fibers causes a gradual increase in pressure, which continues after stimulation has ceased. The “on-off” response to stimulation of striated muscle fibers is different. When stimulation stops, the striated sphincter immediately relaxes, whilst the detrusor continues to contract. A new wave of stimulation increases and maintains sufficient detrusor pressure to cause micturition after stimulation stops. The careful selection of stimulation and stopping times results in a discontinuous, but satisfactory, micturition. Sphincter fatigue due to electrical stimulations, blocking of pudendal nerve motor fibers [66] (LOE4) or use of specific detrusor stimulation by performing an anodal block [67] (LOE4) have been reported, together with poor efficacy.

Stimulation can also help defecation and erection, but it should be remembered that the principal object of sacral nerve stimulation combined with posterior rhizotomy is to achieve urine continence and bladder voiding. Induced erection is a secondary benefit but not an indication for the procedure, and men should be warned that they would lose reflex erection after posterior rhizotomy.

The results of the intervention are summarized in Table 4. Briefly, the outcome with regard to continence and bladder voiding are good (LOE 2-3). Failures result from incomplete rhizotomy, where bladder hyperactivity persists, or from sphincter insufficiency which may be treated by additional placement of an artificial sphincter [44, 45] (LOE3). Incomplete rhizotomy can be surgically completed [44, 45, 68] (LOE 2-3). In all reported series, mean bladder capacity increased significantly (LOE 2-3). Micturition was obtained by electrostimulation with a post-voiding residue (PVR) of ≤ 50 ml in 69 to 100% of patients. All series reported decreased incidence of urinary infection, but the defining criteria were too varied to allow conclusions to be drawn. Posterior sacral rhizotomy probably protects the upper urinary tract from detrusor overactivity. It can resolve the problem of pre-operative reflux [68, 69] (LOE4). However, posterior sacral rhizotomy should be complete. Indeed, in a series of 500 patients, Brindley [68] (LOE3) reported twelve cases of upper urinary tract impairment, ranging from grade I reflux to upper urinary tract dilation.

Martens et al. looked at patients in the Netherlands who underwent a Finetech-Brindley procedure [70]. They investigated the effects on quality of life in a group of 46 patients that still used the implant. They also looked at the presumed beneficial effects of the rhizotomy only, comparing with a group of 70 matched controlled patients that had optimized standard care. The patients had a significant better Specific Impact of Urinary Problems score, general QoL index (Qualiveen), and continence rate, and less urinary tract infections compared to the Control Group. If the stimulator was not used anymore, patients still benefited from the rhizotomy with regard to QoL and continence rate. The subscales of the SF-36 had better scores for the patients who used their stimulator as compared to those who did not use the stimulator and compared to the Control Group. The conclusion was that the active group had a better QoL than the rhizotomy group, and both groups had advantages over optimized standard care.

Schurch [71] focused on the specific problem of dysreflexia and recorded its persistence during stimulation in all patients who had suffered prior to surgery, but with marked improvement in symptoms.

Conclusion

• Bladder denervation is mainly reserved for those suffering complete spinal cord injuries.

Recommendations

• No peripheral bladder denervation technique has passed the test of time (D).
• Injections of neurolytic products to treat detrusor overactivity should be abandoned, since they are ineffective in the medium and long term and expose patients to morbidity (A).
• Sacral dorsal rhizotomies need to be quite extensive to treat successfully neurogenic DO. So they may be performed only in patients with lower limb neurological impairment (B).
• In certain situations, dorsal rhizotomies can be undertaken in association with ventral root stimulators (Brindley’s technique) or even with continent cystostomy (B).
• Electrostimulation of the anterior sacral roots is a valid option for managing neurogenic bladder in patients with spinal lesion, with long-term follow-up (B).
• It must be combined with destruction of all or part of the posterior sacral nerves, and cannot therefore be performed in patients with conserved lower limb motility (B).
• The reflex arc must be intact (B).
• Posterior rhizotomy exposes men to loss of reflex erection and women to a loss in reflex vaginal lubrication (B).
• It is vital to assess the patient carefully before implantation so as to determine whether he/she will be able to mount a toilet or grasp a urinal handrail (B).

3. SURGERY FOR INCONTINENCE ASSOCIATED WITH POOR BLADDER EMPTYING DUE TO DETRUSOR UNDERACTIVITY

Incontinence in neurological patients can be aggravated by deficient bladder emptying and retention. Two mechanisms can be involved: detrusor sphincter dyssynergia (DSD) or bladder hypococontractility. A literature search was undertaken for the terms: neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; sphincterotomy; stent.

a) Surgical treatment of detrusor external sphincter dyssynergia

DSD is a characteristic feature of suprasacral and infrapontine lesions. The aim of sphincterotomy is to produce reflex micturition into a condom catheter, thus protecting the upper urinary tract. For the last thirty years, endoscopic sphincterotomy has been the technique of choice for patients who cannot or do not want to do IC. It is invasive, irreversible and the patient has no adaptation period [76, 77] (LOE3). Prosthetic sphincterotomy using a urethral endoprosthesis (or stent) is an alternative.

Sphincterotomy recommendation supposes a diagnosis of a neurological cause of DSD that is complicated by hydronephrosis, vesicoureteral reflux, autonomic dysreflexia or repeated urinary infections secondary to poor bladder voiding. Patients should have failed or refused IC. Main contra-indications are [78, 79]:

• Impossibility to retain a condom catheter. All sphincterotomy techniques, including stenting, are contra-indicated for men who cannot retain a condom catheter (hence also for women). A semi-rigid penile prosthesis can be placed to help retain the condom catheter [80] (LOE3). However, patients must be informed that there is a 20% to 30% risk of erosion and infection of the penile prosthesis for those with SCI, as opposed to only 2.7% in the general population [81, 82] (LOE3).
• Detrusor acontractility or hypocontractility. Patients with spinal cord injury and no reflex detrusor contraction during urodynamic tests are poor candidates for the various techniques of sphincterotomy.
• Patients who wish to father children and are candidates for vibro/electro-ejaculation and an artificial insemination program.

1. ENDOSCOPIC SPHINCTEROTOMY

Emmett [83] first described endoscopic sphincterotomy in 1948. He performed cervico-prostatic incisions
in patients with SCI, but later realized that the problem lay in the striated sphincter. External sphincterotomy was performed in 1958 by Ross et al. [84]. They carried out cold-blade surgery and placed a catheter (Ch 22-26) for tamponade, since nearly all patients required transfusion (one of the ten patients in the series died after surgery). A few attempts at surgical sphincterotomy via the perineal and subpubic myotomy routes were tried later. Complexity and frequent serious complications explains why these approaches were abandoned [85, 86]. Sphincterotomy with electrocoagulation was finally found to be the best technique.

Endoscopic sphincterotomy morbidity includes hematuria, which can be abundant and sometimes difficult to control, requiring transfusion in 2-13% of patients (LOE2-3). Incision at the twelve o’clock position seems to offer the lowest risk of hemorrhage, with three and nine o’clock sphincterotomies entailing the highest risk [87] (LOE4).

Post-operative impotence is also a common complication. Rates of up to 56% were reported in early series [88-91] (LOE3). More recent series (table 5, LOE 2-3), most using a median, or slightly deviated incision, have not affected sexual function. However, it should be noted that the population concerned may have many other reasons (neurological, psychological, etc.) for suffering from erectile dysfunction. When sphincterotomy is accompanied by complete incontinence there are obvious reasons for psychological difficulties during intercourse. This issue must be discussed with the patient before surgery. The fear of this sequel sometimes causes the patient to decide against surgery; use of an incontinent prosthesis as first-line therapy can enable the patient to gain insight into this potential consequence of endoscopic sphincterotomy.

If striated sphincter section fails, the possibility of bladder neck stenosis should be investigated. This is seen in from 2 to 21% of patients (LOE 2-3). Section of the bladder neck may then improve voiding, but will result in permanent incontinence. Before surgery, the surgeon must make sure that the patient accepts this situation and can use a condom catheter.

Results of endoscopic sphincterotomy are summarized in Table 5 (LOE2-3). Any analysis is made difficult by the absence of unequivocal criteria of success. Some patients are improved by sphincterotomy, even with a 200 ml residue. Most authors use indirect urodynamic criteria to evaluate success (decrease in bladder pressure during micturition, decrease in PVR). The most obvious result is the improvement in autonomic dysreflexia observed in tetraplegic patients. It also appears that the intervention reduces the rate of symptomatic UTIs. However, chronic bacteriuria is not improved [92]. The reported results concerning resolution of hydronephrosis and vesicorenal reflux differ, and in each series, there are very few patients. Another essential point, well known in practice but rarely reported, is the recurrence of neurogenic DSD in many patients [77, 93, 94] (LOE3). Riccotone et al. (LOE3) [94] reported 82% recurrence of symptoms after ten years of follow-up. Juma et al. [77] (LOE3) report similar results after eleven years, with patients undergoing an average of 1.7 sphincterotomies. Pan et al. reported a mean duration of benefit of almost seven years, which could be sustained with a repeat procedure [95]. A single study has tried to address predictive factors for a successful sphincterotomy. In this retrospective study, although detrusor leak point pressure and retrograde perfusion pressure were found to be superior to residual urine volume in predicting sphincterotomy success, results were not statistically significant [96]. 30-68% of patients eventually develop some impairment of the upper urinary tract [77, 95]. Patients who have undergone this surgery must therefore be regularly monitored to detect any distension of their upper urinary tract.

2. Prosthetic sphincterotomy

In 1990, Shaw et al. proposed using a wire mesh stent (Urolume) to treat patients with spinal injury presenting with DSD [97] (LOE3). Since then, various stents have been used. Table 6 lists the types of stent used for DSD, according to classification criteria [98, 99]. They can be placed in various sections of the urinary tract: prostatic urethra, through the striated sphincter or more distal in the sub-sphincteric urethra. Our review is limited to placement through the striated sphincter.

• Temporary prosthetic sphincterotomy

Temporary stents make it possible to carry out a therapeutic test to check the feasibility of condom catheter use, check that placing a foreign body in the urethra does not induce autonomic dysreflexia and ensure the patient accepts the mode of micturition. Moreover, during this trial period, it is possible to study how the bladder empties in the seated position, and assess the necessity of additional treatment for smooth muscle sphincter dyssynergia at the level of the bladder neck. Moreover, as this treatment is simple and reversible, it is possible to propose it very early to the patients, rendering the patient autonomous with regard to carer-assisted catheterization, if this were the prior mode of micturition and leaving the possibility to discuss any fertility and sexual issues, and considering the possibilities of preserving sperm. For patients with SCI, early temporary stent placement (within six months of trauma) theoretically has the added advantage of waiting for recovery of upper limb motility to enable IC, decrease the risk of nosocomial infection during rehabilitation by reducing carer-assisted catheterization, and relieve nursing load during rehabilitation. The last two points, though logical, are yet to be proved by relevant studies. After using a temporary stent, the patient may choose his mode of micturition; i.e. return

to his former state, change to another temporary stent, replace it by a permanent stent, or choose surgical sphincterotomy.

By definition, temporary stents should be self-retaining, easy to remove and must not epithelialize. Only the temporary stent Diabolo [100] is specific for the external urethral sphincter. The results of two types of temporary stenting (test) for incontinence have been published in the same series [101] (LOE3). In a retrospective study of 147 patients, the authors demonstrated a significant effect on incontinence throughout the mean ten month test period, with very low morbidity (15%). The temporary stents were removed easily from all patients without sequelae. After this period, 62.6% of patients chose permanent sphincterotomy, usually by means of a permanent stent. During the study, the authors abandoned the first used stent (Nissenkorn), replacing it with Diabolo.

Memokath is another device that has been studied in neurological patients [102-107] (LOE3-4). Several authors report complications (32-100%) using this stent, which seems to induce a lot of bladder stones and to be quite difficult to remove, especially if it is left longer than 18 months. When used as second-line treatment following failed sphincterotomy, Memokath successfully reduced post-void residuals, but failed to improve urodynamic parameters including bladder capacity, detrusor leak point pressure, bladder compliance, and maximum detrusor pressure [102].

- **Permanent prosthetic sphincterotomy**

Permanent stents are designed to integrate with the urethral wall [108]. They resist the striated sphincter and prevent its closing during reflex contraction. They can be removed if necessary, or at the patient’s request, with recovery of striated sphincter contraction [109, 110]. Permanent stents are made of biocompatible materials such as nitinol (a nickel and titanium alloy) and titanium. They usually consist of a mesh comprising a single thread (e.g. Urolume) or several threads (e.g. Ultraflex). None of the stents are specifically adapted for the urethral striated sphincter. Three have been reported for treating neurological patients with DSD: Urolume, Memotherm and Ultraflex. All can be placed under local anesthesia. Table 7 summarizes the principal series published on these devices. Only Urolume was studied according to strict prospective criteria [92] (LOE1-2). Using stringent clinical and statistical methods, they classified the stent as LOE 1 for effectiveness and morbidity in DSD with a 5-year follow-up. 160 patients with SCI (mean age 36.3 years) in 15 North American centres, were treated prospectively with Urolume for DSD. Urodynamic parameters for micturition pressure, PVR and functional bladder capacity were measured before treatment and then annually up to 5 years afterwards. Mean micturition pressure, the primary criterion, was significantly lower 5 years after stenting. PVR decreased significantly and was maintained after 5 years. Mean bladder capacity remained constant. Hydronephrosis, suffered by 28 patients before surgery, disappeared in 22 (78.6%) and was improved in the others. Autonomic dysreflexia resolved in 70% of cases. The indwelling catheters of 63 of the 86 (84.9%) patients catheterized before surgery could be removed. The percentage of positive urine cultures remained unchanged after stenting. No case of peri- or post-operative bleeding, soft tissue erosion or bladder lithiasis were observed during the study. One case of prosthetic encrustation occurred during the first year; three during the second year; three during the third year; two during the fourth year and five in the fifth year. Urothelial reaction was reported in 44.4% of cases, but 93.3% of these were mild and none required treatment. No erectile dysfunction was reported. Stents had to be removed from 24 patients (15%), four of whom received new implants. 80% of the patients considered their situation improved by stenting, and 84% of physicians considered the treatment effective. 47 patients required supplementary treatment on the bladder neck (endoscopic section in 20 cases).

In the mid-term, prosthetic sphincterotomy using a Urolume stent appears to be satisfactory. However, the situation is not so clear over the longer-term. It is not always easy to remove the stent, especially from patients who have not been monitored regularly. Some teams report highly complex surgery for stent removal, especially in the event of associated urethral stenosis [111-114] (LOE3). A small study (n=12) following patients up to twenty years after insertion, suggests a high rate of complications, as 5/6 patients who completed the 20-year follow-up developed bladder neck dyssynergia requiring incision, 2 patients developed obstructive encrustations within the first year of insertion and another patient developed bladder cancer [115]. However, in those patients who completed the 20-year follow-up, sustained significant improvements in maximum detrusor pressure and duration of detrusor contraction were recorded.

Whether patients should be offered prosthetic or endoscopic sphincterotomy is not yet agreed. Endoscopic sphincterotomy is the preferred standard treatment for DSD, where IC cannot be performed. Two prospective studies carried out in the US in 1994 indicated that prosthetic sphincterotomy was at least as effective as standard sphincterotomy in patients with SCI, and offered advantages in terms of morbidity, duration of hospitalization and cost [116, 117]. The two studies were not randomized. Follow-up was short (mean 15 months), with a potential risk of bias, since the conclusion that external sphincter balloon dilatation is as effective as endoscopic and prosthetic sphincterotomy is not borne out by long-term outcomes [118].

transurethral incision of bladder neck might inter-
overactivity might inhibit detrusor contraction and
The rationale to use BNI was that sympathetic
following BNI, and autonomic dysreflexia became
improvements in DSD, but this theory as well as the
clinical results need to be verified in further studies.
BNI, however has been used as supplementary
treatment in patients who were originally managed 
with a urethral stent. It is not clear whether in those
cases BDND was an overlooked primary dysfunction 
or developed secondary to the use of the stent. It is 
recognized in a large percentage of patients with a permanent stent [92, 115, 124], and is report-
ed to be treatable with BNI although detailed results are 
missing (LOE 3-4).

Recommendations

- Where clean intermittent catheterization is not 
  possible, the long-term use of indwelling cath-
  eters should be avoided (B).
- Whatever type of sphincterotomy is chosen 
  (surgical or prosthetic):
  - Patients must think carefully about the 
    different modes of micturition possible 
    for them (A).
  - The few studies reporting long-term re-
    sults of sphincterotomy demonstrate 
    the vital importance of regular patient 
    monitoring for the recurrence of DSD or 
    blockage (B).
  - This mode of micturition is contraindicat-
    ed in women, and in men with difficulty in 
    maintaining a condom catheter (B).
  - Men who wish to have children should be 
    warned of the risk of ejaculatory duct ob-
    struction (B).
- For patients who have chosen surgical 
  sphincterotomy:
  - The reference technique involves an elec-
    tive 11, 12 or 1 o’clock incision of the ure-
    thral sphincter (B).
  - Although surgical sphincterotomy is 
    the accepted reference treatment for 
    neurogenic DSD, analysis of the litera-
    ture highlights the lack of reliable effi-
    cacy and reproducibility criteria for the 
    technique (B).
- For patients who have chosen prosthetic 
  sphincterotomy:
  - Different types of stent are used, depend-
    ing on whether sphincterotomy is tempo-
    rary or permanent. Stents are complemen-
    tary, and different designs can be used for 
    different situations (B).

3. OTHER SPHINCTEROTOMY TECHNIQUES

Two authors reported using Nd-YAG lasers for 
spincterotomy [120, 121]. Although no randomized 
study has been conducted, comparison with results 
from the literature (with very short follow-up), sug-
gests that these techniques are not as good as 
standard endoscopic sphincterotomy. However, the 
reported morbidity (particularly hemorrhage) was 
reduced (LOE2). External sphincter balloon dilata-
tion was recommended by Chancellor et al. [122], 
with short-term results similar to those of surgical 
spincterotomy. However, the technique has been 
abandoned by its sponsors and the device has not 
been distributed, probably indicating poor efficacy 
in the medium and long-term, compared with other 
mini-invasive methods such as stenting.

b) Bladder neck incision (BNI) for detrusor-bladder 
neck dyssynergia (DBND)

The rationale to use BNI was that sympathetic 
overactivity might inhibit detrusor contraction and 
transurethral incision of bladder neck might inter-
rupt the inhibitory reflex arc and result in restora-
tion of detrusor contractility. In a single retrospec-
tive study BNI was performed in 22 patients with 
high-level SCI and DBND demonstrated upon video-urodynamics, who were previously managed by 
either IC or indwelling catheter [123]. Voiding symp-
toms were complicated by autonomic dysreflexia in 
17/22 patients. Deep incisions were carried out at 
the 5 and 7 o’clock positions, sparing the external urethral sphincter. A satisfactory surgical outcome, 
defined as greater or equal to 2-point reduction in the 
AUA/IPSS quality of life index was recorded in 
86.4% of the patients 3 months post-op (LOE3). 
Presentation of urodynamic results is not, however, 
clear. Significant reductions were reported in those 
patients with preoperative Pdet >15cm H2O and 
significant increases in those with preoperative Pdet <15cm H2O, but it was not clarified whether detru-
sor pressures refer to filling or voiding Pdet. Post-
void residual improved significantly in both patient 
subgroups. While all patients additionally suffered 
from DSD preoperatively, an open urethral sphinc-
ter during voiding was reported in 86.4% of them 
following BNI, and autonomic dysreflexia became 
less severe or resolved in 88.2% of sufferers. The 
authors hypothesized the presence of a urethra-to-
bladder neck reflex pathway to explain additional 

A prospective, multicenter, randomized study com-
paring endoscopic sphincterotomy with prosthetic 
spincterotomy was published in 1999 by Chancellor 
and Rivas, using the Urolume stent [119]. Fifty-
seven patients in three specialist spinal cord injury 
centers were included. The study concluded that 
prosthetic spincterotomy was as effective as en-
doscopic spincterotomy and required shorter hos-
pitalization. These findings are relevant only for the 
short and medium-term. The long-term outcome of 
prosthetic spincterotomy for incontinence remains 
unreported. At present, it is vital that stented pa-
tients be monitored carefully at least once a year 
during the years following implant surgery.

- For patients who have chosen surgical 
  sphincterotomy:
  - The reference technique involves an elec-
    tive 11, 12 or 1 o’clock incision of the ure-
    thral sphincter (B).
  - Although surgical sphincterotomy is 
    the accepted reference treatment for 
    neurogenic DSD, analysis of the litera-
    ture highlights the lack of reliable effi-
    cacy and reproducibility criteria for the 
    technique (B).
- For patients who have chosen prosthetic 
  sphincterotomy:
  - Different types of stent are used, depend-
    ing on whether sphincterotomy is tempo-
    rary or permanent. Stents are complemen-
    tary, and different designs can be used for 
    different situations (B).
4. SURGERY TO INCREASE DETRUSOR STRENGTH

For some patients, the cause of bladder hypocontractility lies in the bladder wall. In this case, the control circuit functions but the bladder muscle is too weak. At present there is no medical treatment for this situation. The general objective is to reduce peripheral resistances as much as possible and where this fails, to propose IC. However, some teams have suggested placing rolled strips of muscle around the bladder. Some authors have also suggested a strip of rectus abdominis muscle. This is easier to perform and may be used essentially for reconstructive surgery, such as in bladder extrophy [125-127] (LOE4). The only team to have published results on bladder hypocontractility in man is that of Ninkovic et al. [128] (LOE2). They reported interesting results from twenty patients suffering from neurogenic detrusor underactivity and requiring self-catheterization. They reported a technique that they had designed in animal experiments [129, 130] (LOE4) and which consisted of transferring a free strip of latissimus dorsi muscle, which was Anastomosed to the epigastric vessels and the lowest branch of the intercostal nerve. Out of twenty patients, with a mean follow-up of 44 months, 60% no longer required IC, with PVR below 100 ml. After complementary surgery on the bladder neck, there was a 90% success rate that was stable over time. The authors reported no heavy morbidity, particularly with regard to the donor site. These promising results were largely confirmed in a multicentre trial involving 24 patients with a median follow-up time of 46 months [131]. Complete spontaneous voiding (mean PVR 25ml) was restored in 71% of the patients, while frequency of CIC was reduced in another 13%. Recurrent UTIs ceased in 91% of patients. A critical increase in bladder contractility index may be required to achieve complete bladder emptying, but the number of patients was too small for safe conclusions. Future development could use tissue-engineering techniques to construct vascularized and contractile strips implanted around the bladder with the same procedure. Reduction cystoplasty, previously used in Prune Belly syndrome has not been reported in neurogenic LUT dysfunction.

Recommendations:

- Latissimus dorsi myoplasty on the bladder is a promising technique that needs to be validated further (C).

5. STRESS URINARY INCONTINENCE (SUI) DUE TO SPHINCTERIC INCOMPETENCE

Some patients with neurogenic lower urinary tract dysfunction will suffer from incontinence due to sphincter weakness. In general, patients with lesions affecting the brain or suprasacral spinal cord will not suffer from this problem, as the sacral sphincter guarding reflexes will be intact. However, patients with lesions of the conus medullaris, the cauda equina or peripheral sacral nerves are at risk of developing neurogenic stress incontinence. Patients with neurological disease may also suffer from stress incontinence due to direct sphincter injury from urethral catheter trauma or as a result of previous interventions such as sphincterotomy or dorsal rhizotomy. In women, SUI may be present for non-neurogenic reasons such as urethral hypermobility due to previous pregnancy and childbirth.

People with neurogenic lower urinary tract dysfunction and SUI may also have impaired bladder storage function. If this is the case, a surgical procedure that treats the stress incontinence in isolation might put the patient at risk of upper urinary tract deterioration (as the upper tracts become exposed to the full force of the bladder dysfunction, having lost the “safety valve” effect of a weak sphincter) or of persisting incontinence. Pre-operative urodynamic evaluation of bladder function is therefore mandatory before undertaking surgery for neurogenic SUI.

The question as to when it is safe to treat neurogenic SUI while leaving bladder dysfunction uncorrected has been studied most intensively in the paediatric age group. Most series relate to children with spinal dysraphism/myelomeningocele and, typically, authors report the necessity to proceed to bladder augmentation in at least a third of patients. Even with a thorough urodynamic and radiologic preoperative evaluation, some patients will have late bladder compliance deterioration [148-165]. However, the issue continues to generate debate and studies have not reached total consensus; for example, Snodgrass et al. [166] (LOE3) published a retrospective analysis of 30 children (mean age: 8.6 years) who had a bladder neck sling procedure and appendico-vesicostomy without augmentation. At 22 month of mean follow-up, only one patient had...
had to undergo a bladder augmentation. In a subset of 16 patients who had urodynamics at 24 months, 13/16 had an increase of their maximum bladder capacity. However, 67% of the patients required anticholinergic therapy. In contrast, Dave et al. [167] (LOE3) strongly advocate the case for simultaneous bladder augmentation. The authors report a series of 15 children followed for at least five years after an isolated bladder outlet procedure (5 Pippi-Salle, 5 slings and 5 artificial urinary sphincter). At a mean follow-up of 11.25 years, all the patients underwent surgery to increase bladder capacity, either for recurrent incontinence or for upper urinary tract deterioration. At present, no definitive conclusions can be drawn as to advisability of routine prophylactic bladder augmentation, but many authors recommend a concomitant bladder augmentation when performing a bladder outlet procedure [168] (LOE4). The option of using detrusor injections of botulinum toxin in children offers a further therapeutic approach in circumstances where there is uncertainty.

A further important consideration when contemplating neurogenic SUI surgery is the means of bladder emptying following treatment of the sphincter weakness. In particular, patients who are emptying their bladders using an element of straining will not be able to empty in this way post-operatively. Patients will therefore need to consider how they will empty their bladder once continence is achieved. The options available to patients will include: IC (either via the urethra or a continent catheterisable abdominal conduit) or the use of a suprapubic catheter (either on free drainage or with a catheter valve). There will be some patients, who have only limited neurological damage, who will continue to be able to empty their bladder using voluntary voiding post-operatively but, even in this group, it is necessary to warn patients of the possible need for post-operative IC and to make sure that they are capable of using the technique before embarking on treatment.

a) Bulking agents

There have been some studies reporting on the use of bulking agents in neuropathic patients (Table 8 and 20-27). Most of the published series relate to the use of periurethral injections in children. Various agents have been used. Polytetrafluoroethylene (TFEILON) was one of the first [169, 170]. It was once popular for treating vesico-ureteric reflux, but it has been progressively abandoned after several authors reported possible particle migration and granulomatous reaction to this product [171, 172] (LOE2). Collagen has also been used, although collagen lysis can lead to the loss of the bulking effect over time [170, 173-180]. Other synthetic products that have been used include polymethylsiloxane (MACROPLASTIQUE) and dextranomer hyaluronic acid copolymer (ZUIDEX) [169, 181-187]. Zuidex is no longer used in SUI, but is in use for vesico-ureteric reflux. Henly et al. [188] demonstrated that distant migration of particulate silicone was observed in animals after periurethral injection with polymethylsiloxane (LOE4). This was not demonstrated with dextranomer acid copolymer injections [189] (LOE4).

One of the main advantages of periurethral injections of bulking agents is that they are minimally invasive and can even be carried out as an outpatient procedure. The product is usually injected in the region of the bladder neck using a retrograde endoscopic approach. The bulking agent is injected at up to four sites with the aim of achieving urethral coaptation. Dean et al. [187] have suggested using an antegrade approach whereby the bladder neck is accessed using a percutaneous puncture into the bladder.

The results of periurethral injection surgery are summarized in Table 8. There are difficulties in comparing results from different series, because patient populations and definitions of treatment success differ. In particular, the criteria for defining “improvement” and “social continence” vary. Therefore, it seems appropriate to consider the proportion of “dry patients” as defining clear-cut success (even if some authors add to this result a notion of “dryness for some hours” between voiding or catheterization). Using this definition, 0 to 36% of the patients are considered to be cured using bulking agents (LOE2-3). Moreover, these results are observed after a mean follow up that rarely exceeds 2 years (LOE2-3), although one series has reported long-term improvement up to 7 years after the last injection [190].

There are other important considerations to be made when interpreting the results of periurethral bulking agents. The first is that the studies in children generally contain patients with two types of problems: congenital urinary tract malformations (epispadias, bladder extrophy) and neurogenic lower urinary tract dysfunction (mainly myelomeningocele). This is of importance because there is some indication that, in children, bulking agents work slightly better in patients with malformations than in those with neurological problems [169, 176, 184, 190]. The global results of the series are therefore probably more optimistic than the results that might be observed in a population of only neurological patients. A second point is that these children have frequently already undergone various surgical procedures, which could modify the results of the injection procedure. Although a high proportion of the patients in these studies use IC, some have satisfactory outcomes while continuing to void spontaneously.

Although the use of bulking agents does not appear to cause any severe complications, there is the suggestion that the presence of deposits of inert material might lead to greater difficulty in performing future bladder neck surgery [184, 197, 190]. It is also important to acknowledge that the failure to correct
incontinence is in itself a complication of the operation [168]. Most authors agree that no more than two injections should be undertaken since further injections are unlikely to produce a long term improvement. Gender and previous bladder/sphincter surgery do not seem to be reliable prognostic factor regarding the success of the injections.

b) Autologous Sling Procedures:

In women with neurogenic lower urinary tract dysfunction, the use of an autologous fascial sling to support the urethra (usually close to the bladder neck) has been widely used to treat stress incontinence. A sling can either be used in isolation or in conjunction with other procedures such as bladder augmentation. Table 9 summarises the results of published case series. Complete continence is observed in 83 to 89% of the patients (LOE3). Once again it should be emphasised that many patients will be dependent on bladder emptying using IC or an SPC, because the patient’s neurological dysfunction may preclude voluntary voiding and because the sling may have to be inserted under tension in order to provide sufficient outflow resistance in the face of neurogenic intrinsic sphincter deficiency. All of the series report a low morbidity rate from the procedure. In particular, the risk of urethral erosion is very low when fascial slings are used. Synthetic sling materials have generally not been advocated when significant sling tension is

DHAC (Dextranomer Hyaluronic Acid Copolymer) PDS (polydimethylsiloxane), PTFE (Polytetrafluoroethylene), NS (Not stated), LOE (Level of evidence)
required because of the risk of secondary urethral erosion [170, 197-199] (LOE3). However, there is a lack of studies that compare the use of autologous tissue and synthetic material. Bladder neck slings appear to be capable of providing good results in children. Some series suggest that girls have better outcomes [166, 191-193].

c) Suburethral tapes

Midurethral tape operations, such as the tension-free vaginal tape procedure, have taken a major role in the management of stress incontinence in the non-neuropathic population but have not been adopted for the treatment of neurogenic stress incontinence; concerns about the risk of urethral erosion have been discussed already. Furthermore, intrinsic sphincter deficiency represents the usual pathophysiology in neurogenic SUI, contrasting with urethral hypermobility in non-neuropathic women.

There is very little published data available on the efficacy of midurethral tension-free tape operations in adult women with neurogenic LUTD. In a retrospective series of 12 women treated by TVT [200] with a mean follow up of 10 years, 9 patients were available for assessment of which 7 were dry and 2 were improved. The authors did not report any urethral erosions on follow up.

For male patients with post-prostatectomy incontinence, the use of synthetic tapes is increasing but, there is very little data for patients with a neurological cause to their incontinence, other than case reports. The use of this type of device in patients with underlying neurological illness should clearly be very cautious until further data emerges from clinical trials (LOE4).

d) Artificial urinary sphincter (AUS)

Since it was introduced in clinical practice [201], the AUS is recognized as one of the most effective treatments for urinary incontinence. It has the inherent advantage that it provides an adequate urethral closure pressure during the urine storage phase of the micturition cycle but then allows voiding to take place in the face of a low bladder outlet resistance. In patients with SUI, it is able to deliver either complete or “social” continence in 75 to 87% with satisfaction rates ranging between 85 and 95%. These rates are provided by published case series that contain a majority of patients with post-prostatectomy stress incontinence (PPI), along with some neuropathic patients. However, outcomes are probably similar for patients with neuropathic stress incontinence and a low-pressure bladder reservoir (LOE4) [202]. It should be noted that most of the published data on the use of the AUS in neurogenic SUI relates to men, although the device is also used in female patients with neurological disease.

Before using the AUS in neurogenic SUI, several factors must be considered:

- Firstly, the risk of implant infection and erosion is probably higher than in the PPI population. It is generally recommended that patients undergo

(LOE: level of evidence, NS not stated)
pre-operative urine culture and sterilisation of the urine before surgery [203] (LOE4).

- Manual dexterity must be sufficient to allow the patient to use the AUS pump - either to open the cuff to urinate, or to allow IC [202]. They must also accept the need for IC should the bladder have reduced contractility. However, some studies seem to indicate that the cycling activation of the pump could be avoided in patients performing IC (LOE3) [204, 205]. Bersch et al. [204] have described a modified technique.

- The cuff implantation site in adult patients with a neurologic bladder dysfunction is debated. The cuff can be implanted via a retropubic approach at the level of the bladder neck or around the prostatic apex. Alternatively the cuff can be implanted around the bulbar urethra using a perineal incision. Proponents of the retropubic approach argue that perineal incisions may cause cicatrisation problems for patients in wheelchairs. Moreover, traumatic catheterization is a well-known risk factor of urethral erosion in the non-neurological population undergoing an AUS [160] (1 to 5.5% in contemporary series) and, although it is recognized that IC is possible in AUS implanted patients [206], the risk of traumatic catheterization and subsequent cuff erosion might be higher when the bulbar urethral site is used. On the other hand, inserting an AUS cuff around the bladder neck is technically more difficult in adults in comparison with peri-bulbar implantation (LOE4). Some investigators are now exploring the possibility of using a laparoscopic technique for sphincter implantation [207].

- It is necessary to know the ejaculatory status of males in order to discuss the possible impact of the device on ejaculatory function. Cuff implantation around the bladder neck may allow patients to achieve antegrade ejaculation [208, 209] (LOE4).

As previously stated, a thorough urodynamic evaluation of the bladder is mandatory in order to evaluate the potential impact of bladder compliance following AUS implantation. This has been reported in several retrospective series (LOE3) [152-165]. The reasons for this change in bladder behaviour are not known, and it has been observed particularly in populations of patients with myelomeningocele [157, 159, 161,162, 164]. In the event of any doubt about the quality of the bladder reservoir, bladder augmentation should be performed. The main results of published series are summarized in Table 10. The continence rate is high, especially when a bladder augmentation has been performed (59 to 100% of the patients). The older series include some patients with the previous version of the AMS 800 (AMS 792). Therefore, it is possible that the long-term outcomes for patients being implanted today may be better than those seen in the past as a result of technical modifications of the device. Device infection, cuff erosion into the urethra and loss of fluid from the implant are the main causes of loss of an AUS. Infection and erosion typically occur in the early months after implant but late erosions are seen [156] (LOE3). The average “survival” for AUS is ten years. This particular point has to be explained to the patient, especially when they are very young. However, it is important to stress that sphincter replacement is usually possible so that continence can be restored. The majority of the authors consider AUS to be the “gold standard” procedure to treat neurogenic sphincter deficiency in men.

e) Surgery of the bladder neck

Three main procedures have been described. Historically, the technique of Young [210], later modified by Dees [211] and Leadbetter [212] came into use, essentially for reconstruction in cases of exstrophy and epispadias. The principle was to mobilise the trigone (after ureteric reimplantation) in order to resect bladder neck tissue, so as to reconstruct the trigone around a small catheter. Although some authors [213, 214] described its use in neurogenic patients, the procedure has rarely been used in this patient group. However, a recent paper describes an interesting hybrid procedure whereby a bladder neck reconstruction was combined with implantation of a fascial sling in neuropathic children with a post-operative continence rate of 82% [77]. Tanagho [215] (LOE3) described a variation of this technique which can be used in difficult situations in incontinent adult patients, when the implantation of an AUS is not possible [216].

The Kropp procedure [217] involves the use of a tubularised flap of the anterior bladder wall, which is used to extend the bladder neck and create an intravesical conduit. The tube is secured to the posterior bladder wall between the ureteric orifices. In the initial technique, the tube was tunnelled submucosally, but this manoeuvre was thought to increase the risk of tube stenosis [218, 219] (LOE3).

A third technique is that described by Pippi-Salle [220]. It is considered to be a variant of the Kropp procedure (also called a Kropp-onlay), with an anterior bladder wall flap that is not tubularised. Initial descriptions involved routine ureteric reimplantation but this was abandoned in later patients as long as there was an absence of reflux [221, 222] (LOE3). In a systematic review, Kryger et al. [168] (LOE4) stated that only data on 83 patients for the Kropp technique and 25 with the Pippi-Salle procedure have been published. Since that review there has been a lack of further significant data concerning the outcomes of these procedures. The continence results are good (50-69% for the Pippi-Salle procedure, 78-81% for the Kropp procedure) [218, 219]. However, several problems exist with the two techniques. Firstly, the techniques do not allow easy endoscopic access to the bladder. This is a major problem because it prevents or limits future endoscopic

*AUS modified**AUS modified and two groups of patients depending of their age at AUS implantation*
procedures (especially ureteroscopy, botulinum toxin injections and litholapaxy). Secondly, 28-45% of patients (especially male) report catheterisation difficulties following a Kropp procedure. For the Pippi-Salle procedure, continence rates are lower than for the Kropp procedure, but fewer cases of catheterisation difficulty have been reported [168]. However, a revision procedure is necessary in significant numbers, and it has rarely been used in male patients.

f) Complete bladder neck or urethral closure

Closure of the bladder outlet may be required if alternative approaches to managing stress incontinence are inappropriate or have failed. In women, closure can be achieved either via a vaginal or an abdominal approach while in men, either the bladder neck or the bulbar urethra can be the site of closure. Bladder drainage is maintained using a continent catheterisable abdominal conduit (e.g. using the Mitrofanoff principle), an SPC or (rarely) an ileo-vesicostomy. Bladder neck or urethral closure can be technically difficult and a secondary operation to close a persistent fistula may be needed in some cases [224]. Interposing vascularised tissue between the bladder neck suture line and the urethral or vaginal closure is a well-described aid to the avoidance of closure failure; a flap of rectus abdominis can be used for this purpose. Bladder neck closure has also been used in children where other means of correcting SUI have failed or are felt to have a limited chance of success. The published series of cases provided some reassurance that children with closed bladder necks do not suffer from excessive complications in the form of renal deterioration, bladder rupture or stone formation.

As a general principle, urethral closure should not be undertaken in cases where it is possible to maintain urethral patency using alternative approaches to treat SUI. For example, patients with neurogenic lower urinary tract dysfunction are at high risk of stone formation in the bladder or upper tracts and it is desirable to maintain easy endoscopic access to the bladder in order to allow potential endoscopic treatment. Finally, preserving the natural urethra may constitute a safety measure if high bladder storage pressures are present or in the event of any complication with bladder access via a continent catheterisable abdominal conduit or suprapubic catheter [225].

Recommendations:

- Patients with stress incontinence in association with neurogenic lower urinary tract dysfunction require careful assessment in order to plan appropriate management. Video-urodynamic study must be used to evaluate both bladder and sphincter function (C).

- The clinical assessment must also evaluate the degree of patient handicap in order to determine whether they can perform self-catheterization, or whether an alternative means of emptying the bladder will be required. (D).

- Patients require careful preoperative counseling with respect to the benefits and risks of different operative approaches

- Autologous slings can be used to treat neurogenic stress incontinence. (B). The use of synthetic slings and tapes is not supported by an adequate evidence base at present. (C).

- Artificial urinary sphincter can be used to treat neurogenic stress incontinence (A).

- Bladder neck reconstruction can be used to treat neurogenic stress incontinence (D).

- Bulking agents can be used to treat neurogenic stress incontinence when there is a demand for a minimally invasive treatment (D). The patient should be aware that the technique has a low success rate.

- Bladder neck closure should be offered to patients who have persistent neurogenic stress incontinence where alternative treatments have either failed or are likely to fail (B).

6. SURGICAL ALTERNATIVES EXCLUDING DENERVATION PROCEDURES TO TREAT REFLEX INCONTINENCE DUE TO NEUROGENIC DETRUSOR OVERACTIVITY

Keywords; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; bladder augmentation; enterocystoplasty; gastrocystoplasty; sigmoidocystoplasty; colocystoplasty; ureterocystoplasty; autoaugmentation; detrusorectomy

a) Bladder augmentation using intestinal segments

The aim of bladder augmentation is to provide long-term protection to the upper urinary tract by reducing the risk of impairment due to high bladder pressure, as well as to improve storage function [231]. First performed in man by Von Mickulicz [232] who used a segment of small intestine, the technique has regained popularity since the 1970s after the introduction of IC [233]. Unlike complete bladder replacement, enterocystoplasty preserves the integrity of the trigone of the bladder with the urethra and ureters, and reimplantation is not necessary. A segment of the gastrointestinal tract is taken out of continuity from the rest of the gut, and sutured onto the bladder. Various augmentation techniques using different segments of the gastrointestinal tract (caecum, colon, and ileum) have been described. Bladder augmentation is indicated wherever bladder capacity and compliance is reduced, or in the event of detrusor overactivity, when all conservative treatments (medical treatments, detrusor injections
of botulinum toxin and/or neuromodulation of the posterior sacral roots) have failed [231, 234].

Before performing bladder augmentation, it is essential to ensure that:

• There is no malignant disease or lithiasis in the bladder.
• Renal function is normal and the upper urinary tract is unimpaired (screen particularly for lithiasis).
• There is no gastrointestinal tract disease (Crohn’s disease, hemorrhagic rectocolitis, short gut syndrome, etc.).
• The patient is willing and capable of self-catheterization. This can be combined with continent cystostomy.

Technical principles:

There are two stages to the surgical procedure: first bladder preparation and then augmentation. Usually open surgery is performed, but recently laparoscopy has been reported [235, 236] (LOE3). At present, except for technical articles on laparoscopy, there are no publications comparing this technique with open surgery.

The bladder can be prepared either by clam cystoplasty or by supratrigonal cystectomy. The preferred preparation depends on the quality of the detrusor, and more particularly on whether the bladder has retained its visco-elastic properties. Where the detrusor is very fibrous and thick, supratrigonal cystectomy should be envisaged, since otherwise exclusion of the ileal patch may occur.

1. Clam Cystoplasty

Clam cystoplasty involves freeing the anterior/posterior surfaces and dome of the bladder. The bladder can be opened either in the transverse plane or sagittal plane, the incision starting and ending about 2 cm above the bladder neck. If the lateral surfaces are not mobilised, the vesical arteries can be preserved to maintain vascularization of the bladder dome. Robot-assisted laparoscopic augmentation cystoplasty has been recently introduced. Preliminary results have been reported in children with spina bifida [237].

2. Supratrigonal Cystectomy

Supratrigonal cystectomy involves resection of the body of the bladder, but retaining the trigone. The bladder is freed under the peritoneum and the superior vesical arteries ligated and sectioned. The bladder pedicles are ligated and sectioned laterally up to the trigone, which is preserved. The body of the bladder is excised 1-2 above the trigone. During the bladder dissection, care must be taken to spare the ureteric vascularization.

3. Ureteric Reimplantation

Ureteric reimplantation must be carefully discussed in the event of vesicoureteric reflux (VUR). Several authors have reported that improved bladder compliance precludes the need for reimplantation (LOE3) [238-241]. They have reported a resolution rate of about 85% for VUR, classified below grade IV. For grade V reflux, improvement was observed in 2/3 of patients. Except for the work of Simforoosh [238], these results were obtained in small heterogeneous series of children (neurogenic bladders and congenital anomalies), and after relatively short mean follow-up times (1 to 5 years).

Hayashi et al. [242] reported on 22 patients treated by ureteric reimplantation during bladder augmentation (LOE3). Their work was original in that it gave detailed account of renal function after long-term follow-up (mean 12 years). Ureteric reimplantation during bladder augmentation did not result in greater morbidity and 97% of patients recovered. Renal function was preserved and satisfactory. The case for ureteric reimplantation during augmentation cystoplasty was supported by a small non-randomised study (LOE2-3), where Wang et al. demonstrated that lack of ureteric reimplantation during cystoplasty in children with neurogenic bladder was a risk factor for residual high-grade reflux, which, in turn, was a risk factor for febrile UTIs [243]. A larger non-comparative non-randomised study (LOE3-4) reported equal success rates for the two methods, but ureteric reimplantation had been mostly reserved for the higher grade reflux cases [244]. These results were presented as part of a literature review which was inconclusive as to the superiority of the results of either method [244]. Accordingly, the need for ureteral reimplantation during bladder augmentation should still be considered, especially for cases of grade V reflux. However, improved bladder compliance will reduce some VUR.

4. Intestinal Segments

The choice of intestinal segment depends on patient’s history and the local conditions. All segments of the gastrointestinal tract may be used, except the jejunum because of the risk of water-electrolyte disorders. The most frequently used segment in adults is the ileum, because it is easy to remove, is close to the bladder and may be shaped easily into a reservoir. Colon segments are used more often in children. The removed intestinal segment must always be detubularized to reduce peristalsis to a minimum and to obtain a reservoir with low pressure. The segment is then placed and sutured onto the bladder in the form of a patch. For supratrigonal cystectomy, the intestinal segment needs to be longer and fashioned into a neo-bladder [234].

Technical variations aim to reduce mucus secretion and reduce the reabsorption of urine by the intestinal mucosa that leads to metabolic acidosis. A number of variant techniques have been proposed but not developed extensively. Seromuscular colocystoplasty lined with urothelium involves removing the detrusor,
leaving the bladder mucosa intact, and then covering it with a demucosalized sigmoid patch [245]. Seromuscular enterocystoplasty necessitates removing the mucosal membrane of the intestinal segment surgically, or destroying it argon beam [246], before placing it onto the prepared bladder [247].

A third technique uses an appendicular-based cecal flap, aiming for a less invasive form of augmentation cystoplasty [248]. The technique involves isolation of a 10-12 cm segment of the ileum, which is placed into the abdomen and then fixed to the urinary bladder. The patient is then catheterized and allowed to recover without bowel anastomosis. These complications distressed patients and nearly 10% regretted having undergone surgery. Although transit disorders cannot be attributed to surgery alone (patients with neurogenic bladder may have intestinal transit disorders unrelated to surgery), patients should be informed of this risk.

Since the gastrointestinal tract mucosa resorbs urine, water-electrolyte disorders may occur. Hyperchloremic acidosis is reported in up to 15% of cases (LOE 2-3). These water-electrolyte disorders may be accompanied by anomalies of calcium metabolism that do not appear to have any significant long-term effect, for example on growth in childhood, but the subject is still under debate (LOE 3) [267-270]. However, care must be taken when treating patients with a marked decrease in creatinine clearance, since metabolic acidosis is no longer compensated [234] (LOE4).

In theory, diversions performed using the ileoceleal junction and the end segment of the ileum would expose patients to a risk of vitamin B12 deficiency (with possible onset of megaloblastic anemia). The fact that the intestinal segments measure less than 50 cm would explain why few patients suffer clinically overt vitamin B12 deficiency.

The risk of cancer development of the newly formed reservoir is particularly important, since urological surgery is often indicated in patients with long life expectancy, many being children. The general consensus today is that patients with a bladder reservoir are at higher risk of developing a tumour than are the general population, but this risk has not as yet been clearly defined. The figures usually given for the risk of tumour development range from 1 to 4.6% [271-274] (LOE 3-4). Most of the published cases concern adenocarcinoma at the junction of the intestinal mucosa with the urothelium. These usually developed long after the initial surgery (over 10 years in most cases). Some patients developed urothelial tumours with the typical risk factors. Two facts should be emphasised with regard to neurogenic bladder (augmented or not):

- The sensitivity and specificity of the routine bladder tumour diagnostic and monitoring tools (urinary cytology, BTA test, simple cystoscopy, etc.) may be reduced. Patient monitoring can only be envisaged by regular cystoscopy with biopsy of suspect areas.

- Monitoring is essential, since many patients develop tumours without symptoms and may not be diagnosed until late.

Monitoring frequency needs further investigation. A review of a series of cystoplasties performed in patients with congenital abnormalities including neurogenic bladder found comparable risk of bladder cancer, compared to control patients managed only by IC (4.6% vs 2.6%, p=0.54) [274]. In addition, a projected

(Max BC: Maximal Bladder capacity, DP: Detrusor pressure at the maximal bladder capacity)
cost-analysis based on post-augmentation malignancy and cost estimates from published reports or US government sources concludes that annual screening with cytology and cystoscopy of children with spina bifida subjected to augmentation cystoplasty is unlikely to be cost effective at commonly accepted willingness-to-pay thresholds, but would be justified if the annual rate of cancer development were more than 0.26% (12.8% lifetime risk) or there were a greater than 50% increase in screening effectiveness and cancer risk after augmentation [275].

The most serious and possibly life-threatening complication is cystoplasty perforation (LOE3). This can happen whichever gastrointestinal segment is used, but occurs more often after ileocystoplasty [276] (LOE3). It is estimated to occur in 5-13% of cases [250] (LOE3). Perforation usually occurs on the graft or at the junction of the bladder with the enterocystoplasty, and often results from high pressure within the enterocystoplasty, or more rarely from traumatic catheterization or urodynamic investigations [277] (LOE4).

6. Functional Outcome

The functional outcome of bladder augmentation by enterocystoplasty is given in Table 11. Only series of patients undergoing bladder augmentation for neurogenic bladder were retained in our analysis. Given the wide range of indications, surgical techniques and enteric segments used, and retrospective nature of studies, it is difficult to draw any clear conclusions. Nonetheless, all authors reported an improvement in bladder capacity and compliance (LOE2-3). More than 90% of patients achieved nocturnal continence, and 91-100% achieved diurnal continence (LOE2-3).

Two quality-of-life studies (LOE2) reported improvement rates exceeding 90% [252, 281]. A 92% satisfaction rate was reported by a long-term follow-up study (mean 14.7 years) and patients would recommend the treatment to a friend [255]. However, a potential bias might arise due to the heterogeneous population analysed in some of these studies, including a mixture of patients with neurogenic and idiopathic DO.

If the bladder compliance defect persists, exclusion or ischemia of the intestinal patch must be investigated [272, 280]. Sometimes urinary leakage is related to sphincter deficiency and may be treated by an AUS [283] or other means of urethral pressure reinforcement [272, 282]. However, most authors consider that this type of adjunctive treatment should not be performed routinely since most patients have a good functional outcome after bladder augmentation, and only those with marked sphincter deficiency prior to surgery require these measures.

7. Possible Alternatives to Enterocystoplasty

- Gastrocystoplasty and ureterocystoplasty

The use of a pedicled segment of stomach (gastrocystoplasty) or ureter (ureterocystoplasty) as an alternative to enterocystoplasty has been reported mainly for children with a neurogenic bladder. In theory, its advantage lies in the absence of metabolic acidosis, but in adults this is very theoretical. Moreover, both these intestinal segments secrete less mucus than the small and large intestines [284-288]. Abdel-Azim et al. [286] reported gastrocystoplasty in adults (LOE3). In the light of their experience with children, they decided to use this technique in a set of young adults (mean age: 23 years, range: 4-32 years). Their paper records that the short-term results (3 years mean follow-up) of gastrocystoplasty were satisfactory, with increased functional bladder capacity and no impairment of the upper urinary tract (LOE3). However, two disadvantages are reported. First, a hematuria-dysuria syndrome requiring occasional use of antacids sometimes accompanied gastrocystoplasty. Second, the maximum bladder capacity was lower than that observed with enterocystoplasty. This may have a benefit for easier bladder voiding, but if the bladder were to lose some capacity, further surgery would potentially be required. The outcome in the very long-term for patients who have undergone this procedure remains unknown.

8. Kidney Transplantation and Augmentation Cystoplasty

The general notion is that augmentation cystoplasty should be beneficial in patients with chronic renal failure and performed prior to transplantation, as a low-pressure reservoir might delay the native kidney’s death and optimize graft survival rates. However, published studies suggest otherwise. In a small series (n=11) of neurogenic bladder patients, augmentation cystoplasty did not affect progression to end-stage renal disease (LOE2-3) [289]. More strikingly, prior cystoplasty was found to be associated with higher risk of graft rejection compared to non-cystoplasty transplants, up to 7 years postoperatively (LOE2-3). Although the authors suggest this may be due to higher rates of febrile UTIs and chronic rejection, it might also be due to a more severe underlying pathophysiology which resulted in the necessity of a cystoplasty in those children [291]. The same group of authors conclude that the timing of augmentation cystoplasty in relation to the transplant surgery (before or after) has no significant effect on the outcome of the transplantation, with respect to graft acute rejection, graft survival (up to 7 years) and incidence of febrile UTIs (LOE2-3) [292]. In terms of serious complications, patients with augmented bladders and a history of renal transplant on chronic immunosuppression were found to have a significantly higher incidence of bladder cancer compared to patients who were not immunosuppressed (15% vs 2.8%) [274] (LOE3).

b) Autoaugmentation by detrusor myotomy

Bladder autoaugmentation without any associated gastrointestinal tract surgery as an alternative to enterocystoplasty was proposed as early as 1972
by Mahony and Laferte [293] who performed detrusorotomies (detrusor incision without resection) to increase bladder capacity and reduce incontinence. With Cartwright and Snow [294], the technique then evolved to detrusorectomy (myectomy). This involves excising a thick segment of muscle from the dome of the bladder, leaving only the mucosal membrane in place. Bladder pressure gradually dilates the “demuscularized” area resulting in bladder augmentation. The intervention, initially described by extra-peritoneal laparotomy, can be performed by video-assisted surgery [295, 296] or by robot-assisted surgery [297] (LOE4). The detrusor can be dissected by laser [298] (LOE3). The area around the detrusorectomy can be protected using the omentum [299] or a striated muscle [300] (rectus abdominis muscle) to prevent perforation and retraction (LOE4).

Techniques using free-graft or pedicled de-epithelialized gastric patches [301, 302] require gastrointestinal tract surgery and were therefore not included in the present work. Furthermore, most of the previously published studies concerned children. All the studies are retrospective and with few patients. For children, most authors [299, 304-7] report poor results after surgery, both symptomatic and urodynamically, together with a risk of upper urinary tract impairment (LOE4). Two authors recently reported better results with certain technical adjustments, namely an extensive detrusorectomy [308] (LOE4) and rectus muscle hitch and backing [300] (LOE4). The last technique supposes a large dissection of the rectus muscle. Urothelium is then sutured to this muscle in the theoretical objective to prevent its retraction and shrinkage.

Only three retrospective series are available for adults. The first, published by Stöhrer et al. in 1997 [309] (LOE3), reports interesting results for efficacy, with increased functional bladder capacity. However, the authors did not report mean follow-up and described a mixed population with 39 patients with neurogenic bladder and 11 patients without. The other published series concerning adults [303, 304] did not confirm these findings but did confirm the marked superiority of enterocystoplasty with respect to both urinary symptoms and upper urinary tract impairment (LOE3). Detrusor myectomy achieves better results for idiopathic DO; nearly all patients (5 of 6) with neurogenic DO were not improved, with a mean follow-up of 79 months [303] (LOE3).

There is little information on specific complications, but detrusorectomy is simpler and seems to present less risk than enterocystoplasty. A comparative retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious, digestive and parietal complications) against only 3% for detrusorectomy [304]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus potentially exposing the patient to an increased risk of rupture [310] (LOE4).

c) Bladder augmentation using biomaterials

Research interest in the role of tissue engineering in bladder reconstruction is growing. This research appears to evolve along three axes [311]:

a. use of acellular natural or synthetic biomaterials: an acellular biomaterial graft is used as a tissue implant which becomes incorporated through the ingrowth of cells of the native host bladder

b. use of biomaterial scaffolds which have been pre-incubated with autologous cultured human urothelial and smooth muscle cells

c. composite cystoplasty, which combines the use of autologous cultured urothelial cells with a host pedicled and de-epithelialized smooth muscle segment.

Most publications concern preclinical studies [312-326] (LOE4). Several biomaterials have been used which can be grouped in 3 categories: (a) decellularized natural matrices produced from a variety of tissues; (b) matrices produced from natural extracted polymers (e.g., collagen, alginate, chitosan and hyaluronan); and (c) synthetic polymers including polyglycolic acid (PGA) and poly-caprolactone (PCL) (see reviews [311, 327]). These biomaterials can only be used after performing clam cystotomy since the area to be colonized should not be too large. It also appears that the use of biomaterials is associated with higher incidence of bladder lithiasis. The best studied natural materials are porcine intestinal submucosa (SIS, Cook) and bladder-derived acellular matrix [318, 328-33].

Results from only two pilot human studies have been fully published to-date [331, 332]. The former reported on neurological patients, the latter on non-neurogenic OAB patients. In a small prospective study of 7 young myelomeningocele patients (LOE 2-3), Atala [332] describes his technique, which consists of seeding patient’s urothelial and muscle cells on a biodegradable scaffold. After 7 weeks, this engineered artificial bladder could be implanted in patients. Although the small number of patients doesn’t allow definitive conclusions, a trend towards an improved bladder capacity and compliance was observed. It was also implied that patients who received cell-seeded collagen-coated PGA scaffolds wrapped in omentum as a vascular bed had the best outcomes. Encouraging results were also reported in 12 women with intractable non-neurogenic OAB who were submitted to bladder augmentation using an acellular matrix of porcine dermal collagen and elastin fibres (Pelvicol, Bard) [331] (LOE4). Significantly improved or cured incontinence was achieved in 67% of them at a 12-month follow-up. Finally, a recent review article [327] claims results in short report form from two small Phase II trials on patients with neurogenic bladders due to either spina
bifida (paediatric patients) or SCI (adults). Success rates of 60% and 67% are reported for up to 2-year follow-ups, depicting patients with preoperative ‘normal bladder cycles’ as the best candidates for bladder augmentation with a tissue-engineered scaffold. Further studies, including larger trials are necessary to evaluate routine use of biomaterials.

**Recommendations**

- Any segment of the gastrointestinal tract may be used for bladder augmentation, but the ileum seems to give the best results in terms of ease of use, risk of complications and efficacy (B). Few data are available concerning gastrectomy and ureterocystoplasty in adults (D).
- When the bladder suffers a significant compliance defect, supratrigonal cystectomy and reconstruction is preferable to clam cystoplasty (B).
- Bladder augmentation may solve low-grade vesicoureteric reflux. In the event of grade IV or V reflex, ureteric reimplantation may be necessary (C).
- Patients should be informed that the most frequent and serious complications are bladder calculi and perforation at the bladder/bowel junction, usually caused by over-pressure (B).
- Bladder augmentation may have sequelae such as intestinal transit disorder, and patients should be informed of this before surgery (C).
- The body of evidence concerning detrusor myomectomy in neurological patients is controversial. Therefore, detrusor myomectomy should not be recommended in these patients with impaired bladder function (D).
- Bladder augmentation using biomaterials or tissue engineering is promising, but the preliminary results need to be confirmed by larger studies (D).
- Due to risk of complications, regular follow up is needed (B).

**d) Cutaneous continent urinary diversion**

For certain patients, urethral catheterization can be or become, unacceptable or even impossible. The following list is not exhaustive, but describes the more frequent reasons:

- Functional limitations of the upper limbs (tetraplegia [346] unilateral or bilateral plexus problems, musculoskeletal trauma problems).
- Cognitive disorders (forgetfulness, lack of comprehension, refusal).
- Difficulties in terms of mobility and/or undressing (spasticity, upper SCI resulting in difficulty in maintaining the equilibrium of the trunk and or limited control of the upper limbs, obesity).
- Failure to reach the urethra independently (more common in women, compounded by the tilted pelvis and all other factors that cause mobility difficulties.)
- Urethral injuries (stenosis, fistulas, hyperesthesia), urethral pain.

In these situations, management requires careful consideration; in some, a continent cystostomy may be an option. The general principle is to permit the emptying of a full bladder, independently and easily, by IC through an efferent tube attached to the wall of the lower half of the abdomen. The absence of any leakage from the cystostomy is controlled by its own watertight system, associated with the return process of a capacitive and compliant reservoir. This will require careful selection of patient candidates, especially when there is any function impairment of the upper limbs (trauma to the spinal cord) [347-9] (LOE3).

Assessment is essential, and must include the motivation of the patient, capabilities for dressing and undressing, capability of catheterization in the planned stomal area, and tolerance for the time and potential discomfort involved. In the case of cognitive difficulties that are too significant, if a severe upper limb dysfunction exists [346], or if compliance of the patient remains an impossible obstacle, continent diversion is not indicated. Impaired renal function can also be a contraindication [350].

In neuro-urology, techniques for heterotopic neo-reservoir (e.g. Koch pouch, Benchekroun, Mainz, Miami pouches) are seldom used initially. They can be offered to patients with VUR, with incontinence through the native urethra despite bladder enlargement, or when closure of the bladder neck will be needed (e.g. uretero-vaginal fistula).

1. **RESULTS OF THE DIFFERENT TYPES OF CYSTOSTOMY**

The series are mainly retrospective (LOE 3) and frequently combine several techniques. This makes the analysis of the results difficult, but some major facts can be gleaned from them. The catheterizable tube must be able to penetrate the intact or enlarged bladder and it must be able to reach the abdominal wall through a direct pathway with easy access for the patient that has already been predetermined by pre-operative research. The pathway of the tube must be direct in order to facilitate self-catheterization. Techniques can be grouped in two major categories : simple tubes implanted with an anti-reflux system and intestinal loop invaginations.

**Simple tubes**

Virtually any anatomical structure that is tubular or that can be tubularized and that is vascularized can be used to make a continent catheterizable tube
The two structures that are the simplest to use are:

- The appendix: Trans-appendicular cystostomy according to Mitrofano's procedure [351] has long been the most used technique (LOE3). Different modifications have been proposed, especially to gain more length by removing a cecal cuff.
- A short, remodeled intestinal segment (small intestine, less frequently the sigmoid or right colon). Yang and Monti simple [352] (LOE3) or double technique and the Yang-Monti technique modified according to Casale in order to gain length by avoiding a double tube [353] (LOE3).

Other structures have been used in a more anecdotal manner, primarily in children: cecum and appendix monobloc [354] (LOE4), bladder [355] (LOE4), stomach [356] (LOE4), distal ureter [357] (LOE4), Meckel's diverticulum [347, 358] (LOE4), or the preputial or clitoral skin [359] (LOE4).

For most authors, continence of the tube was achieved by implantation in the native bladder or in the augmentation via a submucosal path similar to that used in ureteral reimplantation for VUR. (LOE4). The submucosal path length must be at least 2cm, and is adapted to the bore of the tube (two to three times the diameter) [349] (LOE4). A posterior or posterolateral bladder flap (kept in case of a supratrigonal cystectomy) should allow a more solid implantation of the tube to the bladder [360] (LOE2). Direct implantation into the cystoplasty has also been reported. The cutaneous anastomosis is made in the lower half of the abdomen, at the umbilicus, or in the right or left iliac fossa. It seems essential that the site of the stoma be determined preoperatively in patients with functional limitations of the upper limbs. The site is chosen based on the patient's capabilities and the position during self-catheterization (seated in a chair, supine, other). The surgical technique used in this particular case must allow access to any point on the lower half of the abdominal wall [361-3]. Most authors recommend the interposition of a skin flap in the distal end of the tube in order to minimise stenosis of the circular orifice scars. Several techniques have been proposed: flap in V, VOZ [364] (LOE3), and VR [365] (LOE3). However, at present, the results published do not confirm that the risk of stenosis is avoided by any of the techniques.

Table 12 summarizes the results in terms of stoma continence and complications, specifically pertaining to the continent stoma. The necessity of reservoir augmentation (80% of published cases) and techniques allowing reinforcement of ureteral continence are addressed elsewhere. Continent stomas are obtained overall in 75 to 100% of cases (LOE3). Seven studies indicate significant improvement in quality of life after the procedure related to improved autonomy in bladder evacuation, to continence, and to improved sex life [348, 360, 362, 363, 366-368] (LOE2-3).

The rate of stoma complications (16-60%) is dominated by the risk of stenosis, which is most often treatable by a simple dilation [369] (LOE3). Many authors emphasize the fact that this complication occurs most often in the year following surgery. However, Liard et al. [370] (LOE3) reported an elevated (65%) intervention rate at 20 years of monitoring. For most authors the rate of complications related to the tube continence was lower when the segment used was the appendix or intestines remodeled according to Yang-Monti (LOE3). However, these two plasties seem to have equivalent complication rates. Only Narayanaswamy et al. [371] (LOE3) reported higher rates for catheterization difficulty and reintervention with the Yang-Monti tube in comparison to the appendix. The Monti tubes in this study were double tubes in 68% (17/25) of cases, and the majority of the complications were related to the junction area for the two hemi-tubes and not to stoma stenosis. Therefore it seems that this lengthening method should be used with caution. If there is a problem with tube length, the method proposed by Casale [353] (LOE4) has the theoretical advantage of avoiding an anastomosis on the tube or a bent pathway at the junction of the two tubes.

The umbilical anastomosis site for the stoma may be related to an increased frequency of stoma stenosis [355, 372] (LOE3). The poorer vascularization of the umbilicus has been proposed as an explanation [372]. However, results on this point are contradictory with more recent studies [360].

Other types of continent urinary stoma:

Techniques are extremely varied. Two technical approaches can be broadly outlined here:

- Invaginated valves (Koch pocket, Benchekroun, Mainz), in which the continence mechanism is tied to the flattening of the invaginated valve by urine accumulated in the neo-reservoir;
- Ileal-caecal reservoirs, in which a portion of the ileum and the ileal-caecal valve are used as a continence mechanism (Indiana pouch, Charleston pouch, Miami pouch).
- A new technique using a pedicled cutaneous flap which is surgically elevated from a hairless area on the abdomen, tubularized and passed through the anterior abdominal wall directly into the bladder (The Daoud technique) [373].

Data in the literature do not allow a determination to be made as to the superiority of one type of stoma over the others. However, the catheterization difficulties seem to be lower with stomas that use the appendix, and the risk of lithiasis seems to be higher with the stomas constructed using metal staples [374] (LOE4). Several authors have also specifically

reported results in neurological patients [363, 373,
375-380] (LOE3). Continence rates for the stoma
vary between 63 and 100%. Complication rates for
the stoma are between 10 and 23%.
Bladder outlet management; although prospective
studies are missing, evidence from retrospective
analyses (LOE2-3) suggest that continent diversion
combined with bladder neck closure is superior in
terms of functional outcomes to continent diversion
with an open bladder neck, whilst having similar
morbidity [381]. Another series reports primary continence rate following bladder neck closure and continent vesicostomy of 82% [382]. Both series report
however on a mixed patient population.
Recommendations:
• Indication for cystostomy presumes a multidisciplinary evaluation involving the urologist
and a neurologist or a reeducation doctor, as
well as stomatherapy nurses or occupational
therapists for estimating patient catheterization capabilities (A)
• Use of the appendix to carry out continent cystostomy is the standard method in children, but
few long term data are available in adults (C).
The appendix may have a short mesentery, so
a reconigured ileal segment is often needed.
• If the patient has undergone an appendicectomy, the use of a segment of the small intestine can be proposed, with slightly poorer short
term results (C).
• Long term follow up of after continent cystostomy is needed to have a better idea of the long
term results of the various procedures (C).
e) Non-continent cutaneous urinary diversion
Non-continent cutaneous diversion refers to all
methods used to divert urine, and where incontinence remains or where a system of extra-physiological continence is created, i.e. urine low is
continuous and requires a means of collecting urine
attached to the skin. In the context of neurogenic
bladder, these diversions make it possible to obtain
low bladder pressure and to preserve the upper urinary tract. This type of surgery is a last resort for
the many complications related to neurogenic bladder (and congenital anomalies of the lower urinary
tract), in patients for whom other therapies have
failed to help. Urinary diversion techniques, however, have been largely replaced by augmentation
cystoplasty in the treatment of refractory neurogenic bladder, at least in some groups of neurological
patients. The analysis of the US national database
of patients with spina biida between 1998-2005
demonstrated that 3,403 patients were submitted to
augmentation cystoplasty as opposed to 772 treated with urinary diversion. Moreover, patients undergoing urinary diversion required more healthcare


resources, with significantly longer hospital stays, higher total charges and more use of home health care after discharge home [393].

Four techniques are described for non-continent urinary diversions for patients with neurological vesico-sphincter disorders. In order of frequency these are: ileal conduit urinary diversion, ileovesicostomy, cystostomy and cutaneous ureterostomy.

1. **ILEAL CONDUIT URINARY DIVERSION**

Ileal conduit urinary diversion is the type of diversion most frequently performed on neurological patients with bladder dysfunction. Pre-operative location of the intended stoma site is crucial and must be adapted to the patient's main position (wheelchair or bed); the stoma site must be easy to access for management. The ileal segment must be as short as possible to prevent stasis [394] (LOE3). There is a variant to this technique whereby a segment of jejunal loop is removed and a stoma made on the left hemi-abdomen. This technique can be proposed after irradiation of the pelvis minor, if the ileum has been impaired and a short loop must be used (about 10 cm) to avoid metabolic disorder (jejunal conduit syndrome: hyperkalaemia, hyponatraemia, hypochloraemia, acidosis) [395] (LOE3).

In neurological patients, ileal conduit urinary diversion by laparoscopy and by robot-assisted laparoscopy have been described [396-400] (LOE4). Patients seem to benefit from the procedure, though this remains to be confirmed in the medium and long-term [401] (LOE 2). Uretero-ureterostomy on conduit diversion has also been described in neurological transplant recipients in whom the donor ureter is too short to achieve a tension-free ureteroileal anastomosis stricture [402]. Graft survival rates at mean 5.3 years follow-up was 83%.

Some series of neurological patients were evaluated to determine the onset of early and late complications [401, 403-408] (LOE2-3). The first study to use the recently introduced Clavien system reported on a series of multiple sclerosis patients (n-53), of whom 43% developed minor complications (Clavien grades I-II) and 11% major complications (Grades III-IV) [409]. Early series of children can be evaluated to determine the morphology of the upper urinary tract and renal function after urinary diversion over a long period (up to 20 years) [410-415] (LOE3). Despite complications, significant improvements in patients' quality of life were recorded, in both retrospective [410] and prospective studies [401]. The latter, however, noted that only aspects of QOL associated with the limitations and constraints induced by urinary problems were improved, not the overall QOL.

Mortality is estimated between 0 and 3.4% (LOE2-3). The commonest early complication is intestinal occlusion (4 to 12.6%), usually reversible after prolonged intestinal drainage [401, 403, 404, 406-408] (LOE2-3). The risk of gastrointestinal fistula should also be taken into account (0 to 3.3%). As for enterocystoplasty, the current trend is to try to reduce nasogastric tube drainage time to a few hours [416] (LOE3). The most frequent medical complications encountered (3 to 8%) are febrile urinary infections and thrombo-embolism (2 to 3%; LOE2-3). Other major complications include: urinary fistula in 0.3 to 3.4% of patients which may be prevented by placing a ureteric catheter for about ten days (LOE3). This complication could be a risk factor for later uretero-ileal anastomosis stricture (LOE4).

The risk of long-term intestinal occlusion ranges between 5 and 7% (LOE3). Even when a short intestinal segment is used, some patients can experience transient constipation or diarrhoea, which could adversely affect their quality of life [417] (LOE2).

Complications affecting the bladder left in situ. For the particular indication of neurological patients with bladder dysfunction, several authors have proposed not carrying out cystectomy so as to avoid potentially morbid surgery. At present, this is debatable for several reasons:

- There is a risk of pyocystis formation in the unused bladder (21-50%) [403, 404, 408, 418] (LOE3). Even where conservative treatments have been attempted (combining vesicular irrigation with anti-biotherapy) [419] (LOE3), secondary cystectomy is then necessary in a high proportion [404, 410, 412]. For women, a surgical alternative is vaginovesicostomy, which appears to be effective [405, 412] (LOE4).

- The unused bladder frequently becomes infected and may become an “irritative thorn”, especially in patients with spinal injury or multiple sclerosis (LOE 4) [404, 420].

- The risk of bladder neoplasia is higher in neurogenic patients, the principal risk factors being long-term indwelling catheterization (more than 8 years), bladder calculi and smoking [421-423] (LOE3). Moreover, screening by cystoscopy-biopsy is not effective [424, 425] (LOE3).

- Improvement of the cystectomy technique (noticeably laparoscopic cystectomy) has considerably reduced related morbidity [401, 426] (LOE2-3). Supratrigonal cystectomy can be performed in men, preserving the prostate and preventing any genital and sexual sequelae.

*Upper urinary tract complications.* Stenosis of the uretero-ileal anastomosis may occur in the medium and long term. This is very damaging to the upper urinary tract and requires regular monitoring. In contemporary series, it occurs in 2 to 7.8% of cases within 10 years [403-408] (LOE3). For cases followed for more than 10 years, the finding of 16.5 to 50% stenosis is essentially that of early paediatric series
2. i

for undiversion (LOE3-4). In the event of poor functioning of the uretero-ileal anastomosis, some authors suggest endoscopic dilation before further surgical repair of the anastomosis (LOE3) [407, 407, 427-429]. Surgery however remains the reference treatment [427] (LOE3).

The risk of upper urinary tract lithiasis (3 to 31%) is always present in these patients (even without stenosis of the uretero-ileal anastomosis) [403, 404, 407, 408] (LOE3). Patient monitoring should include regular screening of the upper urinary tract to detect any lithiasis and to implement timely treatment (LOE 4). Chronic bacteriuria is frequent but should not be treated if asymptomatic. Both patients and attending physicians must be informed so as to avoid the administration of unnecessary antibiotics. However, the risk of febrile infection persists over the long term and may be predisposed by uretero-ileal stenosis (12 to 34%) [403, 404, 407, 408].

Stoma complications. These are relatively frequent (18.6 to 30%) and varied [404, 407, 408]. The risk of peristomal herniation is the most frequently reported (between 7.7 and 10%). Stomal stenosis may also occur. Stoma complications appear to occur more often in obese patients (LOE3) [430].

Some patients, usually adults who underwent surgery as children and who subsequently to recover a continent system, or who have had complications with their non-continent urinary diversion could ask for undiversion [431-435] (LOE3-4).

2. ILEOVESICOSTOMY

This technique was first described by Cordonnier in 1957 for treatment of three children suffering from myelomeningocele [436, 437] (LOE4). Its theoretical advantages are relative simplicity, the absence of dissection and suture of the ureter, thus preventing ureteral complications and the potential of restoring the integrity of the bladder (only one case described) [438] (LOE4). The surgery consists in removing a 10 cm ileal segment from about 15 to 20 cm above the ileocecal valve. One side of the segment is Anastomosed to the dome of the bladder and the other to the skin halfway between the iliac spine and the umbilicus. A partial cystectomy is performed to reduce reservoir volume and possible urine stagnation. Surgical variants have been described with simple partial detubularization of the ileum before vesico-ileal suture [439], or the creation of a modified Boari flap on the bladder associated with partial detubularization of the ileum [438, 441-444] (LOE3). These improve drainage by reducing the ileal segment. Laparoscopic ileovesicostomy seems to be feasible [440, 445] (LOE4), and robotic ileovesicostomy has been described. A small, retrospective comparative study (LOE3) reported similar results in terms of continence and complications with the open surgery group, although a trend for less blood loss and shorter hospital stays was noted in the robotic group [446, 447].

One of the problems with ileovesicostomy, particularly in women, is the need for further surgery to prevent residual urinary leakage. All authors agree that this significantly prolongs surgery time. This further surgery may consist in closing the bladder neck or placing a suburethral tape [436, 438,443, 448, 449] (LOE3). Some authors propose performing this surgery later, where necessary [439] (LOE3).

Early complications are related to the underlying condition of these patients, which is often poor. No case of post-operative mortality has been reported in the published series [436, 438, 439, 441-444, 446-451] (LOE3). Other early complications were related to poor results of the surgery performed to render patients continent (Table 12). Patients with this type of problem are the most likely to resort to cystectomy with ileal diversion (3 to 6%) [438, 448] (LOE3).

Late complications are summarized in Table 13. Only one series to date has more than five years of follow-up [451]. It should be noted that, despite reduction in complication rates, particularly those related to chronic upper tract infections and stone formation, none of the patients in this series remained complication-free [450]. The largest series to-date also report high complication rates (up to 74%), albeit reduced in comparison with preoperative rates [448]. The most frequent new adverse events appear to be poor emptying related to stenosis of the stoma or the ileovesical anastomosis. Only one group of authors specifically mention problems related to stoma equipment that occur in about 38% of patients [448] (LOE3). The incidence of renal or vesicular lithiasis can be as high as 25% in some series, and several authors report that affected patients had a history of lithiasis [450].

Renal function appears to be preserved with this procedure at least with a mean follow-up of five years (LOE 3) [438, 439, 441-444, 448, 449, 452]. No case of impaired renal function, or even post-operative uretero-hydronephrosis was reported. Two patients in a series with long-term follow-up developed a bladder tumour [444] (LOE4).

3. VESICOSTOMY

Vesicostomy was described by Blocksom in 1957 [453] and detailed subsequently by Lapidès [454, 455]. The technique consists in constructing a bladder tube anastomosed to the skin by making a transverse suprapubic incision to reach the space of Retzius. The stoma is located half way between the umbilicus and the incision. The principal benefits simplicity and reversibility, particularly in children [456-462], making it possible to envisage temporary surgery to treat an acute urological problem. In

pediatric series, an improvement in the symptoms of infection was reported, with 6 to 20% of patients suffering bladder calculi and 6 to 18% stomal stenosis. Hydronephrosis improved or stabilized in most cases. The rate of end-stage renal failure varied between 6 and 18% for mean follow-ups of 6-7 years.

Nowadays, it is rare to conserve a vesicostomy long term. The long-term results of Lapièdes [455] (LOE3) are therefore all the more interesting. At two years of follow-up, there was no urinary infection, 16% poor drainage, 12% calculi, and renal function was preserved. At 10 years, however, end-stage renal failure, mainly due to calculi and infection of the upper urinary tract, and mortality were reported [455, 463] (LOE3). Follow up at intervals ranging up to 20 years, showed the rate of chronic renal failure is around 16.6% [453-464] (LOE3).

Recently, percutaneous button vesicostomy placement under endoscopic control was proposed as a temporary continent alternative to Mitrofanoff in a series of 10 children with neurogenic bladders. The authors only discuss the feasibility of the procedure, not its efficacy [465].

4. Cutaneous ureterostomy

Cutaneous ureterostomy was first performed in the 1960s, to treat children with spina bifida and severe upper urinary tract impairment [466, 467]. The technique was also developed to treat malformative uropathies (exstrophy of the bladder and the posterior urethral valves) [467-470]. During this procedure, the ureters are anastomosed direct to the skin without using intervening gastrointestinal tract tissue. It is only feasible in the context of significant ureteric dilatation, and even then chronic stenting is often needed. The absence of gastrointestinal resection/ anastomosis avoids a major source of morbidity and mortality, but successfully achieving urine containment with appliances can cause considerable problems. In the absence of cystectomy, two short lateral incisions are made in the iliac fossa, at approximately 3-4 cm from the anterosuperior iliac spine. Direct retroperitoneal access is made and the two ureters located on the internal border of the psoas muscle or above the iliac vessels. It is important that the peri-ureteral region be spared and the ureter sectioned as low as possible. The ureter is then catheterized and raised to the skin. The stoma is formed by attaching the ureter to the skin, or by spatulating the sutured ureter on a V-shaped cutaneous incision (separate sutures with fine resorbable thread). Variants are described so as to obtain only one stoma: Y-transuretero-ureterostomy, implantation of both ureters in a single stoma, and implantation of a single ureter (ureter of the less functional kidney ligated, or even nephrectomy). The use of cutaneous plastics may remove the need for ureteral catheterization [471].

The main inconveniences are: cutaneous stenosis if the stoma is left unstented, upper urinary tract infections, and calcification around catheters. Moreover, it is frequently necessary to construct a double stoma. It is used in adults, usually in the context of palliative urinary diversion for those with obstructive pelvic cancer (bladder, uterus, rectum), and rarely in neurological patients [467-472]. Long-term results with a mean follow-up of 8 years are given hereafter: rates of stenosis between 8.7 to 11%, infections from 6.6 to 10% and calculi from 10 to 15.5%) [470, 472] (LOE3). Renal function was preserved for short follow-up times, but fatal end-stage renal failure occurred in up to 26.6% of children during long-term follow-up [469] (LOE3).

This technique is almost never used for neurological patients with bladder dysfunction anymore because conservative treatments (intermittent catheterization, urological endoscopy) have improved and the number of children suffering from spina bifida or presenting with complex malformation of the lower urinary tract has gradually lowered. Moreover, new urinary diversion techniques have been developed.

Recommendations:

- Non-continent urinary diversion is the last resort for patients with neurogenic bladder (A).
- Bladder should be removed during the procedure because of the risk of later complications at this site (B).
- It may be indicated for urological dysfunction or in the event of a motor handicap that prevents other modes of micturition (C).
- Ileal conduit urinary diversion has the best long-term results for non-continent diversion, if the following pre- and peri-operative precautions are taken (B):
  - Pre-operative identification of optimal location for the stoma site, with wheelchair test, if necessary.
  - Utilization of a short intestinal segment (10 cm maximum).
- Minimal dissection of the ureters.
- There are several reports of good results for ileovesicostomy, but the medium-term results need to be confirmed in the long term. Quality-of-life studies should also be performed (C).
- Vesicostomy may be a useful temporary solution, particularly for children (D).
- Cutaneous ureterostomy shouldn’t be used for non continent urinary diversion in adult patients because of the rate of long term complications (B).
Disorders of the central nervous system (CNS) are common, with worldwide estimates of the prevalence of spinal cord injury (SCI) at over 2.5 million, multiple sclerosis (MS) considerably greater than 1.5 million and Parkinson’s disease (PD) approximately 3 million [1-3]. Whilst mobility, pain and bladder dysfunction has been relatively well studied, the bowel and pelvic floor dysfunction has been neglected by comparison. This is doubly unfortunate, as a large proportion of patients with CNS dysfunction experience frequent bowel symptoms, and these symptoms are amongst the most physically, socially and emotionally disabling [4-6]. Most of the literature deals primarily with the bowel dysfunction associated with three common CNS diseases – SCI, MS and Parkinson’s disease. The literature on the most common of all CNS diseases – stroke – is more patchy and often directed towards acute post-stroke problems, as opposed to chronic neurogenic bowel dysfunction. With rapid advances in rehabilitation medicine resulting in increased survival of patients, these individuals are experiencing bowel symptoms for ever-longer periods.

Spinal cord injuries are common, with an estimated 50 people per million sustaining a traumatic spinal injury every year in the Western world [7]. Non-traumatic injury (vascular, infection, tumour) is more common, and cancer alone is estimated to cause more SCI than trauma [8]. Traumatic injury mostly affects young men, and advances in rehabilitation medicine mean that the longevity of paraplegics is similar to the general population while that of tetraplegics is 10 years shorter [9]. Bowel dysfunction affects almost all patients with a chronic SCI – up to 95% report constipation, faecal incontinence is experienced at least once per year by 75% and daily by 5%, with 33% experiencing regular abdominal pain [4, 10, 11]. Inevitably, given the nature and chronicity of the bowel symptoms, they represent a significant contributor to reduced quality of life in SCI individuals [4]. Patients with SCI reported bowel dysfunction as more problematic than bladder dysfunction, sexual dysfunction, pain, fatigue and body image [4].

Bowel dysfunction is less studied, but almost as prevalent in other neurological conditions. The prevalence of MS is approximately 1 per 1 000 [2]. About one-third of MS patients suffer from constipation and one-quarter are incontinent at least once per week [5, 12]. In patients with Parkinson’s disease, constipation, in particular difficulty with defaecation, occurs in 37% [13]. One quarter of stroke survivors experience constipation, and 15% suffer with faecal incontinence [14].

The pathophysiology of pelvic floor and colorectal dysfunction is broadly similar in patients with both SCI and MS. The extent of injury is the most important factor in determining bowel symptoms in both SCI and MS. However, in chronic SCI patients the lesion is usually sharply defined and unchanging, while in patients with MS the lesions typically occur at multiple levels and tend to vary with time.

Gastrointestinal transit is under the complex regulatory interplay of the enteric nervous system and extrinsic autonomic innervation. Parasympathetic innervation accelerates transit, proximally provided by the vagus and distally by the lower sacral roots (S2-S4). The vagus provides parasympathetic input up to the distal transverse colon, so in spinally injured patients, the dysfunctional gut segment is the distal colon. The sympathetic innervation (T9-L2) retards intestinal transit. Standard clinical classification of SCI relates to this, in that lesions are classified as supraconal (above the conus medullaris, where inhibitory input is lost), within the conus or being located in the cauda equina (where excitatory sacral parasympathetic supply is lost).

In supraconal SCI, an “upper motor neurone” type injury of the bowel results; there is slowed whole gut transit [1, 2] and hypertonia and hyperreflexia of the hindgut (i.e. distal to the splenic flexure) [3, 4]. The slowing of transit is autonomic-mediated, but also contributed to by reduced mobility and attenuation of the gastro-colic response [5]. The rectal hypertonia results in reduced rectal compliance and predisposes to reflex defaecation and incontinence. In cauda equina lesions the effenter limb of the reflex arc to the hindgut is interrupted, resulting in a “lower motor neurone” type bowel dysfunction with hypotonia and hyporeflexia [6]. Complete SCI has been shown to result in the most severe degree of bowel dysfunction [7]. However, in incomplete injuries, the relationship is more variable. The ASIA classification of severity of the lesion has not been convincingly shown to relate to magnitude of bowel symptoms, which may relate to the influence of the enteric nervous system in moderating gut-function post-injury.

Anal incontinence rests on an interplay between rectal musculo-sensory function and the internal and external anal sphincters. The internal anal sphincter is a condensation of the circular smooth muscle of the colon. As such, it is not subject to voluntary control but receives an autonomic (excitatory sympathetic and inhibitory parasympathetic input) [8]. Nevertheless, supraconal injury tends not to alter anal tone, whilst the reduced tone of cauda equina lesions may relate to faecal bolus impaction as much as loss of sympathetic input. The striated external anal sphincter is under voluntary control from Onuf’s nucleus in the ventral horn of the sacral
spinal cord via the pudendal nerves. Thus, in complete SCI the voluntary control of the external anal sphincter is lost [9].

Faecal incontinence relates not only to motor factors affecting the sphincter, but also to anorectal sensation. The anal mucosa has a dense network of sensory receptors, and loss of sensation can result in anal incontinence. Rectal hyposensation occurs in both suprasacral and cauda equina lesions, and predisposes to faecal impaction (especially in the flaccid rectum of patients with cauda equina lesions) [9].

The pathophysiology of bowel dysfunction in patients with Parkinson’s disease (PD) is quite different from that of SCI or MS. Dystonia of the striated muscles of the pelvic floor and external anal sphincter explains the defecatory dysfunction [10]; this aetiological factor is supported by the observation that pelvic floor dysfunction is alleviated with L-Dopa [11]. In addition to the pelvic dysfunction, colonic transit time is usually prolonged in patients with idiopathic PD [10]. Two important pathophysiological factors contribute to this: firstly, the number of dopamine producing cells in the colonic wall is reduced in idiopathic PD [12] and secondly Lewy bodies, typical of PD, form in the enteric ganglia [13]. Recent observations have identified that men with a bowel opening frequency less than every 24 hours have an almost threefold risk of developing PD in later life compared to men with a daily or more often bowel frequency [14], suggesting that PD is not just a degenerative disorder of the CNS but also of the enteric nervous system.

III. ASSESSMENT

Patients with PD, where bowel dysfunction can long pre-date neurological diagnosis, often report decades of bowel symptoms. Current bowel symptomatology is next assessed, regarding bowel frequency, stool consistency, faecal incontinence and manoeuvres needed to achieve bowel management. This information is usually gathered from standard patient and carer history, but scoring systems exist which may supplement this. There are standard instruments (Cleveland Constipation score, St Mark’s incontinence score [1, 2], and recently a condition specific score has been developed for neurologic patients [3]. This Neurogenic Bowel Dysfunction (NBD) Score is validated in SCI, but not PD; it is currently being assessed in patients with MS.

Digital rectal examination is an essential component, allowing assessment of rectal filling, resting anal tone, ability to generate a voluntary contraction and it also gives a crude assessment of anal sensitivity. The place of more interventional physiological or radiological transit investigations is not established, but may be appropriate if there is any co-morbidity (prior anal surgery, obstetric history, pelvic organ prolapse). Plainly, patients with alarm symptoms should have necessary colonic imaging performed. Alarm symptoms in this patient group are more difficult to recognise, but any worsening of established bowel dysfunction, weight or blood loss warrants investigation.

IV. CONSERVATIVE TREATMENT

The primary aims of bowel care are twofold: to achieve bowel evacuation in a timely manner and to avoid fecal incontinence. The first step of this bowel care consists of optimizing stool consistency with adequate fluid and fiber intake, and stimulating evacuation of stool on a regularly scheduled basis with digital rectal stimulation. A range of other non-invasive interventions may supplement this: Valsalva or manually-generated external pressure, oral medications – stool softeners, stimulant laxatives and prokinetic agents; diet modification; biofeedback; electrical stimulation and functional magnetic stimulations. The key to successful bowel management is intensive patient education and training. If conservative bowel management fails, surgical management may be necessary.

Search strategy; in updating previous consultations [1, 2], Pubmed items from 2007-2011 were searched with the key words: faecal incontinence, neurogenic, neuropathic, neurologic, neurogenic bowel, bowel management, bowel care, conservative treatment, practice guideline, incontinence, constipation, cisapride, colonic, dietary fibre, laxative, suppositories. From such searches, resulted a number of papers of various levels of evidence described below.

1. BOWEL PROGRAM /BOWEL CARE

Krassioukov et al. [3] in a large literature review found 57 studies on bowel care in SCI. They concluded that multi-faceted programs are the first approach to neurogenic bowel and are supported by lower levels of evidence (LE). There is level 4 evidence (from three pre-post studies) that multifaceted bowel management programs reduce gastrointestinal transit time, incidences of difficult evacuations and duration of time required for bowel management. Coggrave et al. described bowel management in community-dwelling SCI individuals [4]. In 1334 SCI individuals, median 52 years old and with duration of injury of 18 years, the most common intervention was digital evacuation (56%). Less than 30 minutes was spent on each bowel care episode by 58% of respondents, the others needed more time. Reported problems included constipation (39%), haemorrhoids (36%) and abdominal distension (31%). Reduced satisfaction with bowel function was associated with longer duration of each bowel care episode, fecal incontinence, greater number of interventions used and more problems reported. Impact of bowel dysfunction on the
respondent’s life was rated as significantly greater than other aspects of SCI. Emmanuel has summarized the evidence base [5]. Initial management for all subjects is medication review (especially bladder drugs such as antimuscarinics, baclofen, ditropan, codeine analgesia, non-steroidal anti-inflammatory drugs (NSAIDs) and antibiotics) and addressing any unusual dietary habits.

In general, scheduled defecation should be attempted once a day or on alternate days. However, knowledge of bowel frequency prior to injury is important in deciding on the bowel program. The bowel regime approach used at the UK’s National Hospital for Neurology and Neurosurgery [5] includes

- For patients with an upper motor neuron type bowel lesion and normal or minimally impaired anorectal sensation: aiming to have a stool consistency soft enough to be passed after rectal stimulation, but not so loose as to risk incontinence in between bowel actions; stool softened by regular use of gentle osmotic laxatives and stool softeners titrated in dose to obtain a stool of the desired consistency; stimulant laxatives are best used on an as-and-when basis rather than regularly; rectal stimulation is achieved by the simplest means possible (from digital stimulation to suppositories to enemas).

- For patients with an upper motor neuron type bowel lesion and absent or grossly impaired anorectal sensation: aiming as above, but there is less room for adjusting stool consistency, since loose stools will always result in incontinence; fiber-based laxatives are occasionally recommended alongside osmotic ones, although use should be cautious to avoid worsening abdominal distension and flatulence; rectal stimulation is performed as above.

- For patients with a lower motor neuron type bowel lesion: aiming to have a formed stool which is manually removed or irrigated from the rectum; bulking agents can be helpful in this situation, along with softening agents or gentle osmotic laxative use to get the correct consistency of a formed stool. Stimulants are not helpful; manual extraction, enemas or rectal irrigation are required to remove the stool. On rare occasions tiny doses of loperamide syrup may be given after bowel care to minimize the risk of subsequent soiling. The emphasis is on avoiding becoming constipated.

2. SPECIFIC TECHNIQUES

**a) Diet**

Patients with an upper motor neuron type bowel will tend to have slow whole-gut transit, and a high-fiber diet will tend to cause bloating and flatulence. In general reducing the fiber intake – especially of insoluble (i.e. cereal) fiber – is helpful in improving these symptoms. Patients with lower motor neuron type bowel may find that a higher fiber diet helps improve stool consistency and therefore prevent fecal soiling. The most important aspect of diet is to get into a pattern of regular eating, which helps optimize bowel motility. Excessive quantities of caffeine, alcohol and foodstuffs containing the sweetener sorbitol can cause the stools to become looser and hence more difficult to manage [5].

**b) Toileting**

Patients need to have a sense of privacy and comfort to achieve a successful bowel regime. Bowel contractions are maximal on waking up and after a meal or warm drink (the gastro-colic response), therefore many patients should optimize this with scheduled defecation after a warm drink and breakfast. Where possible, it is best to exploit gravity to evacuate the bowel, so sitting on a toilet or commode chair is preferred. When this is not practicable, toileting has to be done on the bed. There are previous case reports on positive effects of using a standing table or a washing toilet seat with visual feedback [3]. Valsalva maneuver (breathing hard against a closed glottis) may help, but should be avoided in patients with significant autonomic or cardiorespiratory problems [5].

**c) Digital rectal stimulation**

Digital rectal stimulation (DRS), involves circular motion of a finger in the anal canal with the intention of causing a reflex contraction of the colon and rectum, and hence a bowel action. A lubricated, gloved finger is gently inserted into the anus and rotated for 20–30 seconds before being withdrawn. If there is no result within 5 minutes the procedure can be repeated at that point. This process also serves as a useful check to see if there is any stool present in the rectum [5]. It was demonstrated that DRS contributes to bowel evacuation in individuals with SCI in part by increasing left-side colonic motility. Mechanical stimulation must be done with caution as it may cause local trauma and induce autonomic dysreflexia (AD) in SCI individuals [2].

**d) Manual stool extraction**

Manual extraction of stool differs from DRS, attempting physical removal of the stool from the rectum with a gloved finger hooking stools out. This technique is only possible when the stools are formed. Manual extraction can be combined with a Valsalva maneuver to improve effectiveness [5]. In a randomized, controlled trial, systematic use of less invasive interventions could not reduce the need for oral laxatives and manual evacuation in individuals with chronic SCI [6]. It provided evidence of acceptability of the technique.

3. CHEMICAL STIMULANTS

Suppositories and enemas may supplement the above by causing a reflex contraction of the rectum. Implicitly, there is little point in using these agents when the rectum is empty on digital checking [5].
Stimulants range in potency, from glycerine suppositories, through micro-enemas, to larger volume stimulant enemas. Ideally, these agents should be retained for at least 10 minutes.

Krassioukov et al. gave an extensive overview of publications on medications. There is LoE 1 evidence to support polyethylene glycol-based suppositories for bowel management. Cisapride did significantly reduce colonic transit time for chronic constipation but did not seem to have clinically useful effects in people with SCI. It has now been withdrawn because of cardiac side effects. Psyllium did not alter colonic transit time but was associated with increased stool frequency in people with Parkinson’s disease. Prucalopride increases stool frequency, improves stool consistency and decreases gastrointestinal transit time in chronic constipation, and has shown some benefit in this patient group [7]. The time schedules for administration of rectal medication may influence bowel responses. The clinical significance of any of these results was difficult to interpret because of the limited number of papers and the quality of the research. During the last three years there has been no research study on the effectiveness of such medications in patients with neurogenic bowel dysfunction.

4. ASSISTIVE TECHNIQUES FOR DEFOECATION

a) Abdominal massage

Abdominal massage with the heel of the palm, in a circular motion from right to left may help increase bowel transit and movement of content towards the rectum [5]. In small controlled trials, positive effects were seen in patients with multiple sclerosis [8] and with spinal cord injury [9].

b) Anal stimulation with water streams

Pulsed water irrigation consists of supplying intermittent, rapid pulses of warm water into the rectum to break up stool impactions and to stimulate peristalsis. Pulsed irrigation evacuation would be a safe and effective method for individuals with SCI who develop impactions, or do not have an effective bowel routine [3].

c) Transanal / Transrectal irrigation (TAI)

Several studies have been published comparatively recently on this technique. Christensen et al. [2009] described how 163 of 348 patients (47 percent) had a successful outcome from treatment with TAI after a mean follow-up of 21 months. Success rates varied between patients with different underlying pathology: for neurogenic bowel dysfunction, the success rate of 67 of 107 (63 percent) was higher than in patients with anal insufficiency, sequela to anorectal surgery, idiopathic constipation, and miscellaneous [10]. Amongst factors correlating with positive outcome were neurogenic bowel, low rectal capacity, and low anal squeeze pressure increment. Two non-fatal bowel perforations were found in approximately 110,000 irrigation procedures.

Faaborg et al. studied long-term application of TAI and found a drop-off in effect, with successful outcome in 46% of neurologic patients after a mean follow-up of 19 months. The rate of success was 35% after 3 years and remained almost unchanged thereafter. TAI was relatively safe, with a perforation rate of about 1 in 100,000 [11]. Whether this perforation rate is cumulative or seen only at the initiation of treatment remains to be determined in long-term studies.

Ausili et al. treated 60 children with myelomeningocele with TAI for three months. Sixty percent (36/60) reported relief from constipation and 75% (12/16) for fecal incontinence. Wheelchair-bound and walking patients showed similar improvements of bowel habit. There was a clear improvement in quality of life. They observed a reduction of urinary tract infections during the course of treatment and few complications [12].

Neel prospectively evaluated the efficacy and durability of combined intradetrusor botulinum-A toxin, endoscopic treatment for vesicoureteral reflux, with anal irrigation in a small group of young (5.3 +/- 2.5 years), incontinent, treatment-refractory myelomeningocele children. Ten of 13 patients achieved stool dryness with anal irrigation 1 to 2 times weekly. Three patients who were stool continent on standard enemas did not require this irrigation system [13].

TAI using a self-administered system results in a lower total cost to society than conservative bowel management [14]. Building on the positive data reported for patients with SCI, continued evaluation in the clinical trial setting is required to further define the utility of TAI in other populations with NBD [15].

5. APPLIANCE/ASSISTIVE TECHNIQUES FOR FAECAL INCONTINENCE

a) Anal plug

Previous studies employing anal plugs have yielded conflicting results [3]. Bond et al. undertook a randomized controlled trial with the Conveen anal plug (Coloplast Limited) used for 12 months in patients, including a number with neurologic bowel. The anal plug proved of benefit to the majority of patients. It did not suit all eligible patients, with in situ plug retention being a problem for some [16].

b) Neuromodulation / Electrostimulation / Magnetic stimulation

Tsai et al. state that functional magnetic stimulation, featuring broad-spectrum application, can be incorporated successfully into other therapies as an optimal adjuvant treatment for neurogenic bowel dysfunction resulting from SCI- both with supraconal and conal/caudal lesion [17]. Kajbafzadeh et al. applied transcutaneous interferential (IF) electrical
stimulation for constipation symptoms in children with myelomeningocoe (MMC). They found sphincter pressure and rectoanal inhibitory reflex significantly improved compared with sham stimulation and pretreatment measures. In 73% of patients, the characteristics of constipation decreased immediately after IF therapy, while in 53% patients, they persisted for 6 months. Frequency of defecation increased statistically significant [18].

In a small pilot study Fu et al. explored the efficacy of neuromodulation. One patient with permanent sacral electrode and neurostimulator implantation was overall successful. Four out of 8 with dorsal penile/clitoral nerve neuromodulation had decrease in Wexner constipation score. Patients also showed a significant improvement in their symptoms and quality of life during follow up. If confirmed, sacral neuromodulation and dorsal penile/clitoral nerve neuromodulation may be effective for some neurogenic constipation. However, there are no predictive tests to anticipate the candidates with the best chance of benefit with the procedure [19].

In the previous literature [4], one good quality RCT, with only a few study subjects, showed that external electrical stimulation of the abdominal wall muscles can improve bowel management for individuals with tetraplegia. In a prospective controlled trial, 25 minutes of electrical stimulation of the abdominal muscles per day, five days a week, for eight weeks, resulted in accelerated colonic transit times when compared to the placebo control group. In a case study, posterior tibial nerve stimulation improved bowel management in incomplete SCI. Functional magnetic stimulation on the thorax and lumbosacral nerves (stimulation placed at T9 and L3 spinal processes) reduced colonic transit times and self-reported symptoms of constipation [4].

c) Quality of life

No specific new study has been published, but in several studies mentioned above an improvement of QoL was shown.

Conclusions

- In reflex bowel, digital rectal stimulation relaxes the external anal sphincter and increases peristaltic contractions by facilitating an excitatory anorectal (ano-colonic) reflex, and enhances bowel movement and evacuation (LOE 3).

- Abdominal massage has beneficial effects on neurogenic bowel dysfunction, including defecation function and fecal incontinence (LOE 3).

- Transanal irrigation is a safe method to improve constipation and faecal incontinence in individuals with neurogenic bowel dysfunction (LOE 2).

- An anal plug can help control fecal incontinence in selected neurological patients (LOE 3).

- Different forms of electrical stimulation seem promising for fecal incontinence and defecation management in neurologic patients (LOE 3).

- To increase adherence rate with bowel care program/clinical practice guideline, implementation strategies should be addressed to care providers (LOE 3).

Recommendations

- Multi-faceted programs are the first approach to neurogenic bowel management and are supported by lower levels of evidence (B). They may consist of toileting, rectal stimulation (digital or with water stream), manual feces extraction, transanal irrigation and other assistive techniques (B).

- Diet can help but multi fibre is not necessarily indicated in patients with upper motor neuron lesion (B).

- Autonomic dysreflexia when using mechanical stimulation and assistive techniques can occur in neurologic patients with a high spinal cord lesion (B/C).

Recommendations for research

- Development of sensitive and valid instruments to quantify bowel dysfunction in neurogenic conditions other than spinal cord injury.

- Well-designed controlled trials with adequate numbers and clinically relevant outcome measures of bowel management are needed, including for administration of stimulants.

- Larger and good quality randomized cross-over trials are needed to confirm the effects of neuromodulation and other forms of electrical therapy for controlling fecal incontinence and reducing constipation in neurologic patients.

- Transanal irrigation needs to be studied in patients with causes of neurologic bowel different from spinal cord lesion and meningomyelocele. Long-term follow up of TAI populations is important to determine the safety, and factors predicting poor outcome.

- Given the prevalence of bowel dysfunction in Parkinson’s disease (which is increasing in prevalence), specific studies in this population are required.

V. SURGICAL TREATMENT

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to December 2011, looking for the keywords; neurogenic constipation and faecal incontinence, surgery,
sacral nerve stimulation, antegrade continent enema procedure, dynamic graciloplasty, artificial anal sphincter and colostomy.

The mainstay of current treatment in neurogenic fecal incontinence is adopting a conservative approach towards reversing the systemic effects and optimizing the mechanics of defecation through the use of laxatives and irrigation approaches. Surgery should be normally reserved for patients who have failed conservative therapy. This section focuses on specific aspects of faecal incontinence surgery in neurogenic patients. Although traumatic lesion of the external anal sphincter in neurologically intact patients is treated by reconstruction, functional impairment of anal sphincter without mechanical defect of the sphincter in neurogenic patients can not be treated by this simple surgical approach. Thus, options for surgical treatment of neurogenic bowel dysfunction are limited. They consist of: 1) sacral nerve stimulation, 2) antegrade continence enema procedure, 3) dynamic graciloplasty, 4) artificial anal sphincter, 5) elective colostomy, 6) postanal repair.

1. SACRAL NERVE STIMULATION

Electrical stimulation of sacral nerve roots has been reported to restore continence in patients with intact muscle structure. The procedure includes a test phase: acute percutaneous testing, today mostly using tined lead electrodes as part of a two stage operative procedure, or temporary percutaneous nerve evaluation, prior to permanent electrostimulation with an implanted neurostimulation device. An electrode inserted into the S3 sacral foramen provides low grade stimulation. If patients respond to acute or temporary percutaneous sacral nerve stimulation tested for 2 to 3 weeks, permanent stimulation can be considered. Thus is achieved with a chronic stimulator implanted under the anterior abdominal wall or subcutaneously in the gluteal region. The first case report with this technique was published by Matzel et al. [1] in 1995 who described a successful outcome in three patients with faecal incontinence. Since then, ten articles have been published [2-11] (Table 14). Matzel et al. [2] reported a multicentre, prospective trial with chronic sacral nerve stimulation in a series of 34 patients at a median follow-up of 23.9 months. At least 83 % of patients had a 50 % or greater improvement in total number of incontinent episodes per week and at least 71 % of patients a 50 % or greater improvement in total number of days per week with continence during the course of follow-up. Continence was fully restored in at least 12 (37 %) patients. Quality of life improved in all four ASCRS (American Society of Colon and Rectal Surgeons) scales (p<0.0001) and in seven of eight SF-36 scales, though only social functioning was significantly improved (p=0.0002). Although 12 patients had 19 device-related adverse events including pain (ten episodes in 9 patients), lead breakage in one patient, recurrent infection needing device removal in one patient and deterioration of bowel symptoms in three patients, resolution rate was 63.2 % and 100 % for all and severe complications, respectively. However, this study excluded patients with neurological diseases.

Similar success rates (73-100%) with this technique have been reported from other centres [3-5, 7-11]. Among these reports, only one case-series by Rosen et al. [12] mainly evaluated faecal incontinence in patients with neurological lesions. In that study, 20 patients (15 neurogenic, 5 idiopathic) with severe faecal incontinence were initially treated by temporary external stimulation over a period of 10-14 days. Sixteen patients (11 with neurogenic causes, including SCI, spinal cord surgery, myelomeningocele and MS) who had shown a positive response to the temporary stimulation subsequently underwent permanent implantation. The median follow-up was 15 months (range, 3-26 months). All patients who had received a permanent implant revealed a marked reduction in their incontinence episodes, as well as an increase in retention time. In the neurogenic subpopulation, the median numbers of incontinence episodes decreased significantly (p<0.01) from 7 (4-15) to 2 (0-5), and a median retention time significantly (p< 0.01) increased from 2 minutes (0-5) to 7 minutes (2-15) after chronic stimulation. Assessment of QOL scales using ASCS questionnaires after 6 months treatment showed significant improvement on all scales. Three patients (2 neurogenic and 1 idiopathic) had severe infections needing explantation of the device and wound drainage 0-3 months after implantation. Another one patient had dislocation of the permanent electrode. No complications were observed in the remaining 12 patients (60 % of total series). All of those patients with functioning systems showed improved incontinence during the follow-up period. Although the mechanism of SNS in improving faecal incontinence is uncertain, rises in anal resting and squeezing pressures and changes in rectal sensitivity and motility have been proposed. Particularly in neurogenic patients, neuromodulation of sacral reflexes and regulation of rectal sensitivity appear to be the major reasons for the functional improvement [7]. Where the diagnostic stage is performed as a staged implant, a tined lead is employed with four active electrodes (compared with a single electrode used in PNE) and has self-retaining flanges, which reduce risk of lead migration. Usage of the tined lead has the benefit of minimizing false-negative results.

Jarrett [2005] [14] reported on experience with sacral nerve stimulation for faecal incontinence in patients with previous partial spinal injury including disc prolapse: the spinal insults were disc prolapse (six), trauma (four), spinal stenosis (one) or occurred during neurosurgery (two). Temporary SNS was performed in thirteen patients (median age 58.5, range 39-73 years). Twelve patients had successful temporary stimulation and proceeded

</table>
to permanent implantation. The median follow-up time was 12 (range 6-24) months, the mean number of episodes of incontinence decreased from 9.33 (7.64 per week at baseline 2.39 [3.39] at last follow-up (p = 0.012). The number of days per week with incontinence and staining decreased significantly (p = < 0.001). The ability to defer defecation improved from a median of “not able to defer” (range 0-1 min.) to being able to defer 5-15 min (range 0->15) mean (p = 0.022). The authors conclude that SNS can benefit patients with faecal incontinence following partial SCI. Holzer et al. [2007] [15] reported on 36 patients included in a trial of SNS, of whom 29 subsequently had a permanent implant. After a medium follow-up of 35 (range 3-71) months, 28 patients showed a marked improvement: incontinence to solid or liquid stool decreased from a median of 7 (range 4-15) to 2 (range 0-5) episodes in 21 days (p = 0.002). Sali ne retention time increased from a median of 2 (range 0-5) to 7 (range 2-15) min. (p = 0.002). The quality of life on all scales among patients who received the permanent implant increased at 12 and 24 months after operation.

Based on a retrospective, non-blinded study without controls comprising 39 patients, Lombardi et al. [16] evaluated the clinical outcome of SNS in incomplete SCI with neurogenic bowel dysfunction: Twenty-three patients were submitted to definitive SNS, maintaining their clinical benefits after permanent implantation with a median follow-up of 38 months. The length of time since neurological diagnosis to SNS therapy represented the only factor significantly related to the success of the implantation. In subjects with constipation [12] the median number of evacuations shifted from 1.65 to 4.98 per week, whereas the Wexner score changed from 19.91 to 6.82 in the final checkup with P<0.05. In subjects with fecal incontinence [11], the median number of episodes per week in the final follow-up was 1.32 compared to 4.55 pre-SNS. General and mental health showed statistically significant improvement. Anorectal manometry showed no important variation compared with baseline. There were no major complications. The authors consider SNS an option for the treatment of neurogenic bowel symptoms for selected patients with incomplete SCI when conservative treatments have failed.

The overview of the studies shows that electrical nerve stimulation is effective in partial spinal cord injury. There are no reports for complete spinal cord lesions.

Conclusions

- SNS is a minimally invasive procedure, and seems to be an option for faecal incontinence and constipation due to functional deficit of the anal sphincter without structural defect in incomplete neurogenic lesions (LoE3/4).

Recommendations

- Studies on larges series with long term follow-up are needed to determine the role of SNS in the treatment of faecal incontinence associated with neurological lesions (D) and identify those patients most likely to benefit.

2. ANTEGRADE CONTINENCE ENEMA (ACE)

The original procedure was developed by Malone et al. [17]. The principles of antegrade colonic washout and the Mitrofanoff non-refluxing catheterisable channel were combined to produce a continent catheterisable colonic stoma. The intention was that antegrade washouts delivered by this route would produce complete colonic emptying and thereby prevent soiling. Malone et al. reported successful results in five children with intractable faecal incontinence. This procedure has been applied mainly to the paediatric population with neuropathic bowel dysfunction and anorectal anomaly, and successful outcome was achieved in 70-100 % [18-38] (Table 15). Several modifications have been reported including laparoscopic technique, left colonic continent stoma, etc. This procedure was also applied to adult neurogenic patients with faecal incontinence, and similar success rates (83-100 %) were reported. Overall, stoma stenosis is the most common complication, affecting 10-41 %. In a study of 62 children with median follow-up of 5.4 (3.25 to 8.25) years, 84% were completely continent or had soiling less than once a month [20]. There was a significant correlation between the level of continence and satisfaction with the procedure. Improvement of self-esteem and psychosocial function after the ACE procedure in children with myelomeningocele has been reported [22].

Casale et al. [39] compared total continence reconstruction to staged-reconstruction of neuropathic bowel and bladder. In this retrospective chart review of all patients with myelomeningocele who underwent reconstruction with a cutaneous catheterisable urinary channel or Malone ACE stoma, the authors were unable to find any differences in the continence rate or stoma complications between total continence reconstruction and/ or staged reconstruction. However, because of shared pathology the authors believe that most patients are likely to require intervention for both gastrointestinal and genitourinary problems. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of requiring major surgical procedures on separate occasions for the two organ systems (LOE 3).

Herndon et al. 2004 [40] reported on ACE stoma in 127 patients (76 females and 51 males, average age at the time of surgery 9.6 years), reflecting a 6-year experience. Diagnoses included myelomeningocele in 116 cases, lipomeningocele in 6, SCI in 2, sacral agenesis in 1 and functional constipation

</table>
in 1. The mean follow-up was 26.9 months. Faecal continence was reported by 91% of the patients, while 13 stoma revisions were required in 11 patients (for stenosis in 10, prolapse in 2 and leakage in 1). Major complications included a caecal volvulus requiring a right hemicolectomy in one patient, small bowel obstruction in two and a shunt infection and/ or malfunction in two. The authors conclude that the in situ ACE procedure has reliable long-term results for treating faecal incontinence associated with neuropathic bowel.

Bar-Yosef et al. [41] performed a retrospective chart review from 1997 to 2007 in a total of 21 patients with myelomeningocele who underwent total continence reconstruction for urinary and fecal incontinence using the artificial urinary sphincter (AUS) and a Malone ACE stoma (using the appendix in 19 patients and cecal-based flaps in 2). There were 19 patients (90%) who reported faecal continence, with two reporting soiling 1 to 2 times a week. ACE stoma stenosis occurred in 3 patients and 2 required revisions. Sixteen patients (76%) achieved complete continence of stool and urine. Therefore ACE stoma and AUS in conjunction provide urinary and fecal continence in a single total continence reconstruction procedure, for patients.

Conclusion and Recommendation

- Antegrade continence enema stomas are effective for controlling faecal incontinence and constipation associated with neurogenic bowel dysfunction especially in neuropathic children (LoE 3; Grade B). Patients should be properly selected to determine appropriate motivation.

3. DYNAMIC GRACILOPLASTY

This procedure consists of transposition of the gracilis muscle around the anal canal and subsequent implantation of a pulse generator to stimulate and entrain the gracilis muscle. Before continuous stimulation is applied, the muscle is trained for 4 to 8 weeks according to a protocol. During a stimulation program the fatiguable type 2 skeletal fibres may be replaced by slow type 1 fibres, which are able to sustain a longer-lasting contraction- though formal documentation of such transition is not evident. Satisfactory continence has been reported in 56% to 81% of patients [42-53] (Table 16). However, all studies presently available include small numbers of neurogenic patients, or there is no subgroup information on the outcome in neurogenic patients.

A prospective study of 200 consecutive patients with a follow-up of at least two years showed a 72% overall success rate. Complication rates are high (42%-92%)- especially infectious complications, which occur in about one quarter of the patients. Impaired rectal emptying occurs in 16% to 29%. A prospective controlled comparative study of a single stage operation with the conventional two-stage procedure showed no significant difference in infection rates, continence rates, morbidity or quality of life between the two groups after a mean 521-day follow up. Chapman et al. [53] reported a systematic review article of this procedure, where they searched articles published until November 1999, and found 40 articles met the inclusion criteria. Mortality rates were around 2% for both graciloplasty and colostomy. However, morbidity rates reported for graciloplasty appear to be higher than those for colostomy. Rongen et al. [42] reported an 80% success rate with this procedure in 16 patients with neurogenic faecal incontinence.

A prospective controlled study comparing dynamic graciloplasty with artificial anal sphincter in 16 patients (8 in each group) showed that both of the two procedures had a high incidence of technical failures and complication requiring re-operation [52], with a median observation time of 44/39 months. In this study, Ortiz et al. [52] came to the following conclusion: the artificial anal sphincter is a more convenient technique than dynamic graciloplasty for institutions treating a small number of patients. However, technical failures and complications during follow-up that require reoperation are very high in both types of treatment.

Conclusions and Recommendations

- Dynamic graciloplasty seems to be associated with high complication rates, and outcome appears to correlate with surgeon’s experience.

- Graciloplasty should be carried out in specialist centres with a reasonably large number of patients, and should be reserved for carefully selected patients with intractable faecal incontinence, where other methods have failed (C).

- Further studies are needed to determine its role in the neurogenic subpopulation.

4. ARTIFICIAL ANAL SPHINCTER

Implantation of an artificial anal sphincter (AAS), also referred to as artificial bowel sphincter (ABS) was first reported in 1987 [54]. The sphincter used was originally designed for treatment of urinary incontinence, but subsequently the device was modified. The system consists of an inflatable cuff placed around the upper anal canal, a pressure-regulating balloon to maintain closure of the cuff, placed in the subperitoneal space lateral to the bladder, and a control pump accessible to the patient to empty the cuff for defaecation placed in the scrotum or labium. The system is left deactivated for 4 to 6 weeks after placement. The reported success rates obtaining acceptable continence range from 41 to 90% [55-70] (Table 17). A multicentre prospective, non-randomized trial in 112 patients with one year follow-up showed 73 revision operations were required in 51 (46%), and the infection rate necessitating surgical revision was 25%. Forty-one patients (37%) have

</tbody>
</table>
had their devices completely explanted [55]. Ex-
plantation rates in the reported series were 20-40%. 
Technical complications like rupture of the cuff, 
which occurred frequently with the earlier versions 
of the device, are now rare. Emptying problems in 
the absence of anatomical stenosis, as described 
for dynamic graciloplasty, have also occurred fre-
quently (13 to 45%) in most series and have neces-
sitated explantation in some patients. Other com-
pliations leading to explantation have been erosion 
of the cuff through the skin, or into the anal canal.

As shown in the Table, most studies have a small 
number of neurogenic patients or do not indicate 
the number of neurogenic patients included. In the 
study reported by Christiansen et al. [63], 10 (59 %) 
out of 17 patients had neurological disorders, and 
the overall success rate was 47%, which seems to 
be lower than the others. The authors mentioned 
that the result in neurogenic subgroup was clearly 
poorer than that in non-neurogenic subgroup.

In a prospective, randomized controlled clinical 
trial of placement of the artificial bowel sphincter 
for the control of faecal incontinence O’Brien et al. 
[2000] [61] compared its effects to a program of 
supportive care and patients were followed for six 
months from operation or entry into the study. The 
principal outcome measure was the level of contin-
ence, measured with the Cleveland Continence 
Score, categorising from perfect control through to 
total incontinence. Secondary outcome measures 
were peri-operative and late complications in the 
artificial bowel sphincter group and the changes in 
quality of life in both groups. In the control group 
(N = 7) the Cleveland Continence Score was not 
significantly altered. The artificial bowel sphincter 
group (N = 7) showed a significant improvement. 
One patient in the artificial bowel sphincter group 
had failure of healing and implantation of the de-
vice. There were major improvements in the quality 
of life for all measures in the artificial bowel sphinc-
ter group. The authors conclude that the placement 
of an artificial bowel sphincter is safe and effective 
when compared with supportive care alone. Peri-
operative and late problems are likely to continue to 
occur and between 15% and 30% of patients may 
require permanent explantation. The authors con-
clude the device is easy and discrete to use, effec-
tive in achieving continence, and able to generate 
an improvement in quality of life (LoE 3).

In an article on “The artificial bowel sphincter in 
the treatment of severe fecal incontinence in adults”, 
Lehur and Meurette [68] concentrated on the most 
recent and significant published data. They state 
that several centers in Europe, the United States, 
and Australia have adopted the ABS to treat se-
vere fecal incontinence not amendable to local 
repair. Reports with larger numbers of cases and 
longer follow-up have recently appeared, providing 
a better assessment of the technique and its pres-
tent place in the treatment strategy of incontinent 
patients. Contraindications include excessive perine-
al descent and severe constipation. In cases of 
neurogenic fecal incontinence it is essential to take 
to account possible associated bowel emptying 
problems and excessive perineal descent. The ABS 
creates an obstacle to rectal evacuation, which can 
sometimes cause considerable evacuation difficul-
ties. Continence restoration should not be achieved 
to the detriment of evacuation capacities. However, 
an objective assessment of the state of pre-opera-
tive transit is not always easy.

Michot et al. [69] described an implantation pro-
cedure of artificial sphincter for anal incontinence 
using a transvaginal approach. Between 2003 and 
2005, the Acticon Neosphincter was implanted via 
a transvaginal approach in nine patients (average 
age 43 (range 25-73) yrs). Successful outcome 
was achieved in eight of nine patients (89 %), with 
a mean follow-up of 21.5 (range 8-38) months; in-
continence scores decreased from 19 (range 18-20) 
before the procedure to 8.6 (range 2-14) at the last 
follow-up. Although it is not stated whether patients 
with neurogenic faecal incontinence are included, 
a transvaginal approach could be considered with 
destroyed or scarred perineum.

Conclusions and Recommendations

- Implantation of the artificial anal sphincter 
  may be undertaken in neurogenic faecal inconti-
  nence, except in patients with previous perianal 
  infections or with a thin and scarred perineum, 
  in whom muscle transposition is preferable.

- Due to the relatively high risk of treatment fail-
  ure and of complications requiring re-opera-
  tion, patient selection and counselling should 
  be very strict (C).

5. COLOSTOMY

Several retrospective studies on the effect of colos-
tomy formation in SCI patients showed a significant 
decrease in the average time spent on bowel care 
per week and improvement of QoL [70-78]. The early 
and long-term complication rates reported are 6 to 
15%, and 15 to 37.5%, respectively. The commonest 
long-term complication is mucus discharge per rec-
tum. One of the more frequent, persistent, problem-
atic complications is diversion colitis [81, 82]. Sym-
pptoms include hemorrhagic purulent rectal discharge, 
abdominal pain and tenesmus. This condition is 
thought to result from a deficiency of luminal short-
chain fatty acids [83]. Steroid enemas, 5-aminosali-
cylc acid enemas or suppositories, or short-chain 
fatty acid enemas have been reported as helpful [84].

Hocevar and Gray [85] published a systemic review 
from January 1960 to November 2007 including pro-
spective and retrospective studies that directly com-
pared clinical, functional, QoL outcomes or satisfac-
tion among patients with intestinal diversions with
patients managed by conservative means. Creation of an ostomy in selected patients provides equivocal or superior QoL outcomes when compared to conservative bowel management strategies. Both colostomy and ileostomy surgery significantly reduce the amount of time required for bowel management. Patients who undergo ostomy surgery tend to be satisfied with their surgery, and a significant portion report a desire to be counselled about this option earlier. There are no clear advantages when functional, clinical, or QoL outcomes associated with colostomy are compared to those seen in SCI patients undergoing ileostomy.

Conclusion

- Elective colostomy may be an option for some SCI patients with severe uncontrolled faecal incontinence (C).

6. POSTANAL REPAIR

Mackey et al. [86] published the long-term results of postanal repair carried out in patients whose incontinence was thought to be because of neurogenic sphincter weakness. Anorectal physiology studies were carried out in 89% of the cases, and the clinical diagnosis of neurogenic incontinence was confirmed by prolonged unilateral or bilateral pudendal nerve terminal motor latency (PNTML) (>2.2 m/s) or increased threshold of anal mucosal electrosensitivity (or both). Patients were selected for surgery only after failure of medical and conservative therapies, including dietary manipulation, loperamide, or biofeedback where appropriate. A total of 111 patients underwent a postanal repair, 57 remained eligible, for whom full data were available. The mean duration of follow-up was 9.1 years (2.2-18.7 years). Mean CCS (Cleveland Continence Score) was 11.7; 26% scored none or minimal incontinence, 26% moderate and 48% severe incontinence. 97% (n = 45) were satisfied with the outcome. A low CCS significantly correlated with good patient satisfaction and was influenced by high QoL score (P < 0.0001). A favourable CCS was associated with a shorter duration of follow-up. Although a deterioration in continence with passage of time was observed, satisfaction amongst the patients was high. Only a quarter of patients showed a very good continence after a mean time of 9 years. Patients undergoing postanal repair are counselled appropriately and have realistic goals regarding their bowel functions in both the short and long term.

The procedure is inexpensive in comparison with graciloplasty and sacral nerve stimulation, and has low morbidity. Additionally, this procedure be useful in the elderly or those with significant co-morbidities. Although long-term continence has been found to deteriorate, the procedure can result in a satisfactory outcome in the long-term in a proportion of patients.

Conclusions and Recommendations

- Postanal repair results in satisfactory outcome in the long-term in patients with neurogenic sphincter weakness. However, this is a single centre experience, which needs further confirmation (C).

E. Specific neurological diseases

I. DEMENTIAS

1. DEMENTIA AND URINARY INCONTINENCE

Methods Using MEDLINE we identified English-language journal articles and reviews published from May 2008 to January 2012, which were added to literature obtained for previous Consultations, looking for the keywords Alzheimer’s disease, vascular dementia, dementia with Lewy bodies, frontotemporal dementia, urinary incontinence, bladder dysfunction, management.

The dementias can be categorized according to clinical presentation, neuropathology and/or etiology into four major dementia groupings, (I) the Alzheimer’s group (Alzheimer’s disease, AD); (II) the vascular group (including large and small vessel disease, particularly white matter disease); (III) the Parkinson’s group (including Parkinson’s disease dementia complex (PDD, being regarded as identical to DLB), and dementia with Lewy bodies (DLB), both being connoted as Lewy Body diseases); (IV) the frontotemporal group (including Pick’s disease and Semantic dementia) [1].

Normal pressure hydrocephalus (NPH) is a less common pathology, but nonetheless important.

2. ALZHEIMER’S DISEASE

a) Epidemiology and prevalence

Alzheimer’s disease (AD) is the most common type of dementia in clinical and autopsy surveys. AD affects mostly elderly people. The symptoms include worsening of the memory, impairment of language and other cognitive functions (analytical thinking, abstract reasoning). Ultimately, there is loss of self-hygiene, eating, dressing and ambulatory abilities, incontinence and motor dysfunction. The onset of incontinence usually correlates with the disease progression (LOE 3)[2]. In other words, urinary incontinence inevitably occurs in the advanced stage of disease, while urinary incontinence is not common in the early stage of AD. This is in contrast with early occurrence of urinary urgency and incontinence in vascular dementia and dementia with Lewy bodies. The prevalence of incontinence in AD is reported to be between 23 % and 48 % (LOE 3) [3, 4]. However, most previous studies did not mention the type of dementia concerning ‘frequency of
urinary incontinence in dementia’. The prevalence of incontinence in dementia ranges from 10% (of out-patients) to more than 90% (of advanced, institutionalized individuals) (LOE 3) [5].

b) Pathology and disease-specific urinary tract problems

AD at the outset was identified by its unique pathology, the amyloid plaques and neurofibrillary tangles containing phosphorylated tau that Alzheimer referred to as “a clotting of fibrils.... in addition an extraordinary number of peculiar patches disseminated throughout the entire cortex.” Amyloid and tau can now be measured in vivo by positron emission tomography and/or examination of the cerebrospinal fluid (CSF). There is a familial occurrence of AD [3]. In such cases, mutations in the genes encoding amyloid precursor protein (APP); presenilin 1 (PSEN1), or presenilin 2 (PSEN2) are reported.

The clinical hallmark of AD is memory impairment. A sense of memory failure, detected by the patient or a close relative, is usually the presenting symptom. Motor and sensory symptoms are absent until late in the course of the disease. However, other cognitive domains, such as language, praxis and recognition skills, are affected even early in the presentation. AD has a gradual and progressive course, typically 10 years from diagnosis to death. The advent of central cholinesterase inhibitors and glutamate receptor antagonists has had a positive effect on the memory symptoms of AD [6-8].

In early stages of AD the prevalence of urgency incontinence is lower than in dementia with Lewy bodies [9, 10]. During stage III (advanced) AD, urinary and fecal incontinence occur due to loss of sphincter control [10]. In a study by Del Ser et al. (LOE 3) urinary incontinence was associated with severe cognitive decline in pure AD but usually preceded severe mental failure in patients with dementia due to diffuse Lewy body disease [10]. Nobili et al. (LOE 3) performed quantitative EEG in AD patients, finding that incontinence was predicted by alpha power in the right side [11]. In another study by Nobili et al. (LOE 3) the value of regional cerebral blood flow from a posterior temporal-inferior parietal area in each hemisphere predicted development of incontinence [12]. A brain computer tomography study done by Sugiyama et al. (LOE 3) in AD patients showed that the degree of brain atrophy was more severe in those with detrusor overactivity (DO) than those without it [13]. DO was found in 40-61 % of their patients [13] (LOE 3). The incidence of DO in AD patients is low as compared with vascular dementia and dementia with Lewy bodies [9]. Haddad et al. (LOE 3) described two patients with vesicoureteral reflex, one of them showing buccosalivary, gastroesophageal, vesicoureteral, urethroprosthetic and urethrovessicular reflex as a consequence of the neurologic dysfunction [14].

c) Diagnosis and treatment

Franssen et al. (LOE 2) examined the occurrence of the following developmental reflexes: the tactile suck reflex, the palmar and plantar grasp reflexes, and the plantar extensor reflex in healthy elderly, cognitively and functionally mildly impaired patients, and patients with AD [15]. Prevalence of all five reflexes was more than 6 times higher for those categories that comprised permanently doubly incontinent patients as compared to those categories that comprised continent individuals. It is interesting that the frequency of developmental reflexes rose sharply with the onset of progressive incontinence, suggesting its cortical origin. As demonstrated above, the development of incontinence in AD patients is associated with cognitive impairment and brain degeneration, suggesting its CNS origin. Therefore behavioural therapy, toilet training and prompted voiding would be most useful treatment modalities for this type of incontinence.

Hutchinson et al. (LOE 3) suggested that caregivers of patients with AD should study the toileting behaviours. This would permit them to provide physical and cognitive assistance while attempting to avoid accidents and catastrophic events [6]. Tariot (LOE 4) stressed the necessity for taking into account different factors (like mobility, cognitive functions, general medical conditions), when planning treatment (also for incontinence) in AD patients [7]. Lancioni et al. reported three AD patients who could learn to use urine alarms [16] (LOE 4). Again the general guidelines should apply for choosing the best management of incontinence in AD patients. The treatment should be tailored to individual patient needs and disease status.

There is still some controversy that the central acetylcholinesterase (ACHE)- inhibitors given by the neurologist might exacerbate urinary incontinence in those patients. Donepezil hydrochloride is a selective central ACHE inhibitor, which decreases degradation of acetylcholine in the brain, then increasing the concentration of acetylcholine in the synaptic cleft [17]. This drug is widely used to ameliorate cognitive decline in patients with AD [18, 19] which is thought to be due to a decrease in cholinergic innervation of the cerebral cortex and the basal forebrain [20]. Since the bladder is innervated by the parasympathetic cholinergic nerves, neurogenic lower urinary tract (LUT) dysfunction occurs in a subset of patients with AD [5, 13].

Although donepezil may facilitate cholinergic neurotransmission mostly in the CNS, common adverse effects of donepezil, such as nausea and abdominal discomfort, have been attributed to the peripheral nervous system (PNS) [18]. Therefore, the increased bladder contraction is reasonably attributed to the PNS effects as seen with other cholinergic drugs. However, according to Sakakibara et al. [2005] the patients with AD showed a slight increase in
the bladder capacity, which cannot be explained by the PNS effects alone [21] (LOE 3). Although it is unknown to what extent central cholinergic circuit may participate in the regulation of micturition, recent experimental studies showed that lesions in the nucleus basalis Mynert in the basal forebrain (central cholinergic nucleus projecting fibres to the frontoparietal cortex) give rise to decreased bladder capacity) [22]. In addition, improved cognitive status and alertness may well lead to proper initiative to hold urine. Central AChE inhibitors including donepezil hydrochloride, therefore, may have complex effects on the LUT function. Although the number of the patients was small, it seems possible that donepezil could ameliorate cognitive function without serious adverse effects on the LUT function in patients with AD. This should be true also for other selective central AChE inhibitors.

Many elderly patients and their caregivers seek medical care for dementia and overactive bladder (OAB) together. In order to answer this, recent clinical trials of a combination therapy of central AChE inhibitors and peripheral anticholinergics for ameliorating both cognition and incontinence are available. In 26 older individuals who had both cognitive problems and overactive bladder (AD in 8, vascular dementia in 5, a combination of AD and multiple cerebral infarction in 8, and others), Sakakibara et al. reported that addition of 20 mg/day propiverine, an anticholinergic agent, to 5 mg/day donepezil improved OAB without any cognitive change [23] (LOE 3). Sink and colleagues retrospectively studied 3536 nursing home residents who were taking central AChE inhibitors, in whom 10.6% were prescribed anticholinergics together [24]. They found no differences in cognitive function between groups of AChE inhibitors alone and AChE inhibitors with anticholinergics (LOE 3). The combined use of a ‘central’ AChE inhibitor and a ‘peripheral’ muscarinic receptor antagonist remains a matter of controversy and needs further clarification, whereas there is a study indicating that this combination would be pharmacologically sound as a site-directed therapy [25].

**d) Guidance for further research**

There is still no cure for AD, which is progressive and a type of dementia-associated disease. We are still lacking studies evaluating LUT disorders in AD. No systematic review has been performed regarding the possibilities of medical management (both pharmacological and behavioural) of incontinence. An open issue also remains the question of aggressive surgery for LUT problems in these patients. Whether we should we offer surgical therapy for incontinence in female patients with stress incontinence and progressive AD is so far unanswered.

**Conclusions**

- Detrusor overactivity seems to be the most common cause of incontinence in Alzheimer’s disease (AD) patients (LOE 3), while the incidence is low as compared with vascular dementia and dementia with Lewy bodies.
- The degree of functional incontinence is associated with cognitive impairment and brain degeneration (LOE 3).
- EEG studies, occurrence of developmental reflexes and regional blood flow studies can predict the development of incontinence in AD patients (LOE 3).
- Selective central AChE inhibitors ameliorate cognitive function without serious adverse effects on LUT functions in patients with AD (LOE 3).
- A combination therapy of central AChE inhibitors and peripheral anticholinergics for ameliorating both cognition and incontinence awaits further studies (LOE 3).

**Recommendations**

- The extensive and aggressive therapy of incontinence in AD patients should be reserved for those with good general status and ambulation (C).
- In the case of ambulatory patients, prompted voiding, behavioural therapy and oral anticholinergics seem to be the treatment of choice (C).

**3. VASCULAR DEMENTIA**

**a) Epidemiology and prevalence**

Vascular dementia is the second most common form of dementia after Alzheimer’s disease (AD) among the elderly. Pooled prevalence from eight European countries was 1.6% for vascular dementia in subjects older than 65, compared to a prevalence of 4.4% for AD (LOE 3) [26]. A meta-analysis of the European studies on the incidence of dementia showed vascular dementia constituted 17.6% of all incident dementia (LOE 3) [27].

In contrast, recent population-based MRI studies suggest that moderate white matter disease (WMD, a major cause of vascular dementia) affects around 10% (7.6–24%) of the general population of persons over 55 years of age [28], comparable to type 2 diabetes. WMD develops into three different geriatric syndromes: 1) vascular dementia (usually mild in the Mini-Mental State Examination and other general cognitive function), 2) vascular parkinsonism, and 3) so-called vascular incontinence, i.e. urinary frequency/urgency with or without incontinence [29]. Among these three syndromes, urinary and gait disorders are more prominent than dementia, and usually precede dementia. Comorbidity of Alzheimer’s disease (a degenerative disease) and WMD (a vascular disease) is not uncommon.

**b) Diagnosis**

Vascular dementia may be the result of a single strategic infarct, particularly involving the thalamus...
and left angular gyrus, or multiple cortical or subcortical infarcts that produce WMD. There is an elevated risk for subsequent dementia in patients who have had a stroke in comparison to controls without any evidence of a stroke (LOE 2) [30]. Diabetes and hypertension are stronger risk factors for vascular dementia than for Alzheimer’s disease (LOE 3) [31]. The apolipoprotein e4 genotype is a risk factor for vascular dementia as well as AD (LOE 3) [32].

The incidence of WMD significantly increases with gene polymorphism of aldosterone synthase, angiotensin II type 1 receptor, nitric oxide synthase, etc., which are all relevant to atherosclerosis (LOE 3).

c) Pathology and disease-specific urinary tract problems

In patients with WMD, diffuse abnormalities are seen in the small deep perforating vessels of the hemispheric white matter, basal ganglia and brain stem. Pathological changes range from lipohyalinosis to fibrinoid necrosis and disintegration of small vessels. Disruption of the blood brain barrier is likely to precipitate or worsen progression of WMD [33] (LOE 3). Positron emission tomography imaging with 18F-fluoromisonidazole showed higher susceptibility to ischemia of white matter than gray matter in stroke cases [34]. Cortical WMD in MRI looks diffuse. However, within the brain, detailed pathology studies confirmed that the frontal lobe is most severely affected [35]. This is in line with documented frontal lobe atrophy on MRI volumetry, where glucose metabolism was also most severely reduced [36] (LOE 3). Corresponding to this, brain perfusion is most reduced in the frontal lobe of subjects with WMD [37] (LOE 3), a finding that remains to be fully explained.

The frontal cortex is now recognized as an important higher center for micturition: damage to the prefrontal cortex, medial superior/middle frontal gyri, anterior cingulate cortex, supplemental motor area and insula result in marked lower urinary tract dysfunction in humans [38] (LOE 3). These clinical observation have been corroborated by functional neuroimaging in humans [39, 40] (LOE 3). Altered spinobulbospinal micturition reflex micturition control may contribute to DO emergence in brain lesions [41] (LOE 3). Functional neuroimaging studies showed that the prefrontal cortex was deactivated in elderly subjects with urinary frequency/urgency as compared with controls [42] (LOE 3). Jirovec et al. (LOE 3) found that cognitive ability and mobility differ significantly between continent and incontinent patients [43]. When the variables were examined together, mobility emerged as the best predictor of the patient’s urine control, followed by cognitive impairment.

The prevalence of DO in WMD cases is reported as 70-91% of patients. In Sakakibara’s study, urodynam-ic studies in 33 subjects found DO more commonly in grade 1-4 white-matter lesions (82%) than grade 0 white-matter lesions (9%) (p<0.05). Yoshimura et al. (LOE 3) found a 47% prevalence of DO which correlated with the presence of dementia [44].

d) Disease specific diagnosis and treatment

No specific diagnostic tests to evaluate dementia-related incontinence have been described. Since patients with dementia and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow standard principle, bearing in mind that this is a population of frail elderly people. The treatment should start with modification of behaviour, and general rehabilitation targeted at making the patient more ambulatory. No other specific treatment in dementia has been described, however certain issues like prompted voiding, anticholinergic drugs and intermittent catheterization have been studied.

In a review of trials where prompted voiding was implemented, Eustice et al. (LOE 1) found that prompting increased self-initiated voiding and decreased incontinence episodes in the short-term [45]. A single small trial suggested that adding oxybutinin, reduced the number of incontinent episodes in the short-term. In a study by Suzuki et al. (LOE 3) the best results were obtained with ambulatory patients with the use of a portable chamber pot and induced urination, while no improvement was seen in bedridden patients treated with anticholinergics [46]. Sugiyama et al. (LOE 3) studied the effects of anticholinergic therapy in patients aged 65 years or older, with and without dementia. The patients received anticholinergic agents for more than two weeks [47]. Urodynamic studies demonstrated significant increase of maximum bladder capacity in the dementia group and the non-dementia group. There was no significant difference in rate of objective improvement between both groups. On the other hand, rate of subjective improvement was significantly higher in the non-dementia group (40%) than in the dementia group (15%). Improvement of functional bladder parameters was not associated however with improvement of subjective symptoms in the dementia patients.

In case of voiding failure, intermittent catheterization (IC) is a treatment of choice. Lieu et al. (LOE 3) found that carer-assisted clean IC is an effective and safe treatment option for persistent urinary retention in elderly female patients with cognitive impairment and other disabilities [26]. With this method of treatment, 54% of the patients were able to void spontaneously and were continent after a median period of 6 weeks with a range of 1 to 40 weeks. 27% had significant improvement in the symptoms of urinary incontinence and the residual urine volumes became progressively smaller. However, 19% failed this treatment modality. The recovery of spontaneous voiding was found to be significantly influenced by the age of the patient, the carer performing the IC and the development of catheter-related UTI. 25% of the study patients developed symptomatic UTI, which was associated with a delay in the recovery of spontaneous
voiding. Its development was also found to be significantly associated with the presence of pre-existing diabetes mellitus, the person doing the catheterization, the presence of dementia and with more predisposing common medical conditions.

Another interesting issue is the surgical treatment in patients with dementia. Two major groups of surgical procedures could be contemplated: prostate surgery and incontinence surgery. Yonou et al. (LOE 3) studied a group of 13 patients with dementia who underwent TURP procedure [48]. Six patients reported good urination, 3 reported some improvement in urination after surgery although requiring IC, and 1 developed incontinence. No specific study addressing the issue of incontinence surgery in woman with dementia has been reported. However, it seems that incontinence surgery in patients with dementia should be reserved only for the cases with good ambulation and without concomitant functional disorders of micturition (overactive bladder, hypocontractile detrusor).

e) Recommendations for further research

Since dementia is not a homogeneous disease, a population study targeted specifically at disorders of micturition is needed. Also, a study evaluating different treatment modalities in patients with dementia (especially anticholinergic treatment for overactive bladder and surgical treatment for stress incontinence) is lacking.

Conclusions

- Dementia-associated incontinence occurs in 30-100 % of patients with dementia (LOE 3).
- The degree of incontinence is strongly associated with the patient’s general status and ambulation (LOE 3).
- There is no one major cause for incontinence in these patients; however overactive bladder is responsible for a significant proportion of incontinence (LOE 3).

Recommendations

- Interventional therapy of incontinence in dementia patients should be reserved for patients with good general status and ambulation (C).
- In case of ambulatory patients, prompted voiding, rehabilitation and oral anticholinergics can be employed (C).
- Where there is a significant post-void residual, intermittent catheterization is the treatment of choice (B).

4. DEMENTIA WITH LEWY BODIES

a) Epidemiology and prevalence

Dementia with Lewy bodies (DLB) is thought to be the third most common type of dementia in the elderly, accounting for 10 – 15% of cases at autopsy. In population-based studies of subjects aged 65 and older, the prevalence of DLB was found to be 0.7%, which is consistent with its rate of 10 – 15% of hospital-based cases at autopsy [49]. The epidemiology of DLB is sparse; age and gender distribution, and potential risk factors have yet to be defined.

b) Pathology and disease-specific urinary tract problems

DLB primarily affects both the basal ganglia (as in Parkinson’s disease) and the cerebral cortex. Lewy bodies and Lewy neuritis are pathologic aggregations of alpha-synuclein (SNCA), a ubiquitously-expressed synaptic protein that has been implicated in vesicle production [50]. Lewy bodies also contain chaperone proteins and elements of the ubiquitin-proteasome system. Immunohistochemical staining for alpha-synuclein has been shown to be the most sensitive and specific method for detecting Lewy bodies and can be used in a semiquantitative grading of severity of Lewy-related pathology [51]. Alpha-synuclein can now be measured in vivo by positron emission tomography and/or the cerebrospinal fluid.

Many patients with DB also have Alzheimer’s disease pathology, which alters the clinical presentation. DLB patients who also have numerous neurofibrillary tangles display more core clinical features of AD [52]. Conversely, Lewy bodies also occur in more than half of all patients with sporadic and early-onset AD [53]. The essential feature for a diagnosis of possible or probable DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Fluctuations (waxing and waning of cognition, functional abilities and arousal, from almost normal to markedly confused or hypersonolent) are a core feature of dementia with Lewy bodies. In DLB, autonomic dysfunctions occur and are included as a supportive feature for clinical diagnosis [54].

Horimoto et al. (LOE 3) found 97 % incidence of urinary incontinence amongst patients with DLB. From the urological point of view, patients with DLB tend to develop urgency and urgency incontinence more often than do patients with Parkinson’s disease (PD) or AD. Similar bladder capacity, detrusor pressure at maximum voiding, maximum urine flow, mean voided volume and post-void residual volume were found in each of these diseases; however, DO, the major cause of urgency and urge incontinence, was more prevalent in DLB than in PD and in AD [9]. Urinary symptoms are seen in one third of patients with DLB. Detrusor overactivity, the major cause of urge and urge incontinence was more prevalent in DLB and AD. No detrusor-sphincter-dyssynergia was observed. DLB patients with detrusor overactivity had significantly higher Hoehn and Yahr scores than did those without detrusor overactivity. Since the prevalence of frequency, urgency, urge
incontinence and detrusor overactivity is markedly lower in AD than in DLB, LUTS may contribute to the differential diagnosis of these two entities.

c) Disease specific diagnosis and treatment

Since patients with Lewy Body disease and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow the general rules, bearing in mind that this is most often a population of frail elderly people (LOE3).

5. FRONTAL TEMPORAL DEMENTIA (FTD)

a) Epidemiology and prevalence

Prevalence studies of FTD are inconsistent (LOE 3), giving ranges of 3.6-15.0 per 100,000 [55]. There is a high familial occurrence of FTD [56]. In such cases, a combination with parkinsonism, and rarely amyotrophic lateral sclerosis, also occurs. The distribution of FTD is equal between men and women. The mean duration of illness from onset to death is 4-6 years, with a range of 2-20 years.

b) Pathology and disease-specific urinary tract problems

Frontotemporal dementia (FTD), also known as Pick's disease, encompasses a diverse group of clinical and pathological disorders. There are several distinct clinical presentations, most commonly behavioral changes, but a language disorder, usually in the form of a progressive non-fluent aphasia, can be the main presenting sign. The most common clinical presentation of FTD is characterized by profound changes in personality and social conduct, including a decline in manners and social skills that are incongruent with the patient's pre-morbid behavior. Affected patients lack emotional warmth, empathy and sympathy and are indifferent to others.

MRI of patients with FTD often shows atrophy in the frontal and temporal lobes (LOE 2), which may be asymmetric [57]. At autopsy, markedly gross atrophy of the frontal and temporal lobes is seen in FTD. On histologic examination the salient features include neuronal loss, micro-vacuolization and astrocytes gliosis centred on cortical layer II. Up to now, molecular pathology of FTD has identified four subtypes. First, classical Pick's disease (Pick body with accumulation of 3-repeat tau); second, mutations in the MAPT (microtubule-associated protein tau) gene; third, accumulation of TDP-43 (TAR DNA binding protein-43) with mutations in the PGRN (progranulin) gene; and fourth, accumulation of FUS (fused in sarcoma) protein.

There is no data on LUTS in patients with FTD, however it is obvious that due to the cognitive state these patients have incontinence, either because they forget to take down clothes when they go into the toilet, or they have difficulty finding the toilet, or they may urinate in inappropriate places and pass urine more often than usual. Moreover, they may be affected by constipation, diarrhoea or faecal incontinence.

c) Diagnosis and treatment

No specific diagnostic tests to evaluate dementia-related incontinence were described. There are no studies which show the significance of LUTS in fronto-temporal dementia. Such studies would be of value in future research projects.

Conclusions

- There are no studies available which show the significance of LUTS in patients with fronto-temporal dementia.
- Since the underlying pathology is gross atrophy of frontal and temporal lobes, autonomic dysfunction including LUTS can be anticipated, but further research is needed.

Recommendations

- The recommendations do not differ from those for other types of dementia.

6. CONSTIPATION AND FECAL INCONTINENCE IN DEMENTIA

Only one paper was retrieved related to the influence of dementia on the prevalence of urinary and faecal incontinence in an age group of 85-year-old men and women [58]. This reported the influence of dementia on the prevalence of urinary and faecal incontinence in 85 year-old men and women in a random sample n= 485 of the total population of 85-year-olds from the city of Gothenburg, Sweden. The prevalence of urinary and faecal incontinence and dementia were 38%, 17% and 29% respectively. Demented men (50%) and women (60%) were more often incontinent than non-demented men (18%) and women (36%). Also, faecal incontinence was more prevalent in demented (34.8%) than non-demented subjects (6.7%): both urinary and faecal incontinence were more prevalent in demented women (43% and 20% respectively) than in men (27% and 11% respectively). The prevalence of urinary and faecal incontinence and dementia were higher in residents of a nursing home or hospital (74%, 51% and 92% respectively) than in subjects living at home (32%, 9% and 18% respectively): of the demented residents in an institution 78% were incontinent compared with 37% living at home.

No specific paper was found on the management of faecal incontinence in demented people. Demented patients may benefit from a bowel habit training programme, which also includes management of constipation with non-pharmacologic (such as exercise and fibre) and pharmacologic measures.

Conclusions

- Although faecal incontinence is prevalent in people with dementia, no paper was found.
dealing with the disease-specific management of faecal incontinence (LOE3).

Recommendations

• Studies should be undertaken to ascertain management strategies for constipation and faecal incontinence in dementia.

7. NORMAL PRESSURE HYDROCEPHALUS

a) Epidemiology and prevalence

Normal-pressure hydrocephalus (NPH) is characterized by a clinical presentation of gait disturbance, memory deficit, and urinary incontinence, combined with dilated cerebral ventricles and normal cerebrospinal fluid (CSF) pressure [59] (LOE 3). The clinical triad of this disorder is very much akin to those of vascular dementia or white matter disease (WMD). Therefore, before performing brain imaging, we have to think about NPH as well as WMD. The syndrome was first described by Hakim and Adams in 1965 [60]. After five decades of investigation, the effectiveness of the diversion of CSF flow by shunt operation in treating this syndrome is well documented [59] (LOE 2). Recent population-based MRI studies also suggest that the incidence of NPH, or asymptomatic ventriculomegaly with features of idiopathic normal pressure hydrocephalus on MRI (AVIM), is to be around 1% (0.51-2.9%) in the general population of persons over 65 years of age [61], being estimated as one-tenth of WMD (LOE 3).

b) Pathology and disease-specific urinary tract problems

Lower urinary tract symptoms in NPH are basically urgency and frequency (overactive bladder, OAB). Sakakibara et al. found urinary symptoms in 93% of 42 idiopathic NPH patients [62] (LOE 3). These symptoms included storage symptoms in 93% of patients (nocturnal urinary frequency, 64%; urinary urgency, 64%; urgency urinary incontinence, 57%; diurnal urinary frequency, 36%) and voiding/post micturition symptoms in 71% (hesitancy 50%; prolongation/poor flow, 50%; sensation of post-void residual, 29%; straining, 21%; intermittency, 14%). Particularly, in some patients urinary urgency/frequency preceded urinary incontinence. Among the clinical triad of NPH, urinary incontinence has been regarded a late symptom. However, as in cases of WMD, gait disturbance and OAB can be the early manifestation of NPH.

Urodynamic findings of 42 NPH patients by Sakakibara et al. included low Qmax (<10 cm/s) in 40%; increased post-void residual (>30 ml) in 43% (average PVR volume 42.1 ml); low volume at first sensation (<100 ml) in 33%; decreased bladder capacity (<200 ml) in 57%; and DO in 95% of patients [62] (LOE 3). Although the number of cases included in other reports has been small (4-12 cases), DO is also most common (63-100%) [63] [64] (LOE 4). The high prevalence of DO suggests altered brain autonomic control in NPH [65].

c) Diagnosis and treatment

Diagnosis of NPH may comprise:

a) Possible features; gait, cognitive and urinary disorders with typical ventricular dilatation in brain imaging.

b) Probable features; improved clinical symptoms by 30 ml withdrawal of the cerebrospinal fluid by a lumbar tap (the Tap test).

c) Definite; improved clinical symptoms by ventriculoperitoneal shunt surgery etc.

Functional neuroimaging in normal volunteers has shown that the anterior cingulate, prefrontal cortex and insula are activated in response to bladder filling as compared with an empty bladder [41]. Although NPH is a diffuse brain disease with dilated ventricles, hypoperfusion in the frontal lobe has been documented in NPH patients using PET [66], single-photon emission computed tomography (SPECT) [67], and perfusion-weighted MRI [68] (LOE 3). Therefore, the frontal lobe is thought to be the anatomical substrate for urinary urgency and incontinence in NPH. According to the study by Sakakibara et al, using 97 NPH patients and [123I]-iodoamphetamine (IMP)-SPECT statistical mapping, there was a significant decrease in tracer activity in the right-side-dominant bilateral frontal cortex and the left inferior temporal gyrus in the severe urinary dysfunction group (p<0.05) [69]. The findings indicate that there is a link between the right frontal hypoperfusion and urinary dysfunction in NPH. Importantly, bladder dysfunction and frontal lobe hypoperfusion in NPH can be reversed after shunt surgery. Recovery rate of OAB and urinary incontinence in NPH ranges from 20-80% [59] (LOE 4). Among them, cerebral perfusion in the prefrontal cortex and mid-cingulate gyrus tended to return normal particularly in patients with good OAB/ incontinence recovery.

Since there is a surgical shunt therapy for NPH, early diagnosis of NPH in patients with OAB is important. In addition to OAB with/without urinary incontinence, patients with NPH commonly have gait disorder (parkinsonian and wide-based gait) and dementia that is milder than Alzheimer’s disease. Differential diagnosis should include vascular dementia or white matter disease. If the shunt surgery failed, or was not applied to individuals with particular reasons such as dementia etc., medical management (pharmacological and behavioural) of incontinence starts. However, no systematic review has been performed regarding the medical management of urinary incontinence in NPH.
Conclusions

- Clinical manifestations in NPH mimic those of vascular dementia or white matter disease (LOE 3).
- Urinary urgency and frequency may precede urinary incontinence in NPH (LOE 3).
- Detrusor overactivity seems to be the most common cause of incontinence in NPH patients (LOE 3).
- Shunt surgery ameliorates urinary incontinence in NPH but the degree varies significantly (20-80%) (LOE 4).

Recommendations

- Typical gait, cognitive and urinary disorders with ventricular dilatation in brain imaging favours the diagnosis of NPH; then a Tap test and a shunt surgery may follow (B).
- However, no systematic review has been performed regarding the medical management of urinary incontinence in NPH if the shunt surgery failed or is not applied to individuals (C).

II. MULTIPLE SYSTEM ATROPHY

1. EPIDEMIOLOGY AND PREVALENCE

Multiple system atrophy (MSA) is a rare, adult-onset degenerative disease of the nervous system of unknown origin. Autonomic failure (postural hypotension and urinary dysfunction) is fundamental to the diagnosis of MSA: it is diagnosed when the criteria of either postural hypotension (systolic blood pressure fall > 30 mmHg or diastolic > 15 mmHg) or urinary dysfunction (persistent, urinary incontinence/ incomplete bladder emptying) or both are fulfilled, along with poorly levodopa-responsive parkinsonism, or cerebellar dysfunction [70]. Based on the major motor deficits, MSA can be classified as MSA-P (Parkinsonism-predominant) or MSA-C (cerebellar-predominant) [70]. The discovery in 1989 of glial cytoplasmic inclusions in the brains of patients with MSA [71] provided a pathological marker for the disorder (akin to Lewy bodies in idiopathic Parkinson's disease), which combined three disorders previously called striatonigral degeneration, sporadic livopontocerebellar atrophy, and Shy-Drager syndrome.

Urinary symptoms of incontinence are caused by neurogenic DO and external sphincter weakness [3] (LOE 2). Sphincter electromyography (EMG) abnormalities were found in 91% of the patients with MSA [72] (LOE 2). Approximately 60% of patients with MSA develop urinary symptoms, either prior to or at the time of presentation with the motor disorder [73] (LOE2). This indicates that many of these patients seek urological advice early in the course of their disease. Although postural hypotension was thought to be a marker for autonomic failure in MSA, Wenning et al. [74] (LOE 2) noted urinary incontinence in 71%, urinary retention in 27%; postural faintness in 53%, and syncope in 15% of 100 patients with MSA. Sakakibara et al. [1999] [73] (LOE 2) found that urinary symptoms (96%) were more common than orthostatic symptoms (43%) (p < 0.01) among 121 patients with MSA. Kirchhof et al [75] (LOE 2), found that bladder symptoms preceded symptoms of orthostatic hypotension in 76% of their 71 male patients. Sakakibara et al. [73] (LOE 2) also found that among 53 patients with both urinary and orthostatic symptoms, those who had urinary symptoms first (48%) were more common than those who had orthostatic symptoms first (29%), and some patients developed both symptoms simultaneously (23%).

2. PATHOLOGY AND DISEASE-SPECIFIC URINARY TRACT PROBLEMS

Sakakibara et al. [1993] [76] (LOE 2) performed an extensive study of the urological symptoms in MSA patients. They found the following prevalence of different symptoms: difficulty of voiding in 79%, nocturia in 74%, sensation of urgency in 63%, urgency incontinence in 63%, diurnal urinary frequency in 45%, enuresis in 19% and urinary retention in 8% of the patients. All of the MSA patients presented with some kind of LUT symptoms; many of them had both storage and voiding urinary symptoms.

In 245 cases of MSA, Ito et al [77] (LOE 2), found that average volume of post-void residuals was 71ml at the first year, which increased significantly to 170ml at the 5th year (p<0.01) after onset of the disease. Patients were not always aware of their post-void residuals. The frequency of weak detrusor ascertained by a pressure-flow analysis was 20% at the first year, which increased to 53% at the 5th year (p<0.05). The frequency of detrusor-external sphincter dyssynergia (DSD) was 12% at the first year, which increased to 39% at the 5th year (p<0.05). Therefore, detrusor underactivity seemed to contribute to voiding dysfunction in MSA more than DSD did. The responsible sites of lesion (micturnition-facilitating area) for voiding difficulty and retention in MSA seem to be the locus coeruleus (pontine micturition center). The work of Bennaroch demonstrated, that in MSA there is severe depletion of catecholaminergic neurons of the Cl and Al areas in the ventrolateral medulla, and this may contribute to orthostatic hypotension and endocrine disturbances in this disorder, respectively. Loss of corticotrophin-releasing factor (CRF) neurons in the pontine micturition area may contribute to neurogenic bladder dysfunction [78] (LOE 2). In addition, the sacral intermediolateral cell columns, where preganglionic neurons innervating the bladder are located, are affected in post-mortem MSA cases.

The prevalence of detrusor overactivity was 61% at the first year, which increased to 75% at the 5th year.
(p<0.05) [77] (LOE2). The frequency of neurogenic pattern in the sphincter EMG was 52% at the first year, which increased to 83% at the 5th year (p<0.05) [79] (LOE2). Abnormalities in the videourodynamic study included open bladder neck at the start of filling in 53% of MSA patients [80] (LOE2). Similar results were reported by others [81]. The responsible sites of lesion (storage-facilitating area) for urinary urgency and incontinence in MSA seem to be the basal ganglia, cerebellum, [82], lumbar intermediate-lateral cell columns where preganglionic neurons innervating the bladder neck are located, and sacral Onuf's nucleus innervating the external sphincter, all of which are affected in post-mortem MSA cases, causing urinary stress incontinence.

Repeated urodynamic studies in MSA patients showed that the cystometrogram changed from DO to low-compliance or acontractile detrusor, and from negative to positive bethanechol supersensitivity [83] (LOE2). In fact, as the disease progresses, symptoms may change from urinary urgency and frequency to those due to incomplete bladder emptying. These findings suggest that the responsible sites of the bladder cholinergic disorder may change from the center to the periphery. The cystograms of patients with MSA often show neurogenic DO with impaired contractile function (DHIC), mostly accounting for urinary urgency / frequency and large post-void residuals, respectively. This condition presumably reflects lesions in both storage and voiding-facilitating areas in this disorder [84].

Beside bladder disorders, patients with MSA may have nocturnal polyuria, which results in nocturia and morning hypotension. In normal children over 7 years and adults, the circadian release of arginine vasopressin from the posterior pituitary gland into plasma peaks at night. This leads to a nocturnal decrease in urine formation. The ratio of nighttime to daytime urine production is usually <1:2, which can be estimated by a bladder diary. A post-mortem study of the brains of patients with MSA revealed the degeneration of arginine vasopressin neurons in the suprachiasmatic nucleus [85] (LOE 2), leading to impairment of the circadian rhythm of the plasma arginine vasopressin concentration in MSA [86] (LOE 2).

3. DIAGNOSIS AND TREATMENT

Since LUT functional disturbances often precede orthostatic hypotension and other autonomic nervous system symptoms in MSA patients, the full assessment of underlying mechanisms of LUT symptoms is of paramount importance.

External sphincter EMG is the most sensitive test. Sphincter motor unit potential analysis showed neurologic motor unit potentials in 93% of those with MSA, suggestive of external sphincter denervation. Palace et al. [87] (LOE 2) demonstrated abnormal sphincter EMG in 93% of MSA patients, which can differentiate this disorder from idiopathic Parkinson's disease. Oertel et al. [88] (LOE2) suggested that reduced genital sensation in females could be pathognomonic for MSA (with equal importance as erectile dysfunction in males). A total of 47% of the MSA patients and 4% of the control group had reduced genital sensation. Moreover, the appearance of reduced genital sensitivity in female MSA patients showed a close temporal relation to the onset of the disease. Hahn and Ebersbach [89] (LOE 2) investigated the value of sonography of the bladder to evaluate post-void residual urine (PVR) for the differential diagnosis between idiopathic Parkinson's disease and Multiple System Atrophy. The positive predictive value of increased residual urine for MSA was 91.6 % in the study, while the negative predictive value was only 67.8 %. They state that bladder sonography is an objective, simple and safe tool that allows one to screen for urinary retention which is highly suggestive, but incompletely sensitive for MSA. Because sonography is easily accessible and rapidly performed, it is feasible for routine assessment of atypical Parkinson syndromes. The overall average volume of PVR was 140 cc in their patients, increasing from 71 cc in the first year, to 129 cc in the second year, and 270 cc in the 5th year.

Aggressive surgical therapy is not recommended in MSA patients. Chandiramani et al. [90] (LOE2) found that all MSA patients who underwent transurethral resection of the prostate (TURP) due to voiding problems were continent postoperatively, most probably due to pre-existing sphincter weakness. The same observations were made by Beck et al. [72] (LOE2), who evaluated the results of TURP and stress incontinence surgery in MSA patients. They concluded that the results of surgery were unfavourable. Patients benefited from IC, anticholinergic medication and desmopressin spray [91] (LOE 3), which improved continence in 82%.

As nearly half of the MSA patients suffer from voiding difficulties, its management by means other than IC would be very attractive. Sakakibara et al. [92] (LOE 3) compared different non-selective and alpha-IA selective alpha blocking agents (prazosin and moxisylite) in the treatment of LUT dysfunctions in MSA patients. The respective means for reductions in residual urine volume for the prazosin and moxisylite groups were 38.1% and 35.2%, and there was lessening of urinary symptoms. Side effects due to orthostatic hypotension were seen in 23.8% of the prazosin group and 10.7% of the moxisylite group. A more recent study showed that the effects of alpha blocking agents, as well as those of TUR-bladder neck, for lessening post-void residuals lasted for up to 2 years in MSA, although during that period patients benefited from the therapies [77] (LOE2). On the contrary, administration of amezinium, an adrenergic drug for ameliorating postural hypotension, may increase the risk of retention and post-void residual volume compared to that before treatment [93] (LOE2). Amezinium most probably...
stimulates the alpha receptors, both in the vascular wall (alpha1B receptors) and the proximal urethra (alpha1A/D-adrenergic receptors).

Both postural hypotension and bladder dysfunction are common clinical features in MSA. Pyridostigmine, an acetylcholinesterase inhibitor, might be effective in lessening post-void residual volumes, since it stimulates muscarinic acetylcholine receptors on the bladder (M2/3-muscarinic receptors) that are innervated by parasympathetic cholinergic neurons. Pyridostigmine also lessens postural hypotension, presumably by enhancing nicotinic acetylcholine receptor transmission in the sympathetic ganglia [94] (LOE3).

Guidance for further research

MSA is a slowly progressive disease without any cure. More research is needed to evaluate the effects of long term LUT treatment and to evaluate the effects of different drug treatment modalities.

Conclusions

- LUT symptoms often precede the clinical manifestation of multiple system atrophy (LOE2).
- The most common LIJT disturbances are detrusor overactivity, detrusor-external sphincter dyssynergia, sphincter and detrusor weakness (LOE2).
- Significant post void residual is observed in about half of the multiple system atrophy patients (LOE2).

Recommendations

- The most sensitive test to detect multiple system atrophy associated LUT abnormalities is sphincter EMG (A), and post-voiding residual volume, especially when differentiating from idiopathic Parkinson’s disease.
- Due to the complex dysfunction and progressive nature of the disease, aggressive treatment and LUT surgery (e.g. TURP) are not recommended (A).
- Treatment of choice in case of increased post void residual are alpha blocking agents and IC (B).

4. FAECAL INCONTINENCE

Lower gastrointestinal tract (LGIT) dysfunction is also common in patients with MSA. Sakakibara et al [95] (LOE2) performed a bowel questionnaire in 15 patients with MSA and in 10 age-matched healthy control subjects. The MSA group showed decreased bowel frequency (< 3 times a week) in 9, difficulty in expulsion in 11, and faecal incontinence in 3; the control group showed decreased bowel frequency in only 2, mild difficulty in expulsion in 2, and IC (B).

Constitution in MSA most probably results from slow colonic transit, decreased phasic rectal contraction and weak abdominal straining, whereas faecal incontinence results from weak anal sphincter due to denervation. The responsible sites for these dysfunctions are still not known. However, as described in idiopathic Parkinson’s disease, they most probably reflect lesions of both central and peripheral nervous systems that regulate the LGIT.

LGIT functional disturbance is often preceded by LUT dysfunction in MSA patients. Abnormalities in colonic transit time and rectoanal videomanometry in MSA were mostly similar to those in idiopathic Parkinson’s disease, except for the sphincter denervation and resultant fecal incontinence in MSA.

When treatment of the bowel disorder in MSA is planned, use of objective parameters is recommended in order to clarify the action of drugs. A few such studies are available: Eichhorn and Oertel [98] (LOE3) gave polyethylene glycol 3350, an osmotic agent with high water binding capacity, in 2 patients with MSA, and found an improvement in stool frequency and difficult defecation in both
patients. Similarly, Sakakibara et al. [99] (LOE2) measured colonic transit time in 4 patients with MSA. After administration of calcium polycarbophil, an osmotic and highly bulking agent, colonic transit time of total and the right segment shortened significantly. Liu et al. [100] (LOE2) performed colonic transit time and rectoanal videomanometry in 7 patients with MSA. After administration of mosapride citrate, a novel selective 5-HT4 receptor agonist, the patients showed a shortened total and recto-sigmoid segment colonic transit time, lessened first sensation and an augmented amplitude in phasic rectal contraction. During defecation, mosapride augmented the amplitude in rectal contraction and lessened the volume of post-defecation residuals significantly. Similar results were obtained in a study by Sakakibara et al. [101] (LOE2), in which dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action), was prescribed.

MSA is a slowly progressive disease currently without cure. More research is needed to evaluate the pathophysiology of LGIT dysfunction, and to evaluate the effects of different drug treatment modalities.

Conclusions

- Patients with multiple system atrophy have often abnormal bowel function (LOE2).
- The most common bowel disturbances are slow colonic transit, decreased phasic rectal contraction and weak abdominal straining; faecal incontinence results from weak anal sphincter, due to denervation (LOE2).
- Bowel dysfunction, such as constipation, is common and has significant impact on quality of life of patients with multiple system atrophy (LOE3).

Recommendations

- More studies on neurologic bowel dysfunction and management in patients with multiple system atrophy are needed before giving any recommendation.

III. PARKINSON’S DISEASE

1. URINARY INCONTINENCE

Parkinson’s disease (PD) is a movement disorder due to degeneration of dopaminergic neurons in the substantia nigra and a loss of dopamine-containing nerve terminals in the basal ganglia. Degeneration of the nigrostriatal pathway is accompanied by decreases in corresponding biochemical markers, including dopamine, tyrosine hydroxylase, dopamine metabolites, and dopamine transporter. These central nervous system changes also have influence on autonomic function; the most common problems are gastrointestinal (constipation), perspiratory (hypohidrosis) and urinary systems [102].

LUT dysfunction in PD was estimated to occur in 37-71% in uncontrolled studies. Among these, in a study of Hattori et al. [103] (LOE3) 60% of PD patients had urinary symptoms, which could be divided in the following categories: storage LUTS in 28%, voiding in 11%, and both types in 21%. The prevalence of urinary symptoms correlated with severity of the disease, but not with the duration of illness. Gray et al. [104] (LOE3) reported that LUT functional disturbances in PD are not disease-specific and only correlated with age. In the more recent, control-based studies [106-109] (LOE2) the prevalence of LUT symptoms (LUTS) was found to be 27-64% using validated questionnaires [105-107], or 53% in men and 63% in women using a non-validated questionnaire that includes a urinary incontinence category [7], with all of these values being significantly higher than healthy controls. The majority of patients had onset of the bladder dysfunction after the appearance of motor disorder. In one study, urinary incontinence in PD frequently occurred in conjunction with fecal incontinence, whereas no significant relation was observed between bladder and sexual dysfunction. Bladder dysfunction substantially affects the quality of life in patients with PD [108] (LOE2). Bladder dysfunction in PD correlates with neurological disability [105] (LOE2), and stage of disease [108] (LOE2), both suggesting a relationship between dopaminergic degeneration and LUTS. LUTS was more common in a group of PD patients with older age, as in healthy populations. Among LUTS, nocturia (night-time urinary frequency) is the most prevalent symptom (>60%) [105-108] (LOE2). Patients also complain of urinary urgency (33-54%), daytime frequency (16-36%), and urinary incontinence in 26% of males and 28% of females. These figures are almost the same in untreated, early PD patients [109]. Although less common than storage symptoms, PD patients also report voiding symptoms. In the study by Sakakibara et al. [110] (LOE2), PD patients had significantly higher rates of delay in initiating urination (44% of men), prolongation/poor stream (70% of men), and straining (28% of women) compared with the control group. However, despite the voiding symptoms, PD patients have low post-void residuals.

a) Pathology and disease-specific urinary tract problems

The net effect of the basal ganglia on micturition is thought to be inhibitory [111]; in PD, the bladder becomes overactive. Functional neuroimaging during bladder filling resulted in activation in the globus pallidus of normal volunteers and in the putamen in PD patients with detrusor overactivity [112] (LOE2). In contrast, dopamine transporter imaging (indicating brain dopamine neurons) was decreased in PD patients with urinary dysfunction than in those
without it [13] (LOE2). The micturition reflex is under the influences of nigrostriatal dopamine (both inhibitory in D1 and facilitatory in D2) and GABA (inhibitory). Deep brain stimulation in the subthalamic nucleus results in amelioration of motor disorder as well as increased bladder capacity and decreased post-void residuals [114] (LOE2). Therefore, urinary dysfunction in PD could reflect degeneration of the nigrostriatal dopaminergic cells associated with specific motor disorders. In addition to the nigrostriatal dopaminergic projection, the ventral tegmental area (VTA, the A10 cell group)-limbic cortex and the hypothalamic (the A11 cell group)-spinal cord dopaminergic projections are presumably involved in urinary dysfunction in PD.

In a study of PD and multiple system atrophy (MSA) patients, Sakakibara et al. [116] (LOE2) found urinary symptoms in 72% of PD patients. They were mostly attributed to DO (81%) and external sphincter relaxation problems (33%). Failure of sphincter relaxation may reflect bradykinesia, rather than true DSD. During micturition, PD patients did not demonstrate DSD, but impaired detrusor contractility was observed in 66% of women and 40% of men. In addition, patients with PD had partial bladder outlet obstruction, e.g. mean bladder outlet obstruction index was 43 in men (equivalent parameters gave a value of 40 in women). Nevertheless, average volume of post-void residuals in PD was only 18 ml. Similar observations were reported by Defreitas et al. [117] (LOE2). These urodynamic findings are almost the same in untreated early PD patients [110].

b) Specific diagnosis and treatment

In the differential diagnosis of PD and parkinsonian-type MSA, large post-void residuals, open bladder neck, and neurogenic change in sphincter motor unit potentials are common in MSA [115, 118] (LOE2), whereas they are rarely seen in clinically typical PD [119]. However, recent evidence suggests that PD with dementia, or dementia with Lewy bodies, may have large post-void residuals and neurogenic change in the sphincter motor unit potentials [120], thereby mimicking MSA (LOE3). Bladder dysfunction in PD parallels other autonomic dysfunctions [121], cardiac denervation [122], and falls [123] (LOE3).

Lеводопа and other antiparkinson medication may affect bladder function in PD. To date the results are not consistent and the responses are not straightforward. Some reports have shown storage-facilitating effects of dopaminergic drugs; a questionnaire study reported that voiding symptoms (intermittency and sensation of residual urine) were more common in those taking levodopa and bromocriptine (D2-selective agonist) than in those taking levodopa alone [111a] (LOE2). In contrast, Kuno et al. [124] (LOE3) showed that change of bromocriptine to pergolide (D1<2 agonist) brought lessening of nocturia, and Yamamoto [125] (LOE3) described improvement of DO by pergolide. Others have shown voiding-facilitating effects. In early PD [126] (LOE2) and advanced PD with the on-off phenomenon [127] (LOE2), a single-dose of levodopa exacerbates DO in the filling phase, but also improves bladder emptying through increased detrusor contractility. We still do not know the reasons for the discrepancy between different studies.

There are several factors underlying the complex bladder behaviour in PD. Post-synaptic dopamine D1 (excitatory) and D2 (inhibitory) receptors have a millimolar affinity to dopamine, whereas dendritic D2 (inhibitory) autoreceptors have a picomolar affinity to dopamine. Therefore, when levodopa is administered externally, it may first stimulate dendritic D2 autoreceptors, which might suppress the nigral cells and facilitate the micturition reflex. In cases of PD under long-term treatment with levodopa, dopamine receptors are down-regulated. Bladder overactivity might also involve an activation of D2 receptors in the spinal cord [128] (LOE2). In addition, in experimental animals, single doses of apomorphine showed a biphasic effect [129] (LOE2).

There are no specific studies on systematic anticholinergic drugs to treat neurologic DO in PD patients. A systematic review of anticholinergic use (centrally acting) to treat PD was done by Katzschlager et al. [130] (LOE I). Cognitive adverse events of anticholinergics are a concern, particularly in elderly PD patients. This was first described in 1997 by Donnellan et al. in PD patients with overactive bladder [131] (LOE 3). They gave oxybutynin in four patients, who subsequently developed dementia, which reversed after discontinuation of oxybutynin. Factors underlying the cognitive effects of these medications include: 1) central muscarinic receptor affinity, e.g. high M1-receptor selectivity; and 2) easy penetration of the blood-brain barrier (BBB), e.g. high lipid solubility (water versus oil partition coefficient [LogP]<3; number of hydrogen bonds<3); a neutral charge or low degree of ionization (polar surface area<90A); and a less bulky (number of rotatable bonds<5) and smaller molecular size (<450Da) [132] (LOE 2). Most anticholinergics are non-selective muscarinic blockers, but darifenacin is an M3-selective antagonist. Regarding BBB penetration, most anticholinergics have a molecular size between 300-400Da. Oxybutynin can readily penetrate the CNS. Trospium, a quaternary amine, has a high polarity that may limit BBB penetration.

Deep brain stimulation (DBS) is a treatment option in advanced PD. The subthalamic nucleus (STN) is regarded as the key area in the indirect pathway, which is dominant in the parkinsonian state. DBS inhibits many cells within the STN, probably due to depolarization block and release of GABA from activation of inhibitory afferent terminals. In the STN, neuronal firings related to the micturition cycle have been observed in cats [133] (LOE2). DBS increased
bladder capacity, facilitated bladder afferent pathways, and augmented activity of the prefrontal cortex in the brain of PD patients [134] (LOE2). DBS can cause urinary retention [135] (LOE3). Intravesical botulinum toxin injection seems to be a promising method to treat intractable DO in patients with PD [136, 137] (LOE3). For voiding failure, the treatment of choice is IC; however, PD patients rarely have post-void residual volume > 100ml.

As in MSA, a very important issue in PD affected patients is the indication for pelvic surgery. Myers et al. [138] (LOE2) found that women with PD and LUT complaints have a lower maximum cystometric capacity and a higher rate of DO at lower bladder volumes in comparison with non-neurologic controls. Therefore surgery for stress incontinence in women with PD should be performed only when no significant DO is present, since this type of surgery can evoke or aggravate DO and subsequent urgency incontinence. A secure diagnosis of BOO is needed before considering transurethral prostate resection in PD, and the neurological diagnosis of PD likewise needs to be secure, since MSA inevitably develops urinary retention in the course of neurologic illness. In true PD, prostate surgery is not contraindicated, whereas it is in MSA.

Conclusions

- In Parkinson’s disease, LUT symptoms are associated with degeneration of dopaminergic neurotransmission (LOE2).
- The most common LUT disturbances are detrusor overactivity, and detrusor hypocontractility (LOE2).
- The effect of levodopa on LUTS in PD patients remains to be fully elucidated (LOE3).

Recommendations

- Detrusor overactivity in PD patients can be treated with antimuscarinic drugs (B).
- For voiding failure with significant post void residual, the treatment of choice is intermittent catheterization (B).
- LUT surgery for patients with Parkinson’s symptoms is an option, but MSA should be excluded. However stress incontinence surgery should not be offered to patients with significant detrusor overactivity (C).

2. CONSTIPATION AND Fecal INCONTINENCE

Lower gastrointestinal tract (LGIT) dysfunction is common in Parkinson’s disease (PD). In recent, control-based studies, the incidence of decreased stool frequency (< 3 times a week) in PD patients ranges from 20% to 81%, difficulty in stool expulsion 57-67%, and diarrhea 21% [139, 140] (LOE2). All of these values are significantly higher than in the normal population (range, decreased stool frequency, 0-33%; difficulty in stool expulsion, 26-28%; diarrhea, 10%). Fecal incontinence affects 10-24% in PD [139, 141] (LOE2). Therefore, constipation is the most prominent LGIT symptom in patients with PD. Indeed, PD is a risk factor for elderly nursing home residents to have constipation. Bowel dysfunction affects the quality of life in patients with PD. The rate of dissatisfaction for bowel dysfunction (59%) is significantly higher than for urinary (28%) or sexual dysfunction (29%), although the prevalence rate of all three dysfunctions is almost the same (more than 60%). The rate of dissatisfaction for the bowel dysfunction in PD is also significantly higher than in healthy controls (16%) [141] (LOE2).

Difficulty in expulsion, and diarrhea are more common in the higher grade of Hoehn and Yahr staging, suggesting a relationship between dopaminergic degeneration and LGIT symptoms. Fecal incontinence in PD occurs commonly with urinary incontinence, whereas no significant relation has been seen between bowel and sexual dysfunction. Constipation in PD is often associated with a low coefficient of variation in electrocardiographic R to R intervals [142] (LOE3). The findings indicate that parasympathetic dysfunction might underlie these abnormalities.

Intestinal pseudo-obstruction (IPO), also called paralytic ileus, is the most severe presentation of constipation in patients with PD and constitutes a medical emergency. The incidence of IPO/ volvulus is 2.4-7.1% [143, 144] (LOE3). The clinical features are mean age 78.5 years with illness duration 5.3 years, with no gender bias; constipation was seen in all and urinary dysfunction in most. Although rare, emergency IPO needs hospitalization and may lead to a poor outcome. Therefore, preventative treatment of constipation, including consideration of prokinetic drugs is necessary, particularly in elderly PD patients.

There seems to be an association between the frequency of bowel movements and the future risk of developing PD [145] (LOE1). This observation is in line with the pathological staging of PD by Braak et al. [146] (LOE1), in which disease process in the central nervous system starts earlier in the dorsal motor vagal nucleus than in the substantia nigra in PD. From a clinical perspective, it is of particular relevance that patients may see gastroenterologists or physicians first because of their bowel dysfunction, prior to a correct diagnosis of PD being made. Therefore, constipation as the initial presentation of PD is akin to urinary dysfunction as the initial presentation of multiple system atrophy.

a) Pathology and disease-specific problems

The enteric nervous system generates the peristalsis responsible for bowel content transit [147] (LOE2). The components of peristalsis are contraction on the oral side of the bolus, and relaxation on
the caudal side. Cholinergic receptors have a major role in the contraction proximally. The strength of cholinergic transmission is regulated by opposing receptors: serotonin 5-HT4 receptor-mediated excitation and dopamine D2 receptor-mediated inhibition [38]. Post-mortem studies of bowel in PD have shown decrease in dopaminergic myenteric neurons and the appearance of Lewy bodies along the proximal-distal axis, being most frequent in the lower esophagus, but scarce in the rectum [148-150] (LOE2). Thus PD affects not only central, but also peripheral (enteric) nervous system.

LGIT function primarily consists of [1] colonic transport of the bowel content to the anorectum, [2] transient storage in the anorectum, and [3] defecation. In PD, constipation results primarily from decreased transport and/or disturbed anorectal evacuation. Fecal incontinence may result from disturbed anorectal reservoir function, or overflow secondary to constipation. Previous reports have shown that total colonic transit time (CTT) is increased beyond the normal threshold in 80% of PD patients, which translates into an increased average CTT ranging from 44 hours to 130 hours [139, 141, 151] (LOE2), and 98 hours in de novo PD patients [48] (LOE2), all of which are significantly longer than the CTT in controls (range, 20-39 hours). Prolonged CTT has also been documented in PD patients without subjective constipation. Slow colonic transit is the major cause of decreased stool frequency. The slow colonic transit is likely to reflect a decrease in slow waves and spike activities of the colon [147].

In resting anal manometry, the anal pressure of PD patients is low or normal [139, 141, 151] (LOE2). The resting anal pressure may reflect sympathetic innervation in the internal anal sphincter, since lesions or anaesthetic blocks at T12-L3 (where the sympathetic preganglionic neurons are located) substantially lessen the anal pressure. Similarly, most PD patients have normal anal pressure increase on squeezing. This finding corresponds to a lack of neurogenic changes in the external sphincter EMG. Nevertheless, latent anal sphincter dysfunction may explain the fecal incontinence that occurs in most advanced cases. In slow-filling rectoanal videomanometry, PD patients had the same rectal volume at first sensation and a maximum desire to defecate, and the same rectal compliance as control subjects [141, 152] (LOE2). In contrast to the bladder, the normal rectum shows spontaneous phasic contraction. However, the amplitude of the spontaneous phasic rectal contraction in PD patients is significantly less than that in control subjects. The decreased spontaneous phasic rectal contraction may share the same aetiology with the decrease in CTT.

During defecation, healthy subjects utilize the final wave of spontaneous phasic rectal contractions. However, rectal contraction on defecation in PD patients is smaller than that in controls [141] (LOE2). In addition, in PD patients abdominal straining is smaller. In PD patients, paradoxical anal sphincter contraction on defecation (PSCD), or anismus, is observed in studies using sphincter EMG, radiography, and anal pressure measurement. The mechanism of the impaired straining in PD may include rigidity and reduced contractility of the axial muscles, and a failure of coordinated glottis closure. However, neuronal degeneration in the brain of PD patients relevant to straining is yet to be clarified. Mathers et al. [153] consider PSCD a focal dystonia. Dysfunction in the suprasacral descending pathway to the external sphincter may be a contributing factor. Aporphine was shown to lessen PSCD [153] (LOE2). This effect was not antagonized by domperidone, which does not penetrate the BBB, suggesting that CNS pathology may contribute to PSCD.

b) Disease-specific diagnosis and treatment

Insoluble dietary fibers produced an improvement in stool consistency and an increase in stool frequency in PD, which paralleled an improvement in levodopa absorption [154] (LOE3). Dietary fibers such as psyllium[155] (LOE2) and polyethylene glycol 3350 [156] (LOE2), or bulking and highly hydrophilic agent polycarbophil [157] (LOE2), improve constipation in neurodegenerative disorders, including PD. Although psyllium does not alter CTT or anorectal parameters in PD patients, polycarbophil shortens the total CTT, particularly in the proximal bowel segments.

It is possible that levodopa and other anti-parkinson medication may affect bowel function in PD. Endogenous dopamine is thought to inhibit intestinal motility via D2 receptors. Tateno and Sakakibara performed the quantitative lower-gastrointestinal autonomic test (QL-GAT, a combination of colonic transit and manometry) in 19 early, untreated PD patients before and after administration of 200 mg/day of levodopa [158]. Levodopa augmented rectal contraction, lessened paradoxical anal sphincter contraction on defecation (PSCD, anismus), and thereby ameliorated anorectal constipation, without apparent adverse effects. This might be brought about by both peripheral and central dopaminergic stimulation.

Since levodopa is absorbed from the small intestine, bowel dysfunction in PD may interfere with levodopa absorption, worsen the motor disorder, or even lead to malignant syndrome [140, 159] (LOE3/4). Domperidone, a peripheral D2 receptor antagonist that does not cross the blood-brain barrier, causes a mean 12% increase in peak plasma levodopa concentrations that occurs a mean of 10 min earlier than when levodopa is given alone [160] (LOE3).

The selective 5-HT 4 receptor agonist cisapride [161], though no longer licensed, and newer agents such as mosapride [162] (LOE2) and tegaserod [163] significantly reduce CTT and ameliorate constipation in PD. Mosapride shortened total CTT
(particularly the caudal segment), and augmented the amplitude in rectal contraction during defecation in patients with PD [162]. Notably, improvement of parkinsonism is more significant with pergolide-mopsapride than with pergolide-domperidone, presumably reflecting better levodopa absorption. Similar results were obtained in PD by dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action) [164] (LOE2). A series has shown a role for Botulinum toxin A injections into the puborectalis muscle [165] (LOE3).

**Conclusions**

- Patients with PD often have abnormal anorectal function (LOE2).
- The most common bowel disturbances in PD are slow colonic transit, decreased phasic rectal contraction, weak abdominal straining, and paradoxical sphincter contraction on defecation (anismus) (LOE2).
- Bowel dysfunction such as constipation is common and has significant impact on quality of life of PD patients (LOE2).

**Recommendations**

- More studies on management of neurologic bowel dysfunction in PD are needed.

**IV. CEREBRAL LESIONS AND CEREBROVASCULAR ACCIDENTS**

Listing of terminology used for the searches: cerebrovascular accident, cerebral lesions, bladder dysfunction, urinary incontinence, faecal incontinence.

**1. URINARY INCONTINENCE**

Cerebro-vascular accident (CVA) is the third most frequent cause of death in industrialised countries, after myocardial infarction and malignancies. Based on age-dependence of CVA and the increasing age of the population, the importance of CVA is increasing: currently one out of 200 people will suffer from a CVA, 80 to 90% of them above the age of 65. The 5-year-survival rate is 56% in men and 64 % in women.

At the time of maximal impairment following a CVA, 41.1% of 4499 patients (46.0% of females and 37.3% of males studied) had urinary incontinence [167]. An analysis of the symptoms of 532 patients seen within 7 days of their stroke found that the presence of urinary incontinence appeared to be a more powerful prognostic indicator for poor survival and eventual functional dependence than a depressed level of consciousness [168, 169]. It was suggested either that incontinence was the result of a severe general rather than specific loss of function or that those who were incontinent were less motivated to recover from both continence and more general function impairment. Outcome was so much better in those who remained or became dry that it seems possible that recovery of continence may promote morale and self-esteem, which might hasten overall recovery. Urinary incontinence with impaired awareness of bladder sensation seem to be associated with poorer outcome than urgency urinary incontinence with preserved bladder perception [170]. 20-30% of patients still suffer from urinary incontinence six months after the CVA if no proper treatment has been instigated [171]. Six months after stroke, 16% of patients experience urine loss, and that urinary loss was perceived as urinary incontinence when it occurred at least monthly [172].

a) **Pathology and disease specific LUT problems**

Prior to the findings of functional brain imaging studies, all that was known about the cortical control of the bladder was based on clinical studies of patients with brain lesions. The most influential study was that by Andrew and Nathan, 1964 [173]. The typical clinical picture of frontal lobe incontinence they described was of a patient with severe urgency and frequency of micturition and urgency incontinence, without dementia, the patient being socially aware and embarrassed by the incontinence. Micturition was normally co-ordinated, indicating that the disturbance was in the higher control of these processes. The authors made the comment: “this paper was written because people did not believe that there was such a thing as cerebral disturbance of the bladder”.

There have been a number of urodynamic studies of patients who have developed urinary symptoms after CVA, disparate cortical lesions. In general, voiding is normally co-ordinated, as patients do not show DSD, and the commonest cystometric finding is DO [174-176].

At 3 months, 53% of stroke patients have significant urinary complaints [177]. The commonest LUTS were nocturia in 36%, urgency incontinence in 29% and voiding difficulty in 25%. Urinary retention was seen in the acute phase of illness in 6 %. A significant positive correlation was found between the occurrence of a urinary disturbance and hemiparesis. Brain imaging techniques confirmed a more anterior location of brain lesions in these groups. Urodynamic studies on 22 symptomatic patients showed DO in 68% and uninhibited sphincter relaxation in 36%. DSD was reported in 14%, which should not occur in suprapontine lesions; whether DSD was appropriately diagnosed, rather than representing a hold-on manoeuvre to prevent urinary leakage, could not be clarified from the paper. There was some indication that lesion size was related to the occurrence of urinary symptoms. In contrast to the findings of Maurice-Williams [178] and Kuroiwa et al. [176], who found a correlation of urinary incontinence with lesions of the right brain hemisphere, Sakakibara
et al. [177] could not find a preponderance of right sided lesions for incontinence. Their findings suggest that the damage to the antero-medial frontal lobe, its descending pathway and to the basal ganglia is mainly responsible for micturition dysfunction in stroke patients. An epidemiological study showed an association of hemispatial neglect due to right hemisphere and urinary incontinence [180]. In the latter study, no urodynamic tests were done, and urinary incontinence might have been secondary to general neglect syndrome.

Urinary incontinence in stroke patients is usually interpreted as the loss of central inhibition. However, loss of bladder perception as a concomitant factor may also be relevant. Deficit of bladder sensation seems to be associated with poorer general outcome. Such patients have more parietal lobe but less frontal lobe impairment than patients with urge urinary incontinence and preserved bladder sensation [177]. Patients with frontal lobe lesions (tumours) and damage to the right superior bifrontal region have temporary incontinence, whereas permanent incontinence was associated with bilateral damage [180].

Urinary retention has also been described in patients with brain lesions. Three case histories of elderly females with various forms of right frontal lobe pathology were described as urinary retention. In two, one with an abscess and the other with a haematoma, successful treatment brought recovery of bladder function [181, 182].

An experimental model for studying the effect of forebrain lesions and voiding dysfunction was developed in the rat by occluding the middle cerebral artery under pentobarbital or halothane anaesthesia. At thirty minutes after recovery from anaesthesia bladder capacity in animals with cerebral infarct was markedly decreased. The decreasing bladder capacity continued as long as four months after arterial occlusion. Based on the effects of two different types of receptor antagonists on OAB induced by left middle cerebral arterial occlusion, the authors [183] concluded that the NMDA receptor (N-methyl-D-aspartate) has a role in the development of OAB after CVA. A glutamate receptor antagonist thus might be beneficial for OAB caused by cerebrovascular disease, as the induced potentiation of bladder reflexes seems to depend on NMDA glutamate transmission (LOE 4).

Brainstem lesions give a different profile from hemispheric lesions. In 1926 Holman [184] noted that voiding difficulty could be a sign of tumours in the posterior fossa. In a series of patients with brain tumours, Ueki et al. [185] reported voiding difficulty to occur in 46/152 (30 %) of patients with tumours in the posterior fossa, while urinary incontinence occurred only in 3 (1.9 %). Renier and Gabreels [186] found urinary retention in 12/17 children with pontine glioma. There are a number of case histories published presenting difficulties with micturition in various brain stem pathologies [187-190].

Sakakibara et al. [189] reported the urinary symptoms of 39 patients who had brainstem strokes. Almost half the patients had urinary symptoms, nocturia and voiding difficulty in 28 %, urinary retention in 21 % and urinary incontinence in 8 %. The problems were more common following haemorrhage, probably because the damage was usually bilateral. Urinary symptoms did not occur in those with lesions of the midbrain, but they did in 35 % of those with pontine lesions and in 18 % of those with medullary stroke. Urodynamic studies in 11 symptomatic patients showed DO in 8/11, low compliance in 1/11. Detrusor acontractility occurred in 3 of the 11 at three months, six months and 3 years after the occurrence. A non-relaxing sphincter on voiding was found in 5/11 and uninhibited sphincter relaxation in 3/11 (LOE 3).

### b) Disease-specific diagnosis and management

Basic diagnosis comprises a targeted history and clinical investigation, urine analysis, postvoid residual urine and a bladder diary. In patients with significant residual urine of over 100 cc or more than 50 % of bladder capacity, a urodynamic investigation may help to differentiate between detrusor weakness, and functional or morphological outflow obstruction.

Urinary incontinence within seven days of acute stroke has a highly predictive prognostic value for long term outcome [168, 191] (LOE3). Large lesions involving the frontal lobe, which is relevant to bladder control, might also affect the motor function. Immediately after the CVA, an indwelling transurethral or suprapubic catheter allows control of the urinary output in the Stroke Unit. Diuresis should be monitored. Once the stroke situation is stabilised and diuresis is normalised the catheter should be removed and the patient put on intermittent catheterisation if voiding is inefficient. In the early stage after the stroke, urinary incontinence can be managed by a condom catheter or by pads. Further treatment comprises behavioural therapy (initially toileting, later on micturition training) and anticholinergic therapy, if the voided volumes are below 250 cc. The patient's ability to squeeze the anal sphincter voluntarily is a good prognostic sign for subsequent return of continence. In the early phase, especially during catheter drainage, special care must be taken to avoid urinary tract infections with secondary complications. In diabetic patients low dose infection prophylaxis is recommended (LOE 4).

Behavioural intervention has a good outcome for urinary incontinence after stroke [192-194] (LOE 4). When urinary urgency and incontinence persist after stroke, anticholinergics are generally used, but no systematic survey of anticholinergic use in post stroke patients is available. One trial has reported suburothelial injection of botulinum A toxin
V. MENINGITIS-RETENTION SYNDROME

Urinary retention in childhood, young adults, and in women is very uncommon, and may reflect a neurological disorder [196]. Spina bifida occulta/tethered cord syndrome is one such disorder known to lead to urinary retention without marked neurological abnormalities, except for saddle anesthesia [197]. Fowler’s syndrome is another disorder that causes urinary retention, particularly in neurologically-intact young women, and isolated urethral sphincter hypertonicity underlies this condition [198]. Benign inflammatory nervous diseases also cause acute urinary retention, in which patients lack apparent urethral outlet obstruction, but exhibit only minor neurological as well as cerebrospinal fluid (CSF) abnormalities. Based on the mechanism of urinary retention, these disorders can be divided into two subgroups: disorder of the peripheral nervous system (PNS) (e.g. sacral herpes, with unilateral sacral pain, sensory signs and often skin rashes in the same area [199]); and disorder of the central nervous system (CNS) (e.g. meningitis-retention syndrome (MRS), with fever, headache, stiff neck, and minor pyramidal signs). Previously the latter condition has been only occasionally reported, but now it is recognized as a specific category [200, 201], which is considered to be a very mild form of acute disseminated encephalomyelopathy (ADEM) (LOE3). Since it is rare, true prevalence of MRS has not been fully investigated.

In its typical form, ADEM appears after vaccination or after exanthematous infections, and serological and pathological studies have suggested that ADEM is of parainfectious/ autoimmune origin [202]. Antecedent/comorbid infections are diverse, e.g. human herpes virus 6 [203]. A combination of signs of encephalitis (e.g., disturbance of consciousness, epilepsy, and hemiparesis), signs of myelitis (e.g., sensory disturbance below the level of the lesion, spastic paraplegia, whereby flaccid paraplegia may occur in the initial shock stage), and lower urinary tract (LUT) / bowel dysfunction typically occur in patients with ADEM. Lesions observed in brain MRI are usually confined to the white matter. Lesions in the spinal cord involving the conus are also seen [201]. CSF pleocytosis, increased protein, mildly decreased glucose content, increased myelin basic protein (MBP)/oligoclonal bands, and a lack of increased viral titres, are all features of this disease. Patients with ADEM commonly exhibit LUT dysfunction [204, 205], which varies from urinary retention to urgency incontinence. LUT dysfunction appears to be related to pyramidal tract involvement, and most probably reflects the severity of the spinal cord lesion. Urodynamic findings have included detrusor overactivity in the storage phase, brisk bulbocavernous reflex, and DSD (reflective of a suprasacral spinal cord lesion); detrusor areflexia in the voiding phase (reflective of either acute spinal shock or conus lesion); and neurogenic sphincter EMG in one of four patients studied (reflective of a conus lesion) [204, 205]. The responsible lesion sites in cases of LUT dysfunction have appeared to be the

Regarding further research, there is a need for further epidemiologic studies of the true incidence of LUT symptoms including incontinence after CVA in the longer term. Evidence is lacking concerning efficacy and safety of currently used therapeutic interventions. Controlled studies comparing behavioural therapy and anticholinergic medication alone and in combination would be useful.

Conclusions

- Incontinence after CVA is a prognostic indicator for survival and eventual functional dependence. (LOE 2).
- The commonest urological problems after stroke are nocturia (36 %), urgency incontinence (29 %) and difficulty in voiding (25 %). (LOE 2/3)
- There is a positive correlation between the occurrence of urinary dysfunction and hemiparesis. (LOE 2/3)
- Urodynamic studies revealed detrusor overactivity in 68%, and sphincter relaxation problems in 36%. (LOE 4)
- Damage to the antero-medial frontal lobe and its descending pathways, and the basal ganglia are mainly responsible for voiding dysfunction in stroke patients. (LOE 3)
- With brainstem pathology, symptoms of impaired voiding (urinary retention) predominate. (LOE 3)

Recommendations

- As the urological symptoms, especially incontinence are very distressing, urological care is mandatory for these patients (B).
- Prevention of early urinary tract infection, especially during the acute phase of indwelling catheterisation, is needed. Thereafter, behavioural training and anticholinergic therapy are the mainstays of treatment (C).
- Intermittent catheterisation is occasionally necessary, due to inefficient voiding. This may be in men with pre-existing infravesical obstruction, who can consider standard management of bladder outlet obstruction if they achieve satisfactory general recovery (C).
cervico-thoracic spinal cord, and, to a lesser extent, the conus [206] (and possibly the spinal nerve roots [207]) in patients with ADEM. In addition, cases of ADEM presented with LUT dysfunction as the only remaining consequence of the disease, thus suggesting that LUT innervation was selectively vulnerable in these cases. Recently, it is also reported that cases of ADEM/parainfectious myelitis initially presented with urinary retention [208, 209] or leaves urinary retention as the sole sequel [210]. In some cases, abnormal F-waves were recorded, suggesting conus or radicular lesion [201]. Although aseptic meningitis is a common neurologic disorder, a combination of aseptic meningitis and acute urinary retention (MRS) has not been previously well recognized. The clinical manifestations of Sakakibara’s three cases [200] are mostly the same as those of the six reported cases in the literature (including cases written in Japanese) [211]. The clinical manifestations of MRS cases differ markedly from those of ADEM, because other than presenting with aseptic meningitis, MRS cases lack the following: apparent encephalitic signs such as disturbance of consciousness, epilepsy or aphasia; and myelitic signs such as gait abnormalities, or sensory-level abnormalities. Only one patient reported by Fukagai et al. showed drowsiness without meningeal irritation. Whereas brain and spinal cord lesions typically appear in ADEM, such change is not observed in MRS. However, a reversible splenial lesion was noted in the brain MRI of a patient with MRS [212].

The CSF examination showed a mononuclear pleocytosis of 38-370/mm3, normal to increased protein content (up to 260 mg/dl), and normal to mildly decreased glucose content (up to 33% of that in the serum). All viral titres studied in the CSF and the serum of such cases were negative. Nevertheless, it appears likely that the urinary retention in such patients is of neurologic aetiology, since none of the patients appear to exhibit urologic abnormalities such as prostatic hyperplasia, and also because a strong chronological association is observed between the onset of urinary retention with, or just after, the occurrence of the aseptic meningitis. As it is observed in ADEM, antecedent/comorbid infections or conditions with MRS include angiostrongylus cantonensis [213, 214], Epstein Barr virus [215], and herbal medicine use [216], whereas such antecedent infections are not apparent in the remaining cases [217, 218].

Urodynamic study results have shown that all patients examined had detrusor areflexia, which results in an inability to contract the bladder on voiding, and some patients had an unrelaxing sphincter. Detrusor areflexia originates from various lesion sites along the neural axis; most commonly, PNS lesions are observed. However, CNS lesions that affect the spinal cord or the brain can also cause detrusor areflexia, which is particularly seen in the acute shock phase of patients with transverse myelitis (often immune-mediated) or ADEM. A case report described repeated urodynamic studies in one patient, in which an initially areflexic detrusor became overactive after a 4-month period, suggesting an upper motor neuron bladder dysfunction [219]. As described above, encephalitic features are absent in patients with MRS. However, three MRS patients (including Sakakibara’s cases 1 and 3) showed the brisk lower extremity reflexes suggestive of mild myelitis. In one of Sakakibara’s cases, MBP was increased, which is suggestive of CNS demyelination. Therefore, it appears possible that MRS is a very mild variant of ADEM, which selectively affects LUT innervation.

Arriving at a diagnosis is easy when a combination of aseptic meningitis and acute urinary retention is confirmed, although such a diagnosis should be made both urologically and neurologically, in order to exclude sacral herpes, a benign variant of Guillain-Barre syndrome (inflammatory radiculitis), typical ADEM, myelitis with leg weakness [220], herpetic brainstem encephalitis, chemical meningitis, focal subarachnoid bleeding, and other common causes of neurogenic urinary retention (e.g., diabetic neuropathy, lumbar spondylosis, etc.). For the differential diagnosis, detailed history, brain/spinal MRI and nerve conduction study are necessary.

The term “Elsberg syndrome” has been occasionally used, which is rather vaguely assigned to sacral myeloradiculitis of undetermined etiology, sacral herpes, sacral vasculitic neuropathy, possible MRS, possible ADEM, or conus infarction. However, in contrast to the majority of “Elsberg syndrome” cases, Kennedy, Elsberg, and Lambert [1913] [221] reported five cases of pathology-demonstrated cauda equina radiculitis. Clinical pictures of these cases were characterized by rare CSF abnormalities (only one of the four cases described showed an increased cell count as well as increased protein levels); no clinical meningitis; subacute/chronic course (in one case the course of disease was subacute: 3 months, but in the remaining four cases, the course of disease was chronic: 4.5-36 months); the patients presented with typical cauda equina motor-sensory-autonomic syndrome (in particular, four of the patients had apparent muscle atrophy/weakness in the lumbosacral segment); Wallerian degeneration of the spinal afferent tracts; and mild upper motor neuron signs. The authors assumed that the etiology of these cases was either inflammatory or toxic. The exact cause of these five cases remains uncertain, although clinical pictures of these cases resemble, at least in part, those of paraneoplastic [222] or autoimmune lumbosacral radiculoplexus neuropathy [223]. Clinical features of sacral herpes or MRS differ markedly from those of Kennedy’s cases.

Since MRS has a benign and self-remitting course (i.e., a duration of 2-10 weeks), the effectiveness
of immune treatments (e.g., steroid pulse therapy) remains unclear, although such treatments may shorten the duration of the disease. Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension (LOE4).

Since MRS is rare, true prevalence has not been fully investigated and evaluation of this is warranted in future research. Similarly, in order to shorten the urinary retention period, the effectiveness of immune treatments (e.g., steroid pulse therapy) in MRS remains unclear, and future research is desirable.

Conclusions

- Meningitis-retention syndrome, with fever, headache, stiff neck, and minor pyramidal signs, is thought to be a very mild form of acute disseminated encephalomyelitis (ADEM).
- Both urologists and neurologists may encounter this disorder.
- Initially the bladder is areflexic, but soon becomes normal or overactive during the course of the disorder.

Recommendations

- Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension in patients with MRS.

VI. ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

Acute disseminated encephalomyelitis (ADEM), also known as post-infectious encephalomyelitis, is a demyelinating central nervous system (CNS) disorder that usually follows infection, or more rarely vaccination [224]. ADEM can be confused for MS; indeed, the early symptoms of ADEM are similar to an acute relapse of MS. Presence of constitutional symptoms such as fever and headache, and the simultaneous involvement of various parts of the CNS may help differentiate this condition from MS. However, it can be difficult to distinguish the two, and the only sure way is follow up and the observation of any relapses over time.

ADEM is a disease that is characterized by an inflammatory reaction and demyelination in the brain and spinal cord. In contrast to MS, there is a tendency for perivenous localization of pathological changes [225]. Bladder dysfunction is common in ADEM. In a consecutive series of sixty one patients with ADEM, 20 (33%) had evidence of LUTD [205] (LOE 3/4). Lesions in the cerebral and spinal cord white matter result in LUTD. Both voiding and storage symptoms are reported in ADEM, however the pattern of bladder dysfunction depends upon the time point at which they are assessed. In the acute stage, Panicker et al. reported that voiding dysfunction is more common; in their series of 20 patients, 16 were in urinary retention [205] (LOE 3/4). Urodynamics demonstrated detrusor overactivity in four patients and underactivity in four patients. Incontinence was reported more often in patients with frontoparietal white matter changes in MR imaging [205] (LOE 3/4). In the series of Sakakibara et al., patients were followed up for 3 to 38 months, and seven of nine patients with retention were able to pass urine once again, five had difficulty in voiding and four developed urinary frequency or urgency incontinence. Motor unit analysis of the external sphincter revealed polyphasic neurogenic changes in only one of four patients. They also observed that bladder disturbances in ADEM seemed to be as common and severe as in MS [204] (LOE 3/4). LUTD is common especially in patients with lower limb pyramidal involvement [205].

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of ADEM. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction often recovers [202, 205]. If suitable, IC could be considered. Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication, once it is confirmed they are not retaining urine.

For future research, there are currently only limited studies evaluating the natural history of LUTD in ADEM and patients should be followed up to assess lower and upper urinary tract changes with time. There is a dearth of information about the role of botulinum toxin or sacral neuromodulation in this condition.

Conclusions

- In the acute phase of ADEM, LUTS may be seen in a third of patients (LOE 3/4).
- Both voiding and storage dysfunction are observed in ADEM (LOE 3/4).
- Recovery of LUT functions occurs, along with the recovery of motor weakness (LOE3/4).

Recommendations

- Patients with ADEM and bladder symptoms should be managed according to their symptoms, and the findings on urodynamic tests, particularly post-void residual (C).
- LUTS can change as the disease stabilises; re-evaluation during follow-up is therefore recommended (C).
- Patients with overactive bladder symptoms are likely to benefit from antimuscarinic pharmacotherapy, once they are shown not to be retaining urine.
VII. SPINAL CANAL STENOSIS

About half of the patients with intractable leg pain in spinal canal stenosis also have bladder symptoms – urinary difficulty with high post-void residual (PVR) and reduced flow rate and/or incontinence indicating effects on the cauda equina. Such symptoms, including urinary incontinence usually improve after surgical decompression.

Schkrohowsky et al [2007] [226] reported that one third of patients with achondroplasia developed SCS, especially at the lumbar level, and 77% of these had urinary incontinence. According to Jønsson and Sass [2004] [227], in the County of South Jutland, Denmark during a 5-year period [1996-2000], the annual incidence of SCS was 272 per million inhabitants. Of 340 cases diagnosed with SCS during that period, only one patient presented with acute cauda equina syndrome. This was a 74-year-old woman with SCS from L2 to L4, who presented with urinary retention and fecal incontinence (FI) for the preceding 24 hours; after urgent surgery she recovered from her anal sphincter paresis within 5 days and from her bladder paresis within 5 weeks.

Goh et al [2004] [228] carried out a comprehensive retrospective review of the clinical features, radiological changes and outcome of 75 patients with radiologically diagnosed lumbar SCS; imaging of the lumbar spine showed that moderate to severe central spinal stenosis correlated with complaints of weakness and abnormal motor power on clinical examination. The commonest symptom was numbness or tingling of the legs. According to the study of Inui et al [2004] [229], 58.8% of the 34 patients were diagnosed with neuropathic bladder; however there was no difference in the cross-sectional area of dural sac between those with and without neurogenic bladder dysfunction in patients with lumbar SCS. Nonetheless, the anteroposterior diameter of the dura was shorter in those with bladder dysfunction, and a critical size for the dural sac of patients was reported as 8 mm.

Usually signs and symptoms of compressive neuropathy of multiple lumbar and sacral roots is an indication for surgical intervention, but relatively unknown as a post-operative complication [230]. Four years after diagnosis, 65% had undergone surgical decompression; a third of patients felt that their symptoms had improved while a quarter felt that they had worsened. Imran and Halim [2005] [231] reported a 63-year-old man who developed acute cauda equina syndrome due to fat graft compression after decompressive laminectomy, posterior instrumented fusion with pedicle screw fixation for spinal stenosis of L5 and S1 vertebral levels, and free fat grafting to cover the exposed dura; three days postoperatively, gradual neurological deficit started with sensory loss and weakness of the affected dermatomes and myotomes, followed by FI on the 12th postoperative day; and immediate removal of the fat graft resulted in recovery from cauda equina syndrome. Another case was reported by Tubbs et al [2005] [232]; a Caucasian girl who had idiopathic growth hormone deficiency and Klippel-Feil and Duane’s syndromes with symptomatic stenosis of the first cervical vertebrae presented with episodes of loss of tone with subsequent falling, facial cyanosis, UI, hand weakness, and difficulties with swallowing; following suboccipital craniectomy and the removal of the posterior arch of the atlas, her symptoms were resolved and UI improved.

To demonstrate narrowing of the lumbar canal with compression of the cauda equina, CT or MRI is often recommended, to reveal either bony or soft tissue compression [233]. Miyata et al [1998] [234] studied the relationship between bladder function and roentgenographic changes in the spinal canals of ossification of posterior longitudinal ligament (OPLL) patients. CO2-filling cystometry, uroflowmetry and PVR were measured and the vertical extent of OPLL and the degree of SCS was estimated by X-ray films and CT. The occurrence of abnormal detrusor activity had no relationship to the degree of canal stenosis, while the occurrence of an areflexic or underactive detrusor correlated with the vertical extent of OPLL [10]. Yamanishi et al [1998] [235] found DO in 14 lumbar canal stenosis patients (29%) and most of them had voiding symptoms and had storage symptoms which seemed to be caused by the irritation of sacral roots. Of 10 patients followed up after surgical decompression, DO disappeared in 5 patients, improved in 1 patient and remained unchanged in 4 patients [235]. Lee et al [1997] [236] did an expansive cervical laminoplasty in patients with non-traumatic cervical spondylodystrophy with myelopathy and found that age greater than 60 years at the time of presentation, duration of symptoms more than 18 months prior to surgery, preoperative bowel or bladder dysfunction, and lower-extremity dysfunction were associated with poorer surgical outcome.

Conclusions

- Patients with spinal stenosis, especially at lumbar levels, may present with bladder and bowel involvement – urinary retention/incontinence and faecal incontinence (LOE 3/4).
- Lumbar canal stenosis may cause either detrusor underactivity/acontractility or overactivity (LOE 3).
- Imaging helps diagnose spinal stenosis, while urodynamic study categorises neurogenic bladder dysfunction (LOE 3/4).
- Acute symptoms of incontinence or urinary retention may recover after decompression of spinal stenosis (LOE 3/4).
The nerve roots of L2 to S4 that occupy the spinal canal below the termination of the spinal cord, at the lower border of the L1 vertebra, form a tightly-packed bundle giving the appearance of a horse’s tail—hence they are referred to as the “cauda equina”. Damage to these nerve roots produces a characteristic pattern of symptoms called the cauda equina syndrome where bladder, bowel, sexual dysfunction and sensory loss of the perineum are the predominant complaints. Table 18 lists the common causes for a cauda equina syndrome.

2. LUMBAR DISC PROLAPSE

Medline/ Pubmed [1966-2012] searched for keywords: Disc prolapse (or disc hernia), bladder dysfunction, neurogenic bladder, sphincter dysfunction, bowel dysfunction, fecal incontinence, and constipation.

Central lumbar disc prolapse compresses sacral nerve fibers to and from the bladder, the large bowel, the anal and urethral sphincters, and the pelvic floor. Cauda equina syndrome due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [237-244]. Clinical features of the cauda equina syndrome include low-back pain, bilateral sciatica, saddle anesthesia, and urinary retention, loss of urethral sensation as well as constipation and erectile dysfunction [240, 243, 245, 246]. Those patients with cauda equina syndrome usually have some sensory disturbance in the sacral dermatomes. A retrospective cohort study with prospective clinical follow-up showed that bowel dysfunction at presentation was associated with sexual problems at follow-up [247].

The most common urinary symptom associated with lumbar disc prolapse is acute urinary retention [248, 249]. At the onset, acontractile detrusor with impaired bladder sensation is a typical urodynamic finding [240, 246, 248-250]. Severe denervation of pelvic floor [248] and external urethral sphincter [10] is also frequently demonstrated. Detrusor overactivity may occur [250-252]. Urinary disorders usually follow or accompany more obvious neurologic symptoms, such as lumbar pain and perineal sensory disturbances, that prompt the appropriate diagnosis. However, sometimes voiding disturbances may be the only or the first symptom of this condition, which makes it more difficult to diagnose [240, 246]. Nevertheless, urgent MRI assessment is recommended in all patients who present with new onset urinary symptoms concomitantly with lumbar back pain or sciatica because it is impossible in a significant proportion of patients to exclude the diagnosis of prolapsed intervertebral disc in the context of referral with suspected cauda equina syndrome.

Emergency surgical decompression has been reported to increase the chance of satisfactory neurological recovery in patients with cauda equina syndrome due to central lumbar disc prolapse [240, 254, 255]. In a meta-analysis of surgical outcomes, Ahn et al. [2000] [243] reported that a significant improvement in sensory and motor deficits as well as urinary and rectal function occurred in patients who underwent the surgery within 48 hours, compared with those who had the surgery more than 48 hours after the onset of the cauda equina syndrome. Although there is still a controversy [247], most of other reports support the concept that decompression performed within 48 hours of onset of this syndrome resulted in improved functional outcomes [239, 244, 256]. However, acontractile detrusor is usually irreversible, even after immediate decompression [246, 257, 258], although many patients can empty their bladder postoperatively, this may achieved only by straining or changing voiding postures [246, 258]. In contrast to bladder dysfunction, urethral function shows a better recovery after surgery [246, 249].

For future research, good epidemiological studies on the occurrence of lower urinary tract/ bowel dysfunction are needed. This is increasingly relevant with the advent of new, minimally invasive treatment options for disc prolapse.

*Can present acutely

**Recommendations:**

- Surgical decompression is recommended in patients with spinal stenosis having acute symptoms of urinary retention/incontinence and faecal incontinence (A).
Conclusions:

• Cauda equina syndrome is a relatively rare complication of lumbar disc prolapse (LOE 3).
• Bladder and bowel manifestations of lumbar disc prolapse include: urinary retention, loss of sensory functions, decreased sexual functions (LOE 3).

Recommendations

• Emergency surgical decompression is the treatment of choice, the optimum timing is considered to be within 48 hours (Grade B/C).
• Full recovery of lower urinary tract functions, including bladder contractility, is unreliable (Grade C).

VIII. NEUROPATHIES AND MUSCLE DISORDERS

1. GUILLAIN BARRE SYNDROME

Since the eradication of poliomyelitis, Guillain-Barré syndrome (GBS) has become the most common cause for acute, flaccid paralytic disease in many parts of the world [1]. It presents as a rapidly progressing ascending areflexic motor paralysis, with or without sensory and autonomic dysfunction. Following an initial acute progressive phase, which by definition reaches a nadir within four weeks, there is a plateau phase and finally a recovery phase. Symmetrical limb weakness is the common presentation, however there may be in addition cranial nerve and respiratory muscle weakness. The disorder affects children and adults of all ages and both sexes. GBS is amenable to treatment with intravenous immunoglobulin or plasma exchange. However despite this, 4% to 15% of patients die from this syndrome, most often due to cardiovascular autonomic disturbances, respiratory compromise or aspiration. Nearly 20% have persistent disability [2].

Autonomic dysfunction is a frequently-overlooked complication. Cardiovascular autonomic dysfunction is recognized in up to 60% of GBS patients [3]. However, bladder and bowel dysfunction occurs much less often. Indeed, the presence of bladder or bowel symptoms at the onset of disease, or their persistence, casts doubt on the diagnosis [3A] and other conditions such as spinal cord disease needs to be excluded. During the acute phase, it is often difficult to assess LUTD specifically due to neurological dysfunction. Patients are often catheterized as part of their general nursing care to monitor water balance or maintain hygiene [2]. Furthermore, patients may be on medications such as opiates and tricyclic antidepressants, which in themselves can affect bladder and bowel functions. In the largest study to date, Sakakibara et al. [4] studied 65 patients with definite GBS (meeting clinical and neuropsychophysiological criteria) and LUTD was observed in 27.7% (LOE3/4). This figure is almost similar to that quoted by Guillain and others in the early papers about this condition [5, 6].

The condition is characteristically a symmetrical radiculo-neuropathy most often predominantly due to demyelination (Acute Inflammatory Demyelinating Polyradiculoneuropathy, AIDP), but also there are subtypes where axonal damage prevails (Acute Motor Axonal Neuropathy, AMAN). There is a dearth of systematic studies evaluating LUTD in GBS. In a few reports [10-12], detrusor areflexia and disturbed bladder sensation were the common findings, and a non-relaxing urethral sphincter was also seen (LOE3/4). In the study by Sakakibara et al. [4], patients most commonly reported voiding symptoms in 24.6%, including urinary retention in 9.2%. Storage symptoms were noted in 7.7%, urinary urgency in 7.7%. None of the patients in this study became incontinent. Urinary dysfunction was more common in AIDP (39%) than AMAN (19%), although the prevalence of urinary retention was almost the same (AIDP, 7%; AMAN, 11%, respectively). Factors that were associated with bladder symptoms included age, severity of motor weakness (Hughes motor grade) and concurrent bowel dysfunction. When patients were followed up, improvement in bladder symptoms paralleled improvement in motor weakness. Interestingly, there was no correlation between the presence of cardiovascular autonomic dysfunction and bladder dysfunction. Urodynamic studies performed within eight weeks of disease (n=9) showed variable results, demonstrating detrusor underactivity (n=2), DO (n=3), both DO and underactivity (n=5) and non-relaxing urethral sphincter (n=2). Three patients had an elevated post void residual and one patient had reduced bladder sensations [4] (LOE3/4). Their results were similar to the urodynamic findings from Gabavac et al. [12] (LOE3/4).

a) Urinary dysfunction

Urinary dysfunction in patients with GBS tends to appear after the onset of motor weakness in all cases [4]; however, in two patients with axonal GBS, it was reported that voiding difficulty and motor weakness appeared almost simultaneously [7, 8] (LOE3/4). A close relationship between severity of GBS and bladder dysfunction has been reported [8A] (LOE3/4). Lichtenfeld [9] (LOE3/4) has reported urinary retention in one-third of patients requiring ventilator assistance. Even though up to 11% of GBS patients may develop urinary retention at the peak of motor weakness, it will most often improve along with other neurological signs after supportive patient management, with or without immunomodulation. However bladder dysfunction can persist, and it is reported that urinary retention failed to recover for 10 months, even after a patient (with axonal GBS) regained the ability to walk [8] (LOE3/4).
GBS primarily affects the large myelinated fibers, but pathological studies have demonstrated moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord [1,13]. It has been postulated that LUTD in GBS may be arising from inflammatory or immunologically mediated damage of the autonomic fibres of the lumbosacral nerves [1,13, 13A] (LOE3/4). Contrast magnetic resonance imaging (MRI) has demonstrated enhancement of the nerve roots of the cauda equina in GBS [14] (LOE3/4). The possible mechanism for DO might be abnormal spontaneous depolarisations in demyelinated nerve fibres, and impairment of inhibitory spinal cord interneurons, both of which can result in lumbosacral autonomic hyperactivity [13A, 15, 16] (LOE3/4).

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of the disease. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction can recover in parallel to recovery of motor weakness, but in some cases this might be delayed. If suitable, IC should be considered. Wosnitzer et al. reported a successful case of sacral neuromodulation for urinary retention that persisted 18 months after GBS [16A] (LOE3/4). Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication once it is shown they are not retaining urine. Of specific consideration to GBS is the side effect of tachycardia, as many patients may have concomitant cardiovascular autonomic dysfunction.

There are only limited studies evaluating the natural history of LUTD in GBS and long-term follow-up studies of patients are required. Studies evaluating the correlation between LUTD and other evidence for autonomic dysfunction (such as cardiovascular autonomic dysfunction) should be specifically evaluated.

Conclusions

- In the acute phase of GBS, about 25% of patients demonstrate LUT functional problems (LOE3/4).
- Both voiding and storage dysfunction are observed in GBS (LOE3/4).
- Recovery of LUT function occurs along with the recovery of motor weakness. However, in rare cases it might take months (LOE3/4).

Recommendations

- Recovery of LUT functions is expected in GBS; supportive care, including an indwelling catheter or IC, is the treatment of choice for urinary retention (C).

- Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic, once they are shown not to be retaining urine.

- A systematic evaluation of LUTD during the acute phase and recovery following GBS is required to optimize therapy (C).

Bowel dysfunction

Bowel dysfunction occurs less commonly in GBS, in up to 15% of patients [17, 18]. In a study by Burns et al. [17] (LOE3/4) adynamic ileus was noted in 17 out of 114 GBS patients. However, cardiovascular symptoms coincided with ileus in only 5 patients, suggesting a different pathophysiology for these two manifestations of autonomic dysfunction. Indeed in 4 patients, mechanical ventilation and immobilization was implicated. In 8 patients, pre-existing conditions such as prior abdominal surgery or incremental doses of opiates could also be linked to ileus. However, three case reports by Gazulla Abio et al. (LOE3/4) [19], Sawai et al. (LOE3/4) [20] and Noew et al. (LOE3/4) [21] have also shown that paralytic ileus can be the initial presenting symptom in GBS.

There is a lack of good systematic studies on bowel disorders in GBS during the acute and chronic phase of GBS. However, there are some reports suggesting an involvement of bowel autonomic fibers in GBS. Sawai et al. (LOE3/4) [21] performed a detailed bowel function test in a 47-old man with acute motor axonal neuropathy (AMAN) type of GBS who presented with ileus (also called intestinal pseudo-obstruction) by an abdominal X-ray. Sitzmarks showed prolonged total colonic transit time (86.4 hours; normal 16.0-48.0), suggesting slow transit constipation. Pathological studies of GBS have revealed moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord. Therefore, involvement of bowel autonomic fibers might also occur in GBS [21], as shown in an autopsy case of autoimmune gastroparesis [18].

Adynamic ileus or intestinal pseudo-obstruction occurs in up to 15% of patients during a course of GBS, particularly in those with severe motor dysfunction or those under mechanical ventilation [17] (LOE3/4). Recovery of bowel function usually occurs along with the recovery of motor weakness in GBS, after an intensive immune therapy including intravenous immunoglobulin.

There is still a lack of a detailed functional evaluation of the bowel in GBS patients. Such studies are needed in order to optimize the therapy in the future.

Conclusions

- About 15% of patients demonstrate bowel functional problems particularly in the acute
Recommendations

• Supportive care, including laxatives or enemas, is the treatment of choice (C).

2. FAMILIAL AMYLOID POLYNEUROPATHY

Familial Amyloid Polyneuropathy (FAP) is a rare autosomal dominant neuropathy affecting predominantly the peripheral autonomic nerves. Neuropathy starts insidiously in the lower limbs and is characterised by lancinating pains, numbness and impaired temperature sensations.

Autonomic manifestations are common and may be the initial manifestation in nearly 25% of patients [22] (LOE3/4). These include erectile dysfunction, orthostatic hypotension, bladder dysfunction, distal anhidrosis and abnormal pupils. LUTS generally appear early on and are present in 50% of patients within the first three years of the disease. Patients most often present with voiding dysfunction and incontinence (LOE3/4). Often, however, bladder dysfunction may be asymptomatic and uncovered only during investigations. Urodynamics have demonstrated reduced bladder sensations, underactive detrusor, poor urinary flow and an open bladder neck. There may be failure of relaxation of the smooth and striated sphincters as well. Ultrasound scans of the bladder may show bladder wall thickening, a finding which becomes more prominent as the disease progresses, and may represent either amyloid deposition in the bladder wall or detrusor hypertrophy secondary to functional obstruction (LOE3/4). 10% of patients with FAP type I may proceed to end stage renal disease [23] and bladder diaries may demonstrate global polyuria. Bladder dysfunction is likely to be due to small nerve fibre damage and deposition of amyloid substance in the detrusor muscle.

Patients should be followed up regularly, as overdistention is likely to contribute to bladder dysfunction. In the early stage of disease, post-void residual urine will often be less than 100 ml and bladder scheduling and double voiding is often sufficient. However when bladder emptying deteriorates, intermittent catheterization is required.

Lower gastrointestinal dysfunction results in alternating constipation and diarrhea. This occurs concomitantly with other manifestations such as episodic nausea, vomiting, and malnutrition. Anorectal physiology studies have demonstrated prolonged colonic transit time, low anal pressure at rest and loss of spontaneous phasic rectal contractions during squeeze, suggesting an enteric neuropathy [24] (LOE3/4).

Liver transplantation remains the only potentially curative treatment and gastrointestinal symptoms improve in about half of cases [22]. Studies suggest that bladder dysfunction does not improve following transplantation [25] (LOE3/4). Interestingly, the occurrence of urinary incontinence preoperatively has been shown to predict higher postoperative mortality [25].

3. FAMILIAL DYSAUTONOMIA

Familial dysautonomia (FD) or Riley-Day syndrome is the best known of the hereditary sensory and autonomic neuropathies (HSAN). This autosomal recessive condition is characterised by autonomic and small fibre sensory dysfunction. LUTD is known to occur in this condition and patients most often present with incontinence-stress incontinence but also overactive bladder symptoms. The limitation of using antimuscarinics is that it can exacerbate an already dry mouth from the underlying autonomic neuropathy. Less often, patients may have voiding dysfunction manifesting with hesitancy for micturition and high post-void residual volumes, and may be predisposed to recurrent urinary tract infections [26] (LOE3/4).

4. CHARCOT-MARIE-TOOTH DISEASE

Lower urinary tract dysfunction is only occasionally described in Charcot-Marie-Tooth disease. It has been reported in a family with proximal lower limb weakness where it manifested as loss of bladder sensations and urinary retention with detrusor underactivity demonstrated in urodynamics [27].

5. AUTONOMIC NEUROPATHIES

a) Acute Idiopathic Autonomic Neuropathy.

Bladder dysfunction is well recognized in acute idiopathic autonomic neuropathy (acute pandysautonomia). Acute onset autonomic dysfunction is the hallmark, and is thought to be due to lesions of the pre- and postganglionic sympathetic and parasympathetic fibres. Urinary retention and voiding difficulty are common and cystometry demonstrates detrusor areflexia. Bladder dysfunction tends to resolve earlier than other features of autonomic dysfunction, such as orthostatic hypotension. Constipation is common [28] (LOE3/4).

b) Autoimmune Autonomic Ganglionopathy.

Presentation is with rapid onset of severe autonomic failure: orthostatic hypotension, gastrointestinal dysmotility, anhidrosis, bladder dysfunction, erectile dysfunction and sicca symptoms. They have circulating ganglionic acetylcholine receptor (AChR) antibodies. Bladder dysfunction generally manifests with voiding difficulty and incomplete
emptying. Severity and distribution of autonomic dysfunction appear to depend upon the level of antibody titers [29] (LOE3/4).

**c) Pure Autonomic Failure.**

PAF is a degenerative postganglionic autonomic disorder. Nocturia and voiding dysfunction are common and bladder emptying is often affected. Bladder diaries may demonstrate nocturnal polyuria. Urodynamics may however demonstrate detrusor overactivity in some patients [30]. Bladder dysfunction in PAF appears to be as common as, but less severe than, MSA and this could possibly reflect slower progression of the disease [30] (LOE3/4). Constipation is common.

**6. DISORDERS OF THE NEUROMUSCULAR JUNCTION**

Widespread autonomic dysfunction is a hallmark of Lambert-Eaton myaesthenic syndrome (LEMS). This is associated with antibodies to voltage-gated calcium channel (VGCC) of the P/Q-type and patients can present with erectile dysfunction, constipation and bladder dysfunction [31].

In the more common disorder of the neuromuscular junction, myasthenia gravis, LUTS is rare. This is presumably because the auto-antibodies are directed against the nicotinic acetylcholine receptors, rather than the muscarinic. However voiding difficulties have been reported and urodynamic studies have revealed detrusor underactivity in these patients. In fact, voiding dysfunction may herald a new diagnosis of myasthenia or an exacerbation of the disease process [32] (LOE3/4). The proposed mechanism is involvement of acetylcholine receptors in the detrusor muscle or pelvic ganglia [33]. Ganglionic acetylcholine receptor antibodies may be present in some patients [34]. Urinary incontinence is a listed side effect of anticholinesterase medications which are used in treating myasthenia gravis [British National Formulary (online), 2009 March, cited 8 Sept 2009], though in clinical practice this is rarely observed. Intestinal pseudo-obstruction has been reported in patients of myasthenia gravis with subacute autonomic failure.

**7. MUSCLE DISORDERS**

**a) Muscular Dystrophies**

Case series in boys with Duchenne Muscular Dystrophy (DMD) have reported the occurrence of overactive bladder symptoms, and DO has been demonstrated in urodynamics. Symptoms improve with antimuscarinic medications [35] (LOE3/4). The exact mechanism for DO is uncertain, though it is likely to be due to a disturbance of neural control rather than myopathy of the detrusor or external sphincter. Patients may have severe scoliosis as a consequence of their muscle disorder and this, as well as spinal fusion surgery for correcting scoliosis, can contribute to LUTS because of spinal cord compression [36].

Myotonic dystrophy (MD) is an autosomal dominant disorder caused by unstable trinucleotide repeat expansions. The commonest bowel complaint is constipation, however most disabling is fecal incontinence. EMG has demonstrated myotonia and myopathic changes in the external anal sphincter. Bowel incontinence is often refractory to treatment [37] and procainamide (300 mg twice a day) has been proposed as a treatment option [38]. Constipation is usually treated with prokinetics, laxatives and enemas. Bladder dysfunction is variable and less often reported with detrusor overactivity or atonia being documented in urodynamics [39] (LOE3/4).

**b) Mitochondrial cytopathy**

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a rare autosomal recessive disorder characterized by gastrointestinal, extracocular, peripheral nerve and cerebral white matter involvement. The gastrointestinal disease manifests with intermittent diarrhea and pseudo-obstruction. Mitochondrial DNA abnormalities and/or thymidine phosphorylase mutations in the proper clinical setting are diagnostic [40]. Bowel dysmotility has also been reported in Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, acronym DIDMOAD) [41]. Lower urinary tract dysfunction has been described in both conditions, and the latter may be associated with urinary retention and dilated upper urinary tracts [41] (LOE3/4).

**Conclusions**

- Lower urinary tract and bowel dysfunction can occur in a variety of neuromuscular disorders (LOE3/4).
- Both voiding and storage dysfunction are observed in these conditions (LOE3/4).

**Recommendations**

- Patients with neuromuscular disorders with bladder symptoms should be managed according to their symptoms and the findings of urodynamic tests (C).

LUT and bowel dysfunction can change as these diseases progress and therefore follow-up is recommended (C).

**8. PERIPHERAL NEUROPATHY DUE TO IATROGENIC LESIONS (FOCAL NEUROPATHY)**

LUT dysfunctions can occur from damage to the nerves innervating the pelvic organs, anywhere in the course of these nerves through the cauda equina, the spinal nerve roots, the sacral plexus, or to the various individual nerves that arise from the plexus. Most injuries to these nerves are iatrogenic. Extensive pelvic surgery, such as abdomino-perineal resection for
rectal cancer, radical hysterectomy, and aorto-iliac surgery are all likely to damage the pelvic para-sympathetic nerves to the bladder and genitalia. Of course this listing is not complete and almost any surgery in the pelvis could damage some nerves e.g. adenomectomy, radical prostatectomy, prolapse surgery. Additionally, pelvic irradiation, apart from directly affecting the irradiated tissue, could cause damage to the adjacent nerve fibers, resulting in altered functions. A variety of types of voiding, erectile and fecal dysfunctions can result.

a) Hysterectomy (simple and radical).

It is difficult to attribute certain dysfunctions to neuronal damage alone, since hysterectomy directly affects static and dynamic functions of the pelvic structures. Parys et al. [42] (LOE 3) studied 126 women after simple hysterectomy. The results show that 47.0% had DO, 36.7% had urethral obstruction and 24.8% stress incontinence. Sekido et al. [43] (LOE 3) described 9 women treated with radical hysterectomy more than 10 years before the study. Obstructive voiding symptoms and/or urinary incontinence were observed in 7 patients. Cystometry revealed impaired bladder sensation, detrusor acontractility, straining on voiding, and impaired relaxation of the sphincter in all assessable patients. In addition, decreased bladder compliance was observed in 5 patients. Axelsen [44] (LOE 2) studied 100 women after radical hysterectomy and found that those women who reported incontinence had lower urethral pressure. In a prospective study of over 1000 women Jackson et al. found hysterectomy to be an independent risk factor of incontinence [45] (LOE 2). Plotti et al. analysed literature between 1952 and 2010 and found that in studies with follow up longer than 12 months, 34% of patients demonstrated DO and lowered compliance [46] (LOE 2).

The introduction of nerve sparing hysterectomy appeared to reduce urinary and sexual dysfunctions in comparison with the standard radical hysterectomy. It was found that autonomic nerve preservation significantly improved morbidity 6 months after treatment [3-5] (LOE 3). There is however significant lack of long term observations of patients after radical hysterectomy in terms of lower urinary tract neurogenic dysfunctions.

b) Abdominoperineal resection and total mesorectal excision

Retrospective analysis of 52 patients after abdominoperineal resection was performed by Eickenberg et al. [47] (LOE 3). Neurologic bladder dysfunction of various degrees was found in 50% but represented a long-term problem in only 10%. Baumgarner et al. [48], (LOE 3) studied 86 consecutive cases of abdominoperineal resection and described 11 cases of various functional problems of micturition. These reports lack specific tests of LUT functions and are not prospective. At 1 year follow up, dysuria incidence is higher after abdominoperineal resection than after anterior resection [48] (LOE 3).

Curative total mesorectal excision with autonomic nerve preservation can be done with high rates of preservation of such function. Pocard et al. [49] (LOE 3) investigated 20 patients (13 men, 7 women) following curative total mesorectal excision with autonomic nerve preservation for rectal cancer. There was no difference in preoperative and postoperative LUT function, International Prostate Symptom Score or urodynamic results, nor in the results of the quality of urinary function questionnaire. Sexual function and potency were also unchanged in these men. The authors conclude that autonomic nerve preservation is possible and does not impair urinary and sexual function. Also Kim et al. [50] (LOE 3) showed relative safety in preserving sexual and voiding dysfunction with total mesorectal excision with pelvic autonomic nerve preservation. Evaluation was based on uroflowmetry, voided volumes and residual volume, while symptoms were evaluated with the IPSS. There were significant differences in maximum urinary flow rate and voided volume, but no differences in residual volume before and after surgery. The IPPS increased after surgery from 6.2 +/- 5.8 to 9.8 +/- 5.9 (p < 0.05).

Similar results were reported by Turaldo et al. [51] (LOE 3) evaluating incidence and pathogenesis of LUT dysfunction after surgical treatment of rectal cancer in a series of 219 patients with normal urinary function preoperatively. In the immediate follow-up, only 17 patients with dysfunction were observed, 14 stage II, 2 at stage III and 1 at stage IV according to Astler-Koller classification; six months later only 8 patients reported urinary dysfunction and 1 required catheterisation. However no urodynamic studies were performed. There was no correlation of LUT dysfunction with staging, radiotherapy, size of tumour, or surgical technique. However, worse functional results were observed in patients who underwent abdomino-perineal resection.

Lim et al. found that not only surgery but also preoperative irradiation could cause lower urinary tract and anorectal dysfunctions. The maximum resting anal pressures were unchanged after chemoradiation, but the maximum squeeze anal pressures were reduced after chemoradiation. They concluded that preoperative chemoradiation for rectal cancer carries a significant risk of pudendal neuropathy, which might contribute to the incidence of fecal incontinence after restorative proctectomy for rectal cancer [52] (LOE 3). However Lange et al. found that it is mostly the surgery, not the preoperative radiotherapy which is causing urinary dysfunction [53] (LOE 3).

Focal injury to peripheral innervation of the bladder and/or sphincter results in decentralization or denervation of the above mentioned organs. Therefore detrusor hypocontractility (acontractility) and/or sphincteric deficiency will be the result of such
damage. This in turn will result in impaired bladder emptying and/or stress incontinence. No prospective studies referring specifically to the problem of functional disturbances of the LUT in focal iatrogenic neuronal injury in patients after hysterectomy or colorectal surgery have been performed.

Iatrogenic faecal incontinence can be caused by sphincter damage caused during childbirth, and surgery for anorectal problems, trauma, fistulae and abscesses. Vaginal delivery can cause not only sphincteric, but also neuronal damage to the innervation of the anal sphincter [54] (LOE 3). There is a significant paucity of epidemiological data regarding fecal incontinence after pelvic surgery.

Anorectal reflexes and anorectal manometry may predict recovery of function [55, 56] (LOE 3). An interesting test in this specific patient population was described by Nordling et al. [57] (LOE 3). In patients after radical hysterectomy, those who had a completely denervated bladder had a greater rise in maximum urethral pressure during noradrenaline infusion (exceeding 20 cm H2O) than normal subjects (1 to 15 cm H2O). The authors concluded that urethral supersensitivity to noradrenaline may be signify damage of the sympathetic nervous innervation of the LUT.

Detailed knowledge of pelvic neuroanatomy and meticulous preparation of the structures adjacent to nerves potentially at risk is essential [58-61] (LOE 3). Nerve sparing surgery seems to have favourable effect on bladder functions and continence in patients after radical hysterectomy [61-65] (LOE3). Thus it seems that it is the nerve function, rather than the biomechanics of the urethrovaginal complex, which are responsible for incontinence. A method of intraoperative identification of the vesical branches of the pelvic nerves during radical hysterectomy was described by Kuwabara et al. [66] (LOE 3). Postoperative compliance of the detrusor in cases where this method was implemented demonstrated less decrement from preoperative values than in cases with conventional approaches. These patients required significantly fewer days to achieve residual urine volumes less than 50 ml after surgery.

Nerve sparing technique and intraoperative identification of parasympathetic nerves seem also to play a role in rectal cancer surgery. Kneist and Junginger studied 62 patients undergoing mesorectal excision. Pelvic autonomic nerve preservation (PANP) was assessed macroscopically and with the aid of intraoperative electrical stimulation of pelvic autonomic nerves. In 46 patients, preservation of parasympathetic nerves was confirmed and these patients remained unchanged in early and long-term urinary function, contrasting with patients in whom preservation of the nerves was not confirmed [67] (LOE 3).

Should injury to the nerves innervating the bladder/urethra complex occur, the treatment should be based on standard principles and on the results of functional examination of the LUT. Zanolla et al. [68] (LOE 2) suggested that early implementation of rehabilitative treatment (prompted voiding) allows satisfactory functional recovery of the bladder activity in 91% of the symptomatic patients after radical hysterectomy. Another interesting issue is the feasibility of the use of the artificial urinary sphincter to treat stress incontinence in patients with outlet denervation after colorectal surgery, hysterectomy and/or radiotherapy. Only one study on this subject was identified [69] (LOE 3), describing a series of patients after radical prostatectomy and amongst them a patient after abdominoperineal resection with adjuvant radiation. Authors concluded that this method of incontinence therapy should be the method of choice, however there is a significantly greater risk of revision (38% versus 22% in the literature for low risk groups). Bulking agents may be considered after radical hysterectomy, if no other treatment options are possible [10]. If not resulting from sphincter damage, fecal incontinence after colorectal surgery might be considered for sacral neuromodulation [70] (LOE 3).

Future research priorities include good epidemiological research, particularly prospective studies of the true incidence of peripheral injury related functional disorders of micturition. Descriptive studies of diagnostic testing and therapy are needed. A registry database of urinary and fecal incontinence may be established for insight into prevalence and preparation of guidelines on treatment/prophylaxis.

Conclusions:

- Injury to the bladder/sphincter innervation occurs in 30-50% of patients after extensive pelvic surgery (LOE 3).
- Pelvic irradiation could cause nerve damage affecting bladder/bowel functions (LOE 2).
- Fecal incontinence due to iatrogenic innervation damage could occur after complicated labor, anorectal surgery and pelvic irradiation (LOE 3).
- Focal injury results in impaired detrusor contractions and/or external urethral sphincter deficiency or detrusor/sphincter dyssynergia (LOE 3-4)
- The key means to avoid these complications are nerve sparing techniques and intraoperative nerve identification (LOE 3).

Recommendations:

- Patients after extensive pelvic surgery demonstrating functional disorders of micturition should be properly evaluated due to the varied potential underlying mechanisms (C)
• Early rehabilitation of the LUT and of the anal sphincter might improve voiding in a majority of patients (C).

• Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B).

• Autonomic nerve preservation should be considered when performing surgery for rectal cancer. Targeted voiding history before and after surgery and post-operative post-void residual urine measurements are mandatory to minimise risk of secondary detrusor damage through chronic urinary retention (B).

IX. MULTIPLE SCLEROSIS

1. EPIDEMIOLOGY

Even though there are few studies today to confirm it, the impact on the quality of life for patients with vesicourethral disorders (VST) due to multiple sclerosis (MS) is probably significant. Moreover, in a recent cross-sectional study (LOE4), Notvedt et al [1] demonstrated that those patients with VST had distinctly lower quality of life scores on the SF36 scale in comparison with the population of MS patients that is asymptomatic. The tools for evaluating quality of life that take into account VST in MS have been validated so that variations in it over the course of the illness can be measured [2-5].

VST is extremely polymorphic, and it appears in the great majority of cases within the first 6 to 10 years of the progression of the illness [6-11]. Once VST has started (2 to 10% of cases as primary symptom [7, 12-14]), they will present a more elevated risk of developing severe follow-on urological problems (LOE4) [15].

The prevalence of VST in the global population of patients who are suffering from MS is in the order of 30 to 96% [6-8, 10, 11, 13, 14, 16-32] (LOE 2b-4). The size of this interval manifests the differences linked to the type of MS, to the duration of the illness, and to the degree of handicap, as well as to a probable under-evaluation by certain practitioners of the urological problems that develop progressively and slowly.

2. URINARY DYSFUNCTION IN MS

Urinary symptomatology in MS is polymorphic and, like its incidence, probably subject to change over time. The most frequent urinary symptoms are indisputably overactive bladder (OAB) symptoms: urinary frequency (32 to 99%), urgency (32 to 85%), and urge incontinence (19 to 80 %) (LOE2b-4) [7-11, 13-15, 18-22, 24-34].

Obstructive urinary symptoms also exist to a lesser degree: difficulty of voiding and chronic or acute urinary retention. Dysuria was found in 6 to 79% of the patients, and acute episodes of urine retention were reported in 8 to 73% of the patients (LOE2b-4) [8-11, 13, 14, 18-22, 24-35].

All of these studies were carried out most frequently in a retrospective fashion or on a population of patients coming for a consultation for another reason, which can upwardly bias the estimated frequency of the disorders. There was a cross-sectional study from Marrie et al [5] (LOE4) of 16,858 patients. Of those patients, 9688 (57.5%) had responded to the two questionnaires that were posted (Bowel Control Scale (BWCS) and Urogenital Distress Inventory-6 (UDI-6)). The figures confirm the frequency of urinary disorders in the MS population: urinary frequency (28%), urgency (17%), urge incontinence (14%), and difficulty with bladder emptying (12.5%). Independent of the non-response rate, there are several elements that cause us to think that these figures are in actuality higher. Indeed, 65% of the patients complain of having at least 1 episode of urinary tract infection, and the majority of patients have not been treated or had a specific checkup. One can think of this very elevated rate of episodes, labeled “UTI", as manifesting the underlying vesicourethral disequilibrium in numerous patients.

Problems with emptying the bladder are particularly poorly evaluated by patients, with a large number of patients having a significant post-void residual amount without an evident clinical manifestation. In a cross-sectional study (LOE4) carried out in 2004, Kragt et al had also found a proportion of 16% of patients who had a post-void residual (PVR) greater than 100 ml but without any symptoms that were detected by the questionnaires that are normally used in evaluations of MS (EDSS, Guys Neurological disability Scale (GNDS)).

The estimation of the global incidence of these disorders in the body of patients with MS underlines the frequency of VST in this population. In practice, it is therefore important that the tools that are used to evaluate these problems are the most appropriate ones possible, because, all of the authors agree that the fact that VST is often ignored by the doctors who take care of these patients is due to the fact that the patients under-report their symptoms (LOE5). What is more, a certain number of the patients will suffer from uronephrological complications secondary to VST. It is therefore important to be able to isolate the groups of patients that are at risk so that complex examinations that are seen as risky are not imposed upon the entire population of patients who are suffering from MS [8, 29, 35].

In a systematic review of the literature, De Sèze et al [17] found that the duration of the progression of MS was one of the principal factors that influenced the frequency of VST (LOE 2b-4). Thus, the majority of the studies that were carried out in patients who had a duration of the progression of MS of more than...
13 years found a more homogenous frequency for the different symptoms that was in the high range in comparison with the other figures cited up until the present: urinary frequency (38.5 to 99%), urgency (44 to 85%), and urge incontinence (63 to 72%) (LOE2b-4). The frequency of obstructive disorders is likewise markedly more elevated [36-79.5%] [7-10, 14, 18, 20, 25, 28]. A second important factor that is associated with the frequency of VST is the degree of the patient’s physical handicap as estimated by the EDSS (LOE2b-4) (Expanded Disability Status Scale) [1, 8, 20, 29, 36-40]. It is difficult to confirm from these studies whether this factor has a role in itself, however, on the other hand, clinical practice indicates this common sense observation. A person who can compensate for the urgency by going to the toilet beforehand will see the appearance of urge incontinence following the appearance of a new motor or visual handicap (LOE5). The appropriate management of this problem can allow the improvement of urinary disorders without any specific action on the bladder or the sphincter. As in those patients who have medullar injuries, the clinical examination does not always allow the discovery of the specific neurological insults that are associated with VST. Certain authors have found an association between the pyramidal syndrome and irritable VST [8, 14, 20, 29]. No neurological presentation has been found that is associated in a manifest fashion with bladder voiding disorders [10, 41, 42]. No correlation between radiological insults on the central nervous system (localization and intensity) and clinical VST has actually been found [36, 43-45]. The analysis of a series of autopsies that were done on patients who had a sacral and lumbar insult (autopsy series) did not find any correlation with clinical VST [46] (LOE5).

Other associations have been indicated, but they have all been controversial. The type of progression for the MS (progressive or by crisis), the age at which MS started, and the sex, the geographical location where the patient lives, and the like do not thus appear to be associated with a more elevated frequency of VST [14, 20, 29, 36, 38-40, 47]. The age of the patient does not have impact anymore. On the other hand, older patients will have the same problems as the general population (benign prostate hyperplasia in men and stress urinary incontinence in women), and those problems will of course often be more difficult to treat than they are in the general population.

It is difficult to precisely establish mortality from uro-nephrological complications. In a recent study of the causes of death in MS patients in the U.S. that was carried out using death certificates (LOE4), a symptomatic urinary tract infection was considered as a contributing cause to the death in 8.4% of the cases, which made it one of the principal causes that were associated with mortality [48]. In that study, terminal renal insufficiency was not found to be a notable cause of mortality.

a) Infectious complications

The reported frequency of lower urinary tract infections is elevated in the literature, ranging from 13 to 80% [17] [7, 9, 10, 18, 21, 25, 29, 30, 38, 49-52] after at least 10 years of progression of the illness. In the study by Marrie al, 64.6% of the patients indicated at least one annual episode of urinary tract infection. The diagnoses of symptomatic urinary tract infection is therefore very difficult in those patients who have a neurogenic bladder. Indeed, in close to half of these cases the symptoms that are related to neurogenic detrusor overactivity will be complicated by a lower urinary tract infection, as has been well demonstrated by Lisenmeyer et al (LOE 3c) in spinal cord injury patients (SCI) [53]. There is also an incompressible rate of asymptomatic bacteriuria in many neurological patients [54] (LOE4). The occurrence of febrile urinary tract infection (pyelonephritis, orchitis, or prostatitis) is estimated to be between 2 and 23% (9% on average). In addition to the risk of mortality from certain of these infections that has already been underlined, several retrospective studies (LOE5) report an aggravation of MS following an episode of this type [1, 55, 56]. Neurogenic detrusor overactivity is probably a significant factor in the occurrence of upper urinary tract infections. Game et al [57] have also reported a prospective open study in which the injection of botulinum toxin in the detrusor in patients with MS had allowed a significant reduction of symptomatic urinary tract infections to be observed (LOE3c).

b) Alterations of the bladder

Morphological alterations of the trabeculation, thickening of the bladder wall, and diverticula were found in 4 to 75% of cases according to the series (30% on average) [9, 10, 14, 19, 21, 25, 27-31, 34, 38, 49, 50, 52, 58, 59]. These alterations did not have pathological consequences that were different from those that are found in the general population (primarily increased risk of symptomatic urinary tract infections). The exact proportion of vesical calculus is difficult to estimate, because the majority of studies do not indicate the precise site of calculi events. It can be estimated to be in the neighborhood of 5%. Several factors are associated with the discovery of morphological alterations of the lower tract: post void residual greater than 100 ml and a progression of MS of more than 10 years in duration [19, 60]. There is no correlation between VST and the morphological anomalies that were found [14].

c) Bladder cancer

The data on the more elevated risk of a vesical tumor in patients with MS are controversial. Indeed, it is known that those patients who have a neurogenic bladder have had a more elevated risk of developing a particular bladder tumor: epidermoid carcinoma (LOE2b-4) [61-64]. There are other factors that increase this risk in theory, such as tobacco use, indwelling urinary catheters, untreated vesical calculi,
and chronic urinary tract infection. In patients with MS, the use of treatment by cyclophosphamide can be an additional risk. The risk is even further elevated in those patients who have an indwelling urinary catheter or who have been exposed to tobacco. The risk of bladder cancer appears to be slightly increased in those patients who suffer from MS, as a result of risk factors related to their neurogenic bladder as well as from medullar trauma: indwelling urinary catheter, vesicular calculi, and chronic infections. There are other factors that increase this risk in theory, such as tobacco use and treatment with cyclophosphamide. The several studies that have specifically analyzed the risk of vesical tumor in patients with MS (LOE4-5) allow its incidence to be estimated at around 0.29%, which is two to three times higher than the incidence in the general population [23, 65-67]. The diagnoses of these cancers is particularly difficult in neurological patients, especially if they have been catheterized, because the usual diagnostic tools (cystoscopy, cytology, and BTA test) may not be as accurate as usual because of the inflammatory change of the bladder [63].

d) Complications of the upper urinary tract

Renal calculi were found in 2-10% of the cases, hydronephrosis was found in 1 to 16% of the cases, and vesicoureteral reflux was found in 2 to 15% of the cases (LOE 2b-4) [9, 10, 14, 18, 21, 25, 27-31, 34, 38, 49, 50, 52, 59]. Contrary to the case in medullar traumatization and in spina bifida, the incidence of terminal renal insufficiency is rare in patients with MS, and does not appear to be greater than what it is in the general population [68]. On the other hand, a certain degree of renal insufficiency is indicated in certain articles, and may be as high as 2 to 3% in those patients whose illness has progressed for more than 10 years [19, 25, 27].

e) Risk factors in urological complications

As we have specified previously, the great heterogeneity of the clinical signs of VST in MS leads to delayed diagnosis of urological complications. Simple clinical surveillance therefore exposes one to the risk of overlooking a complication that could significantly increase the risk of urinary tract infection, such as post micturition residue (LOE4) [42]. De Sèze et al [17] looked at data based on the literature in an attempt to discern the principal risk factors for urological complications. Those results must be considered with prudence, because the majority of the studies that were used in that analysis were retrospective (LOE4). The duration of the progress of MS is the principal risk factor, with an increase in the frequency of disorders appearing after 6 to 8 years of progression of the illness. These data are consistent with two cross-sectional studies (LOE4) that report a duration of the progress of MS that is significantly more elevated in those patients who have alterations of the upper urinary tract [9, 49]. The second significant risk factor (especially infectious) is the method of urinary drainage. The indwelling catheter (LOE2b-4) [9, 25] has been associated with a number of known infectious complications [69]. The utilization of suprapubic catheters was associated with a reduced risk (LOE3c) [70, 71], however, the series that was published was mid-term (5 to 6 years) and not long term follow up. If one relies on the data that is available for the treatment of patients with SCI, then the best urinary drainage methods are intermittent catheterizations and voluntary voiding (when it can be done without residue) (LOE2) [72].

The third classic risk factor, independent of diagnosis with MS, is the occurrence of post void residual, which is associated with a more elevated risk of urinary tract infection, of vesicular calculus, and, over time, of the distention of the upper urinary tract.

The other risk factors, suggested by many authors, are more rarely reported and do not allow for a group analysis. The urodynamics risk factors will be addressed in the following chapter. The progression of MS and the patient’s sex are not associated with particular alterations of the upper urinary tract. Men were more disposed to have febrile urinary tract infections (LOE4) [8, 9, 25, 35]. Older patients were more susceptible to presentation with urological complications, due on the one hand to the occurrence of urological pathologies at their age, but also probably due to the longer progression since the start of MS [17]. The same factor could explain the data of certain authors who report more frequent urological complications in those patients who have a more severe handicap (LOE4) [9, 14, 15, 51].

f) The role of urodynamics in multiple sclerosis

The clinical manifestation of vesicosphincteric disorder in MS is heterogeneous, and urodynamic examination is indicated in two situations. The first is in cases in which the patient requests treatment for urinary symptoms that bother him or her. The purpose of the examination is to understand the vesicosphincteric disorder that is causing the clinical symptom and to propose an appropriate treatment. The second situation is one in which the patient is considered at risk and for whom a search for additional urodynamic risk factors is to be carried out.

With urodynamic examination before the treatment of urinary symptoms, the most frequently found anomaly is detrusor overactivity, which is found in 34 to 99% of cases. It is defined by the presence of detrusor contractions outside of the bladder filling phase. The second anomaly was detrusor underactivity, which was found in 5 to 37% of the cases [6, 9-11, 18, 20, 22, 24-26, 28-30, 32-36, 38, 50, 52, 59, 73, 74]. In those patients who have urinary symptoms, a normal cystomanometry was found in at the most 30% of the cases [21, 25, 33].
Regarding the sphincter, vesicosphincteric dyssynergia (VSD) was found in 6 to 82% of the cases (35% on average). It is defined by the absence of relaxation or by the reinforcement of the electrical activity of the external sphincter during vesicular contraction for micturition, and is the object of needle electromyography of the anal sphincter [58, 75]. VSD is associated indifferently with detrusor overactivity or detrusor underactivity, although the association of detrusor overactivity with VSD (43 to 80% of cases [7, 18, 34, 50, 51]) is more frequent than that of detrusor underactivity with VSD (less than 10% [9, 73]). OAB syndrome seems to more often be the result of DO, especially urgency incontinence [20, 52] (one of the incontinence risk factors that was found was the female sex and the existence of low closure pressure [25]). Obstructive VST was as often associated with DO as it was with detrusor underactivity, and there is also often an associated VSD [10, 20]. VSD does not appear to correlate to the type of urinary symptom [20].

The urodynamic presentations progress through time in a manner that cannot be predicted, especially from the detrusor component. However, VSD, when it is demonstrated in a patient, most often persists without change [26, 59, 73, 76].

The role of the urodynamic examination (UDE) in a patient who is considered at risk for urological complications is much more debated. Certainly, UDE is indicated because of the association of certain UDE anomalies with the possible occurrence of urological complications. The purpose of UDE is therefore the exclusion of an area of risk for the occurrence of complications. Even though this approach is today the most agreed upon, it is useful here to remember that, at least in the case of MS, it has never been evaluated in a strict fashion as part of a prospective protocol. This is explained in part by the fact that sometimes many years will pass before the urological complications occur, which makes the task of evaluation very difficult. The adversaries of proceeding in this fashion propose a more pragmatic approach, with regular surveillance of simple criteria (post micturition residue, renal echography) and they propose a therapeutic approach only in those patients who present with a complication. This approach has the advantage of simplicity for the patient and for the doctor. The theoretical risk is that of the late diagnoses of a future complication (indeed, close to 50% of asymptomatic patients have urodynamic anomalies (LOE4)) [21] and of having to therefore propose a therapy to the patient that is more intensive than what could have been proposed had an earlier diagnosis been made.

The three elements of UDE that were strongly associated with urological complications were detrusor overactivity, bladder compliance failure, and VSD [9, 77]. The relationship between DO, bladder compliance failure, and the alteration of the upper urinary tract are classic in neurogenic bladders. The advent of the use of intradetrusor botulinum toxin reinforced the notion of causality between an elevated intravesical pressure regime and the risk of alteration of the upper urinary tract, because certain authors indicated a disappearance of vesicorenal reflux after injection of botulinum toxin, at which time the intravesical pressure regime normalized [57]. The relationship between urological complications and VSD is more debated [15, 29, 35]. The practical difficulties of researching this anomaly, the invasive nature of the electromyogram that is necessary for confirmation, and the absence of targeted therapeutic efficacy for VSD restrict this systematic search.

3. COLORECTAL DYSFUNCTION IN MS

a) Epidemiology

Digestive disorders are very frequent in patients who have MS, and, like the urinary disorders that are to blame, when they are significant they have a significant impact on patients’ quality of life (LOE4) [1, 5, 78]. What is more, the patients seem to tend to be ashamed of these problems and seldom report them. Clinicians have few tools at their disposal for evaluating this impairment. Consequently, digestive disorders are often undetected (LOE3-4) [27, 34].

Taking into account the great diversity of definitions in the several studies that are concerned with this problem, one is obliged to regroup the digestive symptoms into two large groups: those symptoms that can be defined as “retentive”, including abdominal pain, flatulence, and constipation on the one hand, and those symptoms that can be defined as “irritant”, including false urge to defecate, diarrhea, and/or incontinence of stool and/or gas on the other hand. Digestive disorders of both types were found in 45 to 68% of the cases (LOE 4) [27, 78-82]. The frequency of the “retentive” symptoms was clearly the more elevated, ranging from 31% to 54% [27, 78-82]. The frequency of the irritant symptoms ranged from 6 to 20% [27, 78-82]. The authors who had sought to flush out the more exceptional episodes of incontinence found a frequency of at least one episode of that type in the months that preceded the interview in 29 to 30% of the cases [27, 79]. Finally, a proportion of about 20% of the symptomatic patients had a combination of irritant and retentive disorders [27, 78-82]. The figures were clearly more significant than in the general population, where the “retentive” disorders have a frequency that is estimated to be around 2 to 20% and the “irritant” disorders have a frequency of 2% [83].

Risk factors for digestive disorders in MS have not been identified, to enable [27, 78-82]. Similarly, the duration of the progress of MS does not appear to be a factor that influences the frequency of digestive disorders. The factor that seems to be the most important is the estimated degree of disability (LOE3c-4) [82, 84]. Thus, Munteis et al. [84] found in
a case control study (LOE 3c) a frequency of digestive disorders that exceeded 21.2% if the patients had an EDSS between 0 and 1. This frequency exceeded 78% in those patients who had an EDSS that was greater than 4.5. Other risk factors were suggested (LOE4), but they seemed to have an influence that was less clear, such as female gender, the existence of related urinary disorders, age, and taking anticholinergic treatments [27, 78-82, 84].

b) Pathophysiology of MS-related digestive disorders

Few studies have been carried out specifically in patients who have multiple sclerosis. One of the difficulties is the frequent existence of related treatments that can themselves bring about the specific symptoms. The colic transit times can be extended or shortened in those patients who present with digestive disorders [85-87]. Several anorectal manometry anomalies were in evidence: reduced tone and compliance, a reduced sensation of filling and incoordination of the external anal sphincter during expulsion, with an onset of the phenomenon known as paradoxical anal sphincter contraction. In patients with faecal incontinence, a decrease in anal canal pressures and hyper-reactivity of the rectal wall have been shown manometrically. In the most recent of these studies, Munteis et al [84] has found that the anomalies that are found the most often are those of maximal sphincter pressure, of anal inhibitory reflex (which occurred later than in the control population), and the presence of paradoxical contraction of the puborectal musculature during straining. These anomalies might be able to allow the proposal of biofeedback re-education in affected patients. However, at present the benefit of this approach has not yet been proven.

X. SPINAL CORD LESIONS

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Spinal cord injury (SCI) including cauda equina injury usually causes impairments of urinary functions such as urinary incontinence (UI) and/or difficulty in urination. Studies on prevalence of bladder management in chronic SCI persons [1-3] (see Table 19) and one study in patients with chronic cauda equina lesions [4]. About 8%-11% of chronic SCI persons had normal voiding [1,2], not different from the time after initial rehabilitation [2]; and more normal voiding in tetraplegics then paraplegics [2].

According to the study from Denmark [2], at discharge from the initial rehabilitation period of 233 traumatic SCI patients, bladder-emptying methods were as follows: 12% normal voiding, 57% suprapubic tapping, 19% abdominal pressure, 5% Crédé manoeuvre, 11% CIC, 2% SIC, 8% urethral indwelling catheter (IDC), 0.4% suprapubic catheter (SPC), 0.4% sacral-anterior-root-stimulation (SARS), and 5% use of condom-catheter or diaper. When dividing the patients by years of injury (before 1981 and after 1980), there was a decreasing trend of using suprapubic tapping (drop from over 60% to 45%), abdominal pressure (from over 20% to 15%) and Crédé manoeuvre (from over 12% to 1%) but there was an increasing trend of using CIC (rise from 0% to 26%). Over times, 37.5% to 46% of SCI persons changed their bladder-emptying management [2,3]; 28% found their bladder-emptying methods to be a problem; of these 58% were tetraplegic [2]; and the biggest bother bladder management to the subjects was in the compression or straining group (over 50% of the subjects) [1].

There was a statistically significant difference in the frequency of urinary tract infection (UTI) between the bladder management (P< 0.001) [1]; the frequency of UTI was high (about 70%) in the mixed group (65% used CIC with other methods) and the CIC group and less (less than 50%) in the groups with catheter free [1]. According to the study financed by Medicon Valley Academy and Coloplast A/S and done in Denmark, of those using CIC, 92% reported using hydrophilic-coated catheters [2] but there was no report about frequency of UTI. However there was a report of reused silicone catheter for CIC in 28 SCI men done in Thailand [5] with the average time of usage of each catheter of 3 years, 36% reported fever with cloudy urine and 64% of foul smell urine; however, where the frequency of CIC is higher, the abnormality of the urethra was lower (F; 0.05) [5].

In a large prospective cohort study, Drake et al. [4] reported the changes in bladder management method with advancing time after SCI, finding that 29% of patients with SCI for at least 20 years changed method over the 6 year period. Podnar et al [5] studied 55 patients with chronic cauda equina or conus medullaris injury: 76% of the patients reported LUT dysfunction, 70% had urinary incontinence (UI) (56% of men and 71% of women); and a post void residual (>100 ml) was found in 40% of men and 17% of women. Perianal sensation was abnormal in 96%, electromyography (EMG) of the external anal sphincter (EAS) muscle in 88%, and sacral reflex in 84% of patients; using multiple linear regression analysis, perianal sensory loss (P=0.0001) and female gender (P<0.02) had a significant positive effect on urinary incontinence score [5].

b) Pathology and disease-specific LUT problems

Pontari et al. [6] analyzed 7 bladder specimens from 6 cervical SCI patients and 1 L1 congenital myelomeningocele (MMC) and compared them with bladder specimens obtained from 8 organ transplant donors to determine whether the muscarinic receptor subtype mediating contraction alters, and found that whereas normal detrusor contrac-
tions are mediated by the M3 receptor subtype, in patients with NBD, contractions can be mediated by the M2 muscarinic receptor subtype [6]. Haferkamp et al [2006] [7] evaluated the role of neuropeptide Y in 31 patients with NDO and 7 patients with stress urinary incontinence (SUI) and concluded that the reduction of neuropeptide Y-containing nerves, inhibiting the contractile response of the detrusor, may play a role in the development and persistence of NDO in SCI patients. Oner-Iyidog˘an et al [2004] [8] found that urine 8-iso PGF2a concentrations were significantly increased in SCI with hyperreflexic group (median value 0.89 pg/mg creatinine) compared to both normal control (0.52 pg/mg creatinine) and SCI with areflexic groups (P < 0.001); and the lowest concentrations of urinary 8-iso PGF2a were observed in the areflexic group (0.22 pg/mg creatinine) [8].

According to the study of viscerosensory pathway of the lower urinary tract (LUT) by Schmid et al [2004] [9], after electrical stimulation (ES) of the posterior urethral mucosa (single square pulses of 0.2 ms, 2 to 3-fold sensory threshold, 60 mA in complete SCI patients), evoked skin sympathetic responses (SSRs) of the hand could be recorded in 14 of 15 sensory incomplete SCI patients with disturbed urethral sensation but not in 13 sensory complete SCI patients with loss of any urethral sensation. Electrically evoked urethral sensations resembled the subjective desire to void at full bladder reported by controls and patients [9].

Schmid et al [10] did a comparative study of motor evoked potentials (MEP) and evoked pressure curves (EPC) from the urethral compressive musculature (UCM) in 9 healthy persons and 33 patients with neurogenic UI (15 SCL, 14 cauda equina lesion, and 4 multiple sclerosis). In healthy subjects the central latency was 19.0 msec, the peripheral latency was 4.25 msec, and the ratio between central and peripheral latencies was 4.4. In patients with incomplete SCL, the central latency was significantly delayed (22.7 msec), whereas the peripheral responses were normal; and the ratio (5.5) was increased. Those with a complete SCL showed no UCM reaction after transcranial stimulation, whereas peripheral responses were normal. The increased ratio of 6.0 indicated a SCL. Ten patients with incomplete cauda equina lesions and UI had normal central latencies but prolonged peripheral latencies of 6.7 msec; the ratio of 3.4 indicated a lesion of the sacral caudal roots. In patients with complete cauda equina injury neither central nor peripheral responses could be evoked [10].

According to Dai and Xiao [2005] [11], the thresholds of stimulation on ventral root were 0.02 ms duration, 0.2–0.4 mA, (mean 0.3 mA+/–0.07 mA), compared with 0.2–0.4 ms duration, 1.5–3 mA (mean 2.3 mA+/–0.5 mA) for dorsal root (P<0.01) to cause evoked potentials and EMG. The continuous stimulation for about 3–5 seconds on S2 or S3 ventral root (0.02 ms, 20 Hz, and 0.4 mA) could result in bladder detrusor contraction, but the strongest bladder contraction

over 50 cm H2O was usually caused by stimulation on S3 ventral root in 7 of the 10 patients [11].

1. Urodynamic Studies

Ockrim et al [2005] [12] found that in men with SCI, cystometric variables and detrusor overactivity (DO) remained consistent over sequential studies while in those with LUT symptom of urge, a significant decrease in the number and pressure of involuntary detrusor contractions (IDCs) in consecutive cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. Chou et al [2006] [13] did a retrospective study on urodynamic studies to provide reference ranges for “normal” variability in urodynamic parameters that can be considered as “no real change” from one study to the next. Fifty consecutive individuals with SCI had 2 trials (trial 1 and trial 2) of urodynamic studies done 5 minutes apart, and the following data were collected: maximum cystometric capacity, opening pressure, maximum detrusor pressure, volume voided, and postvoid residual (see Table 20).

Generao et al [2004] [14] did a retrospective review of SCI cases with 1-year minimum follow up to determine the effect of SCI on the developing bladder and kidneys using video-urodynamics, sonograms. In 42 children (average age at injury of 5.3 years and mean follow up of 5.5 years), 40 used CIC and 37 took antispasmodics. No patient had reflux, hydronephrosis or renal scarring. Safe bladder capacity, the pressure specific volume at 40 cm water or less, was less than the expected capacity in 80%, 58% and 50% of cervical, thoracic and lumbar injured patients but 100%, 76% and 67% of the respectively groups undergoing multiple urodynamics had increasing capacity with time.

Ersoz and Akyuz [2004] [15] investigated bladder-filling sensation in 73 consecutive traumatic SCI patients to determine to examine the quality of the preserved sensation and to determine the potential for sensation-dependent bladder emptying in this patient group. Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and 38.9% of the patients with complete lesions above T11. There were statistically significant differences between three groups with respect to bladder sensation category (P<0.001). About 86% of the patients with incomplete lesions, 53% of the patients with complete lesions below T10 and 22% of those with lesions above T11 had bladder-filling sensation before Pves reached 25 cmH2O and simultaneous bladder capacity of more than 150 ml was present in 61.2, 41.2 and 22.2% of the patients in the groups, respectively. Bladder-filling sensation investigations were reliable in terms of bladder filling sensation category in 36 SCI patients who had second cystometric examination.

To quantitatively measure bladder mucosal sensory function, Ukimura et al [2004] [16] used neuroselective Current Perception Threshold (CPT) tests in 8 healthy volunteers and 38 patients with NBD. Standardized neuroselective CPT measures were obtained from the left index finger and the mucosa of the posterior bladder wall. The CPT values in the bladder could be determined using the neuroselective measures in all patients but three who had no sensory response (absence of sensation) caused by complete SCI. In the 8 patients with NDO due to incomplete supra-sacral SCI, the bladder CPT value (4.0 +/- 1.9) at 5Hz was significantly lower (P<0.01) than that in the controls (26.2 +/- 17.7). In the NBD determined to be underactive (n=11, including post pelvic surgery, post infra-sacral level SCI and diabetes patients), the higher CPT values of bladder mucosal sensory functions were found at 5Hz (p<0.05), 250Hz (p=0.07), and 2000Hz (p<0.05) compared to the controls. As described in the section diagnosis of neurogenic urinary incontinence, no fibre specificity has so far been found depending on frequency of current used or current type.

2. Detrusor (external) Sphincter Dyssynergy

Schuch et al [2005] [17] assessed types of DSD in 105 chronic SCI males and evaluated the change in the DSD pattern over time. Results showed that those with an incomplete sensory and motor SCL presented with DSD type 1 whereas those with complete sensory and motor SCI lesion had DSD type 2 to type 3. A correlation was also found between the AIS and the DSD type but not between the DSD type and the level of lesion; and at medium to long-term follow-up, a significant change was found in the DSD type [17]. Generally, presence of DSD was determined by increased wire needle EMG activity and/or by dilated bladder neck and proximal urethra during detrusor contraction, in the absence of valsalva or attempt to inhibit voiding. De et al [2005] [18] did a comparative study to explore the diagnostic congruence for DSD between needle EMG and voiding cystourethrogram (VCUG) in the neurogenic population. They found 60% agreement and 40% disagreement between EMG and VCUG for diagnosis of DSD. Binomial testing demonstrated significant disagreement (P < 0.000) in observed proportions [18]. By retrospectively analyzing clinical data consisting bladder and EAS EMG from 41 SCI individuals with NDO, Wenzel et al [2006] [19] found that the onset of bladder contractions was detected within 1 sec of the start of the EAS contraction for both synergic and dyssynergic human subjects; and they concluded that this detection could be used as a control signal to deliver inhibitory ES to arrest nascent bladder contractions and maintain continence [19].

3. Complications Related to Urethral Indwelling Catheterization (IDC)

During 2004-2006, at least three papers reporting urinary complications related to prolonged urethral IDC such as follows: the catheter balloon of a Foley catheter inserted only half-way was inflated in the urethra distal to the stricture and a long-term IDC caused urethral erosion and a severe degree of hypospadias (Vaidyanathan et al, 2004) [20]; contracted bladder followed by autonomic dysreflexia (AD), gross hematuria and extravasation of contrast media due to improper technique of voiding cystourethography (Kovindha et al, 2005) [21]; and continuously incontinent despite a catheter and low bladder compliance leading to a urinary diversion to achieve continence (Stoffel and McGuire, 2006) [22]. In chronic SCI, IDC was associated with higher mean levels of C-reactive protein (CRP) while intermittent catheterization was associated with lower levels of CRP when compared with other methods of bladder management [Frost et al, 2005] [23].

4. Vesicoureteral Reflux (VUR)

VUR seems common among SCI patients with upper motor neuron (UMN) neurogenic bladder. According to the study of Linsenmeyer et al [2004] [24], there was an association of posterior position of ureteral orifices and reflux (p = 0.004) but no differences were found with regard to bladder capacity, bladder wall compliance, or voiding pressures between the reflux group and nonreflux group.

5. Stone Formation

Linsenmeyer and Linsenmeyer [2004] [25] found that the majority of bladder stones were calcium phosphate (46.8%) or struvite (26.7%). According to the retrospective study in 32 patients with NBD, Matlaga et al [2006] [26] found renal stones were infectious in etiology in 37.5% (12 struvite/carbonate apatite) and metabolic in 62.5%. All with struvite calculi were infected with urea-splitting bacteria.

Stone formation is usually related to IDC. In 2006, there were five papers reporting on such. Ke et al. [27] found bladder calculi with a nidus of hair that could have been introduced into the bladder accidently during the cystostomy catheter replacement. According to the retrospective study of Ku et al [28], over the 17 years 28% and 15% of 140 men were diagnosed with bladder and renal stones for a total of 59 and 25 episodes, respectively; bladder stone was more common in patients injured when aged > or = 24 years than in those injured when aged <24 years (OR 2.5; 95% CI 1.1-5.7; P = 0.03); patients with complete injury had a greater risk of renal stone formation than those with incomplete injury (OR 4.1, 95% CI 1.3-12.9; P = 0.016); renal stone was more common for patients with urethral catheterization than for those voiding spontaneously (OR 5.7, 95% CI 1.3-24.6, P = 0.021) and for patients with bladder stone than for those without (OR 4.7, 1.5-15.1; P = 0.01). According to the review by Ost and Lee [29], recurrent UTI, IDC, VUR, and immobilization hypercalcuria were major risk factors for the development of urolithiasis.

According to the retrospective study of Ozawa et al [2005] [30], the incidence of bladder stone in urethral IDC was 1.11 times/100 months, cystostomy was 1.05, contemporary urethral IDC at night time only was 0.96, CIC-wet was 0.61, and CIC-dry was 0.21; and the urethral IDC group had significantly higher incidence of bladder stone than CIC-dry (p<0.05).

Linsenmeyer and Linsenmeyer [2006] [31] did a prospective cohort study by examination of IDC for encrustation at the time of removal for cystoscopy and found that 35% of 49 SCI individuals had bladder stones. Catheter encrustation was noted in 13 patients and 11 of them also had bladder stones i.e., a positive result for catheter encrustation had a positive result for bladder stones 85% of the time. Thirty-six individuals had no catheter encrustation; of these, 16% were found to have bladder stones.

6. Bacteriuria

In a retrospective study, Jayawardena and Midha [2004] [32] suggested that healthy asymptomatic
SCI patients who came for annual evaluations should not have routine urine cultures if they are at low risk for UTIs; that is, <6 WBC/HPF in the urine and/or nitrite negative [32]. Svensson et al [2004] [33] studied the occurrence of bacteriuria in SCI patients with NBD who used CIC. Of 344 cultured samples, there were 285 isolates: coagulase-negative Staphylococci (27%), Enterococci (25%), Klebsiella spp (19%), and Escherichia coli (12%); and bacteria grew at concentrations of 105-108 cfu/L, but only a few at 104 cfu/L. Levendoglu et al [2004] [34] prospectively studied in 27 SCI patients who applied CIC during the initial rehabilitation and 40 controls. E. coli was predominantly isolated from the urine and the urethral cultures of both female and male patients; there was concordance between urethra and urine cultures concerning the growth of E. coli (P=0.82); and Pseudomonas was colonized more in male patients [34]. Waites et al [2004] [35] found that among 77.1% of men with bacteriuria, uropathogens were shown in the perineum in 57.4% and in the urethra in 85.2%; differences in the occurrence of uropathogens in men with and without bacteriuria were statistically significant, and organisms were present in higher numbers in men with bacteriuria.

7. Epididymo-Orchitis and Other Complications

Over the 17-year follow-up study of Ku et al [2006] [36], of 140 male patients (24.3% complete, the average age at onset of 24.8 years old, the average time since SCI of 16.9 years), 27.9% were diagnosed with epididymo-orchitis; and in multivariate analysis, patients on CIC had a 7.0-fold higher risk (OR, 6.96; 95%CI, 1.26-38.53; P=0.026); however, a history of urethral stricture lost statistical significance (P=0.074). Nambari et al [2005] [37] reported a C4 tetraplegia man presenting with a necrotic ulceration on the ventral aspect of the penis and scrotum of 2 days duration and diagnosed with fulminant Fournier gangrene. Vaidyanathan et al [2004] [38] reported cases of a perirenal haematoma due to warfarin and a tumour like of necrotic slough and debris in the bladder.

8. Quality of Life (QoL)

Oh et al [2005] [39] conducted a prospective trial involving 132 SCI patients and 150 controls matched to age and sex to determine the psychological and social status of patients using CIC. According to health-related quality of life (HRQOL), the Medical Outcomes Study 36-Item Short-Form General Health Survey (SF-36) scores did not reveal any significant differences between the men and women in the patient group. When patients and controls were divided into two groups according to sex and age, the SF-36 scores of the patients were significantly lower than the controls across both sex and all age groups, other than the energy and vitality scale, the differences for which were not statistically significant in women and those younger than 50 years. Later Oh et al [2006] [40] used the Beck Depression Inventory (BDI) with SCI patients on CIC and control group and found that, the average total BDI scores were 20.3+/−1.0 in the patient group and 11.4+/−0.5 in the control group, respectively (P=0.001); 69.6% of 102 the patients reported severe depression; female patients had a 3.8-fold higher risk (OR 13.83; 95%CI 1.42-10.31; P=0.008) of depression than male patients; and those who were unable to perform catheterization independently had a 4.6-fold higher risk (OR 4.62; 95% CI 1.67-12.81, P=0.003) of depression than those who were able to perform self-catheterization.

c) Disease specific management

1. Urological Follow-up Practice

According to cohort studies [4, 5, 41], there was evolution of bladder management by time, outcomes and complications in both pediatric onset and adult onset SCI; treatment was modified in a substantial proportion of patients over the observation periods. Regular urodynamic follow-up is warranted for protection of the upper urinary tract (UUT) and maintenance of continence, however, urological follow-up practice varied: in Bochum, Germany, follow-up included urodynamic evaluation, sonography of the UUT and LUT, urine examination, and evaluation of renal function and treatment modifications were based on the urodynamic findings [42]; in the Spinal Injuries Units of U.K., all units performed routine upper tract screening, ranging from annually to every 3 years [43].

According to the retrospective chart review of Sepahpanah et al. [44], the 24-hour creatinine clearance (CCr) was highly variable from one evaluation to the next and the within-subject standard deviation (SD) for CCr was 25.9mL/min; for all comparisons of repeatability, variability, and reliability, serum creatinine was superior to CCr; and renal ultrasound results and post-void residuals were the major factors in changing medical management with regard to renal function preservation. To determine the accuracy of bladder stone detection by abdominal x-rays of individuals with SCI, 13/62 (20.97%) of stones found during cystoscopy were detected by the x-ray; the detection by x-ray was 33% for stones 1.0 cm to 1.49 cm, 33% for stones 1.5 cm to 1.9 cm, and 54% for stones > or = 2.0 cm; and 57% for volumes > or = 1.0 cm3 [25]. In addition, long-term SCI individual with aged 50 to 60 or more should be screened for prostate and bladder cancer [45, 46]; however, PSA cannot be used in patients with IDC and diagnosis should be based on prostatic biopsies [45].

2. Intermittent Catheterization (IC)

IC is recommended as the safest method of bladder emptying for SCI persons with NBD [47], especially for those who have sufficient hand skills or a willing caregiver to perform the catheterization [48]. Mizuno et al [2004] [49] reported a paraplegic
woman using CSIC for 27 years who had no complications and absence of UI due to underactive and normal capacity bladder. However SCI men on CIC, according to the retrospective comparative study of patients on CIC had a 7.0-fold higher risk of epididymo-orchitis [28].

3. Techniques

Previously, recommended bladder training with CIC was time-dependent, however, some experienced bladder over-distention, especially in those with polyuria that made an IC programme unmanageable [50]. Polliack et al [2005] [51] compared volume-dependent IC (VDIC) following bladder volume measurement by a portable ultrasound device in SCL patients with time-dependent IC (TDIC). After 12-30 days follow-up, the number of IC per patient per day, the time required to perform volume measurements and IC, and their total cost, were approximately 44, 49, and 46% lower in the VDIC group than in the TDIC group. UTI was found in three patients in the TDIC group and in none in the VDIC group.

4. Type of Catheter

In developed countries, there is a variety of urethral catheters available for SCI individuals.

However, in reviewing all controlled trials comparing methods of using catheters in people with neurogenic bladder dysfunction, Jamison et al [2004] [52] could not draw any conclusions regarding the use of different types of catheter. According to the multi-centre RCT of De Ridder et al [2005] [53], 57 SCI male patients completed the 12-month study; 64% of those using the SpeediCath hydrophilic-coated catheter experienced 1 or more UTIs compared to 82% of those using the uncoated polyvinyl chloride (PVC) catheter (p = 0.02); and twice as many patients in the SpeediCath group were free of UTI. According to another multi-centre study of Bjerkklund Johansen et al [2007] [54], of 378 SCL (the mean duration of IC was 4.6 yr) who completed a 12-d trial of the novel hydrophilic catheter: LoFric Primo, 55.2% of the patients were happy to continue with the novel device, which was 74% of patients using standard PVC catheters and 36% of those using prelubricated PVC (p=0.04).

In a developing country, such as Thailand, Japanese reusable silicone catheters were reused and median duration of usage for each catheter was 2 years. Electron microscopic findings of the reused catheters for 2 years revealed encrustation but no obstruction in the lumens and 20% increase in stiffness. Demographic data, urinary management and complications did not have significant relation to the abnormality of the urethrogram or UTI [21].

Ozawa et al [2005] [30] applied a contemporary (reusable) balloon catheter at night time only. After a mean follow up of 41 months, the incidence of febrile episode was as follows: CIC-wet 3.36 times/100 months, IDC 2.96, cystostomy 1.26, the contemporary catheter 0.57, and CIC-dry 0.42. The incidence of febrile episode in CIC-wet and IDC were significantly higher than in CIC-dry (p<0.05). The incidence of bladder stone was as follows: IDC 1.11 times/100 months, cystostomy 1.05, the contemporary catheter 0.96, CIC-wet 0.61, and CIC-dry 0.21.

5. Bladder Relaxants

Many SCI individuals with NDO experienced high detrusor pressure with incontinence and post-voiding residual, bladder relaxants – antimuscarinic drugs, usually are prescribed for those applying CIC as well as IDC. Tolterodine, 2 mg twice daily [55], controlled release oxybutynin (OXY-XL) [56], doubled dosage of tolterodine ER or Trospium [57] and self-selected dosages (SSD) of tolterodine and oxybutynin [55] showed reduction in degree of UI and increase in IC volumes, and cystometric capacity; but the side effect of dry mouth was differed significantly when comparing tolerodine SSD with oxybutynin SSD (P < 0.05) [55].

6. Intravesical Vanilloid Instillation

According to a review article [58], intravesical treatment options may either act on the afferent arc of the reflex such as local anaesthetics or vanilloids or on the efferent cholinergic transmission to the detrusor muscle such as intravesical oxybutynin or botulinum toxin. Clinical trials and case series done in SCI with NDO proved the efficacy of intravesical instillations of various concentrations of resiniferatoxin (RTX) by cystometric/ urodynamic parameters and degree of UI [59-64]; intravesical capsaicin (CAP) also improved in symptoms and urodynamic parameters [57,61], without a significant difference between the CAP and the RTX groups [61]. When compared RTX with injection of 300 units botulinum A-toxin diluted in 30 ml normal saline, both treatments provided significant reduction in mean catheterization and episodes of incontinence, and a significant increase in mean first involuntary detrusor contraction and in mean maximum bladder capacity at 6, 12 and 24 months after therapy; while botulinum-A toxin significantly reduced also the maximum pressure of uninhibited detrusor contractions more than RTX at all follow-up time points [59].

7. Treatment of DSD

In those using reflex voiding to empty bladder, it is recommended to attempt use of non-surgical methods – for example alpha-blocker and botulinum toxin injection into the urethral sphincter [48]. According to the study of Reitz et al [2004] [65], 12 male SCI patients with NDO and DSD received 10 mg of isosorbide dinitrate sublingually and found that nitric oxide significantly reduced external urethral sphincter pressures at rest (p < 0.05) and during dyssynergic contraction (p < 0.05); and the mean post triggering residual volume was significantly reduced (p < 0.05).
8. Prevention of UTI

According to 2 double-blinded, placebo-controlled RCTs [66, 67] studying the effectiveness of cranberry supplement (400-mg cranberry 3 times a day for 4 weeks [66] and 2 g per day for 6 months [67]), at preventing UTIs in SCI individuals with NBD, bacterial count, white blood cell (WBC) count, bacterial counts in urine, urinary pH or episodes of symptomatic UTI did not differ between the placebo and cranberry groups. According to another RCT to determine the effectiveness of methenamine hippurate (MH) (1 g twice-daily) and of cranberry (800 mg twice-daily), MH as well as cranberry did not have a significantly longer UTI-free period compared to placebo Lee et al [2007] [68]. In addition, when taking phosphorus supplementation, there was no significant change in urine pH during the 2-week period compared to when the patient was off supplementation Schlager et al [2005] [69].

9. Antibiotic Prophylaxis

Some advocated antibiotic prophylaxis for recurrent UTI [43]. To determine the safety and efficacy of a weekly oral cyclic antibiotic (WOCA) regimen consisting of the alternate administration of an antibiotic once per week over a period of at least 2 years to prevent UTI in SCI adult patients, symptomatic UTI dropped from 9.4 to 1.8 per patient-year; and no severe adverse events and no new cases of colonization with multiple drug resistant bacteria were reported [Salomon et al, 2006] [70].

10. Bladder Irrigation

Waites et al [2006] [71] conducted a randomized, double-blind comparison of twice daily bladder irrigation using 1 of 3 different solutions for 8 weeks with 30 mL of (a) sterile saline, (b) acetic acid, or (c) neomycin-polymyxin solution in community-residing persons with NBD who used IDC. Results showed that the 3 irrigants had no detectable effect on the degree of bacteriuria or pyuria; no significant development of resistance to oral antimicrobials beyond what was observed at baseline; but all groups had a significant increase in urinary pH.

11. Treatment of UTI

Bycroft et al [2004] [43] found few routinely treating asymptomatic UTI in SCI individuals using catheters; and the range of recommended duration of treatment for symptomatic UTI was 3-14 days (mean 6.3).

12. Electrical Stimulation

Lavano et al [2004] [72] reported improvement in bladder emptying and continence in 6 neuropathic patients treated with sacral nerve stimulation (SNS) and results were unchanged during the follow-up (maximum 26 months) in all except 1 patient. Kutzenberger et al [2005] [73] reported a 17-year experience with sacral deafferentation (SADF) and implantation of sacral anterior root stimulator (SARS). Of 464 paraplegics receiving a SADF-SARS, complete deafferentation was successful in 94.1% and continence was achieved in 83%. With a mean follow-up of 6.6 years, 420 out of 440 paraplegics used the SARS for voiding (frequency 4.7 per day) and 401 used it for defecation (frequency 4.9 per week); UTI declined from 6.3 per year preoperatively to 1.2 per year postoperatively and kidney function presented stable. Hansen et al [2005] [74] applied automatic event driven ES of the dorsal penile/clitoral nerve triggered by Pdet exceed 10 cmH2O and reported during stimulated filling Pdet never exceeded 55 cm H2O and an average bladder capacity increase of 53% was achieved in suprasacral SCI patients.

d) Guidance for further research:

Most of the papers relating to epidemiology and pathology of urinary incontinence in spinal cord lesion patients were case series; and few papers were clinical trials or RCTs relating to pharmaceutical treatments. As UTI is a common complication among SCI individuals, further RCT to prove whether a weekly oral cyclic antibiotic for UTI prophylaxis as well as optimal dosage, effectiveness and safety of bladder relaxants including drugs for blocking nerves innervating bladder is beneficial in SCI with NBD should be done. Regarding types of catheter, RCT should be conducted to prove whether to reuse catheters is safe. In addition, to make an automatic, event driven electrical stimulation for the treatment of NDO suitable in a clinical setting further investigations are needed.

Conclusions:

- The profile of muscarinic receptors in the bladder may be altered in patients with neurological disease (LOE 3).
- Skin sympathetic responses and motor evoked potentials may help assess autonomic and somatomotor pathways of the lower urinary tract. (LOE 3).
- In patients with neurological disease, individuals often change their method of bladder management, influenced by a range of factors including renal function. (LOE 2)
- Long-term urethral indwelling catheterization leads to bladder and urethral complications (LOE 3).
- Encrustation of a catheter is predictive of bladder stones; abdominal x-ray is not an adequate method to detect bladder stones (LOE 3).
- Volume-dependent intermittent catheterization may offer advantages compared with time-dependent intermittent catheterization. (LOE 3)
- Combined clean intermittent catheterization during the day time with indwelling contemporary balloon catheter at night time showed less
• Increased dosage of Tolterodine or Trospium gave a better effect to control neurogenic detrusor overactivity with incontinence. (LOE 2)

• Urethral flora may be a bacterial source for the development of urinary infection. (LOE 3)

• Low bacterial concentrations in the urine (<10^5 cfu/L) of patients on intermittent catheterization might be due to contamination. (LOE 3)

• Cranberry extract, methenamine hippurate or phosphorus supplements were not found to be effective in acidifying urine or preventing urinary tract infection. (LOE 2)

• A weekly oral cyclic antibiotic seemed efficacious in preventing UTI. (LOE 3)

• Bladder irrigation was not effective in reducing bacteriuria in persons with neurogenic bladder using indwelling catheterization. (LOE 2)

Recommendations:

• Regular urological monitoring, at least annually, is appropriate to early detect complications and to adjust bladder management in patients with neurogenic bladder dysfunction. (A/B)

• Recommend urine culture only there is high risk of urinary tract infection. (C)

• Routinely inspect catheters for encrustation, as an early indicator of risk of bladder stone formation. (C)

• Cystoscopy is necessary if bladder stones are suspected. (C)

2. FAECAL INCONTINENCE

a) Epidemiology and prevalence

[According to Dvorak et al, 2006] [75], in patients with central cord syndrome, bowel and bladder continence was reported by 81% in those with American Spinal Injury Association (ASIA) motor score improvement from a mean of 58.7 at injury to a mean of 92.3 at follow-up. However, neurogenic bowel dysfunction (NBoD) is common among spinal cord injury (SCI) patients (Table 21). From 2004 to 2007, there were 6 studies reporting epidemiology of NBoD in chronic spinal cord injured (SCI), from various countries [76-80] (more details see section D1 in this chapter). Apart from SCI [2-6], there were other spinal cord lesions (SCL) that causes NBoD such as tumors (e.g. a conus medullaris ependymoma and filum terminale lipoma [81]; a clear cell meningioma along the thoracic and lumbar levels [82], neuroblastoma [83]); venous congestive myelopathy, mostly at thoracolumbar and/or conus medullaris levels [84]; transverse myelitis [85]; and iatrogenic [86, 87]. Tanaka et al [2006] [85] 77% of 22 transverse myelitis (average age at onset 8.8 years, mean follow-up 7.1 years) had NBoD.

b) Pathology and disease specific lower gastrointestinal (LGIT) problems

According to electromyography (EMG) of external anal sphincter (EAS), 18 and 22 of 64 patients with cauda equina or conus medullaris lesions had bilateral and unilateral EMG abnormalities [88]. Using anorectal manometry, the maximum anal resting pressure of a 26-lumbosacral SCI patients group with mixed symptoms of constipation and/or FI was slightly lower than that of a 13-normal volunteers control group [89]. During defecation, 88.5% of the patients but 7.7% of the control group significantly showed pelvic floor dysfunction (PFD). Rectoanal inhibitory reflex (RAIR) was identified in both groups. The rectal volume for sustained relaxation of the anal sphincter tone in lumbosacral SCI patients group was significantly higher than the control group. The mean rectal volume to generate the first sensation was significantly higher in SCI patients than in the control group. Regarding constipation, its association with level of injury was supported by many studies, i.e. upper motor neuron vs lower motor neuron NBoD. Decreased colonic pressure activity was found during sleep in SCI individuals and may contribute to delayed colon transit time after SCI [90].

Furlan and Fehlings [2006] [91] examined the characteristics of the top 100 most frequently cited articles (so-called “citation classics”) on traumatic SCI that were published between 1986 and 2003, and compared this selected professional literature with the consumers’ perspective on the key issues in SCI research. From a SCI consumers’ perspective, the areas of greatest interest included motor function, bowel and bladder control, sexual function, and pain. Motor function was the leading topic in the matching list between professional literature and consumers’ perspective. According to Anderson’s quality of life (QOL) survey of the SCI population [2004] [92], regaining arm and hand function was most important to quadriplegics, whereas regaining sexual function was the highest priority for paraplegics; and improving bladder and bowel function was of shared importance to both injury groups. Later, according to a web-based survey of 286 SCI population aged 18 years or older completed the survey, results showed that bladder and bowel concerns during sexual activity were not strong enough to deter the majority of the population from engaging in sexual activity [93]; however, bladder and/or bowel incontinence during sexual activity was a highly significant concern in women with SCI. In addition, the occurrence of autonomic dysreflexia (AD) during typical bladder or bowel care was a significant variable predicting the occurrence and distress of AD during sexual activity [94].

FI had 10 times more impact on QOL than those with no FI and NBoD had significant impact on their QOL [95]. They had significantly lower Gastrointestinal QOL score as compared with the normal persons [96]. There were no statistically significant differences in satisfaction or QOL between those with colostomies and those with traditional bowel care programs; however, 55.7% of those with colostomies and 41.7% of those without colostomies were very unsatisfied with their bowel care program [97].

c) Conservative bowel management

According to the “Neurogenic Bowel Management in Adults with Spinal Cord Injury” Clinical Practice Guideline published by the Consortium for Spinal Cord Medicine [98], rectal stimulations help assist elimination of the stool: mechanical stimulations – digital rectal stimulation (DRS) and manual evacuation; and chemical stimulations – suppository and mini-enema (liquid suppository). Korsten et al. [99] used a manometric catheter to assess colonic motility at baseline, during DRS, and after DRS and evacuation of barium oatmeal paste in six subjects with SCI; and results showed that manometric changes in response to DRS were accompanied by expulsion of barium oatmeal paste in every subject by the fifth DRS. In patients with cervical SCI, a significant increase in systolic blood pressure (BP) was induced by insertion of rectal medications and persisted during additional DRS, and the manual removal of stool induced AD were reported; however, systolic BP recovered to pre-program values within 5 min after defecation[100].

Uchikawa et al. [101] reported a successful bowel movement in 75% of 20 SCI patients by using a modified washing toilet seat equipped with a camera monitor and an electronic bidet to facilitate precise hitting of the anal area with water streams to stimulate bowel movement for a maximum of 30 minutes. Regarding transanal irrigation, it showed improvement in constipation, FI and symptom-related QOL in SCI individuals [102].

Push up, abdominal massage and a forward-leaning position may aid evacuation by increasing abdominal pressure [98]. Ayaş et al. [103] studied in patients with SCI and showed that abdominal massage gave positive effects – increase in frequency of defecation per week, decrease in total colonic transit time and lesser FI. As contraction of the abdominal wall musculature plays a role in normal defecation, Korsten et al. [104] assessed whether an abdominal belt with implanted electrodes would improve difficulty with evacuation in SCI individuals and demonstrated that neuromuscular stimulation of the abdominal wall improved defecation function, including time to first stool and total bowel care time.

Oral medications to enhance bowel movement have been used, but evidence of efficacy is lacking. Cisapride does not seem to have clinically useful effects in people with SCI [104]. Korsten et al. [105] did a randomized, blinded design, to test the efficacy of neostigmine in SCI persons with defecation difficulty by infusing one of three intravenous infusates (normal saline, 2 mg neostigmine, or 2 mg.
neostigmine + 0.4 mg glycopyrrolate – to prevent neostigmine’s muscarinic effects) on separate days and determining on bowel evacuation of the barium paste, heart rate and airway resistance; and results indicated that both neostigmine and neostigmine + glycopyrrolate resulted in prompt bowel evacuation. Studies have shown that neostigmine + glycopyrrolate intravenous administration is safe and well tolerated in persons with chronic SCI [105, 106] and studies have been under way to assess the efficacy of neostigmine by other routes [106].

d) Guidance for further research

Most of the studies reported were case series and used different definitions of faecal incontinence and constipation. Therefore further researches should base on internationally acceptable definitions so that they can be compared. In addition, RCTs on rectal or anal stimulations both mechanical and chemical as well as medications promoting bowel movement are needed.

Conclusions:

- Constipation is more common than faecal incontinence among people with established SCI (LOE 3).
- Constipation is more common in those with preserved sacral reflexes, whereas faecal incontinence is more common in those without sacral reflexes. (LOE 3)
- Faecal incontinence has impact on the QOL of SCI individual and is a substantial concern for women with SCI during sexual activity. (LOE 3)
- Digital rectal stimulations aid bowel evacuation in individuals with SCI, in part by increasing left-side colonic motility. (LOE 3)
- Transanal irrigation with water improves constipation and quality of life in individuals with SCI. (LOE 2)
- Abdominal massage may be effective in enhancing bowel movement and defecation. (LOE 3)
- Anal stimulation by water stream may be effective in stimulating bowel movement and shortening bowel care time. (LOE)

Recommendations:

- Encourage adherence to the clinical practice guidelines on neurogenic bowel management in adults with spinal cord injury (A).
- Apply mechanical stimulation e.g. digital rectal stimulation, to aid bowel evacuation especially in those with preserved sacral reflexes (B).
- Use chemical stimulants when mechanical stimulation fails (C).

- Beware of autonomic dysreflexia during bowel care, especially in those with a high SCI lesion (C).
- Consider transanal irrigation with water for those with severe chronic constipation and faecal impaction (B).

XI. MYELOMENINGOCOELE

The following text describes the literature relating to adult patients.

1. URINARY INCONTINENCE

Myelomeningocele (spina bifida) is one of the most common birth defects of the spine and brain. It occurs in 1-2 births per 1000, potentially involving all levels of the spinal column (lumbar 26%, lumbosacral 47%, sacral 20%, thoracic 5% and cervical spine 2%). Associated Arnold–Chiari malformation is seen in 85% of children, often requiring ventriculoperitoneal shunting of cerebrospinal fluid. Ingestion of folic acid prior to conception and during the first trimester of pregnancy has significantly reduced the incidence of this problem and other associated neural tube defects. The neurologic defect produced is quite variable and cannot be totally predicted by the vertebral level of the lesion. Additionally the fibrosis associated with myelomeningocele closure, may tether the cord. Subsequent growth of the infant or child will produce further neurologic problems, manifesting as changes in bladder, bowel and lower extremity function.

The incidence of urethrovesical dysfunction in myelomeningocele is not absolutely known, but most studies suggest it is very high (>90%). Similarly, ano-rectal dysfunction is very common, but its exact incidence has not been reported. Congenital neurologic bladder dysfunction with spina bifida and sacral dysgenesis that manifested itself only at middle age in a 48-year-old male is reported by Kaneoya et al. (LOE4) [1]. Yamamura et al. reviewed the literature of tethered cord of adult onset and found 56 cases published (LOE 3) [2].

The two major consequences of the vesicourethral dysfunction are urinary incontinence and hydronephrosis which can occur early or later in life. There are many studies documenting the urodynamic characteristics of the vesicourethral unit in myelomeningocele patients but almost all in children. Almodhen and colleagues examined myelomeningocele patients in postpubertal age and correlated these findings with upper urinary tract changes [3] (LOE 3). Of the 26 patients with urinary incontinence before puberty, 12 achieved continence following puberty. Hydronephrosis remained stable in 4 patients, improved in 3 and was new onset in 3, whilst vesicoureteral reflux persisted in 1 patient, resolved in 4 and was new onset in 1. Regarding the urodynamic findings in patients...
achieving urinary continence following puberty, total
cystometric bladder capacity increased significantly
and maximum detrusor pressure and detrusor leak
point pressure showed insignificant changes. Con-
servative treatment is thus a viable option for some
myelomeningocele patients, and with current treat-
ment modalities including IC, significant upper tract
deterioration is rare after puberty.

In the past, much attention has been directed at the
significance of dyssynergia between the external
sphincter and the bladder, and the associated dete-
rioration of the upper renal tracts in these patients.
With the increasing use of IC, more emphasis has
been placed on the pressure the bladder is able to
generate prior to leaking as a prognostic factor in
predicting upper tract deterioration.

Urodymanics is the cornerstone in the diagnosis of
vesicourethral dysfunction in myelomeningocele.
Urodynamic findings may predict the patients at risk
of upper tract deterioration. Controversy continues
as when to initiate these studies, either as soon as
possible after back closure, at the first sign of upper
tract changes, or before considering management
of incontinence. Studies supporting each position
have been reported, although the preponderance of
evidence suggests earlier diagnosis of potentially
unfavourable factors is advisable. Taskinen et al. [4]
examined 30 patients with anorectal anomalies. All
patients underwent spinal magnetic resonance imag-
ing and urodynamic investigation. Major lumbosacral
abnormalities were detected in 57% of patients, in-
cluding 13, 4 and 3 with a tethered cord, syringomy-
elia and caudal regression, respectively. Significant
dysfunction of the LUT in 57% of the cases involved
DO in 11, DSD in 4, distended bladder in 4 and lazy
bladder in 1. When the spinal cord was normal, 54%
of the patients had abnormal urodynamic findings but
when the spinal cord was abnormal, 59% had abnor-
amal urodymanics. When the bony spine was normal,
33% of the patients had an abnormal spinal cord but
when the bony spine was abnormal, 69% had an ab-
normal spinal cord (LOE3).

As hydronephrosis and vesico-ureteric reflux are
a consequence of detrusor dysfunction, synchro-
nous fluoroscopic evaluation of the urinary tract
is advisable at the time of urodymanics. Similarly,
renal ultrasound has become an invaluable routine
serial evaluation in these patients, assessing renal
growth, development of scarring and, most impor-
tantly, hydroureteronephrosis. Repeat urodymanics
and ultrasound may have a role in this patient
population, however recommendations for timing
and frequency of these studies still need to be elu-
cidated. Although renal scans are routinely used,
especially in the myelomeningocele patient with hy-
dronephrosis, the exact role of this study in these
patients is not clear.

Urologic treatment depends on the age of the patient
and the nature of the vesico-urethral dysfunction as
categorized by urodymanics. In a retrospective
study, urinary sepsis accounted for the majority of admissions (62%), while 38 of 62 patients required
60 surgical procedures [5]. Targeting the primary
urological abnormality (the dysfunctional and usually
poorly compliant bladder) allowed implementation
of effective treatments, including regular IC (52%)
in order to preserve upper renal tract function. As-
associated postural abnormalities complicated both
conservative and interventional therapies.

The mainstay of treatment is IC and antimuscarin-
ic medication. As continence is not at issue in the
neonate and infant, treatment may be postponed,
unless upper tract changes are present. Some evi-
dence exists pointing to the fact that early initia-
tion of treatment may prevent subsequent deleterious
bladder changes. Recently botulinum toxin was
suggested as a possibility to avoid invasive surgery
in these patients [6].

In adult patients who in childhood underwent blad-
der augmentation surgery, it is thought that there is
an increased risk of a development of bladder ma-
lignacies. This assumption is made on case reports
only. However a detailed analysis comparing con-
trol group with patients after ileal/colonic cystoplas-
ty revealed that there was no difference (p=0.54)
in the incidence of bladder cancer in patients with
augmentation cystoplasty vs controls [1] (LOE 2).
Screening for bladder malignancies in a myelome-
ingocele group of patients with augmented blad-
der was not shown to be cost effective [2] (LOE2).
Bruschini et al. evaluated 104 patients who were not
managed and followed-up adequately during their
childhood [7] (LOE 3). Reflux and urinary tract dam-
age were found in 30 patients, and 6 patients pre-
sented signs of upper tract damage without reflux.
The cystometry showed DO in 48% of patients, poor
compliance in 49% of patients, increased bladder
capacity in 2% and normal cystometry in 1%. Detru-
sor leak point pressure over 40 cm H2O was associ-
ated with upper urinary tract damage. Patients with
a decrease of functional bladder capacity over 33%
had more renal scars than their counterparts. Over-
all, 26 % of urological untreated myelomeningocele
patients had kidney damage.

On the other hand, work by Olsson and colleagues,
evaluated 175 Swedish myelomeningocele patients
in adult age [8] (LOE 3). IC for bladder emptying
was used by 85%, and 59% used enemas on a
regular basis because of the neurogenic bowel dys-
function. Renal dysfunction was than seen only in
1.7% of the adolescents.

Lumbar to sacral nerve re-routing was suggested to
be a viable alternative to restore voiding and bowel
movement in spina bifida patients. Recently a study
from North America demonstrated a 78% success
rate of this novel treatment modality [3] (LOE3). An-
other interesting treatment option is fetal surgery.
However recent data from an observational study of
28 patients who underwent in utero surgical myelomeningocele closure between 1997 and 2002 demonstrated that at a mean age of 9.6 years 23 used IC to manage the bladder, 24 required a bowel regimen to manage constipation and 6 underwent lower urinary tract reconstruction with enterocystoplasty and a catheterizable bladder channel. Videourodynamic performances in 14 patients at a mean age of 7.4 years revealed decreased bladder capacity in 71%, DO in 35% and increased detrusor pressure in 25% [4]. Management of incontinence and/or upper tract deterioration mirrors the treatment of neurologic bladder dysfunction. Variations in this algorithm include the use of vescicostomy in the younger child who has failed conservative measures and has evidence of deteriorating upper tracts. External sphincterotomy has no routine place in the management of these patients and the use of the appendix vescicostomy in continent LUT reconstruction (Mitrofanoff) has become very popular. Most studies on surgical management of the myelomeningocele bladder are descriptive (LOE 4) at best.

Data from adult and paediatric surveys show renal damage to be the single most prevalent cause of morbidity and mortality; even in children, 30-40% exhibit evidence of renal damage. Additional factors such as chronic infection and stone formation will then render the kidney more vulnerable to progressive loss of renal mass and subsequent chronic renal failure. Renal transplantation is now considered the optimal treatment for end-stage renal disease in all age groups. Although more prone to complications, recent data on patients with meningomyelocele or severely abnormal LUTs demonstrate good patient and graft outcomes [9](LOE 3).

**Guidance for further research**

Further clarification of the role of fetal surgery to repair the neural tube defect is required, especially in term of prevention of damage to the lower urinary tract. Similarly the role of early intervention, conservative or surgical, is required. The timing of surgical intervention needs further study as well as better quality of life assessments and risk/benefit analyses of LUT reconstructive procedures. The development of a tissue-engineered substitute for cystoplasty and nerve re-routing is being studied. Finally, the fate of the adult myelomeningocele patient, especially those who have undergone reconstruction needs to be documented.

**Conclusions:**

- Myelomeningocele is one of the commonest birth defects (LOE 1).
- Incidence is decreased by appropriately-timed folate ingestion during pregnancy (LOE 2).
- Most patients have bladder dysfunction which can lead to incontinence and / or upper tract deterioration (LOE 3).

- The majority will derive significant benefit from conservative measures (LOE 3).

**Recommendations**

- Regular surveillance with urodynamics and renal ultrasound is mandatory from infancy. However the exact timing is not defined. One must observe the general rules for neurogenic bladder (B).
- Early initiation of conservative measures (clean intermittent catheterization, antimuscarinic medication) generally provides protection of the upper urinary tract (B).
- The role of new treatment options, for example biotechnology and nerve surgery, needs to be evaluated (C).
- Extensive surgery is reserved for failed conservative treatment (B).

**2. BOWEL PROBLEMS**

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to April 2012, looking for the keywords myelomeningocele, fecal incontinence, management.

Voluntary control of defecation requires rectal sensation, peristalsis and adequate anorectal sphincter function. Neurological defects in patients with spinal lesions may affect one or more of these components resulting in different types of defecation disorders: fecal incontinence, chronic constipation or both. Incontinence is one of the major stigmas affecting patients born with myelomeningocele [10]. Bowel dysfunction occurs in most children with spinal cord impairment from disease or injury.

Although many different regimens have been used to manage this problem, none has had universal success. Behavioural modification and laxatives failed to achieve an acceptable result because of the persistence of soiling. A small dose of laxatives alone accomplished nothing while administering a large dose to an incontinent patient only resulted in profound embarrassment [11]. Biofeedback was introduced for use in children with intact rectal sensation, but recent trials have reported less encouraging results. “Digital disimpaction” is unpleasant to perform and only succeeds in emptying the distal rectal ampulla.

Bearing in mind that none of these patients can resist the push of peristalsis, the most effective therapy is complete emptying of the colon, since it takes at least 24–48 h to refill again. This can be achieved nowadays by two ways, (A) retrograde colonic enema (RCE) using a special ballon catheter or (B) an operative procedure which allows an antegrade continence enema (ACE). In neurological fecal incontinence, standard enemas are difficult if not impossible to administer, because there is inability to retain
the enema- which flows out involuntarily through the weak anus during its instillation. Therefore a catheter-based RCE system has been developed by industry, the application of which can easily be applied either by the parents or even by children over the age of 7–8 years. Not all children tolerate this procedure, as colonic peristalsis creates pains in some of them. However the reported results are good according to Eire et al. [12]. Shandling et al. [13] reported 100% success in using the enema continence catheter in the management of his patients with spina bifida. These authors regard the RCE as one of the best conservative methods of treatment for relieving fecal incontinence originating from myelomeningocele and other neurological problems.

The impact of ACE surgery in the management of patients with myelomeningocele was analysed by Lemelle et al. [10]. 47 patients were treated with ACE, of whom 41 still used the method at a mean time of 4.1± 1.9 years after the ACE operation. With ACE, faecal incontinence was significantly improved compared with conventional management and neither retrograde rectal enema nor digital extraction were required. In most cases, ACE was performed using the appendix or the caecum. Six patients (12.8%) stopped using the ACE for various reasons, from conduit problems due to stomal stenosis or catheterization difficulties, lack of motivation or “too long time to empty the enema". ACE stoma surgery was applied before, concomitantly or after urinary incontinence surgery in 5, 27 and 10 cases respectively. Enemas were performed at most three times a week, and tap water was used in the majority of patients. Mean volume for ACE was 1.2 L (range 0.25–3.0 L). Mean enema time for colonic washout with ACE was 50 ± 19 min (range 15–90 min), however mean washout duration for ACE tended to be shorter with implantation of the conduit on the left-segment of the colon.

Casale et al. [18] were unable to find any differences in the continence rate or stomal complications between total reconstruction (ACE and continent urine stoma) or staged reconstruction. However, because of shared pathology the authors believe that most patients benefit from intervention in the gastrointestinal and genitourinary tract. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of a second major surgical procedure (LOE 3). Nevertheless, conventional treatment should be tested first, and the efficacy of RCE may be a predictor of the efficacy of ACE on bowel management. Moreover, percutaneous endoscopic insertion is fully reversible and does not present drawbacks potentially encountered with the catheterizable conduit [10]. Nevertheless, experience with the Malone procedure has proved that a suitable continent and catheterizable conduit can be obtained with an appropriate technique. In selected and motivated patients, and with the help of a specialist nurse providing close support in the postoperative period, surgical ACE procedure might be preferred according to the surgeon’s experience.

As no absolute indication has been defined for ACE, other criteria should be used to evaluate clinical outcome of bowel management, including health – related quality of life (HRQoL). The development of a disease-specific HRQoL measure for use with myelomeningocele has been proposed by Parkin et al. [20]. HRQoL assessment should be performed prospectively when ACE produce is planned and performed during pre and post-operative periods. According to Eire et al. [1998] ACE procedure and RCE can be the best options for achieving the best social integration. For wheelchair users and other selected patients, the ACE (being faster and easier) is better than the RCE, which needs some help in its use [12, 15].

Sacral neuromodulation has been described also in the therapy of these patients, but the persistence of continence control and tolerance of the patient need to be evaluated for a prolonged period of time. Sacral neuromodulation may only be successful in a small selected number of patients, in whom preserved anatomy of the sacral nerves permits placement of the electrodes on the sacral nerves [19].

Conclusions (LOE 3)

- Neurologic bowel dysfunction and bowel problems, including fecal incontinence and constipation, are prevalent among myelomeningocele patients.
- Fecal incontinence and methods of bowel care affect the QoL and social activities of myelomeningocele patients.
- The main goal is to empty the colon as much as possible, to achieve continence during the subsequent 24–48 hours. This can be achieved by retrograde colonic enema using a special balloon catheter, or by an operative procedure which allows an antegrade continence enema (ACE).

Recommendations B/C:

- colorectal problems deserve more attention in the treatment of myelomeningocele patients
- Appropriate bowel programme / management should be properly designed for each person, after adequate counselling.

XII. SYSTEMIC AND OTHER CONDITIONS

1. SYSTEMIC LUPUS ERYTHEMATOSIS

a) Urinary incontinence

Nervous system involvement occurs in about half of patients with systemic lupus erythematosus (SLE).
Neurological manifestations of systemic lupus erythematosus are subacute encephalo-myelopathy, subacute myelopathy (rarely) and chronic encephalomyelopathy. Seizures and psychiatric disorders are the most common manifestations; spinal cord lesions are uncommon. Symptoms of LUT dysfunction can occur, however data on prevalence are not available.

Sakakibara et al. (LOE 4) [1] published the findings of 6 women and 2 men, mean age 23 years, suffering from SLE for 2-25 years under immunosuppressant therapy. All 8 patients had urodynamic abnormalities: 5 had decreased urinary flow, 3 increased post-void residual urine, 2 increased maximum urethral closure pressure, 5 detrusor overactivity, and 5 impaired detrusor contractility. Detrusor-sphincter dyssynergia was found in 4 patients and abnormal motor behaviour of the external sphincter during EMG. They found DO more common in patients with brisk deep tendon reflexes (80%) than in those without (33%). Repeated studies during a follow-up period of between 2 months and 8 years showed deterioration in 3 patients including loss of bladder sensation, development of a low compliance bladder and decreased bladder capacity (LOE 4). A study by Duran-Barragan et al. demonstrated similar findings in their series of ten patients and they postulated that LUTD was predisposing the patients to recurrent UTIs [3] (LOE 4).

Yu et al. studied 152 women with SLE and found a significant relationship between central nervous system involvement and the adapted AUA index score. The most common urodynamic finding was a small cystometric bladder capacity (<150 ml; n = 7 patients), followed by a weak urinary flow rate (<12 ml/second; n = 6 patients). In 3 of 7 patients with small cystometric bladder capacities, imaging studies documented a contracted bladder with marked hydroureteronephrosis [2] (LOE 3).

Conclusions

- Half of the patients with systemic lupus erythematosus show nervous system involvement. In 30%, subacute and chronic encephalomyelopathy may cause LUT dysfunction with variable patterns, including; reduced bladder capacity, detrusor overactivity, impaired detrusor contractility, pathologic voiding pattern and increased post-void residual urine (LOE 4).

Recommendations

- The dysfunction pattern may change over time, therefore urological follow-up is recommended (C).
- Urodynamic tests are necessary to define the underlying pathophysiology of the urinary symptoms (C).
- Patients with SLE and voiding dysfunctions should be managed expectantly, according to the urodynamic results (C).

2. HERPES ZOSTER

Herpes zoster (shingles) results from reactivation of the dormant varicella-zoster virus (VZV) resulting in vesicular eruptions of the skin or mucous membranes. Two distinct syndromes due to genital varicella zoster infection, cystitis and urinary retention, have been described. Cystitis classically presents with dysuria, frequency and hematuria and cystoscopic verification of local inflammatory changes on the bladder mucosa should be performed for the diagnosis of herpetic cystitis [4] (LOE 3).

The overall incidence of LUT dysfunction is 4% [5], however involvement is reported as high as 28% if cases of lumbosacral involvement are considered. According to Chen et al., voiding dysfunction following herpes zoster can be; 1. Cystitis-associated, whereby direct involvement of the bladder wall results in herpetic cystitis, 2. Neuritis-associated, due to retrograde spread of infection by the VZV from the dorsal root ganglia of the sacral segments, or 3. Myelitis-associated, caused by herpetic myelitis. Occasionally, patients with skin rash in the lumbar or even lower thoracic dermatomes may develop bladder dysfunction and this is thought to be due to spread of VZV to the sacral segments (LOE 3).

Two case reports describe urodynamics findings in herpes-zoster patients. Usually patients develop complete urinary retention, with or without overflow incontinence due to detrusor acontractility and lack of bladder sensation. Repeat urodynamic studies at week 10 after the onset of the disease demonstrated a return of the detrusor contraction, normalising after 14 weeks [6, 7] (LOE 4).

Herpes zoster-associated voiding dysfunction is a transient phenomenon and is not uncommon in patients with lumbosacral dermatome involvement. Treatment with IC or indwelling catheter placement is recommended in order to avoid secondary damage to the LUT due to chronic urinary retention or UTIs. The disease usually is of a benign clinical course, with recovery of bladder functions.

Conclusions

- 28% of patients with Herpes zoster in the lumbosacral dermatomes show LUT dysfunction, with impaired voiding as the most common symptom (LOE 4).
- The most common symptom is overflow incontinence due to detrusor acontractility and lack of bladder sensation (LOE 4).
- Voiding dysfunction has a transient course and almost every patient will regain normal voiding within 3-4 months, or at the least achieve balanced bladder function (LOE 3).
Recommendations

- Till functional recovery takes place, urinary tract management with intermittent catheterisation or indwelling catheter is recommended ©.

3. HIV

a) Urinary incontinence

HIV virus belongs to the family of retroviruses. This family of viruses is known for latency, persistent viremia, infection of the nervous system, and weak host immune responses. HIV has high affinity for CD4 T-lymphocytes and monocytes. HIV binds to CD4 cells and becomes internalized. The virus replicates itself by generating a DNA copy by reverse transcriptase. Viral DNA becomes incorporated into the host DNA, enabling further replication. HIV enters the nervous system early, at the time of initial infection, and may immediately cause symptoms, or it may cause delayed-onset symptoms, potentially at any time during the person’s lifetime. All parts of the nervous system may be involved. Neurological disorders could be HIV-related, or due to secondary infections, malignancies, metabolic or nutritional problems and to therapy.

It is estimated that up to 80% of patients are symptomatic in terms of nervous system and for 30%, neurological symptoms are the initial clinical problem, in the absence of anti-retroviral treatment. Neurological syndromes may be the sole clinical problem or cause of death. The following brain symptoms have been described: meningitis, dementia, stroke, seizures, and degenerative disorders. For the spinal cord, transverse myelitis and progressive myelopathy have been observed.

Due to nervous system involvement in HIV infection, consequent effects on LUT function can be anticipated [8]. Shin et al. (LOE3) described a higher prevalence of incontinence in HIV-positive patients as compared to HIV-negative in nursing homes [9]. Whether this represents a true trend, or an observation related to the terminal stage of the disease and associated comorbidities, remains to be elucidated. Gytrup et al. (LOE 3) found voiding problems in 12% of HIV-infected patients, mostly in advanced stages of the disease [10].

Virtually all parts of the body could be involved in AIDS patients, either as the primary location of HIV infection or secondary to HIV-related complications. Among the different manifestations, particular attention should be paid to the primary locations as they develop early in the stage of the disease. HIV can affect all areas of the central and peripheral nervous system- for example, HIV-associated dementia, vacuolar myelopathy, distal sensory peripheral neuropathy and myopathy. Pelvic organ dysfunction has, however, been little studied. Patients may develop voiding dysfunction and chronic retention due to lumbar sacral polyradiculopathy. Prior to the introduction of the newer anti retroviral therapies in the 1990s, infection with cytomegalovirus was the most common cause [11] and other causes include lymphomatous infiltration, syphilis or a herpetic radiculopathy due to herpes varicella zoster or simplex. Mahieux et al. (LOE 3) described a case of acute myeloradiculitis due to cytomegalovirus as the initial manifestation of terminal stage HIV [12]. Matsumoto et al. (LOE 3) [13] reported a case of lumbosacral polyradiculopathy where voiding difficulties and lower limb paresis were the primary manifestation of HIV infection. Another pattern of LUT dysfunction is urgency incontinence and DSD [14] in the context of vacuolar myelopathy.

Begara et al. (LOE 3) performed urodynamic studies in 10 patients with AIDS and voiding disorders and found that the most common symptom was urgency incontinence and the most common urodynamic finding was DSD [15]. In 3 patients they found demonstrable functional disorders of the LUT (2 patients had DO: one of them had a history of encephalopathy from HIV and the other patient had polynuertis; the third patient had myelitis and a urodynamically-diagnosed sympathetic decentralization. Detrusor areflexia was described in 2 HIV-positive patients by Menendez et al. [16] (LOE 3). One of them had an ascending myelitis of probable herpetic origin, the other had a cerebral abscess caused by Toxoplasma gondii.

Since during the course of the disease all parts of the nervous system can be involved, either as the primary location or secondary to AIDS-related complications, no disease specific diagnosis or treatment can be proposed. It is important to observe that sometimes functional disorders of the LUT can be the first manifestation of the HIV infection. When managing the patient with HIV infection one must bear in mind that both storage and voiding problems can occur and that both should be treated according to the results of urodynamic studies.

Future research needs to be supported by a stronger evidence base. All reports of HIV and voiding problems are rather anecdotal and no good prospective studies exist. The need for such studies is particularly important, when realizing that it takes up to 20-30 years from HIV infection to AIDS full manifestation, and that new antiviral treatment modalities could prolong the life of a patient with HIV significantly. Particular attention should be paid to primary nervous system involvement by HIV and the voiding dysfunctions that could be the side effects of HIV drug therapy.

b) Faecal incontinence

As diarrhoea is common in HIV infected patients, faecal incontinence can also occur, mostly due to anal sphincter weakness. The true incidence of HIV neuropathy-related faecal incontinence is not known and further studies are needed [17] (LOE 4). Many of the limitations of knowledge seen with urinary incontinence apply to faecal incontinence.

Conclusions:

- HIV can influence the nervous system and LUT function in two ways: as a result of primary
Recommendations:

- Patients with HIV and nervous system pathological signs and symptoms should be evaluated for functional LUT problems (B).
- Due to the variety of LUT functional damage in HIV patients, dynamic evaluation of LUT function is essential for tailoring of therapy (C).
- No HIV-specific therapy of LUT problems and faecal incontinence is currently available. Due to the variety of functional damage, therapy should be individually tailored, according to the results of functional/imaging studies (C).

4. NEUROSYPHILIS

Neurosyphilis results from longstanding infection with Treponema pallidum. Bladder dysfunction is common, though most classically in tabes dorsalis. The predominant neurological manifestations are sensory ataxia and spontaneous lancinating pains. Voiding dysfunction occurs due to involvement of sacral posterior roots and the dorsal column of the spinal cord, resulting in loss of bladder sensation and significantly elevated post-void residual urine. The bladder is atonic, though there may be some myogenic damage from chronic overdistention. Some patients may demonstrate detrusor overactivity and DSD [18, 19]. The condition is rare and there is no contemporaneous epidemiological data.

5. DIABETES MELLITUS

a) Urinary incontinence

Diabetes is one of the commonest causes of polyneuropathy. Amongst different types of polyneuropathies in diabetic patients “diabetic cystopathy” occurs in 43% to 87% of insulin-dependent diabetics, with no sex or age differences. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment. A Scandinavian study showed that in patients who have had diabetes for 10 years, the prevalence of diabetic cystopathy in those who were insulin-dependent was 2 to 4 per 1000 and in those on oral hypoglycemic agents was 1 to 3 per 1000. The correlation between diabetic cystopathy and peripheral neuropathy ranged from 75% to 100%. Nephropathy was seen in 30% to 40% of cases [20] (LOE 3).

Diabetes duration, treatment type, peripheral neuropathy, and retinopathy were significantly associated with severe incontinence in multiple regression models adjusted for age, education, and history of UTI [21] (LOE 3). Lewis et al. in a cross-sectional studies of 50-90 year old women found that insulin dependent diabetes was strongly associated with urinary incontinence, while non insulin dependent diabetes was not [22] (LOE 2).

Van Poppel et al. [23] reported neuropathological examination of bladder biopsies from 14 patients with severe insulin-dependent adult-onset diabetes, compared with acetylcholinesterase and S100 staining of 38 control specimens. A decrease in acetylcholinesterase activity, due to axonal degeneration was found in all cases. An increase in S100 positivity was found in the majority and is due to Schwann cell proliferation as a regeneration attempt after demyelination or axonal degeneration. When acetylcholinesterase activity decreases and an S100 density increase is found in a patient with diabetes, this combination is highly suggestive of diabetic cystopathy amenable to early symptomatic treatment (LOE 2). Because of the uncontrolled hyperglycemia, patients with DM develop altered NGF activity, which may be a mechanistic factor in the development of diabetic bladder dysfunction [24, 25].

Since the peripheral nerves are involved, the clinical manifestations of diabetic cystopathy might be very different. Usually there is reduced sensation of bladder fullness, and decreased frequency of voiding. This is followed by slowing of the urinary stream and difficulty in voiding due to impaired detrusor contraction. Post-voiding dribbling may also occur. The impaired bladder emptying and urinary retention predispose to urinary tract infections. No prospective studies referring specifically to the problem of functional disturbances of the LUT in diabetic patients have been reported. It has been shown that urine output does not contribute significantly to diabetic cystopathy [26].

Yamaguchi et al. studied 84 diabetic cystopathy patients [27]. In addition to large post-void residual and decreased sensation, urinary urgency, DO, and increased bladder sensation were seen in 55%, 42% and 14%, respectively. The prevalence of DO in patients with increased bladder sensation was 58%. DO increased with age, but not with the duration of diabetes. A brain MRI was performed in 32 cases. The prevalence of multiple cerebral infarction in patients with DO was 76.5%. The authors concluded that urinary urgency is not uncommon in diabetic cystopathy. Both central and peripheral mechanisms are involved [28] (LOE 3).

Ishigooka et al. [29] (LOE 3) described the results of the ice-water test in diabetic patients with and without
cystopathy. 12.5% of patients without cystopathy and 25% of patients with cystopathy did not feel the ice water sensation. Ueda et al. [30] (LOE 2) performed studies evaluating sympathetic skin response in correlation with cystometry. They found that patients without sympathetic skin responses had increased residual urine and decreased detrusor contraction pressure, while patients with a lower amplitude of sympathetic skin response and more prolonged latency than controls had a significant decrease in detrusor contraction pressure. The changes within the bladder function were observed as early as within one year from the diagnosis of diabetes.

Beylot et al. [31], (LOE 2) found that the presence of residual urine in diabetic patients, after exclusion of co morbidities, was strongly associated with peripheral neuropathy. Ho et al. showed increased bladder sensation, followed by DO in 94 female diabetic patients undergoing urodynamic studies [32]. Those patients with OAB are more likely to have impaired voiding function.

No specific treatment has been described in regards to the population of patients with diabetic cystopathy. Therefore general rules as for the other bladder conditions with impaired (absent) detrusor contractions should be followed. Sacral Neuromodulation has been used to treat LUTD in DM, with similar long term results as in non DM patients [33].

Future research should endeavour to give epidemiological information on the incidence of diabetes-related functional disorders of micturition, and specific results of therapeutic interventions.

Conclusions:

- Diabetic cystopathy occurs in up to 80% of insulin dependent diabetes mellitus (LOE3).
- Urinary incontinence is strongly associated with insulin dependent diabetes, but not with insulin independent diabetes (LOE 2).
- Overactive bladder is not uncommon in diabetes, presumably reflecting both central and peripheral mechanisms (LOE 3).
- Patients with diabetic cystopathy generally can have OAB and/or impaired detrusor contractions with increased post-void residual (LOE 3,4).
- Recurrent urinary tract infections might be a long term problem (LOE 3,4).
- There is a lack of specific treatment for diabetic cystopathy.

Recommendations:

- Post void residual measurement and urine dipstick (optional culture) for patients with insulin dependent diabetes mellitus should be performed yearly (C).
- In case of increased post-void residual, prompted voiding might be useful (C/D).
- Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B/C).

b) Faecal Incontinence

Caruana et al. [34] (LOE 3) found that diabetic patients with faecal incontinence showed increased thresholds of phasic external sphincter contraction (P<0.05) and had reduced resting/ maximal voluntary anal sphincter pressures compared with controls (P< 0.05). Increased thresholds of conscious rectal sensation in some incontinent patients with diabetes may contribute to faecal incontinence by impairing the recognition of impending defecation. Nakayama et al. [35] (LOE 3) found that age and diabetes have an independent negative influence on faecal incontinence after stroke. Abnormal internal-anal-sphincter function could be contributory in diabetic patients with faecal incontinence [36] (LOE 3). Russo found that acute hyperglycaemia inhibits external anal sphincter function and decreases rectal compliance, which could explain the aetiopathogenesis of faecal incontinence [37] (LOE 3).

Talley [38] (LOE 3) studied gastro-intestinal symptoms, frequent abdominal pain, bowel-related abdominal pain, reflux, dyspepsia, constipation, diarrhea and fecal incontinence in diabetic patients. There was a clinically significant decrease in QoL scores in diabetics compared with population norms across all subscales. The impact on QoL in diabet es was predominantly observed in type 2 diabetics. For all the Short Form-36 subscales, GI symptom groups were significantly (all p < 0.0001) associated with poorer QoL in diabetes, independent of age, gender, smoking, alcohol use, and type of diabetes.

Conclusions

- Faecal incontinence in diabetes patients may be due to impaired anorectal sensation and/or decreased anal closing pressure after hyperglycemic episodes (LOE 3).
- Gastro-intestinal symptoms impact negatively on health-related QoL in diabetes mellitus (LOE 3).

Recommendations:

- Patients with diabetes and fecal incontinence should have anorectal manometry performed before introducing therapy for fecal incontinence (C/D).
- More studies on neurologic bowel dysfunction and management in diabetes are needed before giving further recommendation (B)

A. General considerations

I. INTRODUCTION

Older people have the highest known prevalence of urinary incontinence (UI) of any group, other than those with specific neurological disease (e.g., spinal cord injury). As the proportion of older people in the populations of the developed world increases, so will the absolute numbers of those with either urinary (UI) or faecal incontinence (FI) or lower urinary tract symptoms.[1] Even if improvement in physical functioning among older people continues, and research in the field is able to demonstrate continuing benefit whilst containing costs, the impact on future health care and long-term care costs will still be profound.[2] Early signals suggest however that the decrease in disability for older people observed in the last two decades of the twentieth century has not been seen in those aged 40 – 64 years[3].

No matter how one defines “older” or “elderly,” this population is characterized by its variety, ranging from active, community-dwelling, working, healthy nonagenarians to bed-bound, chronically ill, functionally- and cognitively-impaired persons in their late 60’s. Because the healthier group is closer in phenotype and physiology to middle aged than to frailer older people, information relating to the management of urinary and faecal incontinence in this group is integrated into the other ICI chapters. This chapter focuses on frailer older people, emphasizing not only the different aetiologies and treatment of UI and FI, but the additional issues of disease burden, disability, altered responses to drug therapy, the role of caregivers, and goals and organisation of care. This chapter is aimed at all those who work with the frail elderly, and is also intended to be relevant to specialists who may find standard approaches ineffective in this population.

The committee took the view that where there is a paucity of data reflecting the efficacy or utility of approaches to the treatment of UI or FI in frail older adults, interventions aimed at community dwelling, fitter older adults should be employed with due regard to the likely benefits, harms, feasibility, expectations and outcomes of treatment, rather than be denied any intervention. The pathophysiology of UI in the frail elderly requires a broader conception of “disease,” centreing on patient-level factors rather than just the bladder or bowel and its neurological control. UI and FI in frail older people is normally a result of multiple interacting risk factors, including age-related physiological changes, comorbidity, polypharmacy and common pathways between them. Furthermore, the impact of urinary or faecal incontinence in the frail elderly includes functional impairment, and extends beyond the affected individual to their caregivers, leading to caregiver stress and an increased likelihood of institutionalisation. Therefore, assessment in frail persons requires a broader scope. Failure to address the multifactorial nature of disease and treatment limits not only clinical care and research, but also important opportunities to improve function and quality of life[4]. Treatment is usually multicomponent, and must address the many associated factors and shared underlying impairments with other geriatric syndromes (for example, by combining lower extremity exercise with prompted voiding)[5]. Drug therapy must be placed in the context of altered pharmacology, polypharmacy, and an increased susceptibility to adverse effects. Effective management may also require system-level approaches, with different models of care (e.g., for institutionalised persons).

The challenge in providing a review of UI in frail older people is the relative dearth of Level 1 evidence for interventions; the frail present multiple challenges for research (not the least of which is substantial trial drop-out due to intervening illness and death) and there is still a systematic problem in including older people in clinical trials[6]. Over and above this problem is the continuing paucity of new clinical trials, despite the clear epidemiological imperative that the oldest-old are the fastest growing group of affected individuals. Intervention studies and outcomes need to be more broadly based, incorporating caregivers, a range of care settings, alternative models of care, and goals of care unique to this population[7].
II. SEARCH STRATEGIES

Overview

Given the broad range of this report, we used multiple searches using the following MESH terms (in caps) and phrases, alone and in combination, using the PubMed and Ovid search engines: AGED, AGED OVER 80, ACTIVITIES OF DAILY LIVING, DEPRESSION, elderly, FALLS, frail, FRAIL ELDERLY, FRAILTY, functional, geriatrics, LONG TERM CARE, MEDICATIONS, NURSING HOME, older, QUALITY OF LIFE, RANDOMIZED CONTROLLED TRIAL; and BLADDER, GYNAECOLOGICAL SURGICAL PROCEDURES, PELVIC FLOOR, PROSTATE, STRESS INCONTINENCE, SURGERY, URETHRA, URINARY INCONTINENCE, URINATION DISORDERS, UROGYNECOLOGY, UROLOGY, VAGINA, VOIDING DYSFUNCTION, nocturia OR nocturia OR “night-time voiding” OR “night-time voiding” OR “nocturnal voiding” OR “night-time voids” OR “night-time” OR “nocturnal voids” OR “night-time frequency” OR “nocturnal frequency” OR “night-time urination” OR “nocturnal urination” OR “nocturnal micturition” OR “night-time micturition” OR “night-time polypuria” OR “night-time polypuria” OR “nocturnal polypuria” OR nocturia) OR ((nuc tur* OR night*) AND (void* OR urination OR micturition OR polypuria OR pollakiuria OR “LUTS” OR “lower urinary tract symptoms” OR “BPH” OR “benign prostatic hyperplasia”) AND (“aged, 80 or over” OR aging OR elderly OR older OR “very old” OR senior OR “all aged” OR geriatric OR frail OR aged) AND (“double blind method” OR “double blind” OR placebo OR placebo OR “controlled clinical trial” OR “randomized controlled trial” OR “random allocation” OR “single blind method” OR “research design” OR “exp clinical trials” OR “clinical trial” OR “single blind” OR “double blind” OR “triple blind” OR “single mask” OR “double mask” OR “triple mask”) (longitudinal OR “natural history” OR cohort OR incidence OR remission OR progression OR prospective OR “community-based” OR “population-based” OR “epidemiol*” OR “follow-up”); TOLTERODINE; OXYBUTYNIN; SOLIFENACIN; PROPIVERINE; TROPIUM; IMIDAFENACIN; DARIFENACIN; FESOTERODINE; Ovid Expert Search Filter; Publication years 2004-11. We included, where possible, information from non-English language articles where an English language abstract with sufficient information was available. References in retrieved articles were reviewed for additional relevant articles. We also searched the Cochrane Database and National Guideline Clearinghouse for relevant systematic reviews, meta-analyses, and evidence-based recommendations.

III. DEFINING THE FRAIL OLDER POPULATION

1. FRAILTY

Who, then, are the frail elderly? Consistent with increasing consensus in the geriatric literature, we define “frail older persons” as those over the age of 65 with a clinical presentation or phenotype combining impaired physical activity, mobility, balance, muscle strength, motor processing, cognition, nutrition, and endurance (including feelings of fatigue and exhaustion) [8-10]. Frailty is not, however, synonymous with disability and comorbidity. In one study, among persons meeting strict phenotypic criteria for fragility, only 22% also had both comorbidity and disability, 46% had comorbidity without disability, 6% disability without comorbidity, and 27% had neither comorbidity nor disability [9]. Frail people usually have multiple chronic medical conditions, take multiple medications, require care from others and assistance to perform some or all of the personal activities of daily living (PADLs) (e.g., bathing, dressing, toileting, and mobility), are often homebound or institutionalised. They have a high risk of intercurrent disease, increased disability, hospitalisation, and death [1,8]. For example, in the US, 10% of all persons over 65 require help or supervision with at least one ADL [11] and the total prevalence of frail elders has been estimated at 6.1% [12]. From the United Kingdom Hertfordshire cohort study of men and women aged between 65-74, the prevalence of frailty was 8.5% among women and 4.1% among men [13].

Several studies suggest that the relationship between UI and frailty is not unidirectional. Incident UI in those over age 65 has been associated with a two-fold increased risk of impairment in ADLs, instrumental activities of daily living (IADLs – e.g., transportation, finances, shopping, laundry, housekeeping), and poor performance on three physical measures, suggesting that incident UI may be an early marker of the onset of frailty [12]. In a population-based study of older Mexican Americans, incident but not prevalent UI was independently associated with functional decline in ADLs, IADLs, and physical performance [14]. Another population-based study found an association between UI and IADL decline, but not ADL decline, nursing home admission, or death, after adjustment for age and comorbidity [2]. The authors suggest that the relationship between UI and adverse outcomes may be mediated by baseline illness severity and functional impairment [2]. A recent Portuguese study showed that older people who presented with either “slowness” or “exhaustion” had a risk of UI almost five times greater than those without [15].
2. IMPACT OF UI ON MORBIDITY AND INSTITUTIONALISATION

UI in frail persons can have much more severe consequences than in healthy older persons. Although one early study suggested that older persons with UI had a higher mortality risk, [16] subsequent studies that more fully adjusted for comorbidity and functional status have not found any association. [2,12, 17,18] Several multivariate studies suggest that patients with new onset UI at the time of stroke have higher rates of death or disability at 2 years (OR 4.43; 95% CI 1.76 to 11.2)[19] to 5 years (OR 3.21 [95% CI 1.04–9.91]), [20] especially if UI persists (OR 7.47 [95% CI 2.29–24.42]).[20]

Given its association with frailty, it is not surprising that UI remains a risk factor for nursing home admission, despite global variation in services and temporal changes in elder care. Studies showing a significant association between UI and institutionalisation have been done in: Finland (men [not women] with urgency UI);[21] Germany;[22] New Zealand (persons > age 65);[23] US (men more than women,[24] after hip fracture,[25] among Hispanic elderly,[14] and patients attending a dementia clinic[26]); Japan (men only)[27], and Hong Kong[28]. Two studies failed to find a significant association after controlling for comorbidity, using US[2] and Canadian databases.[29] It is estimated that the fraction of US NH admissions attributable to UI in men is 0.10 (95% CI 0.08–0.13) and in women 0.06 (95% CI 0.05–0.09).[30] The prevalence of UI at NH admission in the U.S. shows small area variation of almost 50% and differs by race,[31] suggesting that patient and caregiver factors and local resources affect the role UI plays in institutionalisation. An important methodological issue for such studies is the erroneously low prevalence of UI found in administrative long-term care databases when UI is defined by physician diagnosis in the medical record.[32, 33] Another issue, particularly in studies of institutionalisation in persons with dementia, is the failure to include UI as a risk factor [34] or defining it only by a composite function score [35]. The significant association of faecal incontinence and institutionalisation (odds ratio 1.79, 95% CI: 1.00-3.20), in one Canadian study was lost when adjusted for cognition, ADL dependence, and self-reported health[36], although a survey of US geriatricians found that the presence of faecal incontinence was more likely to result in a referral to a nursing home than not [37].

2. QUALITY OF THE DATA

The data on the aetiology of UI in the frail elderly population is limited, and observational studies of varying quality constitute much of this literature. Additionally, longitudinal studies of large numbers of frail individuals are difficult to carry out because of paucity in recruitment and the high rate of natural attrition. Despite the lack of such studies, many relatively large, careful descriptive studies and case series, as well as expert consensus processes, have made important contributions to our understanding of the aetiology of UI in this population.

3. UI AS A GERIATRIC SYNDROME

In older adults, especially those who are frail, UI is considered to be a geriatric syndrome, because many of its risk factors are not directly related to the genitourinary tract.[38, 39] Geriatric syndromes have been defined as “multifactorial health conditions that occur when the accumulated effects of impairments in multiple systems render an older person vulnerable to situational challenges”.[38] Thus, large numbers of different baseline as well as precipitating risk factors may interact with each other in influencing the ability of an older individual to remain continent in the face of common daily challenges (Figure 1). This multifactorial complexity, combined with the fact that most individual risk factors typically account for only a small proportion of the overall risk, have greatly complicated the development of a pathophysiological framework for the study of common geriatric syndromes.[38]

Nevertheless, because common risk factors (e.g. lower and upper extremity weakness, sensory and affective impairment) may be shared by different geriatric syndromes (such as UI, falls, and functional dependence) [40], they may represent particularly attractive sites for intervention development.[38] For example, as proposed by Kuo and Lipsitz,[41] the presence of brain white matter hyperdensities within critical periventricular and subcortical regions could represent key risk factors for the development of different geriatric syndromes such as falls, impairment in executive cognitive function, depressive symptoms, and UI. In fact, recent functional magnetic resonance imaging (fMRI) studies have begun to identify central nervous system areas that are particularly relevant to urgency [42-44]. Therefore, failure of activation within orbitofrontal regions may contribute to an older individuals’ decreased ability to suppress urgency [44]. Connectivity pathways within the right insula and anterior cingulate gyrus may also play a role in maintaining continence.[43, 44] Supporting the concept that declines in connectivity[45] and

---

1005
coordination[46] between different brain regions represent early critical events in aging. These findings suggest the possibility that interventions to prevent the development of white matter hyperintensities, such as control of vascular risk factors, could also prevent UI.

4. AGE-RELATED CHANGES RELEVANT TO UI IN THE FRAIL ELDERLY

Age-related changes in the LUT can function as risk factors for the development, continuation, and worsening of UI in frail elderly persons (Table 1). At the same time, they rarely are alone sufficient to cause UI, and in some persons have no effect on lower urinary tract symptoms (LUTS) or UI. Furthermore, the literature on “normal” LUT ageing has many potentially confounding methodological limitations. Normal ageing changes are difficult to study, because longitudinal data including large numbers of individuals spanning many years are necessary to definitively separate “normal LUT ageing” from confounding factors and comorbidity. Cross sectional studies are subject to confounding by comorbidity and time-dependent cohort effects, such as change in labour and delivery practices. Thus, to date many studies actually describe “age-related” associations, as opposed to normal ageing. Other limitations include: derivation of much of the cellular and neurochemical data from animal studies; morphologic studies based on cadavers with unknown parity, comorbidity, and LUT symptoms; “age-effects” derived from studies of symptomatic persons; and use of surgical patients at tertiary centres as “normal” controls. Even the definition of “normal” can be difficult: is it continence, absence of LUTS, lack of comorbid disease, or normal physiological testing [47]? The following sections focus on findings from more robust and, where possible, confirmatory studies.

a) Bladder. Understanding age-related changes in the bladder is complicated by a paucity of longitudinal data, variable definitions of “normal,” and use of potentially biased (and symptomatic) referral populations. It is difficult to isolate such factors as the role of decreased blood flow, poor voiding habits, comorbidity, central and peripheral nervous system innervation, and reflex patterns as determinants of bladder function in older persons. The research focus has been urodynamic function, neurohumoral responsiveness of detrusor smooth muscle, and ultrastructure. While the key role of the urothelium and afferent systems on micturition are increasingly appreciated (See Committee 2, Cell Biology; Committee 3, Neural Control; and Committee 4, Pathophysiology), there are only limited human data on urothelial changes with age. Urodynamic changes associated with age have typically included smaller voided volume, increased residual volume, smaller bladder capacity, and increased involuntary detrusor contractions (detrusor overactivity (DO)). Correlations with age are often small, suggesting that other factors are at least as important [48]. Urodynamic findings may not relate to symptoms: in a urodynamic study of community-based healthy persons over age 55, DO was found in 42% of continent women, one-third of whom were totally free of LUTS [47]. In another study, charts of 53 consecutive females over age 80 undergoing multichannel urodynamics according to ICS standards were retrospectively analyzed. All of these elderly patients presented with LUT symptoms, yet in 11% urodynamic studies were reported as being normal, with considerable other discordance between symptoms and urodynamic findings [49].

Figure 1. Mechanistic of Geriatric Syndromes
Nevertheless, in a cross-sectional study involving ambulatory, cognitively intact, community-dwelling older female volunteers, maximum urethral closure pressure, detrusor contraction strength, and urine flow rate all declined significantly with age, regardless of whether DO was present or not [50]. The ability of the bladder to empty efficiently also declines in healthy older men and women who have no evidence of bladder outlet obstruction (BOO) or significant confounding disease [47, 51]. A variety of different risk factors associated both with aging and common comorbid conditions may contribute to age-related declines in detrusor contractile function, which may ultimately lead to detrusor underactivity [52, 53]. Decreased contractile function during voiding in older persons is associated with lower urine flow rates and a small increase in post voiding residual volume (PVR) (generally to < 50 ml) [54]. Even in men with BOO, an elevated PVR may reflect decreased bladder contractility rather than obstructed voiding [55]. While some studies suggest a myogenic origin of impaired contractility, others suggest that impaired blood supply, with concomitant ischemic-reperfusion injury causing patchy denervation, leads to decreased contractility (see Committee 3, Neural Control). More recently, Smith highlighted the potential contribution of age- and disease-related declines in bladder afferent sensory activity in contributing to impaired voiding performance seen with detrusor underactivity [56]. Incomplete bladder emptying from all such causes can reduce functional bladder capacity, and thereby contribute to the urinary frequency and nocturia common in frail older persons [52]. The recent development of a model allowing continuous uroflow in mice has led to studies evaluating the impact of normal aging on overall LUT performance [57, 58]. While aging did not influence measures of detrusor expulsive strength, pre-contraction pressures, intervoid intervals, per-void volumes and voiding flow rates all increased with aging [57]. Moreover, aged animals demonstrated

a decreased homeostatic capacity to respond to the challenge of continuous bladder filling, with indirect measures suggesting a role for decreased bladder volume sensitivity [57, 59].

In human studies, the observation that bladder volume at the initial desire to void declines with age may be confounded by comorbid conditions and concurrent medications [60]. Furthermore, unlike the positive association between detrusor contraction strength and DO found in younger subjects, older adults fail to demonstrate this DO-associated increase in detrusor contractility [61]. Moreover, many frail older persons with UI present with a combination of DO on filling and poor contractility during voiding, an association termed detrusor hyperactivity with impaired contractility (DHIC) [52, 62, 63]. In such cases, the bladder contraction does not empty the bladder fully, leaving a large PVR otherwise not explained by BOO. Because DHIC symptoms can include urgency UI, stress and mixed UI, dribbling, frequency, and nocturia, they may be mistaken for other conditions. At the same time, DHIC may be mistaken for DO with normal contractility because significant detrusor underactivity may be present in the absence of any relevant symptoms.

Ultrastructural studies demonstrate cellular changes associated with age-related changes in detrusor function. One series of such studies involved symptomatic and asymptomatic persons aged 65 to 96, using urodynamic testing and electron microscopy of bladder biopsy specimens, which were read in a blinded fashion using explicit protocols [54, 64-68] A consistent, one-to-one correlation between specific urodynamic findings and bladder ultrastructure was observed, although there has been considerable debate about the veracity of these findings and they have not been reproduced and have been disputed by the findings of a later study which found the ultrastructural changes described evenly distributed between normal women (n = 15) and women with detrusor overactivity (n = 22) [69]. The small number of asymptomatic patients with no DO, normal contractility, and no obstruction, detrusor muscle fascicles were largely intact, with two distinctive ultrastructural findings that may be related to ageing alone: muscle cell membranes characterized by numerous “dense bands” and markedly depleted caveolae, and slightly widened spaces between muscle cells with limited content of collagen and elastin. Depletion of caveolae may be related to de-differentiation of muscle cells, which could eventually result in the reversion of actively contractile cells to inactive, synthetically immature cells. A similar phenomenon has been reported in atherosclerotic blood vessels and post-menopausal myometrium, and may be related to reports of increased collagen in bladders from older women [54, 70]. Moreover, lack of oestrogen contributes to, and oestrogen replacement reverses, both caveolar depletion and detrusor fibrosis [71, 72]. Thus, both ageing and post-menopausal decline in oestrogen levels may contribute to bladder muscle cell differentiation and contractile function [52].

The natural history of these ultrastructural changes remains largely unknown. From the ultrastructural studies described above, a subset of 23 patients was followed longitudinally [67]. The previously observed one-to-one correlation between ultrastructure and function was maintained, but it was unclear whether urodynamic or ultrastructural changes occurred first in subjects who developed or had a change in LUTS. The pattern of dense-bands and nondisruptive muscle cell degeneration varied over time: the DO with dysjunction pattern developed in some subjects, and impaired detrusor contractility and the corresponding degeneration pattern was observed to progress in severity or develop. Other investigators have found similar results but without the one-to-one correlation (e.g., see Brierly et al [73]). Clearly, further work is needed understand the associations between changes in ultrastructure, urodynamic features and clinical syndromes.

In addition to such alterations in ultrastructure, a variety of changes involving relevant nerve fibres, receptors and signalling pathways have also been described in bladder tissues from aged animals, and to lesser extent human biopsies. For example, with aging overall, sympathetic nerve fibre density may decrease [74, 75]. Bladder biopsies from older subjects with normal urodynamic profiles typically show little or no evidence of axonal degeneration and the density of some CGRP-positive sensory nerves is maintained in old age, yet the impact of aging on other categories of sensory fibres or on motor fibres remains unknown [54, 74]. Examples of other changes include decreased contractility and calcium fluxes in response to cholinergic agonists or depolarization [76]; increased responsiveness to adrenergic agonists with increased expression of the alpha 1D-adrenergic receptor [75]; declines in phosphodiesterase 5 (PDE5) levels and possibly signaling [77]; as well as decreased P2X1 purinergic receptor expression [78]. Unfortunately, the interpretation and generalisability of these findings is often limited by a failure to include intermediate age-points which would allow investigators to distinguish changes attributable to aging as opposed to maturational processes [79, 80].

b) Urethra. Due to their common embryological origin, the urethra undergoes age-related mucosal and stromal changes similar to the vagina, and urethral changes in older women can be partially inferred from examination of vaginal tissue. Because of the difficulty of obtaining non-cadaveric urethral tissue, data on urethral smooth and striated muscle changes with age are complicated by confounding factors and definitions of controls.
Urethral closure pressure decreases with age [81, 82]. Based on a sample of 82 women aged 20-70, urethral closure pressure was found to decrease by 15 cmH2O per decade [83]. A number of anatomical and physiologic changes may account for this decline. Mucosal thinning and lack of proteoglycans reduce urethral wall apposition; this also may contribute to retrograde movement of perineal bacteria into the bladder causing urinary tract infections [84]. These mucosal changes may extend up to the bladder trigone, causing irritation of sensory afferent nerves, and possibly triggering DO [85]. The submucosal venous plexus in the proximal urethra loses its corkscrew shape, the number and volume of arterial vessels decrease, and vascular pulsations lessen [86]. Several studies, using different measurement techniques, have shown that urethral vascular density and blood flow decrease with age, but not vascular flow velocity [87-89]. However, age explained only 9% of the variability in vascular density in one study [90], and none of the studies controlled for vascular risk factors such as hypertension and diabetes. The relative importance of decreased vascular volume versus hypoxia on urethral functional integrity is unclear. Other alterations in the urethral stroma are increased volume of connective tissue, decreased ratio of proteoglycans to collagen, and decrease in nerve density [91, 92].

Cadaver studies suggest that the number and density of urethral striated muscle fibres decrease with age, especially in the ventral wall of the proximal urethra [93, 94]. These authors estimated that striated fibres decrease by 1% per year. Large inter-individual variations were observed, with age and parity accounting for only a small part of the variability, suggesting that other yet to be defined factors are important. These studies also found that cross-sectional striated muscle fibre area decreased while fibre diameter was preserved. Another cadaver study by the same group found that circular smooth muscle width was 25%-50% higher in younger women (aged 20-39 years) than older (aged 70-89), and that younger women had higher fibre counts [95]. Smooth muscle loss in the older women correlated with loss of striated muscle in the anterior urethra. Moreover, a recent study raised the possibility that TNF-alpha may contribute to age-related rhabdosphincter satellite cell death and muscle loss with aging [96]. Urethral sensation, measured as current perception thresholds, was significantly higher in older women in two studies (by the same authors), one comparing 48 asymptomatic women and 13 with urgency UI [85], and another in asymptomatic women [97]. The authors concluded that age-related LUT sensory neuropathy could contribute to the higher prevalence of overactive bladder (OAB) symptoms with age; however, urethral sensation thresholds were higher in women with urgency UI when controlled for age and parity [85], and the “asymptomatic” older women may have had urodynamic DO [97].

With age, the urethral meatus generally moves toward the vaginal introitus, and may be difficult to see if there is considerable introital stenosis. Caruncles (benign violaceous soft swellings—often appear at the meatus, and are not problematic unless they cause discomfort or obstruction. Urethral diverticula can be a diagnostic challenge, especially in older women, because the symptoms (dysuria, pain, UI, frequency, urgency, dyspareunia) may be attributed to postmenopausal changes, age, OAB, or urgency UI [98]. Diverticula should be considered in women who have repeatedly failed “conventional” UI treatment. Diagnosis requires imaging by voiding cystourethrogram, ultrasound, or magnetic resonance scans. Urethral obstruction is relatively uncommon in older women, and is nearly always secondary to other LUT dysfunction (e.g., pelvic organ prolapse) or is iatrogenic (from LUT/pelvic surgery or radiation. In men, age-related decrease in striated sphincter muscle cell density occurs as well, [99, 100] and has been associated with increased muscle cell apoptosis [99]. While some investigations describe an increase in resting prostatic urethral pressure with age, [101] others note the increase occurs only to the sixth decade then subsequently decreases, along with a shortening of sphincteric urethral length [102]. These discrepancies may reflect differences in prostate volume and morphology.

c) Pelvic floor. Pelvic floor changes in normal older men have not been well studied. In women, the effect of age on pelvic floor structure and function is difficult to differentiate from the effects of hormonal status and parity [103]. A number of studies are cross sectional rather than longitudinal, and focus on symptomatic women. For example, a questionnaire study of over 4,000 community women aged 25-84 found no association between age and stress UI (SUI), OAB, or anal UI, after adjustment for obesity, birth history, menopause, and hormone use [104]. Similarly, in a random sample of 343 Austrian women aged 18-79 years, impaired pelvic muscle contraction (graded by the Modified Oxford Scale) was weakly associated with parity and body mass index but not age [105]. In contrast, a recent study combining an interview, physical exam and transperineal ultrasound identified age as a weak (r = -0.25) but statistically significant predictor of pelvic muscle weakness and levator ani morphometry even after controlling for obvious confounders [106]. Evidence of denervation and changes in pelvic striated muscle fibre number, type, and diameter have been found in asymptomatic and nulliparous women (see Committee 2, Cell Biology). For example, in a sample of 82 nulliparous women, neither levator function (measured by resting vaginal closure force and augmentation of vaginal closure force) nor pelvic organ support (on pelvic exam) showed an association with age [85]. A his-
tomorphometric study, using levator ani muscle from 94 female cadavers (aged 15-58), 10 male cadavers (aged 23-35), and 24 women undergoing pelvic surgery, found that myogenic cell damage was associated with both parity and age (< average age 35), but there was no difference between nulliparous women, men, and women with pelvic organ prolapse and/or UI [107]. Total collagen content in pelvic muscle and fascia declines with age, with increased cross-linking and decreased elasticity, [108] but this association does not imply a direct causative effect of “ageing.” Constipation may independently contribute to pelvic floor dysfunction in older women [109, 110].

**d) Vagina.** The prevalence of age-related changes in the vagina varies with hormonal status, coexistent vascular disease, and the continuation or lack of sexual activity [111]. The postmenopausal decrease in oestrogen plays a part in many age-associated vaginal changes. Oestrogen is trophic for much of the LUT in women, with oestrogen receptors found in the vagina, vestibule, distal urethra, bladder trigone, pelvic muscles, and ligamen-
tum rotundum [112]. Yet, as the Women’s Health Initiative trial has shown, one cannot assume that the association between low oestrogen levels and physiological changes implies that hormone replacement will reverse these changes, restore function, or reduce symptoms [113, 114]. Moreover, the data are equivocal whether and how LUT oestrogen receptors change in number, density, or function with age [66].

Following menopause, the vaginal epithelium loses the majority of its superficial and intermediate layers. Mucosal thinning may be associated with inflammation, evident as erythema, telangiectasia, petechiae, friability, and erosions. This may be responsible for urgency and frequency in some frail elderly women. In addition, there is loss of epithelial glycogen and lubrication, and mucosal pH increases from 4.5-5.5 to 7.0-7.4. These changes can lead to loss of normal adherent flora (lactobacillus), colonisation with pathogenic organisms such as E. coli and enterococci, and the observed increase in bacteriuria and recurrent symptomatic urinary tract infections (UTIs) in older women [115].

Vaginal blood flow, which is important for mucosal integrity and submucosal fullness, decreases with age. Whether this is oestrogen-related, and/or due to concomitant vascular disease is not known. Collagen and lipofuscin deposition in the stroma increases, and may be accompanied by invasion by lymphocytes and plasma cells [115]. The combined epithelial and stromal changes are associated with vaginal wall thinning and flattening of rugae [112]. The vaginal vault may shorten and narrow, and the introital opening decrease (and in severe cases become stenotic), which may make vaginal examination, intercourse, and use of pessaries difficult. However, it is not clear that vaginal shortening is clinically relevant: in one case series of over 3,000 women attending a general clinic, total vaginal length decreased by only 0.08 cm every 10 years [116]. Vaginal shape also may be altered by POP. Because of the multiple potential confounding factors discussed above, a causal relationship between urogenital atrophy and urogenital symp-
toms/LUTS should not be automatically assumed.

Very few randomised trials of oestrogen (oral or topical) for urogenital symptoms include women over age 75, use patient-defined outcomes in addition to physiological measures, or evaluate quality of life outcomes [117]. There are insufficient data to provide an evidence-based approach to symp-
tomatic urogenital atrophy in older women. Oral oestrogen should not be used, but expert opinion supports topical oestrogen treatment (cream, intravaginal tablets, or oestrogen-impregnated pessary-like ring). The validation of vaginal self-swab collection specimen collection offers new opportunities for extending relevant questions to epidemiological studies of older women living in the community [118].

**e) Prostate.** Histological benign prostate hyperplasia (BPH) is strongly age-related [119], and may lead to prostate enlargement (BPE) and outlet obstruction (BOO). While many LUT changes in women are associated with lower oestrogen levels, BPH results from the development of an oestrogen-predominant hormonal milieu in the prostate. The trophic prostatic androgen, dihydrotestosterone, is formed by the 5-α reduction of testosterone. Dihydrotestosterone levels decrease with age, while oestradiol concentrations increase in the prostate stroma and remain constant in epithelial tissues, leading to an increase in the oestradiol/dihydrotestosterone ratio and promoting stromal prolif-
eration [120, 121]. Epithelial hyperplasia in turn is mediated by an array of stromal factors [122].

Histological BPH occurs in nearly 80% of men by age eighty [119]. Mean prostate volume increases with age but is very variable; its strongest predictor is prostate specific antigen level of >1.4-2 ng/mL [123]. LUTS in men increase linearly over time, with the fastest increase during the seventh decade, such that by age 80 approximately one-third of men have received treatment for moderate to severe LUTS [124]. Natural history studies and random-
ized intervention trials, however, consistently demon-
strate that symptomatic progression of benign prostate disease is not inevitable. LUTS remit in about one-third of symptomatic men without treat-
ment [125]. Approximately one-third to one-half of affected men develops DO. Thus, even in the presence of demonstrable BPE and/or BOO, the aetiology of LUTS is multifactorial, making prostate-related LUTS in older men a diagnosis of exclusion. Never-
theless, age-stratified normative values for prostate
volume, PSA level, as well as indicators of clinical symptoms, quality of life measures and urodynamic parameters may help in such decisions [126].

Although most patients are asymptomatic at the time of prostate cancer diagnosis, this is another possible cause of LUTS, including urgency UI, in older men. However, evaluation for prostate cancer in frail elderly men is rarely if ever indicated, given the high likelihood of limited remaining life expectancy.

The evidence is contradictory as to whether prostatic inflammation, either acute or chronic, contributes to urinary retention and LUTS in frail older men. In a single institution case series of 374 men undergoing TURP for acute urinary retention (AUR) or LUTS, pathological evidence of acute inflammation was significantly more common men presenting with AUR than LUTS (70% vs. 45%) [127]. However, in a much smaller case series of 70 men presenting with AUR, there was no association between inflammation from prostate infection and AUR [128]. Nevertheless, a recent study demonstrated phenotypic changes and an increased differential expression of a variety of genes involved in inflammation and oxidative stress within glandular adjacent stroma microdissected from young and aged mouse prostates [129]. Such changes may play a role in promoting the development of BPH, BPE and cancer in aged prostates [130].

**f) Other changes.** The role of various neurotransmitters in the central and peripheral nervous system in UI is under active investigation (see Committee, Cell Biology). Nevertheless, age-related changes in the actions of these neurotransmitters, their receptors, or the cellular events they stimulate may contribute to the development of UI in frail older persons.

The prevalence of both asymptomatic bacteriuria and UTIs increase with age [115], and the two are often found together in the frail elderly. Age-related changes in immune function, vaginal epithelium, faecal incontinence, and insufficient hygiene related to disability, cognitive impairment, and/or lack of caregivers may predispose the frail elderly to bacteriuria and recurrent UTIs. However, the role of otherwise asymptomatic bacteriuria (often found in association with pyuria) [131], in the aetiology of UI in frail elderly people remains unclear [132]. Treating otherwise asymptomatic bacteriuria in frail elderly patients with chronic, stable UI does not, in general, reduce UI severity [133]. UTI symptoms may be subtle and non-specific in this population, and include worsening of UI, altered mental status in patients with dementia, decreased oral intake, or a minor but important decline in functional ability [133]. At the same time, current consensus criteria for UTI are poorly sensitive and only fairly specific for UTI in frail elderly. In a prospective cohort of 340 nursing home residents, in which UTI was defined as pyuria (>10 white cells) with >100,000 colony forming units on culture, the McGeer, Loeb, and revised Loeb UTI criteria had sensitivities of only 19-30% and specificities of 79-89% [134].

**5. FACTORS OUTSIDE THE LOWER URINARY TRACT CAUSING OR CONTRIBUTING TO UI**

Of 8,688 participants in the English longitudinal study of ageing, of whom 4,417 had one or more diagnoses, there were shortfalls in receipt of basic recommended care, most noticeable in areas associated with disability and frailty [135]. A hallmark of UI in the frail elderly population is the wide variety of factors and conditions outside the lower urinary tract that can cause or contribute to leakage (table 2).

**a) Medications.** Older people consume a high proportion of prescribed medications. Those over 65 years of age comprise between 12 – 16% of the population in the US, UK and Canada but consume 32%, 50% and 45% of prescribed medications respectively and are therefore at greater risk of experiencing adverse events associated with their use [136-141]. The risk of difficulty in controlling urination in community dwelling older women taking medications with LUT effects was about 30% higher compared to those who did not take such medications (OR 1.31 [95% CI 1.05–1.21]) Overall, 20.5% of these women reported incident incontinence at Year 4 (3 years from baseline). We found one additional study since the 4th ICI which examined 959 elderly community dwelling women from the Health, Aging and Body Composition Study, multivariate logistic regression analyses revealed that current users of alpha blockers (adjusted odds ratio (AOR) =4.98, 95% confidence interval (CI) =1.96-12.64) and oestrogen (AOR=1.60, 95% CI=1.08-2.36) had a greater risk of urinary incontinence than nonusers. There was no greater risk of UI associated with current use of anticholinergics, central nervous system medications, or diuretics [142]. Many classes of medications commonly prescribed for the frail elderly can cause or contribute to the development of UI (Table 3). The possibility that UI could be caused by a medication should be taken into account before prescribing drug treatment for UI in older persons.

**b) Co-morbid conditions and functional impairment:** The prevalence of urinary incontinence (UI) is increased in the presence of frailty. The elderly are prone to frailty and commonly have co-morbid medical illnesses. In a large population-based observation study UI (defined as use of pads) was independently associated with one or more other geriatric conditions (cognitive impairment, injurious falls, dizziness, vision impairment, hearing impairment) in 60%, two or more conditions in 29% and three or more in 13% [143].

In a sample of 572 older Latinos participating in a programme to increase walking, medical comorbidity was independently associated with higher rates of UI (OR 1.66). A higher degree of physical activity was independently associated with lower rates of UI (OR

Hypertension, congestive heart failure, arthritis, depression and anxiety were associated with a higher prevalence of UI. A linear correlation was found between prevalence of UI and the number of comorbid conditions. (correlation coefficient =0.81) [144].

A decline in physical health has been associated with an increase in the incidence of incontinence. [145] In an observational study of 6,361 community-dwelling women, aged 65 and older, participating in the study of Osteoporotic Fractures, after adjusting for confounders, women with recent physical function decline (a worsening of 1 standard deviation from baseline) were more likely to report weekly incontinence (OR 1.3) for decline in walking speed over 6 metres and (OR 1.4) to stand from sitting. [146]. The Nurses’ Health Study found that moderate-intensity physical activity including walking resulted in a 20-25% reduction in the risk of developing UI in older women [147].

Likewise, impaired cognition is associated with an increased likelihood of UI. For example in a UK cross-sectional survey of over 15,051 subjects, persons with cognitive impairment (Mini Mental State Exam score <= 23, prevalence 18%) were significantly more likely to have UI (adjusted odd ratio [OR] 1.3), impaired hearing (OR 1.7), poor vision (OR 1.7) have had at least two falls in the previous six months (OR 1.4), and report poorer health (OR 1.9) [148].

Comorbid conditions can affect incontinence through multiple mechanisms e.g. diabetes mellitus, present in approximately 15-20% of frail elderly, Table 3. Medications that can cause or contribute to UI in frail elderly persons

UI = urinary incontinence
may cause UI by diabetes associated LUT dysfunction (DO, OAB, cystopathy and incomplete bladder emptying) or by poor diabetic control (hyperglycaemia causing osmotic diuresis and polyuria). The Nurses Health Studies, NHS and NHS II [149] showed an increase in weekly urgency incontinence (OR 1.4) in women with type 2 diabetes compared to those without. Findings from the NHANES 2001-2002 Survey showed that prevalence of UI was significantly higher in women with impaired fasting glucose and diabetes mellitus compared to those with normal fasting glucose. Two microvascular complications caused by diabetes - peripheral neuropathic pain and macroalbuminuria (approaching significance) were associated with weekly UI.[150]

See Table 2 as to how comorbid medical conditions can contribute to UI

c) Neurological and psychiatric disorders: A more detailed summary of neurological disorders and their impact on UI is covered in Chapter X. Neurological and psychiatric disorders are highly prevalent in the frail elderly. Neurological conditions in the elderly commonly associated with urinary incontinence include stroke, dementia of the Alzheimer’s type (AD), multi-infarct dementia or a combination of the two, Diffuse Lewy body (DLB) disease and Parkinson’s disease. Less common conditions include Normal Pressure Hydrocephalus and Multiple System Atrophy (MSA). Each of these conditions is associated with the development of brain lesions that can interfere with the normal ability to inhibit voiding as well as affecting cognition. These conditions are associated with impaired mobility and also affect the ability to toilet independently.

In Alzheimer’s disease UI is often associated with severe cognitive decline whereas in DLB it usually precedes severe cognitive impairment [4]. Occurrence of UI was significantly earlier 3.2 yrs in DLB compared with 5.9 yrs in Alzheimer’s dementia [151].

Normal pressure hydrocephalus should be considered as a diagnosis in any frail elderly person who presents with new onset of UI in association with gait disturbance and cognitive impairment. A subset of these patients benefit from surgical implantation of a cerebrospinal fluid shunt [152].

LUTS, UI and urodynamic DO are common in older persons with Parkinson’s disease. A logistic regression analysis of 3,414 Parkinson’s disease patients found a significant correlation of orthostatic hypotension and urinary incontinence with age and duration of the disease. The presence of UI in people with Parkinson’s may in turn increase their risk for disability: in one series of patients with Parkinson’s, UI increased the risk of falling by nearly six-fold. Urinary symptoms are often non-responsive to L Dopa therapy and there is an increased risk of cognitive decline in people with Parkinson’s disease when given anticholinergic agents [153, 154].

Multiple system Atrophy presents with a combination of impaired autonomic function, Parkinsonism (MSA-P) or cerebellar ataxia (MSA-C) or both [155]. It frequently begins with bladder dysfunction and erectile dysfunction in males. It is associated with bladder symptoms of DO and often progressing to incomplete emptying. The early appearance of LUTS and high post void residuals may help in pointing to a diagnosis of MSA-P rather than Parkinson’s disease [156].

With the introduction of magnetic resonance brain imaging into routine clinical practice, reports in older patients have increasingly emphasized the presence of structural abnormalities involving the white matter[157]. Terminology has also undergone a great change, moving away from subcortical atherosclerotic encephalopathy (Binswanger’s disease, a specific and relatively rare form of dementia), towards leukoaraisis [158] and, most recently, to the concept of white matter signal abnormalities (WMSA).[157, 159]. A dichotomous diagnosis of “cerebral white matter lesions” on CT scans provided by a radiologist demonstrated no relationship to the presence or absence of UI. A semi-quantitative measure of global WMSA appears to be associated with increased urgency UI and nocturnal frequency [160]. In 699 non-disabled elderly subjects with WMSA on MRI there was a significant difference in prevalence of urgency but not incontinence between mild and severe groups [161]. WMH have been linked to severity rather than to the presence of incontinence [162].

d) Depression. As in younger people, the frail elderly with UI have a higher risk of depression, a finding that has been replicated across cultures. Depression in older persons with UI may be under-diagnosed and under-treated: in one study of homebound adults with UI and severe depression, only 35% carried a previous diagnosis of depression and only 34% had been prescribed an antidepressant [163]. UI may add to the burden of depression by decreasing life satisfaction and self-rated health and by its association in frail elders with comorbidity. [164-167]

Studies of the association of depression and UI in older persons are consistent across several depression measures. The validated Centre for Epidemiologic Studies-Depression scale was used in two U.S. studies: a cross-sectional analysis of nearly 10,000 community-based people found an adjusted risk ratio for depression with UI 1.39 [95% CI 1.24, 1.55)] [168]. A large community-based study of older Mexican Americans reported an adjusted OR for depression of 1.94 [95% CI 1.46-2.59)] [169]. The emotional disturbances and social isolation subscales of the Nottingham Health Profile Questionnaire was associated with urgency but not stress urinary incontinence and have included studies in Asia [145, 170]. Although no association between UI and depression was found in a Korean study of
135 community living elderly aged greater than 85 years, it used a higher cut-off (>7) on the Geriatric Depression Scale and, unlike many other studies, found no association between UI and mobility[171]. Self-report of depression or sadness has and has not been associated with UI. [172-174]

Psychological distress, assessed by the General Health Questionnaire, was associated with UI in African Americans (adjusted OR 5.60 [95% CI 1.88–16.67]), but not in whites, in a cross-sectional study of community based older persons with mean age 67 years[175]. However, a longitudinal analysis of the same population over 13 years found that people with UI and psychological distress were more likely to report UI-specific functional impairment (e.g., avoidance of social activities, shopping, and physical activities) (adjusted OR 6.55 [95% CI 1.94-22.12]). Additionally, persons with UI and condition-specific functional loss were more likely to develop psychological distress (OR 3.66 [95% CI 1.61–8.33]) [176].

EpiLUTS, a large cross-sectional internet study, showed significant impairments in mental health and HRQOL when different urinary symptoms were combined [177, 178]. The US sample of the EpiLUTS study, involving 2,485 men and 2,877 women aged 65 and older, found OAB was associated with significant impairment in HRQOL. Rates of Anxiety of >7 on the HADS-A were 16.4% for men and 23.6% for women with OAB compared to 3.3% and 8.6% with minimal or no symptoms. Similarly rates for depression on the HADS-D were 17.3% and 15.7% for OAB compared to 4% and 6.4% in those with no or minimal symptoms. [179]

A case controlled study of 100 elderly men attending a Urology outpatients, matched with 100 age matched controls from the community and Geriatric outpatient clinics, found those with moderate to severe LUTS had worse HRQOL. This was evident in a number of ageing male symptoms including depression, decline in feelings of general well-being, decreased sexual performance and decreased muscle strength [180].

The direction of the causal relationship between UI and depression in frail persons is unclear, as nearly all of these studies were cross-sectional. The results of the one available longitudinal study suggested that it is not UI itself but UI-specific functional loss (e.g., avoidance of social activities, attending church, etc.) that is most closely associated with psychological distress, even after controlling for important covariates [163].

e) Falls: Overactive bladder (OAB), present in up to 20% of older adults, and its component symptoms of urinary urgency and urinary incontinence, urinary frequency, and nocturia have been identified repeatedly as risk factors for falls among community-dwelling older adults [181-186]. Mixed incontinence (a combination of urgency and stress incontinence) has also been associated with falls risk in women 70 years and older [187]. In hospital, the need to use the toilet has been reported to increase falls, especially among older patients [188]. Urinary incontinence is also associated with falls in institutionalized older persons [189, 190].

f) Stroke: Conservative interventions (e.g. bladder training, pelvic floor muscle training and prompted voiding) have been shown to have some effect in Cochrane systematic reviews, but have not had their effectiveness demonstrated with stroke patients. UI may have particular prognostic implications after stroke, being associated with greater mortality, a poorer functional recovery and an increased likelihood of institutionalization than those following strokes who regain continence. Of 1,187 patients aged 60–96 with stroke, those with low bladder maintenance scores (more dysfunction) fared worse with rehabilitation than those with higher scores [191]. A survey of stroke unit practice in Australia showed that less than half had a formal plan for continence care and in the UK, as part of the national sentinel audits of stroke, there was little advance in continence care [192, 193]. A comparative study of stroke nursing found a dearth of evidence and treatment focused on containment and social continence, highlighting the need for systematic assessment and management [194].

g) Recommendations for research

Further research is required to:

1. Examine the effect of treatment for UI in older people with Parkinson’s disease
2. Examine the temporal association and mechanism underlying falls and UI in frail older persons
3. Examine the effect of structured treatment for UI in older people following stroke.

h) Recommendations for practice

1. Clinicians need to assess and manage co-existing co morbid conditions which are known to have an impact on continence status or the ability to successfully toilet.

6. ENVIRONMENTAL FACTORS

This section addresses those factors unrelated to underlying pathophysiology which affect continence status in frail older persons.

- The physical environment
  - Processes of and/or quality of care
    - assessment
    - practices that reduce mobility
    - toileting assistance
    - staffing levels and skill mix
    - use and misuse of continence products
In this section we defined processes of care as the instrumental procedures involved in the assessment and management of incontinence relating to frail older persons.

**a) The physical environment**

Although the physical environment is considered a risk factor for incontinence in frail older adults, there is limited research on this topic. We located seven publications with evaluative data on this topic: two of these studies were conducted over 40 years ago [195, 196] prior to the establishment of internationally agreed standards for reporting trial data. Three were published from a series of projects conducted in the USA to examine the impact of the physical environment on specific problems of people with Alzheimer’s disease and related disorders [197-199]. One qualitative study was identified that employed an ethnographic design [200]. Each of these studies involved individuals in long-term care institutions. One study evaluated the prevalence and risk factors for incontinence in a sample of 5,418 community-dwelling frail older adults who were receiving home care services [201]. Environmental barriers as well as the use of physical restraints, along with UTIs were the most common reversible risk factors for urinary incontinence: increasing the risk of urinary incontinence by over 50% [201]. In this study, environmental hazards included a lack of access to the toilet, unavailability of grab rails, inappropriate toilet seat height, inadequate lighting, and inadequate toileting substitutes such as commodes or urinals.

Attempts to evaluate the effects of enhancing the physical environment of long-term care on rates of incontinence were first reported by Chanfreau-Rona [195, 196]. In both studies, the intervention involved enhancing visual access to the toilet by painting toilet doors in bright colours and strategically locating pictorial signs and other visual cues. In addition, staff were asked to accompany residents to the toilet at predetermined ‘peak times’ and to employ operant conditioning techniques to reinforce residents’ appropriate toileting behaviour. In the first of these trials, 24 elderly female residents, most of whom had cognitive impairment, were purposively assigned to either the intervention, or to usual care for seven weeks [195]. The same procedures were repeated in a subsequent trial (1986), [196]. Although reductions in incontinence were noted for residents in the experimental groups compared to the control groups, the extent to which these reductions were related to the intervention is difficult to determine as both studies lacked power and did not control for confounding factors. Nonetheless, these studies represent an early, multifaceted intervention that involved evaluating the effect of changes to the physical environment to reduce incontinence in among frail older adults in long-term care.

According to the findings of a series of projects conducted by Namazi and colleagues, the overall physical environment has a considerable impact on the well being and quality of life of individuals with Alzheimer’s Disease (AD), affecting their ability to function in the face of incontinence, distraction and disorientation [197]. One of the projects focused on the clinical utility of using environmental cues (i.e. signage, colour differentiation and images) in a dementia-specific unit to assist compensate for resident’s visuo-perceptual deficits [198]. The most effective environmental cue in terms of orienting individuals with AD to the toilet was a combination of using a sign with the word ‘toilet’, together with ‘wayfinding’ arrows on the floor. No single strategy was suitable for all individuals with AD due to the variability in the ability of individuals with AD to perform all of the tasks associated with successful toileting. The researchers therefore recommended “to maximize the remaining strengths of those who are afflicted with AD, each component of the morphology which creates difficulties for AD patients must be identified and treated individually”. In essence, individuals with AD may need individually targeted cues that address identified specific areas deficit.

In a second project, Namazi and colleagues [199] systematically examined toilet use in a dementia-specific unit under two conditions: with the toilet highly visible to residents, and with the toilet concealed. The frequency of toilet use increased when toilets were visually accessible during the 45 hours of observation. Visibility and accessibility of toilets may be an important factor in supporting individuals to maintain continence.

Toilet accessibility also featured highly in a qualitative study conducted by Sacco-Peterson and Borell [200]. Using ethnographic methods, the researchers collected over 200 hours of field observational data and conducted in-depth interviews with nine residents. They reported that different aspects of the facility’s physical and socio-cultural environment influenced residents’ abilities to maintain autonomy in self-care. For example, there was an inadequate number of toilets, inadequate privacy for toileting, inappropriate toilet heights, excessive distances to the toilet, and a lack of call light, toilet paper, soap, paper towels, lighting and commodes. Despite the challenges of negotiating this ‘defeating ward geography’, many residents attempted to participate autonomously in toileting, whilst others were deterred because of a fear of falling.

**b) Processes and quality of care**

In a systematic review of the prevalence and risk factors for urinary incontinence in nursing homes Offerman and colleagues [202] identified 46 risk factors for urinary incontinence in nursing homes. These factors were grouped into 1) locomotion, 2) cognitive function and 3) drugs. However, in addition to these risk factors, the reviewers stated “differences in the care process and quality of care can also influence urinary incontinence prevalence;
reasons for a less-than-optimal approach in nursing homes may include, for example, inadequate knowledge of and skills for urinary incontinence in general, inability to use guidelines for urinary incontinence care, insufficient staffing and poor communication among healthcare professionals” (p. 291). They recommended that risk factors related to care processes be further investigated.

Two studies offer qualitative data on how processes of care in nursing homes may represent a risk factor for incontinence. For example, descriptive information derived from semi-structured interviews with six elderly women from two nursing homes in Canada, suggests that some residents experience an environment characterised by rituals and routines, pad rationing, limited assistance with pad changing, restrictions on the type of products available, set times for toileting and pad changes, ageism, and a lack of recognition of attempts to maintain continence [203]. Sacco-Peterson and Borell [200] also found that ‘toileting assistance was provided at set times, and ‘if residents required more assistance other than at set times, pads were used’. Pad use also correlated with residents’ mobility level, rather than their cognitive or continence status. Additionally, night-time use of pads often started following a fall at night. Residents did not divulge their difficulties to staff, and were reluctant to ask for help and thus staff members were unaware of residents ‘difficulties and efforts. Residents valued the capacity to exercise some power and autonomy with regard to self care, and didn’t want to be ‘a bother to the nurse’. Thus, their attempts to maintain continence may be undermined by care processes that unintentionally diminish an individual’s independent toileting.

c) Assessment

A comprehensive assessment to determine type and causes of incontinence is an essential precursor to appropriate management. However, many people with incontinence do not have access to this assessment, and are therefore at risk of remaining incontinent (Table 4). This finding is consistent for older adults across different countries and settings.

d) Knowledge

A lack of knowledge about incontinence and its management may operate as an antecedent to care processes that inadvertently promote incontinence. A number of studies reveal gaps in nurses’ and nursing aides’ knowledge about and attitudes toward older people with incontinence in long-term [204-224], as well as acute care [221, 225-229]. Other research highlights gaps in medical practitioners’ knowledge about incontinence [230-234]. For example, a survey of general practitioners (GPs) knowledge of investigation modalities and treatment options for individuals with faecal incontinence in the UK, found that only 32% were aware of at least one investigation, and 32% were aware of at least one form of surgical treatment [230]. In a cross-sectional national survey to determine knowledge, attitudes, and management of urinary incontinence among family physicians in Canada, less than half (46.0%, 284/617) indicated that they had a clear understanding of incontinence and just 37.9% (232/612) had an organized plan for incontinence problems [234]. Szonyi and Mil-lard [232] reported a significant improvement in GPs knowledge about incontinence following receipt of an education package.

Knowledge about incontinence and its management in the general community is also lacking, especially amongst men, those aged 85 and older, and those with lower levels of education [235]. For instance, a nation-wide consumer survey conducted in the USA in 2000, found four in ten people (41%) thought that loss of bladder control was a disease and a similar percentage (38%) believed it was a natural part of ageing [236].

e) Processes of care that reduce functional status

Impaired functional ability can cause or contribute to incontinence in frail older persons. Care processes that restrict or minimise mobility and the ability to function constitute a critical risk factor. The use of physical restraints is one such practice. Although restraint-free care has been recommended as standard, restraints remain widely used in long-term care – ranging from 12-47% internationally [237]. In a multivariate analysis of data from 2,014 residents from 270 USA Medicaid-certified nursing homes, Brandeis and colleagues (1997) identified that urinary incontinence was independently associated with impairment in ADLs (OR = 4.2; CI = 3.2,5.6), dementia (OR = 2.3;CI = 1.8,3.0), the use of anti-anxiety/hypnotic medications (OR = .7;CI = .5,1.0) (all P < .04) and the use of restraints of the trunk (OR = 1.7; CI = 1.5,2.0), restrained to a chair (OR = 1.4; CI = 1.2,1.6), and bedrails (OR = 1.3; CI = 1.1,1.5). Similarly, in a community-based sample of frail older adults, the use of physical restraints was a key reversible risk factor for urinary incontinence [201].

f) Lack of toileting assistance

An obvious, yet often overlooked risk factor for incontinence is a lack of toileting opportunities and assistance for individuals who are care-dependent. Research from USA shows that the frequency of toileting assistance actually provided in nursing homes is too low to maintain continence [238].

In recent years, the UK media has drawn attention to the fact that many people in hospital do not receive timely assistance to use the toilet: a situation that contributed to the establishment of the “Dignity in Care Campaign” – launched in 2006. In response to concerns about neglect in aspects of personal and healthcare, the British Geriatrics Society proposed that the ability to use the toilet in private was in fact, a marker of human rights, and developed a

  - pelvic examination (2%) |
“Behind Closed Doors Campaign”. The aim of the campaign was to empower, educate and influence providers and policy makers to adopt a more proactive stance to demand better continence care. A more recent campaign, again led by the British Geriatrics Society, titled “Do not forget the person” was launched in March, 2010. The extent to which such awareness raising activities affect day-to-day care processes in the absence of structural change and resources requires evaluation.

Structured toileting programmes require a staff to patient ratio of 1:5. A lack of staffing or institutional understaffing represents a key risk factor for incontinence among individuals who are dependent on another person to use the toilet. Factors which have been identified in the success (or otherwise) of such programmes are covered in Section 7.

g) Staffing levels and skill mix

Estimating and achieving the optimal level and skill mix of any workforce is a challenge. In long-term care where residents' have chronic health problems and complex health needs, this problem is exacerbated by a high staff turnover. Nurses consistently cite inadequate staffing levels as a major barrier to continence care [239-243]. The extent to which patients and residents’ continence care needs are considered in formulas designed to establish the right staffing level and skill mix is unclear. The time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management and manage incontinent episodes require consideration in service planning.

h) Use and misuse of continence aids

For many people, continence aids represent a means by which they can achieve effective and discrete containment of incontinence, minimise physical discomfort and optimise psychological and social function [244]. At the same time, overuse and misuse of continence aids, may represent a risk factor for incontinence and, for pads, urinary tract infection. Although continence aids have an important place in the control of incontinence, their use in the general community, in hospital settings, and in long-term care institutions is widespread (Table 5). For example, in the largest and widest audit of continence care conducted in the UK and involving over 6,000 patients across primary and secondary care trusts, and care homes, containment strategies (i.e. the use of continence aids) far exceeded all other forms of documented continence management [245].

• Community / home care / primary care

Extrapolating data from users of absorbent pads in one area in Sweden, Samuelsson and colleagues [246] found 6.4% of all women and 2.4% of all men in the country, used continence aids: equating to 3.7% of the total population. Most of these users were aged over 75 years of age and 21% lived in special accommodation. Other studies have examined use of continence aids in targeted populations. For example, among individuals receiving home care services in European countries, rates of continence aid use vary from 29-52% (mean 39%) [247] to 57% [248]. And across primary care trusts in the UK, containment strategies are used by 48% of patients [245].

• Acute care / hospital / secondary care

Rates of continence aid use in elderly patients in acute care across a number of countries are similar and range from 55.1% in Italy [249], 56% in the UK [245] to 60% in Singapore [250] and Australia [251]. Not only are they widely used but they are often used indiscriminately. One of the earliest studies to draw attention to an overreliance on pad use was conducted by Starer and Libow [252] who found more residents using pads than those with incontinence. More recently, Otsaszkiewicz and colleagues found that in the inpatient care setting, pads were inappropriately used for some patients, and were underused for others [251]. Of 121 patients who were using pads at the times of the survey, 50(41%) reported no UI or FI in the preceding 24-hours. However, 18% of patients who had no pad did report such an episode. This mismatch between incontinence and pad use has been noted in other research. [253] [249]

• Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes

We located six studies that provided data on the use of continence aids in long term care facilities. These were conducted in the UK [245, 254], the USA [255-257], and in Norway [258]. Wagg and colleagues reported that of 488 residents from 27 care homes included in the national audit of continence care in the UK, 307 (63%) used a containment strategy to manage their incontinence [245]. Rodriguez and colleagues reported similar rates based on interview data from managers of 66 care homes in Birmingham [254].

In the USA, Brandeis and colleagues reported a higher rate of pad use (84%) in their sample of 2,014 residents from 270 Medicaid-certified nursing homes[255]. Eighty-four percent were managed with pads/shorts, and more than one third of incontinent patients were managed with two modalities. A recent evaluation of the use of urinary collection devices by 57,302 patients from five skilled nursing facilities found that pad use remained relatively stable over a 12 month period [256]. Pad use among a sample of 11,549 newly admitted 75-84 year old residents was 58.7% at admission and 61.1% twelve months later. This rate was higher for residents aged 85 years of age and older (i.e. 60.3% at admission and 62.6% one year later). In a survey of patterns and treatments of urinary incontinence in 13 special care units in the USA, Pringle-Specht and colleagues (2002) re-

ported that 72% (n=105) of residents used a continence aid: the most common type of aid being a continence brief or pad (n=93) [257].

According to Omli and colleagues who estimated the daily pad usage of 153 elderly residents from six nursing homes in Norway, 77% of residents use pads [258]. Omli and colleagues also found that residents’ pads were changed infrequently (i.e. an average of 2.3 times a day (range 0.5-8.0) for female residents and 3.1 times a day for male residents (range 1.0-9.0). Moreover, urinary tract infections were associated with pad use (41 vs. 11%; P = 0.001): but not with fluid intake or number of pads changes. Residents pad usage did not correlate well with the volume of their incontinence:

As inappropriate use of continence aids may contribute to onset, or continuation of, incontinence, it is important that clinicians who advocate or authorise their use, are familiar with evidence-based guidelines that advocate an active approach to diagnosing and treating incontinence.

1) Recommendations for research

Further research is required to:

1. explore the physical environment as a risk factor for UI in frail older adults, and to evaluate the effect of modifying the environment.
2. explore the extent to which socio-cultural factors and care processes in particular, influence frail older adults’ abilities to maintain autonomy and continence.
3. identify the association between fear of falling, reduced mobility, and UI in frail older persons.
4. evaluate the effect of awareness raising activities that aim to enhance day-to-day continence care processes in healthcare settings.

2) Recommendations for practice

1. Environmental cues such as toilet visibility, signage, colour differentiation and images should be used to compensate for visuo-perceptual deficits in frail older adults with cognitive impairment.
2. As remaining physical strength and extirity varies in individuals with cognitive impairment, each component of the toileting process which creates difficulties for such patients should be identified and treated individually.
3. Awareness raising activities should be conducted to enhance day-to-day continence care processes in healthcare settings.
4. Ensure that the time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management and manage UI episodes are considered in service planning.

5. Continue to address gaps in healthcare practitioners’ knowledge about preventing and managing incontinence in frail older persons.
6. As inappropriate use of continence aids may contribute to onset or continuation of UI, clinicians who advocate or authorise their use, should be familiar with evidence-based guidelines that advocate an active approach to prevention, diagnosis and treatment.

II. ASSESSMENT OF THE FRAIL OLDER PERSON WITH UI

Recommendations for the basic assessment of the frail elderly persons with UI are summarised in the algorithm (see Summary Document). Because UI in the frail elderly is multifactorial, it is essential to conduct a comprehensive assessment with the goal of identifying all potential contributing factors. Collaboration among primary care physicians, geriatricians, surgical specialists, nurses, other health professionals, and caregivers, both formal and informal is usually necessary for optimal assessment and management.

Since the last Consultation, the European Association of Urology published guidelines on UI which include those for frail older men and women. These are largely based on the findings of the 4th ICI [259]. The UK NICE guidelines for the management of lower urinary tract symptoms in men contain no specific recommendations for older men but are perhaps more age applicable than those which exist for UI in women.[260, 261] The US government sets minimum quality standards for UI assessment and management in long term care, but these standards, along with basic fundamental principles of UI, are poorly understood by long term staff [262]. Two groups, the US Assessing Care of Vulnerable Elders (ACOVE) project and the UK Clinical Effectiveness and Evaluation Unit, have developed quality performance measures for UI care in frailer older persons, using structured literature review and expert panel review.[263-267] These measures are not guidelines per se, and in some instances lack sufficient detail. Although both groups have demonstrated using their measures that UI assessment and care by practitioners in the US and the UK is poor, and of a lower standard than that afforded to younger adults, there is evidence that integrated services are more likely to provide a higher standard of UI care [268] Thus, there is an urgent need to re-establish the fundamentals of UI assessment and management for all personnel who care for frail older persons with UI and ensure that there is adequate service provision.

1. COMPONENTS

a) Identification of frail older persons. Health care providers can screen older patients with UI for
frailty using the Vulnerable Elders Survey, which can be administered in person or by phone [269]. Persons with a score of 3 or greater have four-fold increase in the risk of death and functional decline compared with persons with lower scores. A patient self reported scale in which those people classified as either frail or pre-frail had higher frequency of hospitalization, a higher probability of co-morbidity and higher mortality than those classified as non-frail has recently been reported [270]. However, caution still needs to be exercised when classifying an older individual as frail as there is considerable heterogeneity within this group [271].

b) Primary care assessment. Physician education using a modified version of the ACOVE model to reach a large group of primary care physicians resulted in between 80% and 92% of them planning to make a change in their practice behaviour [272], although no formal assessment of carry through was undertaken. Geriatricians’ and primary care physicians’ (PCPs) UI assessments were compared in a randomized multicentre study involving 364 subjects, 42% of whom self-reported UI to the investigators. Geriatricians were significantly more likely to detect UI (59% of cases vs. 16%), regardless of the severity of UI, and were more likely to refer to Continence Programmes (25%); all referrals by PCPs were to urologists.[273] An assessment strategy based on clinical evaluation, simple cystometry, and several criteria for referral was compared with urodynamic diagnosis. Approximately 25% of patients met criteria for referral, half of patients accepted urodynamic evaluation, yet urodynamics changed the treatment plan in only 12% of the patients who did not meet the a priori criteria for referral [274].

Practice patterns and adherence to US UI guidelines were evaluated by retrospective chart review of 300 consecutive patients aged >65y, seen by either an internist or geriatrician for UI at a tertiary care centre. Geriatricians ordered more testing, such as urodynamics, before referring patients to a surgical specialist. [275] Overall, primary care practitioners rarely follow the US Agency for Healthcare Research and Quality UI guidelines (now obsolete). [276] and nursing home practitioners rarely follow the Federal guidance for UI (now obsolete), [276] and nursing home practitioners rarely follow the Federal guidance for UI according to the "Practical manual for LUTS evaluation and treatment in the elderly For GPs (Japanese)" and found adherence to the manual, reinforced by educational and promotional activities resulted better treatment outcomes [278, 279].

A systematic review of articles identified only 5 studies meeting eligibility criteria, and all were in women. None of studies found sufficient diagnostic evidence (defined as positive > 5 and negative likelihood ratios < 0.02) for different types of UI. The best was a general population study reporting the utility of history and exam for the diagnosis of SUI (positive and negative likelihood ratios 3.23 and 0.40, respectively) [280]. Adding a nurse practitioner to general practitioner care for adult patients with UI can reduce the impact of UI [281].

c) Cough stress test. We found no additional evidence on the utility of the cough stress test since the last consultation. Utility of the cough stress test was studied in 97 incontinent female long-term care residents using blinded comparison with single channel cystometry. Of the 77% in whom single channel cystometry diagnosis was congruent with the stress test (i.e., urodynamic DO with negative cough test, no DO and positive cough test), all were correctly classified; no woman with SUI was missed nor were any with DO misclassified.[282] An analysis, 200 older women with UI found that provocative full-bladder cough test was as effective as radiographic or urodynamic pressure measurement in detecting SUI. Clinical diagnosis incorporating the cough test with leakage symptoms was 78% accurate, with only 6% false negatives for SUI, but was only 44% accurate with 45% false negatives for urgency UI [283].

d) Postvoid residual measurement. We identified no studies evaluating the impact of PVR measurement on clinical diagnosis and treatment outcomes. One study of 100 patients consecutively admitted to a geriatric ward found that 34% had PVR > 50 mL; these patients tended to have more UI (57% vs. 38%, p > .05), greater functional dependency, and a higher mortality rate (36% vs. 9%).[284] A study of the residual urine in a randomly selected community dwelling sample of men and women aged 75 years of age found more than 10 ml of residual urine in 91 of the 92 men (median 90 ml; range 10-1502 ml), and in 44 of the 48 women (median 45 ml; range 0-180 ml). The significance of this single measurement could not be estimated [285].

e) Urodynamic testing. Urodynamic testing is feasible and safe, even in frail nursing home residents. [63] There is no evidence, however, that urodynamic diagnosis changes the outcome of treatment. Expert guidelines have recommended urodynamic testing before surgical or minimally invasive UI treatment in frail elders [286].

f) Ultrasound estimation of bladder weight. A single study of men attending the uroflow clinic of mean age 65 (range 23 – 90) detected no statistically significant differences in ultrasound estimated bladder weight between men with Qmax <10mL/min versus those with >15mL/min [287].
2. SUMMARY OF EVIDENCE

1. Active case finding and screening for UI should be done in all frail older persons because many do not spontaneously report their symptoms. (Level 1).

2. Screening for frailty is possible with short screening instruments (Level 1).

3. Current quality of primary care assessment of UI in frail elders is poor (Level 2).

4. Cough stress test has moderate accuracy in frail institutionalized women (Level 2).

5. No recommendation is possible on the utility of PVR testing in the assessment of UI in frail elderly (Level 4).

6. Urodynamic testing is feasible in frail older people (Level 1) but it is unlikely to change management or outcomes except, perhaps, in those considered for surgical treatment of UI (Level 4).

3. RECOMMENDATIONS FOR EVALUATION (SEE ALGORITHM)

The essential first step is to actively case find in the frail elderly, as the condition is generally under-reported. The second is to identify treatable, potentially reversible conditions and other factors (medications, environment) that can cause or contribute to UI. Although UI associated with such factors has been commonly called “transient UI,” for most frail elderly it is a chronic and often progressive condition. It is important to evaluate for such contributing factors because their amelioration may improve UI directly, make UI more amenable to other interventions, and overall improve the patient’s (and carer’s) quality of life.[288]

The common, treatable, potentially reversible conditions that can contribute to UI in frail older people can be defined by the mnemonic DIPPERS ((Delirium, Infection [urinary tract], Pharmaceuticals, Psychological, Excess fluid (in/out), Restricted mobility, and Stool impaction [and constipation]). This is a useful aid to teach and remember these conditions [289]. Cognisance must be made of the potential to overtreat asymptomatic bacteriuria as apparent infection because of the risk of adverse outcome [290].

III. FACTORS IN MANAGEMENT

1. BACKGROUND

This section highlights the issues that distinguish management of incontinence in frail older people from that of healthier older adults. These include preferences for care, goals of care, determination of costs and benefits, special issues in drug treatment, and issues unique to frail elderly men. They incorporate knowledge of physiological, psychological, sociological, and economic changes associated with frailty and advanced age, and reflect the importance of patient-centred goals and the role of caregivers in this population. These factors provide the context of continence care and should be incorporated into the management of all incontinent frail persons, regardless of the choice of specific treatment.

2. ROLE OF COMORBIDITY IN MANAGEMENT DECISIONS

Many frail older people will have co-existing disability and comorbidity, both of which can influence the clinical presentation and assessment of UI, as well as responsiveness to interventions. Frail older people are not only at higher risk for unintended adverse effects from treatment (e.g., fulminate Clostridium difficile colitis from antibiotics used to treat otherwise asymptomatic bacteriuria), but also may realise additive benefits in domains other than UI [291] from UI treatment that is aimed at underlying comorbidity and impairment (e.g., topical oestrogen for irritating urogenital atrophy reduces recurrent UTIs); and a nursing home exercise programme done in the course of toileting improves both physical function and UI [5]). Likewise, management of chronic cough from obstructive pulmonary disease may benefit stress urinary incontinence.

3. DEFINING OUTCOMES FOR TREATMENT

Outcome measures must be fundamentally different from those used in healthy older persons, because of the heterogeneity of this frail population regarding comorbidity, remaining life expectancy (RLE), patient perceptions, personal values, and the involvement of caretakers and proxy decision makers. Unfortunately, intervention studies in the frail elderly remain focused on objective disease related variables and seldom, if at all, take account of these factors. Additionally, comorbidity is frequently used as an exclusion criterion in therapeutic trials. A review of care home residents’ views on continence showed that they valued having independent bowel and bladder function, but believed incontinence to be inevitable and intractable. Residents often had low expectations, and declined further evaluation and treatment [292]. There are no data on frail older peoples’ expectations from specific treatments.

Although quality of life (QoL) is a key concern for UI in all persons (see Committee 5, Initial Assessment Including Quality of Life), and has special relevance in frail elderly with limited RLE, there are few validated QoL outcome measures applicable to this population. Only one validated UI-related QoL measure is derived specifically from patient-based data among persons older than 65, and these subjects were community-dwelling and relatively healthy [293]. None of the ICI-endorsed UI-related QoL measures have been validated in oldest-old or cognitively and/or functionally impaired persons. Traditional UI QoL domains—e.g.,
impact on IADLs, travel, sexual relations—are often not relevant to frail elderly, and there could be significant “floor effects” for social and role function domains. One alternative QoL domain for frail elderly is social interaction, especially for nursing home residents;[294] an analysis of cross sectional and longitudinal data from over 100,000 US nursing home residents found that prevalent and especially incident UI had negative impact on social interactions, particularly among persons with moderate ADL impairment.[294] An analysis of older Medicare beneficiaries over 65 years of age, and including those over 85, found significant impairment of QoL, in accordance with that found in younger people[295].

The profound question when considering UI outcomes in frail older persons is, “Is complete cure ever possible?” In short, this depends on patient factors, specific treatment(s), and the target outcome. While no geriatrician endorses “ageism” and therapeutic nihilism, research evidence suggests that complete dryness is unlikely for certain frail patients, particularly frail institutionalised persons with severe cognitive and functional impairment. Even “intractable” UI is amenable to interventions that may improve the patient’s urinary and bowel function and quality of life[4]. The Frail Elderly Committee of the Third ICI introduced an alternative continence paradigm for frail elderly (Figure 2), which subsequently was generalised for all persons with UI[296]. In this paradigm, people with “dependent continence” are dry as a result of ongoing assistance, behavioural treatment, and/or medications. UI would return if the interventions ceased, a situation analogous to chronic disease models[297] such as “controlled hypertension” or “controlled diabetes.” Persons with “independent continence” are cured without need for ongoing treatment (e.g., dry after successful anti-incontinence surgery). For patients who are unable to achieve independent or dependent continence, “contained incontinence” should be possible by use of appropriate products such pads, catheters, and appliances (See Committee 20, Management Using Continence Products), thus providing “social continence” or “accepted incontinence.”[298, 299] The balance between the degrees of continence achieved may vary as UI severity changes, and are dependent upon patient and caregiver preferences. All of these continence outcomes encompass a common need: to be both realistic and hopeful about UI in frail elders while avoiding nihilism and neglect; maintaining comfort and dignity and preventing avoidable complications of UI.

Although the ICS standardisation document on outcomes in older patients is now over 10 years old, little progress has been made and many of the identified needs still pertain (see Recommendations for Research)[7].

4. ROLE OF REMAINING LIFE EXPECTANCY IN TREATMENT DECISIONS

Remaining life expectancy (RLE) is a key yet often misunderstood concept in treatment decisions for frail older people. RLE is not uniformly short in this population; moreover, there is a demographic trend of increasing RLE, with a smaller proportion of persons spending their remaining years living with disability[300]. Evidence shows that many health care professionals will underestimate life expectancy[301]. Reference to actuarial tables produced for insurance purposes is often enlightening. Incorporation of RLE into treatment decisions in urology and gynaecology has been studied only in relation to cancer treatment. Only two studies, both in prostate cancer, examined specialists’ ability to estimate RLE. Canadian urologists were more accurate in estimating longer RLE: using scenarios based on actual patient data, 31% were accurate within 1 year, 67% within 3 years, and 82% in estimating greater than or less than 10 years in 82% of responses[302]. Comprehensive Geriatric Assessment can help estimate remaining life expectancy and can help predict treatment-related morbidity and mortality in older men with prostate cancer[303].

Walter and Covinsky[304] developed a graphical tool for estimating quintiles of RLE by age. Medical conditions most closely associated with shorter RLE are class III/IV congestive heart failure, end-stage renal disease, and oxygen-dependent chronic obstructive pulmonary disease. Estimates of RLE are significantly affected by frailty and cognitive impairment[305]. Functional status has a dramatic impact on life expectancy. For example, 75-year-old men and women without limitations have life expectancies 5 years longer than those with ADL limitation and more than 1 year longer than those limited in mobility[306]. Alzheimer’s dementia decreases RLE profoundly (by nearly 75%) among older persons who otherwise would be in the top quintile of RLE[307]. Compared to older persons with at most one IADL deficit, persons with more deficits have significantly higher 5-year mortality (with two deficit, adjusted RR 1.46 [95% CI 1.20 – 1.78]; with three or more deficits, adjusted RR 1.64 [1.26 – 2.14]) [305].

5. PREFERENCES FOR CARE

Because there are multiple treatment options available for frail older adults with UI, and individualised care should be emphasised, obtaining patients’ and carers’ opinions regarding preferences and goals for care is essential for quality care planning. It should not be assumed that persons with cognitive impairment are unable to make their care preferences known or participate in treatment decisions and all reasonable efforts to help them to do so should be made.

Preferences for toileting and changing were studied in 111 nursing home residents with UI; residents...
preferred an average of 2 pad changes, 1.5 toilet assists, and 2 walking assists more than they actually received, yet even these levels were lower than guidelines recommend, suggesting that residents may have reduced expectations based on their experience [308]. In a second, residents of board-and-care facilities and two nursing homes, their family members, and facility nursing staff were given definitions of and information about five UI treatment options (indwelling catheter, prompted voiding, adult diapers, electrical stimulation, and medications) [309]. Respondents were asked their preferences between pairs of treatment options (e.g., “diapers” versus prompted voiding). Most of the board-and-care respondents were continent, although some were undergoing UI treatment at an outpatient clinic. Patients and family members were evenly divided between “definitely” and “probably” preferring prompted voiding versus diapers. Almost 80% of nursing staff, however, preferred prompted voiding to diapers. Families perceived staff members as unwilling to perform prompted voiding, and some thought prompted voiding was degrading to the resident and that it was bothersome to be asked to go to the toilet frequently. Using a similar method, a German study with 117 geriatric hospital patients (mean age 85; 43% with UI), 72 staff members, and 71 family members, found that most patients preferred diapers (79%), medications (78%), and scheduled toileting (79%) over urinary catheters, and 64% preferred scheduled toileting [310]. When choosing between diapers and medication, equal proportions preferred each option. Patients with greater functional dependence were more likely to prefer catheters, and those with experience with diapers were more likely to prefer medications and toileting. Notably, spouses showed moderate to almost perfect agreement with patient preferences, but those of other family proxies had only slight to fair agreement. In a qualitative study of 25 women with pelvic floor dysfunction living in residential facilities, residents expressed a desire to live with their problem rather than undergo assessment and management, emphasizing the need to include the patient in management decisions at the outset [311].

6. COSTS AND BENEFITS OF UI TREATMENT IN FRAIL ELDERLY

An overall discussion regarding UI-related costs is covered by Committee 22, Economics of Incontinence. The following discusses UI cost issues specific to the frail elderly.

a) Estimating Costs. For the majority of developed countries, the greatest increase in population is occurring in the oldest old, those > age 85. This group has the highest prevalence of UI, and accordingly the increased prevalence of lower urinary tract symptoms will result in higher UI care costs. Such an increase has already been observed between 1992 and 1998 amongst US women aged > 65 [312]. The costs of care for older persons has
been estimated at double that for people under 65, but care for those older persons living in institutions was less than for community dwelling individuals [313]. Likewise, the cost of OAB in five European countries is estimated to rise by one billion Euros between 2000 and 2020,[314] and in the US it has been estimated that by 2030 the greatest increase in demand for UI care (81%) will be in older women aged 60-89 with OAB symptoms [315]. In one US study using a community managed care population, the presence of OAB and comorbidity doubled the associated costs of UI care [316]. In South Korea, the estimated cost of treating overactive bladder was 117 billion Korean Won (KRW) in 2006 and 145 billion in 2007. The estimated total cost in treating stress urinary incontinence was 122 billion KRW in 2006 and 59 billion in 2007 [317].

Costs can be expressed as direct costs, indirect costs, and intangible costs [318]. Previous estimates have focused on diagnostic costs, treatment (including routine care and pads), and consequence costs (skin irritation, urinary tract infection, falls, fractures, additional nursing home and hospital admissions, longer hospital length of stay). Direct healthcare costs are most often estimated but there is a lack of meaningful research into indirect costs and those related to comorbidity in the frail elderly. Intangible costs have not been considered in these estimates because of their subjective nature and the methodological difficulty of collection and estimation. Much of the evidence for the cost of UI in older persons has been gathered from either epidemiological surveys or analyses of claims from insurance databases; these have often involved many assumptions or complicated formulae to calculate final costs. There is a consistent theme that the cost of caring for older adults with UI will increase, but the estimated magnitude of this increase is variable.

For the frail elderly, especially those in long term care, cost calculation is especially complex. The greatest costs for UI care in nursing homes are by far nursing labour costs [319]. Extrapolated costs for nursing home admission due to UI was $6 billion (2000 US dollars),[30] with institutional costs of UI management and consequences of $5 billion (2000 U.S. dollars). [320] In one small 6-month study, the mean daily cost of UI care, including direct nursing care, indirect nursing overhead, and supplies, was $9.09 (+ $ 10.52 ) per resident (2003 U.S. dollars) [321]. The costs for UI pads alone in Dutch long-term care have been estimated at 160 million Euros [322]. In an Australian sub-acute care setting, the costs of daily UI care was $49 AU, with most spent on staff wages [323]. In Canada, researchers found that 1% increase in UI prevalence was associated with an 11-12% increase in costs [324]. The extra nursing time needed to maintain toileting programmes contributes to high costs [325]. Routine garment and laundry costs may be lower than estimated because in practice residents are not changed as often as needed. In addition, for prompted voiding to remain effective, such things as regular refresher education programmes for staff or wet sensors may be necessary, and thus are rarely considered in cost estimates. Moreover, the time period over which the costs and benefit are calculated needs to be explicit because both benefit and costs will change, and patient morbidity and mortality need to be considered. The costs of correcting functional and medical causes of UI are rarely considered. Also, the potential differential in costs across the span of cognitive and functional impairment has seldom been assessed,[326] despite evidence that UI care costs are closely related to the degree of functional impairment [327]. Some surveys suggest that the costs of care for younger community dwelling adults outweighs that associated with the elderly, but there are wide variations of estimates depending upon the population studies [328].

Costs related to caregivers of frail persons with UI living in the community include lost wages, decreased productivity (both within and outside of the home), the additional number of caretaking hours when a frail person develops UI,[329] and the cumulative effect of increased strain and burden, along with any resultant illness. Overall, there is still limited data on costs of UI treatment in other residential (such as assisted living or rest homes) and acute care settings [330 (2004)], costs may vary by access to care. Because so many frail elderly are homebound or live in institutions, they often do not have the same access to the UI therapies as other populations. Their health care providers may be limited to primary care physicians, community nurses, and care assistants or aides with little to no expertise in UI management. Specialist consultation may be minimally available in home or long term care settings, leading to a focus solely on behavioural management and/or containment products. An assessment of a multi-component intervention based upon absorbent products, a structured skin care regimen, and nursing advice on incontinence associated dermatitis revealed that incontinent residents used an average of 5.19 absorbent products, at a mean cost of € 1.79 per day. Following introduction of the intervention, the mean number of absorbent products consumed per day was 2.02 per incontinent patient, at a mean cost of € 0.97 per day [331].

Cost relates strongly to reimbursement, which varies considerably from country to country, depending not only on structure of the health system but special programmes for the aged and persons with UI (see Models of Care below). Within particular countries, there may be further variation based on insurance, co-insurance, drug versus procedure coverage and incentives, access to care, programmes for vulnerable populations, and urban/rural differences.

b) Benefit and effectiveness of treatment. The ability to define the benefit of UI treatment in frail older people is highly dependent on the individual, their caregivers, and the health care system.
comes research indicates that patients value quality of life, which encompasses many domains besides reduction in UI (See Committee 6, Symptom and Quality of Life Assessment). Even cognitively impaired people can still express treatment preferences [310, 332], so it is also possible to evaluate domains of quality of life (e.g., social interaction) [294] and assess treatment satisfaction directly or behaviourally. At the same time, we found no data on the value or utilities frail elderly or their caregivers assign to varying degrees of UI (with or without treatment intervention) versus “dryness.” Standard outcomes such as quality adjusted life years (QALYs) may overestimate effectiveness in older people,[333] not just because of potentially different utilities, but because of the altered importance of “years of life saved” in a population with variable and sometimes limited remaining life expectancy.

The need for novel and specific outcomes for use in both trials of UI interventions and clinical care of incontinent frail elderly people continues. Outcomes measured by single item tools of perceived benefit or satisfaction with treatment are unlikely to be generalisable across the heterogeneous older population. It should not be assumed that perceived benefit of treatment can be measured with the same tools across cultures and health systems, unless such tools are sensitive to differences in such things as reimbursement and provision of continence services and supplies. The association between expectations, preferences, and outcomes needs to be prospectively studied in relevant ad representative populations. New approaches and tools to assess UI-specific quality of life in cognitively-impaired frail elderly are needed, as well as better understanding of the interaction between functional impairment and the impact of UI [294]. When QALYs are included as an outcome in UI treatment trials in older persons, they should be specifically analysed by age and also possibly health status.

7. ISSUES IN DRUG TREATMENT

a) Age-related changes in pharmacology. Specific age-related changes in pharmacokinetics, alteration in drug absorption, distribution, metabolism and clearance, and their potential effect on UI drugs, are shown in Table 6. Age-related pharmacokinetic changes are rarely considered in planning the duration of time off previous UI medications, placebo-run in periods, and wash-out periods in UI drug trials in older persons. The numerous factors potentially affecting drug clearance in such patients, as well as previous and/or cross-over compounds, may confound observed drug effects. Age-related changes in pharmacodynamics have been described for benzodiazepines, beta-adrenergic agents, and opiates [334, 335] but there are few available data concerning change, even in these, other than for limited numbers of community dwelling older people.

b) Availability of low dose agents. One effect of the under-representation (if not exclusion) of frail older persons in UI drug studies is a lack of knowledge regarding minimal effective drug doses for this population. The age-related changes in pharmacology noted above suggest that some UI drugs may be effective at lower than standard doses in frail elderly with concomitant decreased adverse effects [336]. This issue is especially relevant for extended-release preparations, which cannot be divided into smaller doses. There are some data supporting the effective use of low dose oxybutynin in older persons, but such studies are exceptional [337, 338].

c) Inappropriate polypharmacy. Approximately 60% of people over age 65 take at least one prescribed medication, and about one-third take more than five prescribed drugs. In addition, many take over-the-counter and naturopathic or herbal agents, with the rate of use varying across countries and cultures. The likelihood of adverse drug reactions (ADEs) and drug interactions rises exponentially as the number of medications increases. This has led to the recommendation in geriatric prescribing to “subtract before adding,” to consider whether target symptoms might be due to medications before adding another drug targeting those symptoms. This approach is relevant in geriatric UI, as UI may have been precipitated and/or worsened by medications (see Table 3). Changes to existing drug regimens should be considered in the management of UI in all frail older people. The national audit of continence care in the United Kingdom reported that of older adults, mean age 80 years, only 27.5% (2082/7572) had documented evidence of a medication review [339].

d) Adverse drug effects. ADEs are extremely common in older persons,[340] with rates up to 35% among community-dwelling persons aged > 65 in the US [341], and up to two-thirds of long term care residents [342]. In a recent UK study, 59% of ADEs requiring hospital admission involved patients aged > 60 [343]. Factors associated with higher ADEs in the elderly are higher drug doses, age-related pharmacological changes, polypharmacy, comorbid conditions, and the interactions between them and female sex [344, 345]. Older people are at higher risk of ADEs from antimuscarinics because of age, and comorbidity-related changes in muscarinic receptor number and distribution, blood-brain barrier transport, and drug metabolism [346]. Whereas antimuscarinic ADEs in younger persons are bothersome, in the frail elderly they can result in serious morbidity such as sedation, heat intolerance, delirium, and falls.[4]

A major antimuscarinic ADE of concern in frail adults is cognitive decline, yet there is little data about its actual incidence or prevalence. Cognitive effects may be under-detected because they are clinically subtle, neither asked about nor reported by the patient, or mistaken for age-related diseases

and ageing [347, 348]. Persons with pre-existing cognitive impairment (especially from conditions known to affect central cholinergic pathways) may be at greater risk for this ADE although there are some data to suggest that those with established dementia may not experience cognitive decline following therapy with anticholinergic agents [349]. Actual incidence rates of cognitive impairment with antimuscarinic agents for UI are difficult to estimate because of probable under-reporting [64], the different measures used across studies, failure to specify the measure in published trials, the use of proxy measures (such as quantitative EEG), and differences in psychometrics and clinical relevance of self-report, physiologic, and performance measures of cognition.

Xerostomia is common in older people [350]. A study of 175 acutely hospitalized community dwelling older people (mean (SD) 82 (5.7) years) and 252 outpatients (mean (SD) 77 (5.7) years) found that 63% of the hospitalized elderly and 57% of outpatients complained of dry mouth. Dry mouth was more common amongst those on multiple medications [351]. In general, older people, women and those taking multiple medications are more likely to report the symptom. Antimuscarinics clearly may exacerbate this condition, leading to concerns about deteriorating dental health and a 2011 warning to the Food and Drug Administration from the American Dental Association [352]. Meta-analyses of bladder antimuscarinics show minor variations in the incidence of dry mouth from clinical trials, with oxybutynin associated with the highest prevalence [353]. A recent subcut analysis of a randomized controlled trial of solifenacin, 5mg/day, versus oxybutynin 5mg tid, examined the tolerability of both drugs in subjects under and over the age of 65 years, the study found that dry mouth was no more common amongst those over the age of 65 but was more common and more severe with oxybutynin [354]. In those over 75 years of age treated with 8mg versus 4mg of fesoterodine from a pooled analysis of data from registration trials, dry mouth was more common in the older aged sample [355].

Another antimuscarinic ADE to which the frail elderly may be predisposed is decreased visual accommodation, yet this has been specifically evaluated only in young healthy volunteers,[356] and
drug trials typically report only “blurred vision,” without further characterization.

The incidence of increased PVR as an ADE is seldom reported in clinical trials of antimuscarinics for UI or OAB. When it has been reported, the magnitude of increase is seldom of clinical significance. The incidence of acute urinary retention with antimuscarinics in general is low, but it has not been systematically evaluated in the frail elderly. There is no consensus as to what constitutes a sufficiently high PVR to preclude antimuscarinic treatment or to require dose adjustment of an already prescribed agent. If urinary frequency or UI worsens after an antimuscarinic is started or increased, then PVR should be checked because an increased PVR will lower functional bladder capacity and worsen UI. PVR should be monitored in frail older men treated with antimuscarinics who may not reliably report changes in LUTS or voiding difficulty. The majority of men with clinically relevant outlet obstruction are excluded from treatment trials and the results of such studies should be viewed in that light.

e) Drug interactions. Because frail older people take higher numbers of drugs and usually have several comorbid conditions, drug interactions are more common [357]. All antimuscarinic agents for UI will have additive side effects when combined with other anticholinergic agents. Antimuscarinics could potentially alter the absorption of other drugs by slowing gastrointestinal motility.

Drug-drug interactions for oxybutynin, solifenacin, darifenacin, and tolerodine include potent CYP3A4 inhibitors (azole antifungals, macrolide antibiotics, cyclosporin, and vinblastine). Fesoterodine, a pro-drug that is converted to tolerodine by non-specific esterases, is also dependent upon CY3A4 for its excretion. There is one case report of interaction between tolerodine and warfarin in 2 older patients, [358] which has not been seen in healthy volunteers. Naturopathic/ herbal preparations should also be considered for potential interactions, especially in areas where these agents are used frequently.

There is still uncertainty regarding interactions between antimuscarinic agents for UI and cholinesterase inhibitors (CEIs) used for dementia. There is evidence CEIs can cause or worsen UI from a case report [359] and also a case series of 216 consecutive patients with probable Alzheimer’s disease attending a memory treatment centre [360]. In the latter, CEI treatment was overall associated with 7% risk of new UI: the highest risk was observed in patients with more behaviour problems, and lower risk in patients who demonstrated positive cognitive and/or behavioural response to CEI. Further evidence for an interaction between antimuscarinics and CEIs comes from a database study of nursing home residents in one US state [361]. Residents with dementia, newly treated with cholinesterase inhibitors, were more likely to then be prescribed a bladder antimuscarinic than those residents with dementia not given a cholinesterase inhibitor, an example of a geriatric “prescribing cascade.”[362] Concomitant use of antimuscarinics (extended release oxybutynin and tolerodine) and cholinesterase inhibitors in nursing home residents was associated with a decline in ADL function in the most functionally able residents but there was no worsening of cognition, probably because the cognitive measure (MD-S-COG) was inadequately sensitive. More importantly, there was no case of delirium observed [363]. A recent study in which the primary objective was to assess the cognitive impact of trospium chloride in older people with dementia treated with galantamine over a six month period. The study hypothesised that galantamine in combination would not result in any adverse outcome such as that reported by Sink [363]. 46 subjects with UI and dementia were enrolled, 10 withdrew from the study. No effect on cognition or activities of daily living was detected over the duration of the study. A within group analysis demonstrated an improvement in nocturia and reduction in pad use in this combination group [364]. A small study reported some positive effect of the treatment of UI with propiverine in subjects with probable AD taking cholinesterase inhibitors [365]. Although intuitively illogical, given the opposing pharmacological actions, there seems to be no reason not to use bladder antimuscarinics for older people with dementia. The current weight of evidence appears to be that a positive outcome in terms of bladder control can be achieved without a significant detriment in either cognition of activities of daily living.

Drugs also may interact with comorbid conditions (drug-disease interactions), such as diseases that affect hepatic or renal metabolism and clearance, slow gastric motility (e.g., advanced diabetes), predispose to delirium, or are associated with impaired central cholinergic transmission (Alzheimer’s and Parkinson’s diseases).

f) Potentially inappropriate drugs for older persons. Efforts at quality improvement for older populations have led to the development in several countries of expert consensus guidelines regarding inappropriate drugs for older persons,[366, 367] although the continuing relevance of these guidelines has been questioned and alternative systems suggested [368, 369]. A revised Beers criteria was introduced in 2012 [370]. These guidelines focus on drugs with lower risk-benefit ratios and higher potential for drug-drug and drug-disease interactions, and are used for nursing home regulation and quality performance measurement. The concerns regarding oxybutynin and tolerodine in causing urinary retention have been removed. All bladder antimuscarinics are included because of their risk of causing constipation and darifenacin, fesoterodine, flavoxate, oxybutynin, solifenacin, tolerodine and...
tropium are noted with respect to their anticholinergic properties.

8. SPECIAL ISSUES UNIQUE TO FRAIL OLDER MEN.

Although their ranks thin into the ninth decade, men still comprise a significant portion of frail older persons. The prevalence of UI increases in men after age 80, going from about one-third of the rate in women to the same. Over the past ten years, the prevalence of UI in US male nursing home residents aged 65-74 has increased to a greater extent than in female residents (from 39% to 60%, compared with 45% to 59%) [371]. At the same time, frail men are under-represented in UI treatment trials, whether behavioural, pharmacological, or surgical (see also Committee 15: Surgery for Urinary Incontinence in Men). Since the time of the last ICI, the European Association of Urology has summarized their recommendations (2012) for Urinary incontinence in frail/older men and women [372].

This under representation is unfortunate, because results from treatment trials in frail women cannot be directly extrapolated to men for several reasons:

- **Differences in comorbidity**: frail older women have higher rates of functional impairment and chronic disease and geriatric syndromes which may mean that frail men may be more likely to respond to behavioural intervention [373, 374]. For older adults who become incontinent, a composite measure of physical performance (rising from a chair, walking, balance) is a better predictor of UI incidence in men than in women [375].

- **Differences in the relationship between UI and cognition**: one systematic urodynamic study of nursing home residents with UI found a significant association between DO and more severe cognitive impairment in women, but not in men (although power was likely low, as the number of men was only 17) [63].

- **Differences in caregivers**: more older men have living spouses who can provide care, with a potential impact on the risk and type of caregiver burden associated with UI management.

- **Prostate cancer**: nearly all men in their ninth decade have histological evidence of prostate cancer. However, it is not clear that frail elderly men have an increased risk of prostate cancer-specific mortality, especially given that their RLE is primarily affected by comorbid conditions. The need to screen for and treat prostate cancer diminishes with functional status, comorbidity, and RLE [376]. At the same time, more men are living with the sequelae of prostate cancer treatment, particularly stress UI after radical surgery.

- **Benign prostate disease**: the prevalence of histological BPH, BPE, and BOO increase with age, and is associated with LUTS, UI, and DO. In the urodynamic study cited above, 29% of men had BOO and 59% had DO as the predominant cause of UI, versus 4% BOO and 61% DO in women [63].

- **Risk of urinary retention**: because of age-related decrease in detrusor contractile function and increased likelihood of BPE and BOO, it is often assumed that frail elderly men have a higher prevalence and risk of urinary retention. However, this has never been demonstrated. Among NH residents with UI, the prevalence of underactive detrusor was similar in women and men (38% and 41%, respectively), despite the higher prevalence of BOO in men [63].

- **Differences in device usage**: A nationally-representative survey of adults in the US showed that older men were nearly three times less likely than older women to use pads to contain leakage (15% vs. 45%) [377]. Newer data from Scandinavia, where some countries provide absorptive pads as part of the health care benefit, showed that this gap might be narrowing (22% vs. 48%), and that increased functional impairment was associated with greater pad usage [378]. In a survey of patients recruited from family practice clinics in the Netherlands, the gender difference for pad usage by older adults with UI was even higher, with 4 out of 5 women using pads versus 1 of 9 men using pads [379]. Men are also more likely to be users of indwelling catheters, both in the long-term care setting [256] and in the community [378].

- **Differences in medical treatments**: there are medications that might be used by only one gender, or might have distinct side effect profiles. Alpha-blockers in particular should be cautiously considered in men with suspected outlet obstruction from prostate disease, due to their potential side effects of causing orthostatic hypotension. (Grade C) [372]. The interactions of UI and other conditions with regards to orthostatic hypotension and risk of falls merits attention. In a German registry of 3,414 patients with Parkinson’s disease, for those with urinary incontinence (716; 21%), orthostatic hypotension was reported for 14% of the men, yet only 9% of the women [380]. On the other hand, for women and men who had strokes and urinary incontinence, both were equally more likely to sustain a fall after stroke, though women were more likely to sustain an injury (OR 1.5) than were men [381].

- **Differences in surgical treatments**: there are gender-specific devices and surgical approaches that do require active management on the part of the patient. In particular, certain frail older men might not be appropriate for placement of an artificial urinary sphincter due to co-morbidity, medications and cognitive and/or functional impairment would not allow for the individual to manage the device on his own (Grade C) [372].

Despite the issues noted above, evaluation and management of UI in most frail older men follows the same roadmap as for frail women (see Algorithm).
9. SUMMARY OF THE EVIDENCE

1. Patients and caregivers have clear preferences for the type of UI management, and they are often discordant between the two groups (Level 2).

2. Age-related changes in pharmacokinetics affect antimuscarinic drugs for UI and should be incorporated into treatment planning. (Level 1-2)

3. Drugs may be effective at lower doses in frailr compared with healthier older persons (Level 3).

4. Polypharmacy increases the chance of adverse reactions to drug therapy. (Level 1)

5. Adverse drug events are more common in the frail elderly. (Level 2)

6. Drug-drug and drug-disease interactions are common in frail older persons (Level 1-3).

7. The economic burden of UI in frail elderly, as well as the cost-benefit, cost-effectiveness, and cost-utility of its treatment, has been incompletely characterised (Level 4).

8. The majority of drugs for treatment of overactive bladder remain flagged as potentially inappropriate medications for older people (Level 3-4).

IV. TREATMENT OF URINARY INCONTINENCE IN THE FRAIL ELDERLY

1. LIFESTYLE INTERVENTIONS

As treatable and potentially treatable correlates of and risk factors for UI are determined, interventions that ameliorate their effects have been devised. Several lifestyle interventions have been evaluated in healthier older and younger women, including dieting and medication to help with weight loss, dietary modification, fluid selection and management, and constipation management (See Committee 12, Adult Conservative Management). Although many health care professionals advocate lifestyle interventions to treat UI,[382-385] we did not locate any studies investigating these interventions for the frail elderly. Some of these interventions may be inappropriate for or impractical to use in frail older people, for example weight loss, yet advanced age alone should not preclude use of lifestyle interventions if assessment warrants this. Inadequate fluid intake and dehydration are common in long-term care residents [386]. Dehydration may actually increase the risk of UI in frail elders, because of its significant association with constipation and delirium, both known risk factors for UI [387-389].

a) Quality of data and results.

We located articles addressing lifestyle interventions for UI in older women, but the number of oldest-old subjects was very small, few to none appeared to be frail, and no studies stratified results by age. Two very small older trials and one recent small RCT [390] raise the possibility that increased hydration for incontinent frail elderly may actually decrease UI [391, 392].

b) Summary of the evidence (see Table 7)

1. No recommendations are possible regarding lifestyle interventions for UI in the frail elderly (Level 4).

2. BEHAVIOURAL INTERVENTIONS

Behavioural interventions have been especially designed for frail older people with cognitive and physical impairments that may affect their ability to learn new behaviours or to actively participate in self-care activities. These interventions evolved from classical behavioural change theory, using antecedent and/or consequent conditioning to shape the desired behaviour. Because behavioural interventions have no side effects, they have been the mainstay of UI treatment in the frail elderly [393].

</table>
interventions, also called voiding programmes, used predominantly in frail adults, all of which require active caregiver participation, include:

- **Prompted voiding**, involving prompts to toilet with contingent social approval, is designed to increase patient requests for toileting and self-initiated toileting, and decrease the number of UI episodes. It was first used in the 1980s for incontinent nursing home residents [394].

- **Habit retraining**, which requires the identification of the incontinent person’s individual toileting pattern, including UI episodes, usually by means of a bladder diary. A toileting schedule is then devised to pre-empt UI episodes. There is no attempt in habit retraining to alter an individual’s voiding pattern [395, 396] 

**Timed voiding** involves toileting an individual at fixed intervals, such as every 3 hours. This is considered a passive toileting programme; no attempts are made at patient education or reinforcement of behaviours, or to re-establish voiding patterns [397]. Other terms used to describe timed voiding are scheduled toileting, routine toileting, and fixed toileting [393, 397].

**Combined toileting and exercise therapy.** Functional Intervention Training incorporates strengthening exercises into toileting routines by nursing home care aids (nursing assistants) [398]. Another combination intervention, administered by occupational or physical therapist, involves toileting and mobility skills [399].

Cognitive and functional impairments common in frail elderly persons may preclude the use of some of these interventions. In addition, the context in which care is provided has been implicated in the provision of continence care [400-402]. Staff buy-in for the intervention is considered an important component to behavioural interventions [403]. Consideration of organisational and social factors and interplay among older adults, by the healthcare team, is considered important to implementation of evidence-based practices [404].

Although pelvic floor muscle rehabilitation has not been studied extensively in frail older persons, age and frailty alone should not preclude their use in appropriate patients with sufficient cognition to participate [405, 406]. Similarly, a combined behavioural modification programme involving pelvic floor muscle exercises, bladder training, and information about lifestyle modifications that prevented UI in community-dwelling older women aged between 55 and 80 years [407], could be effective in some frail older women, but we located no studies that reported on promotion or maintenance of urinary continence in frail older adults.

**a) Quality of data**

Since the last ICI, we identified a metastudy of systematic reviews for bladder training, prompted voiding, habit retraining, and timed voiding using a metastudy framework [396]. This metastudy confirmed our earlier findings. The majority of trials included in the systematic reviews did not determine the type of UI, or sufficiently describe whether comorbidity that possibly contributed to UI was evaluated or treated. Randomised trials in long term care have overwhelmingly depended on research personnel to supervise or conduct the interventions. Studies repeatedly show that, once a trial ends, the long-term care staff rarely maintains the intervention at the same level, if at all. Outcome evaluation is usually limited to “wet checks” (percentage of times the patient is found to be wet on a set schedule) and not UI, and no studies report cure or patient-based outcomes, such as satisfaction with treatment and quality of life. No studies reported impact on caregivers. One trial investigated the effects of prompted voiding, exercise, fluid and food intake on faecal and urinary incontinence. Trained research staff provided the intervention 5-days a week between 7am to 3:30pm for 12 consecutive weeks [390]. Few intervention studies have been conducted with incontinent hospitalised and home-bound frail elders. One study with hospitalised older patients found that the main intervention used for urinary incontinence was absorbent products [408]. Incident urinary incontinence at hospital discharge was associated with absorbent product use during hospitalisation [409].

Limitations in many studies include: small samples with low power to detect significant differences; variable terminology and operational definitions making comparisons across studies difficult. Additionally, there is little ethnic or cultural diversity; much data are limited to women, especially in nursing home trials. There is little focus on night-time UI; little consideration as to the psychological impact of toileting programmes on patients and caregivers, and no long-term follow up [393, 410]. Many studies excluded frail older adults with terminal illness, inability to respond to a one-step command, or poor language ability [411-414]. Ethical concerns for human subjects prohibits withholding treatment, thus true “control” groups were nearly impossible to create. Two studies used delayed treatment as controls [413, 414] The frequency of the intervention varied across studies as well, with toileting conducted every two hours over 12-hour, 14-hour, and 24-hour schedules [394].

**b) Efficacy (Table 8)**

**Prompted voiding** is more effective, in the short-term, than no intervention for improving daytime dryness in nursing home residents and some home care clients (Level 1) [415]. A three-day trial of prompted voiding should be initiated, and the intervention should be continued, but only in those that achieve appropriate toileting rates (the number of times the resident voided into the toilet divid-

</table>
ed by the total number of voids) of > 66%, or a wet check rate (number of times the resident was wet when physically checked) of <20% [416]. All others should be managed by check and change. This approach allows prompted voiding to be targeted just to the approximately one-third of residents who are eligible for and respond to prompted voiding, and could help decrease the considerable time and labour costs now used for inappropriate, unsuccessful toileting [417]. The 2005 revised US guidelines for continence care in nursing homes approved this approach as quality care [418]. Prompted voiding with food and fluid management and exercise was effective in reducing UI frequency and increasing the number of appropriate toileting episodes. Those nursing home residents with less cognitive impairment (higher Mini Mental Status Examination scores) showed lower improvement than those with more cognitive impairment [390].

The large majority of prompted voiding trials were conducted in the United States. No data are available about the long-term effects of prompted voiding and there is no evidence relating to the adoption of such programmes in other jurisdictions.

There is insufficient evidence to determine if timed voiding improves continence (Level 4) [419]. No additional intervention studies on timed voiding were located since the previous International Consultation. Several of the studies included in a systematic review had only female subjects with cognitive impairment, and included use of additional interventions such as antimuscarinic drugs (propantheline or flavoxate), staff education, bedside commodes, and absorbent products.

There is insufficient evidence to determine if habit retraining improves continence (Level 4) [420, 421].

**Functional Incidental Training (FIT)** incorporates endurance and strengthening exercises (e.g., sit-to-stand, bicep curls) while an aide conducts prompted voiding with a resident. FIT significantly improves physical endurance and UI (measured by wet check). Across several different long-term populations, FIT led to a 38% reduction in daily urine loss [5, 398, 399]. However, all FIT efficacy trials relied on trained research nursing staff, FIT costs more than usual care, and it may be difficult to implement in nursing homes without changes in existing staffing levels, limiting its generalisability [5, 422, 423].

**Operant behavioural strategies** have shown some effectiveness in improving UI in long-term care residents (Level B) [394, 395]. The underlying principle is that behaviour is modified by its consequences, even in frail adults [424]. A balance must be struck, however, between encouraging self-care activities and patient preferences for care and functional ability, on-going evaluation of the frail older person’s status, and treatment effectiveness.

c) **Summary of evidence**

1. Prompted voiding is effective in the short-term treatment of daytime UI in nursing home residents and home-care clients when caregivers comply with the protocol (Level 1).
2. Prompted voiding is ineffective and should not be used for people who need the assistance of more than one person to transfer; these people should be managed with “check and change.” (Level 1).
3. Prompted voiding should not be continued in eligible persons who have less than a 20% reduction in wet checks (Level 1) or toilet successfully less than two-thirds of the time after a three-day trial; these people should be managed with “check and change.” (Level 1).
4. Interventions combining toileting and exercise, decrease wet checks and improve endurance in nursing home residents, including those with psychiatric disease (Level 1).
5. Interventions combining prompted voiding, exercise, fluid and food intake interventions improve UI frequency and appropriate toileting (Level 1).
6. It is uncertain whether habit retraining reduces UI in frail older persons (Level 4).
7. It is uncertain whether timed voiding reduces UI in frail older persons (Level 4).
8. There are no proven interventions to reduce night-time UI in frail older persons (Level 4).
9. There are no proven interventions to reduce the incidence of UI in hospitalized frail older persons (Level 4).

d) **Interventions with caregivers and long term care staff**

Acute care patients have preferences for urinary incontinence treatment that is significantly discordant to hospital staff. For example, nurses and physicians preferred scheduled toileting over diapers more than the patients [310]. The authors suggested that communication about treatment preferences should occur.

3. **INTERVENTIONS WITH LONG TERM CARE STAFF AND CAREGIVERS**

Many frail elderly people rely on family, caregivers, or residential and/or nursing staff for toileting assistance and personal care. These carers may not be available as frequently as necessary for the frail elder to maintain continence, and even if available they may not be able or willing to provide the needed assistance. Research has shown that the frequency of toileting assistance actually provided in US nursing homes is too low to maintain continence [425, 426]. There is dissonance between
nursing home surveyors, nursing staff, and nursing home administrators' knowledge and beliefs about UI and its management, which may be an important barrier to effective UI care [427]. A number of studies suggest that nurses in acute and long-term care settings continue to provide urine containment interventions rather than promoting continence [249, 250, 253, 255-258, 428-432]. For example, 99% of residents with UI in one study facility wore absorbent products and only 3% had received UI treatment [433]. Moreover, nursing staff preferences for UI management (toileting) often conflict with those of residents and their families' patient treatment preferences (medications and garments) [309, 310, 434]. Acute care patients' preferences for urinary incontinence treatment also differ from hospital staff preferences [310]. For example, nurses and physicians preferred scheduled toileting over diapers more than did the patients [310]. The authors suggested that communication about treatment preferences should occur.

In long term care, a two-pronged behavioural intervention to UI care, one geared towards the resident and the other geared towards staff members, appears necessary [435-437]. Nursing assistants play a key role in the success of behavioural programmes, and organisational schemes need to be devised to create incentives for them to keep residents continent [438]. Direct care providers will be unlikely to implement programmes unless residents and their families advocate for them [439]. This advocacy, however, appears unlikely if, based on their experiences, nursing home residents have reduced expectations and do not anticipate receiving sufficiently frequent and prompt toileting, and therefore express no desire for more frequent toileting [426]. One documented barrier to toileting programmes in long term care is their labour intensity. Bladder training programmes are considered one of the three most time consuming activities for long-term care staff [321].

A number of approaches have been trialled in an attempt to promote continence and to improve the management of incontinence care in long term care facilities. One involves a specialty practice exemplar model to improve continence care in long-term care, with a nursing faculty member with expertise in the assessment and treatment of UI having a clinical practice in a facility. Graduate nursing students, working with this individual, focus on the Minimum Data Set Resident Assessment Protocol for UI. Assessment and treatment skills ultimately are transferred to the facility nursing staff members through several mechanisms, including staff education and improved continence care systems [440]. Quality assurance programmes using incontinence quality indicators have also been proposed [441]. A clinical leadership model in the sub-acute setting in Australia used a staff empowerment and mentorship model to make evidence based changes related to continence care during the patient’s stay and on discharge [442]. The effectiveness of clinical leaders may depend on a number of factors including, but not limited to their educational preparation for the role; the extent to which they feel supported; and; maintenance of the role (i.e. succession planning).

a) Quality of data.

Several authors point to the difficulty of conducting research in long-term care settings [435, 436, 443]. Factors such as staffing ratios, changes in administrative and regulatory policies, and fiscal issues are beyond researchers' control. Several investigators report that staff compliance was less than total, and some experienced problems with staff training. For instance, in one study several staff members did not attend group-training sessions and needed one-on-one training, and other staff members did not perform the protocol or document its use, especially when staffing levels were low [436]. Little staff intervention research to improve continence in older persons has been conducted in the acute-care setting.

b) Results

1. INTERVENTIONS WITH LONG-TERM CARE STAFF

A recent systematic review of the management of incontinence and promotion of continence in older people in care homes concluded that use of incontinence pads and toileting programmes comprised the most common management strategies, and assessment processes were inconsistently used [444]. Assessment protocols are a key first step in the process of identifying residents' individual continence care needs. A number of assessment tools have been developed for this purpose. They include, but are not limited to:

- the Resident Assessment Instrument/Minimum Data Set (RAI/MDS) used in US nursing homes;
- the ‘Continence, History, Assessment, Medications, Mobility, Plan’ (CHAMMP) tool, developed to support the use of the RAI/MDS [445],
- the ‘Capital Health Authority (CHA) Screening Tool’ for use within community and clinical settings in Canada, [446], and
- the Continence Assessment Tools for Residential Aged Care’ for use within Australian long-term care settings [447].

Toileting assistance programmes also play a central role in optimising continence for frail older adults in long term care settings. One group of researchers investigated the effect of a scheduled toileting programme on the incidence of nursing home staff injury, using a quasi-experimental design using a 75 bed unit and a similar comparison unit [448]. Fifty residents in the intervention unit were selected to participate based on an assessment indicating their eligibility for a toileting pro-
programme. Mechanical lifts were purchased for the intervention unit in anticipation of an increase in toilet transfers. Regular toileting increased from 12% pre-intervention to 67% in the intervention and 26% in the comparison unit. Staff injuries related to toileting did not increase in the intervention group, and the staff also noted less resident agitation. A pre-post test trial of toileting assistance programmes involving 153 elderly residents in Japan also reported improvements in residents’ continence status following a multifaceted intervention. Managerial support was key to the success of the intervention, as was the involvement of a clinical leader on each unit to oversee the protocol [449].

Although toileting assistance programmes are effective in reducing incontinence rates when implemented, and in-service classes on UI, in-service classes alone do not improve resident toileting. In one study, only 70% of toileting assists were completed [435]. The authors noted that staff members believed that toileting was “not worthwhile” for some residents. In a randomised study using advanced practice nurses (with post-graduate training) to work with staff to implement evidence-based protocols, residents in the intervention arm experienced significantly greater improvement in UI compared with those receiving usual care [450].

In response to knowledge deficits, some researchers have developed and trialled education and awareness-raising strategies, designed to enhance knowledge, that would subsequently lead to improvements in practice that would, in turn, enhance the quality of continence care in long-term care [205, 208, 220, 403, 451-455]. For example, a number of countries have established post-graduate and continuing education courses that prepare nurses and physiotherapists to address the broad spectrum of continence issues.

However, the association between improved knowledge and improved practice is not straightforward. Some researchers reported improvements in knowledge that did not translate into improvements in practice [205, 220, 453]. Cognisant of this dilemma, Henderson and Kashka [212] examined the association between knowledge, beliefs, attitudes and practice about incontinence in a sample of 126 nurses from hospital, home health and long-term care settings in Texas, USA, using a tool titled ‘the Urinary Incontinence Scales’. Using a multiple regression analysis, they found that although participants’ knowledge and belief were positively associated with their self-reported practice, attitude alone had a direct effect on self-rated practice [212], thus highlighting the need for educational strategies that address the effective behaviours associated with caring for incontinent persons. In response to this finding, and to greater calls for UI content in nursing curricula, as part of a larger educational programme on rehabilitation, one researcher designed a novel six hour experiential learning activity for nursing students to experience wearing an absorbent incontinence product [452]. Twenty-one senior nursing students volunteered to participate in the pilot trial. Using the Urinary Incontinence Scales to measure participants’ attitudes, beliefs, knowledge and practice, the researchers reported a post-test median increase of < 1% in attitude scores; 3.6% in belief scores; 4.4% in knowledge scores, and 47.6% in practice scores.

Given the longstanding challenges surrounding the uptake of evidence into practice, in 2005, Stollee and colleagues conducted a qualitative study to explore the factors within the work environment that impacted the effectiveness of continuing education. Data were derived from a series of focus groups with a sample of 35 staff and managers of long term care facilities, in Ontario, to collect information about factors affecting transfer of learning. This information was collated and a Delphi approach was used with 34 experts in long term care to validate and refine the list of factors. The need for managerial support was ranked as the most important factor. This was followed by: sufficient resources to implement new learning; the learner’s belief in the practicality of training; integration of the learning into ongoing practice; staff feeling valued; on-the-job reinforcement of learning; knowing change of practice is supported; seeing benefits of new approaches; and attitudes toward elderly people [456]. Whilst all of the above mentioned resource factors are important to optimise evidence-based continence care practice, a number of researchers draw attention to the need for theory to inform improvements in the quality of care [395, 457-462]. However, many translation of research into practice models for LTC rely on the belief that usual care staff are able to implement better care if they know what to do and are properly motivated [463]. One of the key steps in the process of translating evidence-based knowledge into practice is to identify potential barriers to change [464].

Research literature on UI in long-term care identifies extensive barriers to UI care [433, 463, 465]. A staff survey revealed that nursing assistants believed prompted voiding was very helpful to residents in reducing the frequency and volume of incontinent voids, but that inadequate staffing, staff work load, turnover, and absenteeism were significant barriers to prompted voiding. They believed that increased numbers of staff, improved communication, ongoing education, and alternative modes of care delivery were necessary to facilitate prompted voiding. Overall, staff believed toileting programmes improved resident quality of life but the realities of long-term care made them difficult to implement [466]. Nursing assistants believed that UI was a normal part of ageing and that nothing could be done for it, 99% of residents with UI in the study facility wore absorbent products and only 3% had received UI treatment [433].
A further challenge to continence care in long term care is the fact that differences may exist between documented care, reported care, and actual care. For example, when staff perceptions regarding completed toileting assistance were compared to research staff observations, staff over-inflated the percent of toilet assists they completed (stating 80-90% when the observed was 70%) [467]. Staff members also believed that residents were happier with a prompted voiding programme, yet only 52% thought the programme improved residents' continence. In another study, long-term care facility residents reported a mean of 1.8 daily assists to the toilet, regardless of whether they were on a toileting programme or not [439].

Another approach to translating evidence based protocols into practice, to enhance continence care for individuals living in long term care, involves the use of quality management programmes. Schnelle and colleagues tested a computerised quality management programme for prompted voiding in a convenience sample of 85 residents in eight US nursing homes [468]. Each facility was asked to identify staff members for the following roles: main contact person; quality control specialist; two licensed personnel who would conduct UI assessments; and two nursing/health care assistants who would implement the prompted voiding intervention. Information on the computer system included UI assessment and residents wetness rates. Research staff monitored the database and provided the nursing staff feedback by telephone consultation. The programme was effective in improving dryness for six months while research staff monitored the database, but only one facility continued the programme after the research ended [465]. The researchers noted that current incentives for nursing homes to maintain UI management systems are insufficient.

One disincentive that needs to be addressed, at a resource and policy level, is the fact that toileting assistance programmes require statistically significantly more staff time than the practice of checking and changing residents' pads. Engst and colleagues reported that the latter practice was 0.3-4.5 per resident [478]. There is some evidence to suggest residents may spend long periods of time in bed overnight (returning to bed after dinner about 6.30pm and waking between 0600-0700hrs), and staff conduct pre-scheduled rounds to reposition residents and change their pads [478]. In this study, although senior staff stated that such rounds were conducted every two hours during the night; the number of observed rounds was 0.3 - 4.5 per resident [478].

Interventions that have been trialled in an attempt to enhance the quality and duration of sleep for residents' with incontinence include:

- a daytime physical activity programme [480]
- a daytime physical activity programme combined with a night staff behaviour programme aimed at reducing noise, light and sleep-disruptive care practices [481].

Interventions for continence care in frail older adults should also aim to minimise the incidence of incontinence-associated dermatitis (IAD). Palese and Carniel [472] describe a three-phased multi-intervention incontinence care programme in a long-term care facility in Northern Italy that reduced the incidence of IAD, and the number, and cost of absorbent products. The intervention consisted of an assessment process, the introduction of new absorbent continence aids, a structured skin care regimen and advice and education from a Continence Nurse Advisor. To this end, it is important to use tools that help staff differentiate between IAD and pressure ulcers such as the Pressure Ulcer Classification (PUCLAS) education tool [473].

2. Interventions to Manage Night-Time Incontinence in Long-Term Care

Night-time sleep in long-term care residents is often fragmented and disrupted [474-479] and much of this fragmentation and disruption is caused by noise, light and incontinence care routines [476-478]. There is some evidence to suggest residents may spend long periods of time in bed overnight (returning to bed after dinner about 6.30pm and waking between 0600-0700hrs), and staff conduct pre-scheduled rounds to reposition residents and change their pads [478]. In this study, although senior staff stated that such rounds were conducted every two hours during the night; the number of observed rounds was 0.3 - 4.5 per resident [478].

As reduced mobility is a major risk factor for incontinence, further attention should be directed toward developing, implementing and evaluating interventions that increase residents' functional skills, or at the very least, minimise their functional decline, and prevent falls. van Houten and colleagues [399] report reductions in the daily loss of urine for elderly dependent women randomized to an 8-week individualised training programme of mobility and toileting skills. Two systematic reviews affirm the value of rehabilitation and falls minimisation strategies for frail older adults in long-term care [189, 471]. Given the association between the use of restraint and incontinence in long-term care settings, interventions designed to prevent and reduce restraint use should also be adopted.

These resource costs may however be offset over time by improvements in residents' functional abilities. Another cost minimisation strategy is to identify and target residents who are most likely to benefit.
• a two or four hourly incontinence care schedule based on an individualised assessment of each resident’s skin health [482].

• an individualised incontinence care routine combined with feedback to usual care staff about methods to reduce noise levels [483].

• a two or four hourly prompted voiding schedule based on an individualised assessment of each resident’s skin health [484].

• a four or eight hourly pad changing regime based on an individualised assessment of each resident’s skin health [485].

The combined findings of these trials suggest that continence care at night in long-term care settings can, and should be individualized based on an assessment of residents’ skin health; their ability to spontaneously move in bed; and on their sleep/wake status. It should also be based on an assessment of residents’ preferences. Whilst toileting assistance should be available to residents’ during the night as well as day, one study suggests that prompted voiding is not effective or well tolerated at night. The researchers concluded that ‘in general, incontinent nursing home residents are not responsive to prompted voiding at night, even when the prompts are carried out so as to be minimally disruptive to sleep [486]. Clearly, further research is needed about residents’ preferences for nighttime continence care.

One of the main reasons for residents’ sleep disruption is due to the time-honoured practice of waking residents with incontinence to check their continence status and to reposition them in order to minimise the risk of pressure ulcers. The Agency for HealthCare Policy and Research Agency, (now the Agency for Healthcare Research and Quality) identified incontinence as a risk factor for pressure ulcers in its now archived Clinical Practice Guideline for Pressure Ulcers in Adults (1992). The guideline also recommends that ‘any individual in bed who is assessed to be at risk for developing pressure ulcers should be repositioned at least every two hours if consistent with overall patient goals’. However, advances in the design and absorbency of pads and of pressure relieving devices, may mitigate the number of times residents’ need such care. Fader and colleagues randomly assigned 81 residents of residential homes in the UK to either a four or an eight hourly nighttime pad changing regime [485]. They found no evidence that the less frequent pad changing regime had an effect on skin erythema or on skin pH. However, residents on the less frequent pad changing regime had wetter skin (P=0.01; 95% CI: 2.89-21.39) and five residents developed grade 2 ulcers. Further research on this issue is warranted to guide practice.

3. Interventions with Caregivers

Family caregivers of frail elders with UI report a high level of physical fatigue (70%) [487]. This is particularly so for family caregivers of individuals with UI and dementia [488]. Upton and Reed conducted a qualitative study on caring in the context of incontinence and dementia and reported that the relentless nature of incontinence was psychologically draining and demanding on caregivers. This was particularly the case if the care-recipient had challenging behaviours; in which case, incontinence typically presented as a behavioural problem [488]. Similar findings were reported by Hutchinson and colleagues [489] who used an ethnographic design, to examine the range and variation of toileting problems and management strategies used by family and employed caregivers of individuals with Alzheimer’s Disease (AD). The researchers reported that toileting emerged as a complex event with many stages and as a task that was unaesthetic and unpleasant for caregivers and clients. It also occasionally triggered a severe emotional response from the person with AD. Caregiver’s responses were variable, however, some read cues and interpreted toileting behaviours. These findings from qualitative research draw attention to the complexities of managing incontinence in the context of dementia.

Family caregivers report embarrassment and social isolation as their most frequent emotional responses to UI, and a need for information about resources, in a small pilot study, caregivers at home felt that the requirements of a behavioural protocol were more than they could manage [490]. However, in contrast to long term care staff, family caregivers were adherent with prompted voiding 89% of the time, and 93% were somewhat or completely satisfied with the decrease in UI [491]. Using data from a cross-sectional survey of the Dutch national prevalence measurement of Health Care Problems, Du Moulin and colleagues found that more than half incontinent older adults (mean age 80) living at home and receiving home care services, had no diagnosis of the type of incontinence. The most common management strategy, regardless of diagnosis, was the use of pads [492].

c) Recommendations for practice

• Family, caregivers, or residential and/or nursing staff dealing with different levels of UI (mild, moderate, catheter managed) have different educational needs and require different levels of support.

• Interventions to support family caregivers of individuals with UI may need to be adapted to suit formal carers or staff in long-term care so that they accommodate the organisational context.

• a one-size fits all approach will not accommodate the diverse needs of older people in long term residential care.
• Interventions or approaches to caring for an individual with UI and cognitive impairment need to be tailored to the person’s unique abilities and disabilities.

• Interventions for UI should be theory-based, multi-component, interdisciplinary and person-centred.

4. PHARMACOLOGICAL TREATMENT

a) Background

This section deals with the management of the frail elderly. The pharmacological management of UI in healthy older persons is discussed in Chapter 10, Drug Treatment. Specific treatments for bladder outlet obstruction and associated LUTS in frail elderly men are outside the scope of this chapter; special issues in the care of frail older men with UI are discussed above.

Frail persons with UI should be considered for drug treatment only following a comprehensive evaluation of remediable causative factors, and if they are appropriate for and have had a trial of behavioural and lifestyle interventions. Drug treatment should not generally be used for persons who make no attempt to toilet when aided, become agitated with toileting, or are so functionally and cognitively impaired that there is no prospect of meaningful benefit. Even so, a recent study of US nursing home residents suggested that only a small proportion of incontinent residents potentially suitable for drug therapy ever received it [493].

b) Quality of data

Since the last ICI we located a further 13 randomised placebo controlled trials (RCTs) of antimuscarinic medication, involving subjects over the age of 80. As before, the majority of studies addressing frail older people are of only modest quality, reflecting their vintage. The available RCTs were predominantly done in the US, with a small number in Europe, the UK, Germany, Taiwan and Japan. All focus on antimuscarinic treatment of presumed urgency UI. UI diagnosis was overwhelmingly symptom-based; only three studies included urodynamic evaluation. There have been two large studies of older people, one in Europe and one in the US; the latter targeted at frail older people identified by the VES-13 [494]. For most studies however, it was impossible to identify whether subjects were frail, even though the spread of co-morbid condition and co-existing medication suggests a representative sample of community dwelling older people except where the study was performed in an institutional environment, in which it is reasonable to assume a high prevalence of functional and cognitive dependence.

The methods of blinding and randomisation in RCTs were seldom specified. Other than those conducted by the pharmaceutical industry, most studies were generally small and potentially under-powered, and others lost power because of high dropout rates due to illness and death (inevitable in trials with frail elderly persons). Because of these issues, many RCTs provide only Level 2 evidence. Some larger studies in older persons without clear frailty are included here, to recognise an increasing emphasis on including older persons in drug trials.

Precise descriptions of the target population - including the definition of “frail persons” and a comprehensive description of the degree of cognitive and functional impairment - were usually absent. Although some investigators included information on patients’ functional and cognitive status, as well as comorbid conditions, the descriptions were often only qualitative, and none addressed these issues adequately in the analyses. Explicit, concurrent behavioural therapy was used in most nursing home studies, yet may have occurred in many others although these are usually specifically prohibited in trials managed by the pharmaceutical industry. Combination therapy and high comorbidity could have attenuated differences between drug and placebo, and make it difficult to compare results directly with studies in healthy older and younger persons. Outcomes in care home studies were universally assessed by UI frequency (pad-weighing, bladder diaries, and wet-checks), and none reported quality of life outcomes.

In at least six studies, investigators treated subjects with “urinary tract infection” (usually defined as pyuria and bacteriuria in the presence of UI) before initiating antimuscarinic therapy, and one study excluded such subjects. In another, investigators treated urogenital atrophy with oestrogen prior to antimuscarinic therapy, possibly leading to an additional amelioration of symptoms. However, no other reversible causes were addressed prior to entry or randomisation in most studies.

The generally low quality of these trials reflects not just study design, but the larger issue of the difficulty of doing large, prospective intervention trials in frail populations. Moreover, UI in frail elderly is universally a multifactorial problem involving a large number of factors beyond the bladder. Thus, the expectation that drug therapy targeted solely at urodynamic DO or SUI would markedly improve/cure UI in this population is unlikely to be realised. Additionally, the reporting of adverse events relevant to managing older people appears to be deficient. A meta-analysis examining the measurement and reporting of CNS outcomes showed that, 77% (242/314) of eligible trials identified, neither measured nor reported CNS outcomes. Of the remaining 23%, it was difficult to ascertain whether CNS adverse events were systematically measured or spontaneously reported. Only one of 72 trials objectively measured changes in cognitive performance. Age-stratified analyses of CNS outcomes from trials...
in adults aged 65 and older with overactive bladder were found in only eight publications [495].

c) Results

Results from randomised trials are summarised in Table 9; the following sections discuss specific drugs in detail.

1. Oxybutynin

The majority of older studies in frail older persons used immediate-release oxybutynin (oxybutynin-IR). There are two studies of extended release oxybutynin (oxybutynin-ER), one examining cognitive effects in nursing home residents with dementia and urgency UI.[496] and the other involving community-dwelling women over age 65 [497] Published trials of the efficacy of transdermal oxybutynin included subjects up to age 100 and in institutional care settings, but did not stratify results by age or comorbidity [498].

The pharmacokinetics of oxybutynin-IR and its active metabolite, N-desethyloxybutynin, in one study tended to show greater plasma levels and bioavailability with increasing frailty and age.[499] Another found peak levels in 21 octogenarians similar to those reported in young normal males (12.5 ng/mL vs. 8.9 ng/mL) [500]. A study of the pharmacokinetics of transdermal oxybutynin showed no significant difference in plasma levels between young and old (up to 77 years) subjects [501].

- Efficacy. An early, small (n=15) trial of oxybutynin-IR and habit training in long-term care residents showed no effect on UI episodes.[502] However, in a subsequent and larger study in long-term care residents study who had failed prompted voiding alone, the addition of titrated oxybutynin-IR resulted in a significant but modest reduction versus placebo.[503] Wet-checks decreased from 27% at baseline to 20% on drug and 24% on placebo, leading the authors to conclude that the improvement was not clinically significant, especially given the continuing requirement for nursing intervention. However, their a priori definition of “clinically significant improvement” (one or fewer episodes of daytime UI) was achieved by 40% on drug but only 18% on placebo (p<0.05). The dose generally associated with improvement was 2.5 mg three times daily. In another controlled study of UI in long-term care residents (n=24), there was little effect of oxybutynin-IR 5 mg twice daily given for 8 days, but all residents were toileted 10 times daily, and the dose may have been too high and given too infrequently.[504] In a randomised two month trial in frail community-dwelling elderly, oxybutynin-IR plus bladder training was subjectively and objectively superior to bladder training alone in improving urinary frequency (95% CI 6-27 fewer voids per 2 weeks) but not UI.[505] Insufficient information was available regarding a Japanese study in 75 “elderly” patients to assess the population and outcomes.[506] A study in 416 community dwelling older persons, including the fitter elderly, found 68% reported a partial or complete symptomatic cure with 2.5 mg three times daily; 30% of subjects experienced ADEs, but only 10% withdrew because of them.[337]

Only one of the two identified RCTs in frailder older people examined the efficacy of oxybutynin-ER. [497] The other examined the effect on cognition [496] and is discussed below. No published RCTs of transdermal oxybutynin in the frail elderly were found, and post hoc sub-analysis of efficacy in subjects over the age of 65 has been published only in abstract form. In a small Japanese case series (n=13, mean age 75) in persons with urgency UI and cystometric DO, intravesical oxybutynin caused no significant increase in mean bladder capacity one hour after installation of 5 mg oxybutynin at pH 5.85.[507] In four patients who continued twice daily installation, two had UI “disappear” and one “markedly decrease” (duration until effect not noted). No patient developed an “increased PVR” (not defined).

- Predictors of efficacy. Predictors of efficacy were studied in one study in persons with urgency UI and urodynamic DO (n=41, mean age 79) treated with 2-4 weeks of oxybutynin-IR (5-15 mg/day).[508] Factors associated with baseline urine loss (by pad weighing) were impaired cognitive orientation (on the Cambridge Mental Disorders of the Elderly Examination), number of daily voids, and fluid intake. Persistent urine loss after treatment was associated with impaired orientation, reduced sensation of bladder filling during cystometry, and most significantly global cortical under-perfusion on single photon emission computed tomography scan, suggesting that cortical factors are the main determinant of the severity of urgency UI before and after oxybutynin. In a study of 80 older patients (mean age 74), patients with dementia (by Hasegawa dementia scale) were less likely than cognitively intact patients to report subjective improvement in UI with antimuscarinic agents, despite similar objective outcomes.[509] However, these results could reflect treatment-associated cognitive effects.

- Adverse reactions. A comparative sub-analysis of oxybutynin IR versus solifenacin in subjects below or above 65 years of age (mean 71 years in >65 year age group) showed subjects receiving oxybutynin IR at a fixed dose of 15mg/day were over eight times more likely to have dry mouth than were those receiving solifenacin 5mg /day, irrespective of age (OR 8.88; 95% CI 3.91–20.17) [354] (Note that the median dose of oxybutynin used in clinical practice is 5mg bid). A comparative study against once daily trosplum chloride conducted in subjects up to the age of 91, but with mean age 61 (SD 12.4) years showed oxybutynin to be non-superior to trosplum in terms of resolution of UI episodes, but was associated with twice the incidence of dry mouth (7.7% versus 4.1%) [510].

</table>
Cognitive side effects from oxybutynin have been reported in older persons. In one case series, four older men with Parkinson’s disease and mild-severe cognitive impairment developed confusion, psychosis, hallucinations, behavioural disturbance, and/or paranoia after receiving oxybutynin-IR (5-15mg/day), which resolved when oxybutynin was stopped.[511] Of note, each patient was also on L-dopa (co-beneldopa) and selegiline, and the observed effects could reflect drug-drug interactions. However, these results are belied by a large RCT in which oxybutynin-ER 5 mg daily did not cause more delirium than placebo in NH residents with UI and dementia.[496]

There are case reports of reversible peripheral neuropathy confirmed by re-exposure in a 70 year old woman taking oxybutynin-IR 5-7.5 mg/day[512] and recurrent heat stroke associated with oxybutynin in one elderly patient.[513] Few studies have addressed cardiac effects. A small study of older persons in the community with UI (n=20, mean age 75) found no change in resting heart rate or electrocardiogram evidence of either prolonged PR interval or QTc, or QTc dispersion after 4 weeks of oxybutynin-IR (mean daily dose 7.6 mg [range 2.5-10 mg]).[514] Using a large administrative utilisation database, no association was found between antimuscarinics (oxybutynin, flavoxetine, hyoscymine) and ventricular arrhythmia and sudden death.[515] Post-marketing adverse events with extended release oxybutynin include tachycardia and hallucinations.

2. **Tolterodine**

Since the last ICI, we identified no further studies of tolterodine for OAB/ DO. Analysis of the studies of tolterodine in “older patients” does not allow any conclusion to be drawn about the frail elderly. For example, “older” patients in one RCT of tolterodine-ER were all community-dwelling, able to complete a 7-day bladder diary, had a high prevalence of previous antimuscarinic treatment (53-57%), and a low prevalence of arthritis (15-18%), unlike most frail older persons.[516] Although several trials include elderly persons in their ninth and tenth decades,[516-518] mean age (~64 years) was much lower, persons with “unspecified” disease which the investigator thought made the patient unsuitable and/or “renal disease” were excluded, and results were not stratified by age. In a secondary analysis of a large, open label German trial of tolterodine-IR 2 mg twice daily, higher age was significantly associated with “less favourable efficacy.”[519] However, the absolute difference in odds was only 0.019, there was no association of tolerability with age, only mean age is described, and UI frequency was based on patient report, not bladder diaries, all of which fail to add up to a clinically meaningful difference. In a non-randomised study, tolterodine was given to 48 nursing home residents who did not respond to toileting alone; 31 of these patients had a 29% increase in dryness (versus 16% in residents on toileting alone) [484]. We did locate a trial of 1 year duration of the addition of tolterodine ER 4mg to alpha blocker or 5 ARA therapy in older men (mean age 74.9 years) which resulted in a between group, statistically significant decrease in the storage symptom score on the IPSS [520].

- **Adverse reactions.** There are no prospective systematic data on tolerability in frail patients. There have been case reports of hallucinations (73 year old woman with dementia [521]) and worsening memory,[522] including a 65 year old cognitively intact woman.[523] There is a case reports of delirium when tolterodine was given with a cholinesterase inhibitor [524]. Analysis of prescription-event monitoring in the UK (mean patient age 63) found a significant association between age (>74 years) and psychiatric events and tachycardia (odds ratios not given) [525]. In a similar database study, the age- and sex-adjusted risk of hallucinations with tolterodine was 4.85 (95% CI 2.72-8.66) compared with 10 other drugs (acarbose, alendronate, famotidine, 3 proton pump inhibitors, fiaspente, meloxicam, misoprostol, and nizatidine) chosen for presumed lack of antimuscarinic, cardiovascular, and CNS activity, and available in the database. Important confounders such as other drugs and comorbidity were not evaluated. Similar to oxybutynin-ER, post-marketing information on tachycardia and hallucinations was added to the tolterodine-ER package insert in 2003.

3. **Fesoterodine**

Since the 4th ICI we located four studies of age related pharmacokinetics in younger versus older subjects (although not frail), a pooled analysis demonstrating efficacy of fesoterodine in subjects over the age of 65, stratified into >65 and >75 year age groups, a large prospective study which reported the efficacy of fesoterodine in subjects stratified by age (>65 and >75) years of age and a prospective study in the frail elderly [355, 526]The pharmacokinetic study found no clinically meaningful effect on 5-HMT, the active metabolite of fesoterodine pharmacokinetics or pharmacodynamics after single-dose administration of fesoterodine 8 mg. The efficacy of fesoterodine has also been studied in a European trial in 794 elderly men and women with OAB [527], 47% were men. Forty-six percent of subjects reported urgency incontinence episodes at baseline, and 64% had prior treatment with antimuscarinics. At week 12, the improvement from baseline in urgency episodes (-1.92 v -3.47, p<0.001), micturitions (-0.93 v -1.91, p<0.001), nocturnal micturition (-0.27 v -0.51, p=0.003), severe urgency episodes (-1.55, -2.40, p<0.001), and incontinence pad use were statistically significantly greater with fesoterodine than with placebo. The responses on the treatment benefit scales, OAB-S, PPBC, and UPS were also significantly greater in those in the fesoterodine group versus placebo. The effect of fesoterodine has
also been assessed in vulnerable older people as assessed by the Vulnerable Elders Survey Survey [269], which identifies those at risk of death in the following two years. This 12 week double blind, placebo controlled study including 562 people of mean age 75 years resulted in mean reductions in UUI episodes at week 12 versus placebo (-0.65 (0.21), p<0.0018) and 24h micturition frequency (-0.84 (0.23), p<0.0003) [528].

**Adverse effects:** The cognitive safety of fesotero dine has been assessed in a small single study of cognitively intact older subjects, using alprazolam as an active control and placebo. There were no statistically significant changes in performance on a computer assisted battery of cognitive tests versus placebo [529].

4. SOLIFENACIN

We located a sub-cut analysis from a Canadian study which reported tolerability of solifenacin versus oxybutynin in older subjects, reported above [354]. Otherwise, there were no further relevant studies. Pharmacokinetics of solifenacin have been evaluated in 23 older subjects (mean age 68); t\textsubscript{max} was longer and there was a higher maximum plasma concentration, but the differences from results in younger patients were small and deemed by the authors to be clinically irrelevant [530]. A secondary analysis of pooled Phase III data in patients aged 65 and older (all community dwelling and fit, mean age 72) found similar efficacy to that reported for younger and middle aged persons [531]. However, direct comparison with subjects < 65 yrs from the same pooled trials was not done. Adverse effects in older frailer patients have not been specifically reported. However, data from an open-label, 12-week trial in patients treated by community urologists found that overall treatment-emergent adverse events were more likely in patients aged >80 years (OR 3.9 [95% CI 1.3-11.5]) and taking concomitant medications (OR 1.8 [95% CI 1.2-2.6]) [532]. Patients with concurrent medications were more likely to be male and on average about 12-14 years older, have comorbid disease, and be administered higher doses of solifenacin, yet had no observed increase in heart rate or blood pressure with solifenacin.

**Adverse effects:** The cognitive safety of a single dose of 10mg solifenacin was tested versus placebo and 10mg oxybutynin IR in an exploratory study in 12 cognitively intact older subjects. Solifenacin showed no evidence of impaired cognition or self-ratings of mood and alertness versus placebo [533]. In a 3-way crossover design, chronic dosing of 5mg solifenacin, placebo and 5mg bid of oxybutynin were compared using a similar battery of tests in 23 older subjects with mild cognitive impairment. There was no statistically significant effect on cognition of solifenacin versus placebo. Oxybutynin 5mg bid was associated with impairment in power and speed of attention in a post hoc analysis of pooled time points at 1+2h post dose [534].

5. DARIFENACIN

We located one RCT of darifenacin for OAB in persons aged ≥65 (mean 72), in which there was no statistically significant difference between drug and placebo for the primary end point, UI frequency. [535] There were statistically significant improvements with drug for urinary frequency (-25.3% vs. -18.5% with placebo; p < 0.01) and quality of life, as measured by OAB-q and patient perception of bladder condition. A 2 year extension study in subjects >65 was reported, showing maintenance of OAB symptom improvement over the 2-year period with 44.4% patients achieving > or = 90% reduction in incontinence episodes at 2 years for the 64% (137/214) subjects remaining in the study [536].

**Adverse effects.** Cognitive adverse effects of darifenacin have been prospectively studied in a series of trials. The first was a 3-period crossover RCT in 129 older subjects (mean age 71, 54% of those screened), 88% of whom had co-morbid medical conditions and 93% were on other medications [537]. Cognition was assessed using a standardized computerised test battery. Darifenacin at variable doses did not adversely affect cognition compared to placebo, but results were aggregated so that patients did not serve as their own controls. A subsequent study in cognitively intact older persons (n = 49, mean age 66) using a similar computer cognitive test battery compared titrated darifenacin and oxybutynin-ER with placebo over 3 weeks [538]. Oxybutynin-ER but not darifenacin or placebo adversely affected the primary endpoint, delayed recall on the Name- Face Association test. However, oxybutynin was titrated one week earlier than darifenacin, and to a final dose (20 mg daily) much higher than is commonly used in clinical practice. Also, there were no differences between the two drugs and placebo for many other domains of the cognitive battery.

6. TROSPUIM CHLORIDE

Although often promoted for use in the elderly because of the reduced likelihood that the drug crosses the blood-brain barrier, we found no studies that evaluated the agent specifically in frail older persons. All studies have included “younger elderly,” but even the most recent has not stratified results by age [539].

**Adverse effects:** The effect of 60mg trospium chloride once daily over 10 days on either learning or memory was assessed in 12 cognitively intact older people (≥65 – 75 years). There was no change in standardised testing. Additionally, no trospium was detectable in the CSF of the subjects at day 10 [540, 541]. As part of a larger study of trospuim chloride 20mg bid, 36 (26 completed). Subjects with UUI and dementia, treated with galantamine and trospium) were examined. Subjects with severe dementia were excluded in this
non-randomised, open label study. There was no observable decrement in either cognition, but only measured by MMSE, or ability in terms of activities of daily living in the dually treated group [364].

7. Propiverine

In 46 patients with dementia (mean age 81), there was a 40% decrease in urgency UI with propiverine 20 mg/day for 2 weeks,[542] similar to two small Japanese trials [543, 544] and a German trial in 98 patients.[545] The agent’s high protein binding, extensive first pass metabolism, 15-hour half life (in normal younger persons), and renal clearance [542] need to be considered if used in frail older people. There have been no new trials reporting on either efficacy or tolerability in older people.

8. Imidafenacin

There have been no pharmacokinetic studies of imidafenacin in older people [546]. However, a population pharmacokinetic analysis demonstrated that oral clearance was decreased with advancing age, increasing hepatic function parameters (AST and ALP), food intake, and itraconazole co-administration. The absorption rate constant was decreased with food intake [547]. The drug is metabolised by the CYP3A4 system, and it is affected by drugs which inhibit this system [546]. There appears to be no affect on digoxin pharmacokinetics in healthy volunteers [548]. There are no trial data on older patients using this agent.

9. Duloxetine

There was a statistically significantly reduced rate of clearance of duloxetine in patients over age 65, based on a study in 12 fit women aged 65-77.[549] The authors felt the differences were not clinically significant given the “similar safety profile” of the drug in older and younger women. In three large RCTs in women with SUI, aged 24-83 years, n = 494 [none frail];[550] with OAB, aged 21-84 years [none frail], n = 306 [551]; and with mixed UI, up to age 85[552]), duloxetine decreased UI and urinary frequency, but none stratified outcomes or adverse effects by age. In a newer randomised controlled study of 265 community dwelling older women, 134 treated with duloxetine, of whom 20% had mild cognitive impairment as classified by the modified mini-mental state exam [553], duloxetine treatment led to a statistically significant decrease in incontinence episode frequency (median percent change 51.6%) versus placebo (32.1%) for stress predominant mixed symptoms, but did not reach significance for stress urinary incontinence (53% v 42%) [554]. Duloxetine is neither approved by the US FDA nor recommended by the UK National Institute of Healthcare and Clinical Excellence.

10. Mirabegron

There are no trials of mirabegron in the frail elderly. There are data on the comparative pharmacokinetics in older people, but not specifically the frail elderly. In available studies, there were no statistically significant differences in mirabegron exposure between older volunteers aged 55 years and above and younger volunteers (18-45 years). Similar results were obtained for those aged 65 years and above. AUC was predicted to be 11% higher in a subject aged 90 years of age [555]

11. Oestrogen

Oral oestriol 3 mg/day was compared to placebo for 12 weeks in 34 women aged 75 [84]. The group was highly self-selected; complete results were available for 11 with SUI, 12 with urgency UI, and 8 with mixed. Two-thirds of urgency UI and 75% of mixed UI patients reported improvement; there was no effect on SUI. Four patients reported metrorrhagia and mastodynia. A 10 week crossover trial comparing quinestradol 0.25 mg four times a day with placebo in 18 women in long-term care (type of UI not reported) found a mean 12% decrease in UI episodes vs 22% increase with placebo.[556] The combination of conjugated oestrogen 0.625 mg/day and progesterone 2.5 mg/day was evaluated in a 6 month, placebo-controlled trial in 32 female NH residents with predominantly urgency UI, who also received prompted voiding [557]. In the 21 women who finished the trial, there was no difference in wet checks between drug and placebo despite increased serum oestrogen levels and partial oestrogen effect on vaginal cytology and pH in the women on drug. Two women on the drug developed vaginal spotting, and 10% developed breast tenderness. Similar lack of efficacy despite vaginal changes were found in a case series of 9 frail women (mean age 83) with urgency or mixed UI using an oestrogen-implanted vaginal ring (Estring ®) [558].

12. Miscellaneous Medications

Readers interested in agents which are seldom used in clinical practice should refer to the 4th International Consultation on Incontinence for data relevant to frail older people for information on:

- Epmelon bromide, Flavoxate, Propantheline, Imipramine, Flurbiprofen, Procaine hæmatoporphyrin.

13. Comparative Trials

We found no studies that compared antimuscarinic agents in frail older persons. Other comparative studies in community dwelling elderly, where relevant, are mentioned above.

d) Summary of the evidence

1. Short-term treatment with oxybutynin-IR has small to moderate efficacy in reducing urinary frequency and urgency UI when added to behavioural therapy in long term care residents. (Level 2)

2. Low dose oxybutynin-ER does not cause delirium in cognitively impaired nursing home residents (Level 1)
3. Oxybutynin-IR has been associated with cognitive adverse effects in persons with dementia and/or Parkinson’s disease (Level 3), although the incidence and prevalence are unknown (Level 4).

4. Oxybutynin has been associated with tachycardia (Level 3), but not associated with QTc prolongation (Level 3) or ventricular arrhythmia (Level 2).

5. Oxybutynin is less effective in persons with impaired orientation, cerebral cortical under-perfusion, and reduced bladder sensation (Level 2).

6. Oxybutynin is less well tolerated, versus solifenacin, in older people (level 2).

7. Fesoterodine is effective in ameliorating the symptoms of OAB in frail older people, identified by VES-13 (level 1). There is insufficient evidence to determine the efficacy, tolerability, and safety of the following agents in the frail elderly (Level 4):
   a. Intravesical oxybutynin
   b. Transdermal oxybutynin
   c. Trospium
   d. Tolterodine
   e. Darifenacin
   f. Solifenacin
   g. Mirabegron
   h. Duloxetine
   i. Oral and topical oestrogen

8. Tolterodine is associated with cognitive impairment and tachycardia (Level 3), although the incidence and prevalence are unknown. (Level 4)

9. Solifenacin (5mg/day) is associated with no impairment of cognition in older persons with mild cognitive impairment versus placebo (level 2).

e) Recommendations for practice

- A global assessment of the cognitive and “at risk” status of the patient should be undertaken. Unfortunately, the MMSE and ADAS-Cog seem to be insensitive to change in cognitive impairment due to bladder antimuscarinics [527, 559]. Patients that might be at risk of impaired cognition have been well described [348] and consist of those with mild cognitive impairment, long-standing type II diabetes, alcohol misuse, dementia and Parkinson’s disease. Those with Parkinson’s disease may be exquisitely sensitive [560]. These individuals will need to be carefully assessed, both prior to, and shortly after, initiation of treatment with bladder antimuscarinics. Treatment may necessarily depend upon a global assessment of cognition during the clinical assessment and, if possible, a carer’s impression of change. In addition to the of likely benefit from drug treatment, considering the life expectancy and wishes of the patient, account should be taken of total anticholinergic load, as this clearly increases the likelihood of cognitive impairment. There is evidence of cognitive safety of these drugs, for the most part in cognitively intact older adults, and therefore, prescribing bladder antimuscarinics as single agents is, on the whole, probably safe.

- Those studies using high doses (20mg) of oxybutynin are associated with an increased likelihood of causing cognitive impairment, which may not be apparent to either the patient or the clinician. This drug should probably be avoided in the elderly at high dose, and in those at cognitive risk, in any case. The other antimuscarinics should be initiated carefully, at the lowest dose for tolerability, with dose increases where indicated for efficacy, and reviewed early.

- The length of exposure to anticholinergics seems to be important, studies suggest a lack of decline in those with established dementia [349, 561], but with exposures of at least two years, there is a reported increase in mortality [562-564]. To what extent this is explained by case mix, comorbidity or other factors is not known and will be the subject of further research. Consideration should be given to limiting the overall exposure of antimuscarinics, particularly if in combination with other drugs with anticholinergic properties.

5. SURGICAL TREATMENT IN THE FRAIL ELDERLY

a) Background

Despite ongoing reports concerning the aetiology and pathophysiology of UI in older people, information on surgical management of the frail elderly is scarce [565, 566]. Nevertheless, currently, surgical management of stress incontinence (SUI) in elderly women is the same as in younger stress-incontinent patients [567, 568]. However, the outcomes of anti-incontinence surgery in frail elderly patients may be affected by inherent co-morbidities, as well as impaired bladder and pelvic floor function. There are still very few studies of gynaecological surgery in older frail women, surgical treatment for post-prostatectomy UI in frail men, and minimally invasive procedures, or peri-operative care (including prevention of common postoperative complications) in urological and gynaeological patients. We reviewed the available data and general issues regarding peri-operative care which could improve surgical outcomes in this group. Aspects of surgical treatment of UI in healthy older persons are also covered in 13: Surgery for Urinary Incontinence in Men, Chapter 14: Surgery for Urinary Incontinence in Women, and Chapter 15: Surgery for Pelvic Organ Prolapse.

In providing an evidence-based summary on this topic, we have taken advantage of the recent literature review and research recommendations from
the American Geriatrics Society, New Frontiers in Geriatrics Research: An Agenda for Surgical and Related Medical Specialties. [569]. This project involved systematic literature reviews that were used to generate summary statements and recommendations for research. Their findings and recommendations pertinent to the frail elderly regarding surgical treatment of geriatric UI, geriatric gynaecological surgery, and general care of the geriatric surgical patient are included in the summary statements below. Data supporting these conclusions are available in the monograph [570].

**b) Incontinence surgery in frail elderly women**

Surgical intervention is considered to be the most efficient and durable approach for the treatment of SUI. A wide variety of surgical techniques have been described, among which the mid-urethral sling procedures have gained worldwide popularity. Since the last ICI report on UI surgical treatment in frail elderly appeared, there are few new data on which to base appropriate recommendations for this group. Several studies have used U.S. national hospital discharge databases to examine surgical rates, but unfortunately they either age-adjusted results [571] or used relatively young cut-off points (e.g., <=50 years) [572]. Even in series that do specifically look at elderly women (mean age 78, range 68-90), most patients are cognitively intact (95%) [573]. Cognitive impairment appears to bias against having surgery: in one study, only 0.11% of operations for UI were done in women with dementia, cerebrovascular disease, or hemiplegia combined. Despite the fact that absolute numbers of ambulatory UI surgery cases in women increased from 1994-1996, the percent done in those aged >80 years remained the same (4-5%) [574], with the same proportions for pelvic organ prolapse surgery (5%) [575]. In the US, surgery rates in elderly women vary by region and race [576].

One single-centre, community-based series of 54 patients aged 70 years and above provides a picture of this surgical population. Twenty-eight percent of patients were aged >80, four resided in a nursing home or assisted living facility, 82% had significant comorbidities, and 32% were classified as American Society of Anaesthesiology class III risk. Intra-operative complications occurred in 11% of patients; postoperatively, 11% required intensive care monitoring, 6% had serious complications, 7% became delirious, and 9% experienced a slow return of bowel function. The authors concluded that discharge planning was especially important for these patients, and recommended presurgical planning with regard to discharge destination and likely need for assistance [577].

Although higher complication rates generally reflect the comorbidity common in frail elders (10.4% complication rate with comorbidity vs. 5.8% without it, p<.001) [572], some studies have found age protective (in one, age >73 years is associated with lower risk of vaginal cuff infection and recurrent prolapse following vaginal sacrospinous fixation [578]). The morbidity and mortality for geriatric patients undergoing anti-UI procedures appear to be similar to those of other major non-cardiac surgical procedures [569]. Mortality is inconsistently associated with increased age, and most strongly related to cardiac or cancer complications [579]. Many studies do not uniformly control for the impact of comorbidity on mortality [579]. Pre-operative administration of oestrogen appears ineffective in promoting wound healing [580]. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed-dose and time administered medications in cognitively intact geriatric patients [580]. Choice of anaesthetic agent may affect postoperative cognition and urinary retention. The use of methyl naltrexone to treat opioid-related urinary retention or constipation may become an important adjunct to surgical care in frailler patients [581]. There are few age-specific data on outcomes available, and no studies systematically examine quality of life, functional outcome, or discharge destination.

With the advent of newer "minimally invasive" procedures, there has come some modicum of use in older, albeit, not frail patients. Injection of bulking agents in women appears to be as little effective in younger women as in elderly patients and age does not appear to relate to outcomes [569]. There are several published reports examining outcomes of tension-free vaginal tape (TVT) in the elderly population. However, most of these studies are limited by short term follow-up, small patient groups and confounding variables [582-584]. Hellberg et al. showed that at three months, women ≥75 years old had a cure rate of 81.6% compared with a rate of 92.8% in women <75 years old. At later follow-up, regardless of duration since the TVT procedure, the proportion of women with cure for ‘any’ incontinence decreased with increasing age. Women ≥75 years old had a cure rate of 55.7%, compared with 79.9% in women <60 years old (p= 0.0001) [585]. In one single institutional study, authors showed no significant difference in cure rate (85% vs. 91.3%, respectively). However, follow-up was only 10.4 months [586]. In a randomized controlled trial of tension-free vaginal tape (TVT) versus 6-month wait-list control, the intervention group at 6 months had a statistically significantly greater improvement in mean I-QOL score, patient satisfaction score, and urinary problem score [587]. There was no objective measure of cure. Peri-operative complications were common, with bladder perforation by needle in one-in-five (22.6%) which required 24 hours of indwelling catheterisation; urinary retention (12.9%), and less than 5% with either a urinary tract infection or new urinary urgency (3.2%). In an uncontrolled case series examining the use of the suprapubic arch (SPARC) sling procedure, the outcomes in 43
older women (ages 65-91) were separately examined. Objective cure rate was evaluated by clinical and urodynamic examination and subjective cure rate by using a visual analogue score. At a mean follow-up of 36 months (range, 12 - 54 months), objective and subjective cure rates in 997 women were 91% and 95%, respectively [588]. There was statistically significant improvement in pad weight and pad numbers (from a mean of 5 to 0) and the visual analogue score. No severe intra- or post-operative complications were observed, and no patient developed de novo urgency UI. In a case series, long-term clinical outcomes following placement of a retropubic mid-urethral sling (SPARC) in patients aged 70 and over were compared with outcomes of a younger cohort. Overall success rate after a follow-up of 4 years was 83.2% in the younger group and 53.1% in the group of older patients (p= 0.0003) [589]. In a comparative prospective single-centre study examining safety and efficacy of TVT-O in elderly versus younger stress-incontinent women, after mean follow-up of 30±17 months early and late postoperative morbidity was similar in both groups, except for significantly more cases of postoperative recurrent UTIs among the elderly women (13.7% vs. 6.2%). Incidence of persistent urodynamically confirmed overt SUI was similar in both age groups (5%). However, asymptomatic urodynamic SUI was significantly more common among elderly patients (19% vs. 3.7%, P<0.05). The incidence of persistent OAB was similar in both groups (68% and 62%, respectively), while de novo OAB was significantly more common in elderly patients (11.9% vs. 4.7%, P<0.05) [590].

c) Incontinence surgery in frail elderly men

No specific conclusions can be drawn regarding surgical treatment of UI in frail men. Typical studies of anti-UI surgery in elderly men are very small or fail to stratify results by age and/or comorbidity [591, 592]. One small study (n=46) found that advanced age was not a risk factor for poor outcome after collagen injection for post-prostatectomy UI [593], while another (n=12, mean age 80 years) of trans-urethral resection prostatectomy (TURP) for obstruction-associated urgency UI concluded that cognitively impaired men demonstrated the greatest UI improvement [594]. In a single-institution case series of men aged > 80 years old undergoing TURP (68% of whom had urinary retention), 80% were satisfied with their outcome. Of the men with retention, 80% were able to void with a small PVR by six weeks. Complication rates were 41% (early) and 22% (late) [595]. Urodynamic evaluation of post-prostatectomy UI was recommended prior to surgical treatment, such as implantation of an artificial sphincter [592].

d) General issues in surgical care of the frail elderly

Important factors in the surgical care of frail patients include: preoperative risk stratification (e.g., American Society of Anaesthesiology class, Charlson index, Modified Cardiac Risk Index, Burden of Illness Score [596]; ensuring adequate nutrition, especially when patients cannot take oral feeding or become delirious; proactive management of comorbid heart disease, diabetes, and pulmonary disease; prevention [597, 598], recognition [599], and treatment of postoperative delirium [600]; adequate pain assessment and treatment, especially in cognitively impaired persons [601]; recognition of the hazards of prolonged bed rest [602] and the prevention [603] and treatment of functional impairment; use of specialised care units for the elderly [604]; and discharge planning regarding rehabilitation, need for assistance, and site of discharge. All need to be actively considered and dealt with in any plan of surgical care of frail elderly patients.

e) Summary of evidence

1. No studies were identified regarding gynaecological surgery in institutionalised elderly women. (Level 4)

2. Exogenous administration of oestrogen is ineffective in promoting wound healing after gynaecological surgery in older women. (Level 3)

3. Injection of bulking agents for SUI appears to give minor benefit in women, however the technique is minimally invasive and age does not appear to correlate with outcomes. (Level 3)

4. No studies were identified that evaluate functional or quality of life outcomes after UI surgery in frail older persons (Level 4)

5. Risks of morbidity and mortality for frail patients undergoing anti-UI procedures are similar to those of other major non-cardiac surgical procedures. (Level 2)

6. Surgical mortality risks are still low in elderly persons, and when deaths do occur, they are often due to cardiac or cancer complications. (Level 2-3)

7. Operative mortality is inconsistently associated with increased age, and many studies do not uniformly control for comorbid conditions. (Level 2-3)

8. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed-dose and time-administered medications in cognitively intact geriatric patients. (Level 2)

9. Choice of agent for patient-controlled analgesia may affect postoperative cognition. (Level 3)

10. Some case series and waitlist-controlled trials suggest that minimally invasive surgical approaches may be useful in older adults, yet these trials may have little to do with whether surgical treatments are appropriate in the frail elderly (Level 3)
**f) Recommendations for management**

a. Age alone is not a contraindication to surgical treatment of UI (Grade C).

b. Urodynamic evaluation should be done before considering surgical treatment of UI in frail older persons (Grade B).

c. Preoperative risk should be stratified using established indices (Grade A).

d. Ensure adequate post-operative nutrition, especially in patients who cannot take oral feeding or who become delirious (Grade C).

e. Programmes to prevent post-operative delirium should be utilised (Grade A) along with proactive use of established measures to diagnose delirium (Grade A).

f. Pain assessment in cognitively impaired persons should use measures specially-designed for this population (Grade B).

g. Proactive preventative approaches to hospitalisation-related functional impairment should be used (Grade A).

h. Specialised care units may improve selective outcomes for frail older patients (Grade A).

i. Discharge planning should begin before surgery takes place (Grade C).

j. Patient controlled analgesia can be used in cognitively-intact frail older persons (Grade B).

k. Analgesic agents associated with delirium (e.g., meperidine) should be avoided (Grade B).

l. Long-term outcomes before the operation should be discussed with the patient (Grade C).

**g) Recommendations for research**

- Inclusion of older-old and frailer patients in surgical studies, with stratification of outcomes by age, comorbidity, oestrogen status (women), and urodynamics findings
- Prospective studies to determine the magnitude and severity of common geriatric complications following anti-incontinence surgery
- Develop and validate guidelines for identifying frail elders who would benefit from gynaecological/urological anti-incontinence surgery

**6. CATHETERS**

**a) Background**

The use of indwelling urethral catheters (IDC) is clinically indicated in a limited set of circumstances (see Box 1) and should not be considered as a substitute for nursing care of the frail older person with incontinence [605]. Despite this recommendation, a number of studies report potentially inappropriate IDC use in frail older adults. The information in this section reviews research on rates of IDC use in the frail elderly; the appropriateness of IDC use in this population; complications (morbidity and mortality); management recommendations and recommendations for research. Detailed discussion of key issues related to catheters more broadly, including intermittent catheterisation, is provided in Chapter 20.

**Box 1. Appropriate Indications for Indwelling Urethral Catheter Use**

- Patient has acute urinary retention or bladder outlet obstruction
- Need for accurate measurements of urinary output in critically ill patients
- Perioperative use for selected surgical procedures:
  - Patients undergoing urological surgery or other surgery on contiguous structures of the genitourinary tract
  - Anticipated prolonged duration of surgery (catheters inserted for this reason should be removed in PACU)
  - Patients anticipated to receive large-volume infusions or diuretics during surgery
  - To assist in healing of open sacral or perineal wounds in incontinent patients
  - Patient requires prolonged immobilisation (e.g., potentially unstable thoracic or lumbar spine, multiple traumatic injuries such as pelvic fractures)
- To improve comfort for end of life care if needed

Healthcare Infection Control Practices Advisory Committee [2009]

**b) Quality of the data**

Some of the difficulties in conducting research on use of IDCs are discussed in Chapter 20… We located a number of articles on the use of catheters in frail older persons. These largely described the prevalence of catheters in this population. Few studies addressed the specific complications associated with IDC in frail older adults. It is therefore difficult to determine the relative effect of frailty and ageing on the incidence and prevalence of IDC complications. There is a lack of research on the use of catheters for individuals with terminal illness (i.e. end of life care), and for different cultural groups of frail older persons. Although intermittent catheterisation is associated with fewer risks compared to IDC use, there is limited research on its use in this older group. Guidelines and recommendations that apply
to the IDC use in other populations equally apply to IDC use in frail older adults. Catheter use should be avoided wherever possible and only adopted for those in whom alternative strategies are unsuitable or unsatisfactory, after careful assessment of the patient and their particular problem [606].

c) Rates of IDC use in frail older adults

Despite the presence of guidelines cautioning their use, IDCs are used to manage urinary incontinence and other conditions in a substantial number of frail older persons in long-term care facilities, in the community, and in acute care. The lowest rate reported in the reviewed literature was 3% of women in Swedish nursing homes [607] and the highest was 38.1% in frail older community-dwelling women in Italy who were listed on a Home Health Agency database [608]. In a one-day point prevalence survey conducted in 2009 involving 2625 residents from 78 nursing homes in Sweden, 50 (3%) of women and 135 (16%) of men had an IDC. Just over half (58%) had their IDC at the time of admission to the facility. For many of those who had their IDC inserted since their admission, the catheter was inserted during a temporary stay at hospital [607].

Data from the US Department of Health & Human Services, Centres for Medicare and Medicaid Services (third quarter of 2010) [609] indicates that, in the USA, 7% of residents in long-term care facilities have an IDC, however rates vary between states (4.5% to 12.3%). This finding compares with 7-10% of residents in 1987 [610] and research reported in 2003, from the USA National Nursing Home Survey for 1995 to 1999, on the prevalence of urinary incontinence among female nursing home residents, when 9.5% to 11.7% had an IDC or ostomy [611]. A web-based point prevalence survey of nursing home-associated infections (NHAI) conducted in 2005 in 133 USA Veteran Affairs homes, [612] found 1233 (10.7%) of 11475 residents had an IDC and was reproduced in a follow-up survey conducted by the same researchers in 2007 [613]. Rogers and colleagues [256] analysed data from 57,302 residents admitted to skilled nursing facilities in USA in 2003, and reported that 0.5 million nursing home residents have some form of catheter, and rates vary from 12.6% at admission to 4.5% (P<0.001) at annual assessment. IDC use was associated with male sex, and with conditions such as paraplegia, quadriplegia, multiple sclerosis, diabetes mellitus, renal failure, skin conditions, deep vein thrombosis, aphasia, or end-stage disease, obesity, taking more medications, as well as those who are comatose.

Rates of IDC use in nursing homes in the UK appear relatively stable over time. Based on 2001 survey data from 1125 residents in different healthcare settings for the elderly, 5% (0-20%) of individuals living in residential homes in the UK had an IDC, 10% (0-44%) in nursing homes, and 6% (0-20%) in long-stay wards [614]. Similar rates were reported by McNulty and colleagues in 2003 based on a sample of 4900 residents from registered nursing homes [615], and from a more recent survey involving 3190 residents from 92 homes, where 8% of resident had an IDC, although rates varied considerably with one facility having up to 47% of residents with an IDC [616]. In 57% of care homes, residents received their IDC as a hospital inpatient [616]. A more recent audit of continence care in UK conducted across England, Wales, and Northern Ireland estimated that 13% (62/488) of individuals living in care homes had an IDC [245]. These rates are consistent with IDC rates in individuals living in long-term care facilities in Canada, which range from 5% to 10% [617].

Estimating the prevalence of IDC use in frail older adults living in the community is more difficult as community samples differ, as do methods to define and measure IDC use. With the exception of one study, prevalence data do not differentiate between IDC use among frail and non-frail older community-dwelling individuals. One of the earliest reports on rates of IDC use in the community was based on a sample of individuals receiving district nursing home care in the UK. During the four weeks of data collection (Feb 1987) a total of 1709 patients were being attended by the district nursing services, with 61 (4%) known to have an IDC. In a larger context, the population for the health authority was 178,300 of whom 61 (0.03%) were patients aged from 22-95 years living in the community and had an indwelling urethral catheter (mean age 67.6 years, SD 19.56). A more recent prospective, population-based survey of 4 010 older people >65 years of age (mean age 82.3 ) receiving home care in 11 European countries, found that 5.4% (range 0–23%) of their sample had an IDC [619]. IDC use was more common in men than in women (11.5% versus 3.3%). Rates also differed between countries, ranging from 0% in the Netherlands to 23% in Italy. High rates of IDC use in Italy were also reported in data from 12 Home Health Agencies that provided care for 1004 frail older community-dwelling women (mean (SD) age 83.3 (9.5) years). The researchers reported that in this sample the prevalence of incontinent patients with a catheter was 38.1% [608].

Although some frail older adults are catheterised during an admission to acute care, others are admitted with an IDC in situ. Lahan and colleagues conducted a prospective cohort study to identify the prevalence of geriatric syndromes at preadmission, admission and discharge, and to determine the incidence of new and significant worsening of existing syndromes at admission and discharge. In their sample of 577 patients aged 70 and older who were admitted to a general medical unit of large acute care hospitals, 22/577 (3.8%) had a pre-morbid IDC (within three days prior to the acute illness precipitating admission). IDC rates increased to 98/577 (17%) in the admission period, and decreased to
47/577 (8.1%) at discharge. Although rates of IDC use decreased before patients were discharged from acute care hospitals, more elderly patients were discharged with an IDC than those who were admitted with an IDC [620].

**d) IDC for end of life care**

Incontinence is experienced by many patients toward the latter stages of a terminal illness. Although IDCs are indicated ‘to improve comfort for end of life care if needed’ [605], we found little evidence about managing incontinence for end of life care, or about IDC use in this context. According to the findings of one study, involving 61 patients with terminal illness due to cancer admitted to a palliative care unit (PCU), IDCs may be used in up to 75% of such patients [621]. In this study, 38% (n=23) admitted to the PCU had an IDC in situ prior to their admission and another 36% (n=22) were catheterised during their admission. Complications associated with the use of IDCs in this cohort included: bacteriuria (n=28), encrustation (n=8), bladder spasms (n=4), fever (n=2), and urethritis (n=2). Despite these complications, staff cited ‘patient comfort’ as the main rationale for the use of an IDC. Clearly, further research is warranted to guide clinical care in this area.

- **The appropriateness of IDC use in frail older adults**

Despite guidelines for appropriate IDC use, a number of studies report potentially inappropriate IDC use in older adults. For example, Landi and colleagues report that of their sample of frail older community-dwelling women with urinary incontinence and IDCs, 50% were catheterised without any reasonable justification [608]. Overuse of IDCs is however not limited to community-dwelling frail older adults. Two studies draw attention to potentially inappropriate IDC use for older people admitted to acute care hospital settings. Gokula and colleagues found appropriate indications for IDC use for only 46% of 2845 elderly patients admitted to a large teaching hospital in the US [622]. They reported that only 13% of charts contained information on the reason for the catheter and 33% of charts contained no written order for catheterisation. Similar findings were reported for 133 elderly patients who had an IDC inserted whilst inpatients of a 450-bed, tertiary-care university hospital in central Thailand. Twenty-eight percent of medical records lacked information about the reason for the IDC. The presence of urinary incontinence was cited as a reason in 18% of cases [623].

Anomalies in the use of IDCs were also reported by McNulty and colleagues who found that “almost all homes (114/124, 92%) stated they had an infection control policy, however 31% (38/124) had no written policy on urinary catheter care” [615]. In a later qualitative examination of reasons for variation in IDC use in care homes, McNulty and colleagues found that ‘care homes with a lower urinary catheterisation prevalence, had a more proactive approach to management of continence, using structured toileting regimes and encouraging residents’ mobility’ [624] (p. 709).

- **Complications - morbidity and mortality**

The complications associated with IDCs are well documented and are comprehensively addressed in Chapter 20. However, with respect to frail older adults with an IDC, Kunin and colleagues report the morbidity associated with use of an IDC in residents of a skilled nursing facility is threefold even after adjusting for other factors [625]. This finding also holds true for community-dwelling frail older adults with an IDC [608]. Among residents of Department of Veteran Affairs (VA) long term care facilities in the USA, 1205 of 10939 residents had an IDC and of these, 135 (11.2%) had a nursing home-associated infection. Residents with some form of indwelling device had a three-fold increased risk of a nursing home-associated infection (P < .0001). These factors make it imperative that IDCs are used to manage incontinence only when other methods of managing have been excluded.

- **e) Management recommendations**

As noted in Chapter 20, IDCs should be avoided wherever possible and only adopted for those in whom alternative strategies are unsuitable or unsatisfactory, after careful assessment of the patient and their particular problem [606]. Interventions designed to minimise IDC in frail older adults are the same as those for other populations of IDC users. Interventions include, but are not limited to: the development and dissemination of guidelines, quality indicators, and regulatory initiatives; educational approaches; and promoting intermittent catheterisation as an alternative method of management. Interventions to minimize and address complications associated with IDCs are comprehensively addressed in Chapter 20.

Another approach designed to decrease the inappropriate use of IDCs, and to ensure optimal IDC management is the use of assessment protocols. Regulatory processes in the USA mandate that all newly admitted Medicare/Medicaid funded residents receive an assessment using a standardised form called the Minimum Data Set (MDS). A further level of assessment is triggered when/if a resident is newly incontinent and the Resident Assessment Instrument Minimum Data Set is completed (RAI-MDS). This assessment information in turn, acts as a prompt for staff to design an individualised care plan based on direct contact with residents, appropriate staff, and through use of observation, interviews and record reviews. The MDS and RAI are now used in a number of other countries, including Canada and Iceland, and other countries have developed their own assessment instruments. Ideally, these assessment
Intermittent catheterisation (IC) involves the act of passing a catheter into the bladder to drain urine via the urethra, or a catheterisable channel such as a Mitrofanoff diversion. It avoids many of the problems associated with IDC. Many patients with neurological urinary incontinence perform IC. While IC is performed using a sterile technique in healthcare environments, some patients intermittently catheterise themselves using a clean technique in their own home environment. Advanced age should not constitute a barrier to IC. Pilloni and colleagues (2005) for example, found that of 21 elderly patients in whom IC was initiated because of voiding dysfunction, 12 learnt to catheterised themselves, seven were catheterised by their partners and two by nurses. The majority (18/21) reported improvements in their quality of life [627].

f) Intermittent catheterisation as an alternative to IDC in frail older adults

Intermittent catheterisation (IC) involves the act of passing a catheter into the bladder to drain urine via the urethra, or a catheterisable channel such as a Mitrofanoff diversion. It avoids many of the problems associated with IDC. Many patients with neurological urinary incontinence perform IC. While IC is performed using a sterile technique in healthcare environments, some patients intermittently catheterise themselves using a clean technique in their own home environment. Advanced age should not constitute a barrier to IC. Pilloni and colleagues (2005) for example, found that of 21 elderly patients in whom IC was initiated because of voiding dysfunction, 12 learnt to catheterised themselves, seven were catheterised by their partners and two by nurses. The majority (18/21) reported improvements in their quality of life [627].

g) Research recommendations

- Further research is required on:
  - Rates of IDC use in various populations (especially in community-dwelling frail older adults and those admitted to acute care)
  - Managing incontinence for end-of-life care
  - The effectiveness of interventions to minimise inappropriate use of IDCs such as the development and dissemination of guidelines, educational approaches; the development and dissemination of quality indicators; and regulatory initiatives; and intermittent catheterisation

V. NOCTURIA IN THE OLDER ADULT

1. BACKGROUND

Nocturia is defined as waking at night from sleep one or more times to void, with each void being preceded and followed by sleep.[628] Having a standardised definition is meaningful for the field, but this specific definition is problematic for several reasons. While a single episode of awakening to urinate would be considered nocturia, patients are more likely to be experience significant bother and have decreased quality of life [629], or consult a provider about nocturia if they have three or more episodes.[630] Many clinical trials include only participants with two or more episodes [631]. Additionally, if only a void interrupting sleep and preceding sleep counts, the annoying situation of waking to void and not being able to return to sleep again would not be nocturia, but would still be disruptive [632]. This definition does not take into account the wide range of sleep patterns of older adults. Since some older adults will spend six hours sleeping while others might spend twelve hours in bed, having three episodes of nocturia would be very different for these individuals [633].

Several detailed reviews on nocturia [634, 635] and two convened consensus conferences reports [631, 636] have helped summarise and update the current knowledge regarding nocturia. Even with these sources, the prevalence, impact, pathophysiology, diagnostic assessment, and treatment of nocturia differ meaningfully with respect to the older adult and the frail elderly [633] and merit a targeted discussion. As is the case with urinary incontinence, nocturia often results from the reduced physiological reserve of multiple systems. Because of this fact, diagnostic assessment must be detailed and comprehensive, and multi-component interventions may be necessary for successful treatment.

2. QUALITY OF THE DATA

There are multiple, quality sources of epidemiological data across a broad range of countries and cultures regarding the prevalence of nocturia and associated risk factors. There is a smaller, but growing, body of evidence regarding the incidence and impact of nocturia. In particular, studies of the pathophysiology of nocturia in the elderly have generally been small and disease-focused, examining a single, potential underlying cause of nocturia. As with UI, there are limited data on optimal diagnostic assessment, and therefore recommendations are generally based on expert opinion.[628, 637] The evidence base regarding treatment, particularly with
respect to the frail, is somewhat thin. While there are some treatment RCTs, they are small, include few very elderly subjects. The treatment literature regarding vasopressin and its analogues is robust, yet use of the therapy in the older patient continues to be limited because of the side effect of hyponatraemia. We located no randomised controlled trial data on the effectiveness of multi-component interventions for nocturia in the elderly.

3. PREVALENCE, INCIDENCE, AND IMPACT

The prevalence of nocturia increases with age, and has been reported to be as high as 90% for one episode per night in persons over age 80.[638-643] The prevalence of two or more episodes among men between 70 and 79 is nearly 50 percent.[643, 644] This increasing prevalence is largely due to age-related conditions that underlie the pathophysiology of nocturia (see below). With respect to gender, nocturia for young adults is more common in women than in men, but this gender ratio reverses after age 60 when more men have nocturia.[644]

For those over 75 years of age, the prevalence of nocturia of at least two or more times is much more common in men (70%) than in women (50%) [645).

While higher age is associated with more nocturia, what happens to nocturia, as an individual ages, is a slightly different question. Nocturia is more prevalent in older populations, yet the concept of incidence of nocturia is difficult as the condition both “begins” and “resolves” over time and varies due to imprecision of self-reporting and estimates as to the frequency over a past period of time. In one recent study, participants recorded their urination frequency and voided volumes. Over a 2-year period, the incidence rate of nocturia of an average of two or more times per night was 23.9% and the resolution rate was 36.7%. For the oldest adults participating (70-78 years), they had the highest nocturia incidence (47.1%) and the lowest resolution rate (26.2%) compared to their younger counterparts [646].

Recent data have also highlighted that the prevalence of nocturia in older adults differs by racial group. Multiple population-based epidemiological studies have shown a higher prevalence of nocturia in older men and women who are African-American when compared to whites [643, 647, 648]. While controlling for socioeconomic factors eliminated the differences in prevalence between non-Hispanic whites and Hispanics, differences persisted, although somewhat attenuated, between blacks and whites [649].

Nocturia is also associated with chronic medical conditions such as hypertension and diabetes,[650, 651] advancing renal insufficiency [652, 653] and cardiovascular disease.[654, 655] Clinically, nocturia may be the herald symptom of significant underlying medical conditions and problems, which, if overlooked, might result in significant morbidity and even mortality [631]. Therefore, an older patient bringing up nocturia should be evaluated not only for the causes of nocturia, but also for unrecognised comorbidity, including cardiovascular disease, sleep apnoea, restless leg syndrome, moderate alcohol usage, poor nocturnal glycaemic control, and conditions causing nighttime pain [631].

Nocturia is associated with other important conditions. Nocturia has been shown to be associated with accidental falls.[185, 656] Frail elderly persons with nocturia, who also have gait and balance disorders and other risk factors for falls, are clearly at increased risk for falls [657], injury and hip fracture [658], and consequent morbidity [659]. Despite these facts, no nocturia treatment trials to date have evaluated any impact on fall reduction. Nocturia also has adverse effects on quality of life [660], including an increased risk of depression and poor self-rated health, probably as the result of the impact on sleep [661]. Adults with nocturia also complain that nocturia “makes them feel old” and they worry about falling at night [662] Older individuals described nocturia as simultaneously debilitating, frustrating, distressing and puzzling [663].

To better appreciate the deleterious effects of nocturia, it is important to understand the effects of disrupted sleep [636, 664] When a group of 1,424 elderly individuals, ages 55–84 were presented with a checklist of symptoms that potentially disrupt sleep, nocturia was chosen by 53% of the sample as a self-perceived cause of “every night or almost every night”. Nocturia was cited four times as frequently as pain, which was the next most identified cause of sleep disruption [665]. There is growing evidence to suggest that bother from nocturia is related to the number of trips to the bathroom, but also with the difficulty experienced in trying to return to sleep.[632, 646, 666] In particular, those with nocturia who report difficulty going back to sleep, the prevalence of falls is higher [666]. While the relationship between nocturia and sleep disruption might appear to be self-evident, other lower urinary tract symptoms are also highly correlated with sleep disturbances. [667]

There has been recent and meaningful development in understanding the impact of nocturia on quality of life. A condition-specific instrument commonly used for assessing the impact of nocturia is the ICIQ-NQOL [668], which was developed using a pool of only men (average age 68.2, age range 32-88) recruited from urology practices. Given the absence of women and the likely predominance of men with benign prostatic enlargement as informants, there remains a chance that the instrument does not broadly represent the experiences of all individuals who have nocturia. Other focus groups and one-on-one interviews performed independently with a broader representation of both men and women did demonstrate similar themes, suggesting content validity.[662] Two missing themes,
however, were that nocturia was an “indication of getting older” and made them fearful of falling. Use of the Nocturia Nocturnal Enuresis and Sleep-interruption Questionnaire, which was specifically developed in older men and older women (60-80), showed a greater impact of nocturia in the younger elderly and a greater bother among women compared to men.[663] Use of the generic quality of life instrument, the 15-D, demonstrated statistically significant and clinically meaningful decreases in 15D score and in all 15D dimensions except eating with increasing nocturia.[629] In this study, older women were less bothered by nocturia than were younger women; older and younger men were equally bothered [629].

Notable recent work has shown nocturia to be associated with mortality [659, 669, 670]. It is unlikely that nocturia directly contributes to mortality; nocturia certainly marks other conditions (poorly controlled diabetes mellitus, congestive heart failure, worsening renal insufficiency) associated with bad outcomes. Whether or not these associated conditions should be statistically controlled for is not clear, as they might represent a part of the causal pathway. The association with mortality when examined across the age spectrum shows a stronger relationship with younger than with older individuals [669]. With careful controlling for comorbidities, this association between mortality and nocturia sometimes remains independently significant [671] and other times does not [672]. Though much of the impact of nocturia is believed to result from its impact on sleep, nocturia remains independently associated with mortality even with controlling for sleep disordered breathing [673].

4. PATHOPHYSIOLOGY

The pathophysiology of nocturia is considered to be multifactorial; this is the case for nocturia in elderly persons as well. In age-adjusted analyses from a large survey in Finland, no single factor related to nocturia was present in greater than 50% of those with nocturia [674]. The factors with the greatest impact at the population level were (urinary) urgency, "benign prostatic hyperplasia", and snoring for men, and overweight and obesity, urgency, and snoring for women [674].

A commonly used framework for clinical diagnosis and treatment is that nocturia can be related to one or a combination of three primary underlying causes, all of which increase with age: low bladder capacity (with urinary urgency), "benign prostate hyperplasia", and snoring for men, and overweight and obesity, urgency, and snoring for women [674].

A higher post void residual (>200 mL, 100-199 mL, 50-99 mL versus <50 mL) was not associated with reporting more nocturia [677].

The proportion of 24-hour urine volume produced at night increases with age, even among healthy older adults free of overt comorbid conditions.[678, 679] Studies of frail elderly have shown that the proportion of urine produced at night is close to 50%, rather than less than 30% as in young healthy adults.

Nocturnal polyuria (NP) is more common in older compared to younger nocturics [683-685]. In some elderly persons, this is due to mobilisation of excess volume caused by peripheral oedema, which may be due to venous insufficiency, medications, and/or heart failure. In the case of calcium channel blockers, women younger than 55 years of age, but not older women or men, were shown to have higher rates of nocturia in cross-sectional analyses [686]. In that same study, both hydrochlorothiazide and loop-diuretic usage in men were associated with higher rates of nocturia.

Some studies have suggested that there is an abnormality in the secretion and/or action of arginine vasopressin (AVP) or a loss of the normal diurnal rhythm (with inappropriately low values at night) in many elderly patients with nocturia. [687, 688], which may approach as many as 4% [687]. Another, however, failed to find an association between AVP deficiency (detected by water deprivation testing) and nocturnal polyuria in a series of elderly persons with nocturia. [689] Other research suggests that some frail elderly persons with nocturia have high atrial natriuretic peptide (ANP) levels at night; [690, 691] however, these investigators did not use echocardiography or brain natriuretic peptide levels to detect occult heart failure.

Sleep disordered breathing and sleep apnoea, have also been associated with nocturia and nocturnal UI in the elderly.[690, 692-694] Community-based elderly populations who have higher levels of sleep disordered breathing (>25 breathing events per hour), have nearly double the number of nocturia episodes compared with those with low rates of sleep apnoea [695]. Nocturia is so tightly associated with sleep apnoea that in a population of adult patients presenting to a sleep clinic, it performed similarly as a screening question for OSA when compared to asking about “snoring” [696]; whether or not this held true for the subset of older patients was not reported. Whether this relates to increased ANP production,[690] mechanical forces on the bladder generated during apnoea events,[693] or other mechanism(s) is unknown.

5. DIAGNOSTIC ASSESSMENT

The approach to the assessment of nocturia should be similar to that for UI described above. Special considerations include:
A frequency-volume chart of at least 24 hours duration that includes timing and volume of each void at night as well as during the day, as well as a specific indication of when the individual went to bed with the intention of going to sleep at night and awoke in the morning. Some patients may find this difficult to perform,[697] but face-to-face explanation of the procedure, a hand-held urinal or a receptacle to place in the toilet to measure volumes, and involvement of caregivers may improve compliance and accuracy.

Additional questions in the history that focus on the possibility of a primary sleep disorder, such as asking about sleep quality, daytime sleepiness, snoring, and leg movements at night (this history is enhanced by questioning the bed partner).

Additional history and focused physical examination related to volume overload (e.g., lower extremity venous insufficiency, congestive heart failure); in some cases additional testing such as an echocardiogram or a brain natriuretic peptide level may be helpful in ruling out the latter diagnosis.

6. TREATMENT

While many clinical investigations are trials of single agents, experts [633] would argue that treatment of nocturia in elderly patients should be based on a holistic approach informed by identification of multiple potential underlying causes. There is, unfortunately, little high quality evidence for most treatments, and certainly with respect to combined treatments, for nocturia in this age group. As well, cure, or the complete resolution of nocturia, is infrequently achieved in either clinical practice or research.

The most common primary outcome in clinical trials is reduction in nocturia episodes, as measured by voiding diary or self-reported, average nocturia over a given period of time. Some trials have reported the percent of participants who achieving a 33% [698] or 50% [689, 699-702] reduction in nocturia from the baseline level or the percent of individuals having a reduction equal to 1.0 fewer mean nightly episodes of nocturia [699, 701, 702]. There are few treatments that offer robust reductions of nocturia, with most ranging from 0 to 0.8 fewer episodes of nocturia. The net reduction of an intervention, subtracting the benefit seen in the control or placebo arm is often even smaller. Whether this is due to regression to the mean due to random variation in the symptom of nocturia or a result of monitoring and recording night-time voids is unclear. Patient-level outcomes related to general satisfaction questions, nocturia-related bother, and nocturia-specific quality of life are therefore even more meaningful. Most trials examining nocturia as an outcome were performed prior to the validation testing of the ICIQ-NQOL instrument.[668] An additional important target for therapy is reduction in bother due to nocturia. Unfortunately, there have been few meaningful successes in relating the number of nocturia episodes to the hours spent in bed, which may vary considerably in older persons. [633]

There are several approaches to drug therapy for elderly patients with nocturia; most of the published guidelines suggest targeting “primary” or “principal” causes of nocturia (e.g., nocturnal polyuria). Because older adults with nocturia have multiple potential causes, treatment often will require combination treatment. While some trials may report statistical significance for reduction in nocturia, the clinical meaningfulness of these changes is suspect.[703] Although no specific data are available on RCTs of multi-component interventions, elderly patients with nocturia may benefit from an approach to treatment [704] that combines behavioural strategies, therapy for medical and sleep disorders, and nocturia-specific drug therapy. In another uncontrolled study, lifestyle modifications of 1) restriction of fluid intake, 2) refraining from excess hours in bed, 3) moderate daily exercise and 4) keeping warm in bed resulted in a positive reduction of nocturia from 3.6 episodes per night to 2.7 for 56 participants aged 59-88 (mean age 74.5, 84% male) [705]

a) Behavioural approaches and treatment of comorbidity.

The use of specific behavioural strategies (e.g. altering fluid intake, reducing sodium intake, leg elevation for oedema) on nocturia in older patients have largely been made on the basis of consensus. Using bedside commodes or urinals, and minimising the distance necessary to reach a toilet and providing a safe, adequately lit path may be helpful in reducing the risk of night-time falls related to nocturia, especially in those with underlying gait instability and other risk factors for falls.

The first secondary data analysis of a RCT which demonstrated that behavioural therapy, with an emphasis on pelvic floor muscle exercises and urgency suppression strategies, showed that nocturia was reduced in women (mean age 68) with urgency predominant UI.[699] The median reduction of 0.5 episodes per night was significantly more effective than drug treatment with oxybutynin IR titrated from 2.5mg per day to 5.0 mg three times a day, (0.3 episodes) or placebo (no reduction). A second secondary data analysis of an RCT, that did not show benefit with respect to the primary endpoint of urgency incontinence in women (mean age 55), did not show benefit of behavioural therapy when added to tolterodine 4 mg LA for nocturia. [706] An additional RCT in men (mean age 64) examined the impact of the addition of either titrated bladder relaxant therapy (oxybutynin XL 5-30mg) versus behavioural therapy for pelvic floor muscle exercise in whose 24 hour urinary frequency was not resolved with alpha-blocker therapy. In this trial, nocturia was a secondary outcome. In this study, the behavioral group showed greater reductions in nocturia (mean
= -0.70 vs. -0.32 episodes/night; P = .05) [707]. There are currently no trials of pelvic floor muscle exercises or urgency suppression strategies where individuals were enrolled on the basis of having nocturia with reduction in nocturia as the primary outcome.

b) Pharmacotherapy

1. Antimuscarinic therapy

Members of a recent nocturia consensus conference agreed on the following statements with regards to overactive bladder and antimuscarinics: 1) most patients with nocturia do not have overactive bladder; 2) most patients with OAB do have nocturia; 3) antimuscarinics are not usually efficacious for nocturia; and 4) antimuscarinics may be effective for nocturnal voids due to urgency. [631] In general, if the history, bladder diary, and physical examination suggest that nocturia is related primarily or in part to OAB/DO/urgency UI, then treatment with an antimuscarinic agent should be considered (see Pharmacological Treatment above). There are several trials examining the effect of antimuscarinics for nocturia reduction, including trials of oxybutynin-IR, [699] solifenacin, [708] and tolterodine [709, 710]. Four recent trials have compared placebo to active drug for nocturia without statistical improvement. [711-714] There is evidence to suggest that these agents may be more beneficial in combination with other therapies [715] rather than as single modality therapy. Even when agents from this category have shown statistically significant reductions in nocturia, the net benefit of reduction in nocturia (above that effect shown with placebo) is only by 0.0 to 0.3 episodes. A recent “positive” trial showed a statistical advantage of solifenacin 10 mg over placebo of a net difference of -0.12 episodes per night. [716] Tolterodine demonstrated statistical reduction in nocturia accompanied by urinary urgency (but not overall nocturia). [710] The clinical importance of nocturnal urgency is evident to the patient with the symptom (“I would like to not wake up and have to rush to the bathroom”), but this outcome is not fully nor well established within the literature. Use of anticholinergic medications should be used with caution in at-risk individuals as they may cause worsening of confusion.

2. Agents directed towards benign prostatic obstruction

Alpha-adrenergic agents used in patients with symptoms suggestive of BPO have a modest impact on nocturia, with a mean reduction of slightly less than one episode per night. [689, 717] 5-alpha reductase inhibitors [689] and saw palmetto (Serenoa repens, saw palmetto berry extract) [718] have not shown statistical benefit for nocturia except in one study within one subset of participants age >70. [719] This statistical advantage did not persist beyond one year, and the net benefit compared to placebo was a difference of < 0.2 fewer nocturia episodes.

3. Other medication approaches

Among postmenopausal women, one uncontrolled trial of oestradiol in combination with a progestogen showed a dramatic reduction in nocturia over 6 months, [720] but this was not replicated in another RCT. [721] There are few studies that have focused on treatment of nocturia with the use of medications for sleep. One RCT evaluated melatonin for treatment of nocturia associated with BOO in older men. [722] Melatonin showed only a trend towards reduction in nocturia compared to placebo (-.03 and -0.05 episodes from baseline 3.1 episodes, respectively) but did significantly reduce reported bother from nocturia. A second study compared the addition of either melatonin or a sedative hypnotic (rilmazafoxone) to older men and women (mean age 72) who were already taking a medication for nocturia, and found the addition of either treatment further reduced nocturia one episode (from 3.5 to 2.5 in both groups) [723]. Reducing volume overload associated with lower extremity venous insufficiency or congestive heart failure with a late afternoon dose of a rapid acting diuretic may be helpful in reducing nocturnal polyuria and nocturia in selected patients. [724, 725] Diuretics (specifically bumetanide and furosemide) have been conferred Level 2 evidence, Grade C recommendation by the Committee for Establishment of the Clinical Guidelines for Nocturia of the Neurogenic Bladder Society. [726] Treating sleep apnoea with continuous positive airway pressure can reduce nocturia severity, but these trials have not usually included the frail elderly. [727] Treatment with very short-acting benzodiazepines for patients with primary insomnia, and with dopaminergic agonists for patients with restless leg syndrome, may improve sleep quality, but there are no data to support these approaches.

4. Anti-diuresis treatment Desmopressin

Most older patients with nocturia have increased nocturnal urine output, which is less common in younger patients [685]. This having been said, the value of classification of patients (according to the presence or absence of NP) has not been demonstrated to be a meaningful predictor of efficacy, or lack of benefit, for any treatment, including prediction of response to desmopressin [636]. A large number of studies over the last 20 years have examined the potential role of exogenous AVP (desmopressin or DDAVP) for the treatment of nocturia in older patients [681, 698, 701, 702, 728-743] (table 10). While many have been uncontrolled case series involving relatively small numbers of subjects, more are robust RCTS. In some cases, however, the inclusion criteria, outcome measures, and route, dosing, and duration of DDAVP treatment have varied considerably. The first two, large RCTS using oral DDAVP employed essentially identical designs, with one conducted in men [702] and the other in women. [701] While these trials included some patients older

than 75, the mean age of the participants was closer to “middle” rather than “old” age (65 and 57, respectively). Both found significant reductions in nocturia and nocturnal urine volume, and increases in mean duration of self-reported first night-time sleep episode. However, there were some unusual elements of the trial design. The randomised controlled portion was preceded by an open-label dose-titration run-in, with the subsequent exclusion of subjects who did not experience >20% reduction in nocturnal urine volume or who were intolerant to the medication. Although this approach may be useful for targeting therapy in clinical practice, it raises questions about selection bias and the generalisability of the results. Most individuals in DDAVP oral tablet trials were titrated up to an oral dosage of 0.4 mg, [701, 702] yet older patients can have a significant reduction in night-time urine with much lower doses of 0.1 or 0.2 mg orally.[738, 739, 744]. A major concern related to DDAVP treatment in elderly patients is fluid retention (which can exacerbate underlying cardiovascular disease) and hyponatraemia. In one study, one of the 57 individuals randomized to 0.1 mg DDAVP for year was described as having a “consciousness disturbance due to hyponatraemia (116 mmol/L)” which left him unable to “complete the protocol” (Wang 2011). Many older persons may have pre-existent hyponatraemia due to a variety of medical conditions and drugs and will develop renal insufficiency or congestive heart failure. One review [745] found the incidence of hyponatraemia with DDAVP in older persons to be 0-9% (depending on definition), with the exception of the RCT in men discussed above, in which the incidence of any hyponatraemia was 22% (4% with sodium < 130 mmol/L). Because so few frail elderly were included in these trials, the actual incidence of clinically significant hyponatraemia from DDAVP that might occur with monitoring outside of a clinical trial is unknown. A further review of pooled trial results found that the incidence of hyponatraemia in subjects with normal baseline sodium was <1% (3/336 subjects) in persons <65 and 8% (22/260) in those >65, and 75% (6/8) in older patients with a low baseline serum sodium.[746] Pharmacodynamic studies in younger older men (aged 55-70) found that DDAVP had a prolonged half-life which was in part responsible for hyponatraemia. [747] DDAVP is not useful in frail older persons in nursing homes with nocturia and/or night-time UI because of the lack of efficacy for reducing night-time voids and the very high rate of hyponatraemia [744].

Several attempts at delivering the efficacy of antidiuretic therapy without the side effects have focused on the dosing, mechanism of achieving anti-diuresis, half-life of the agent, and delivery system. Since the last ICI review, data about the efficacy and safety of an orally-disintegrating tablet formulation of DDAVP have been published [698]. The theoretical advantages of such a formulation would be the ability to deliver smaller and consistent level of the drug. The study design evaluated co-primary outcomes of decrease in night-time voids from baseline versus placebo and the ability to achieve a 33% decline in baseline nocturia. Participants were stratified by age <65 and ≥ 65, with 500 individuals over 65 in the study having safety endpoints. At enrolment, all participants needed to have a serum sodium of >135 mmol/L, an estimated creatinine clearance of greater than 60 ml/min (the largest single reason for exclusion during screening, 15%), and a post void residual of less than 150 ml, and, for men only, a peak uroflow of >5 ml/second. The results showed that for men, the minimal effective dosage was 100 microgrammes (-1.38 versus -0.84 for placebo) and for women it was 25 microgrammes (-1.22 versus -0.88 for placebo). Side effects appeared in a dose-dependent fashion, that depended upon both age (older had higher side effects) and gender (women had higher side effects). For those participants over 65 years of age, the following percentages of participants had a reduction of sodium of either 125-130 or <125: on 100 microgrammes, 14.1% and 4.7%; on 50 microgrammes, 6.6% and 2.6%; for 25 microgrammes, 2.6% and 0%. While the 2011 nocturia treatment consensus guidelines [631] stated that "the mechanisms behind desmopressin-induced hyponatraemia are well understood", newer information suggests that the hyponatraemia in women is not fully explained by pharmacokinetic profiles [748]. For elderly individuals, antidiuretic therapy via DDAVP orally absorbable tablets still has a narrow therapeutic window where the dosage that allows for efficacy in the absence of meaningful and potentially serious side effects may be difficult to find.

There have also been trials with staggered DDAVP and diuretics, which have greatly reduced nocturia [740]. Of the participants who completed the trial, 5% had hyponatraemia, not counting individuals who had hyponatraemia during run in.

c) Surgical and procedural treatments

Posterior tibial nerve stimulation has been used in OAB trials. A recent trial [749] demonstrated in 214 individuals a favorable outcome for nocturia reduction in the active treatment group (2.9 at baseline to 2.1 with treatment) that was statistically superior to the effect of sham (2.9 to 2.6, net benefit of active over placebo -0.4 reduction). Of note, there were more individuals over 65 years of age (50%) compared to the sham group (41%) biasing against demonstrating benefit if it were true that older adults responded less well; whether or not these gains are maintained without ongoing treatment is not known [750].

Surgical approaches to treatment of nocturia have long been recognized to be effective, yet overall symptoms improve more than does nocturia specifically. The evidence from trials shows that older patients with the highest symptom scores prior to surgery benefit the most from transurethral resection of the prostate [751], yet nocturia often persists and may
be the least responsive symptom for improvement following the procedure [751-753]. Yet, surgery does reduce lower urinary tract symptoms and may result in reductions in nocturia and improvement in symptom specific QOL [754]. In one consecutive group of 56 patients treated with either TURP or radical prostatectomy (mean age 69) for persistent symptoms despite six months of medical therapy. The group monitored postoperative nocturia counts, hours of undisturbed sleep, and the ICIQ-NQOL which were compared to baseline. In this uncontrolled series, patients had significant improvements in all measured domains, including a 0.8 episode reduction per night [755]. The NQOL outcome measure was most favorable in individuals with the greatest reductions in nocturia or the most uninterrupted sleep. One study used a retrospective evaluation of 298 patients (mean age 70) over a 10-year period, and found that younger men with lower preoperative urinary maximum flow rates had the best post-operative results [753]. Not surprisingly, symptoms post-operatively were not strongly correlated with objective urodynamic findings [756]. On average, less than half of the men operated on had a reduction of nocturia by 50% or more [753]. In a rare RCT where 66 men, aged 52–81 years (mean 68.6), who were believed to have nocturia solely due to “benign prostatic hyperplasia” and who had received no previous treatments of any type, were randomized in a 1:1 fashion to either alpha-blocker therapy (tamsulosin 0.4 mg) or TURP. The prostate volumes and baseline nocturia nearly differed in a statistically significant manner at baseline (51 cm3 and 2.0 mean nocturia episodes versus 59 cm3 and 2.4 for those allocated to surgery). Both groups had a reduction of nocturia to 1.5 (3 months) and 1.4 (6 months), as well as statistical improvements in the ICIQ-NQOL. No treatment was superior to the other and both were statistically significantly improved from baseline [754].

7. SUMMARY OF EVIDENCE

- Late afternoon administration of a diuretic may reduce nocturia in persons with lower extremity venous insufficiency or congestive heart failure unresponsive to other interventions. (Level 2)
- If OAB, DO, and/or urgency UI is felt to be a major contributor to nocturia, antimuscarinic agents should be considered. (Level 3)
- If nocturia is due to insomnia alone, then a very-short acting sedative hypnotic may be considered. (Level 3)
- DDAVP should not be used in frail elderly because of the risk of hyponatraemia. (Level 1)

8. RECOMMENDATIONS FOR MANAGEMENT

- Nocturia investigations should be carried out utilising both frequency-volume charts and validated questionnaires capturing QoL and bother related specifically to nocturia (e.g. NQoL).

9. RECOMMENDATIONS FOR RESEARCH FOR NOCTURIA IN THE ELDERLY [636]

- Validation and clarification of the definitions of both nocturia (in regards to any night awakening owing to the desire to pass urine, the ICS definition, vs. the more clinically bothersome nocturia, of 2 or more episodes)
- Studies to elucidate the reason for awakening
- Ways in which to understand, and potentially diminish, the robust effect of placebo/control arms
- Epidemiological research regarding studies of nocturia involving the following aspects: incidence/natural history, bother, effect on quality of life
- Research regarding what would be a clinically significant improvement
- Further clinical trials examining the impact of sleep focused treatments
- Trials examining the effects of multiple incremental and multicomponent therapies for nocturia
- Algorithms for both initial and subsequent (e.g., cause-specific) management of frail elderly, and men versus women would seem to be desirable.

VI. MODELS OF CARE FOR THE FRAIL ELDERLY WITH UI

1. BACKGROUND

Globally, frail elderly persons receive personal, nursing and medical care in a variety of healthcare and residential settings that employ many different models of continence care. While there continue to be very few studies, and fewer randomised clinical trials that directly examine these models in relation to UI prevention and management, a discussion of selected models is useful in identifying the challenges and opportunities to improve continence care for this population. This descriptive section briefly outlines four models of UI care particularly relevant to the frail elderly: home care, continence nurse advisors, collaborative practices between advance practice nurses and physicians, and long term institutional care. The care of incontinent frail elders in the acute care and assistive living settings is also discussed. A comprehensive review of global models of care is outside the purview of this section. Of note, we located little new information since the 4th ICI. Our findings were confirmed by a systematic literature review of 7 studies that investigated conservative interventions for frail non-institutionalised older adults, some of whom however lived in assisted living, senior apartments, and homes for the elderly, or attended adult day care [757].

2. HOME CARE

Most care for the frail elderly who live at home is provided by informal caregivers such as spouses,
children, other relatives, and in some cases neighbours or friends. Overall, there has been little research on UI interventions for this population but one trial found that behavioural interventions can be effective in selected frail homebound persons with UI and motivated caregivers [758]. Another trial, included in the systematic literature review mentioned above, found comprehensive geriatric assessment (CGA) was effective in resolving UI in 23% and improving incontinence in 44.6% [759]. Overall, however, the informal nature of care at home may lead to important barriers to effective continence care. Firstly, caregivers may not be available 24 hours per day, and thus regular toileting assistance may only be intermittently available. Toileting programmes (e.g., prompted voiding), intermittent catheterisation, and pessary use therefore may be impossible to implement consistently. Secondly, many caregivers for frail persons are, in fact frail, themselves. Spouses and adult children may have medical illnesses and/or functional problems making toileting assistance physically difficult and continence care stressful for them. An internet-based survey with Japanese family caregivers revealed that caring for a family member with incontinence resulted in significantly higher Zarit Caregiver Burden Interview (ZBI) scores than for those caring for a continent family member [760].

In 11 European regions, informal caregivers caring for incontinent older adults were 2.2 times more likely to report feelings of stress or burden [378]. Thirdly, even among caregivers who are physically capable and available to assist with continence care, negative attitudes, lack of knowledge and educational resources may pose substantial barriers to providing the required care.

Trained, paid caregivers for the frail elderly living at home are variably available throughout the world. Such services may include nurses to teach patients and caregivers UI care and management of intermittent or indwelling catheterisation, health care aides or personal care assistants who can assist with continence care, negative attitudes, lack of knowledge and educational resources may pose substantial barriers to providing the required care.

In the US, for example, Medicare (health insurance for persons aged > 65) does not pay for ongoing UI care, only some catheter care and supplies and need-based home skilled nursing and physical therapy, and usually only on a limited basis and following hospitalisation. In a survey of Dutch older adults, > 65 years (mean age 80 years, standard deviation 7.2) who were receiving home care agency services, 46% (n=2866) had urinary incontinence. UI type was diagnosed in 49.8%. Types of UI were as follows: 13.1% stress UI, 33.4% urgency UI, 18.1% mixed UI, and 35.4% functional UI. Use of pads was the most commonly used intervention with scheduled toileting the second most frequently used intervention. In addition, for older adults who had a diagnosis for UI type, only 11% received special skin care [492]. In a study with 4010 older adults who were receiving home care, 1478 (36.8%) were incontinent of urine and the use of pads ranged from 29% to 52% among 11 home care sites in Europe [378]. Thus, even for older adults receiving home care, UI management often remains focused on containment by using pads and other protective products. These can be expensive if not provided or reimbursed through available health services or insurance. Research is needed to determine the magnitude of the problem of frail elders who do not engage in practices to protect skin integrity and devise homemade alternatives to pads, which are neither effective, comfortable, nor safe (especially to prevent incontinence-associated dermatitis [761].

A study conducted in the Netherlands with 19 home health agencies found that 38% of agencies documented the input of a continence nurse to care, but no association between quality systems and UI outcomes was found. The authors defined quality systems as management activities designed to monitor, assess and improve the quality of care [762]. With the demand for home care services expected to increase, these agencies will provide services for an increasing number of frail elderly patients with continence concerns.

3. CONTINENCE NURSE ADVISORS AND NURSE-LED MODELS

In many countries (e.g., UK, Australia, Sweden and Canada, among others), continence nurse advisors who can provide extremely valuable services for frail elderly with UI are available. Continence nurse advisors are highly trained in the assessment and management of both urinary and faecal incontinence. They are generally funded by the government and function as public health nurses for a region associated with one or more hospitals. They serve as advisors and provide education to physicians, nurses, and other health care professionals, as well as patients and their caregivers. They may also assist hospital staff in the assessment and management of UI in the hospitalised frail elderly, and coordinate follow up care in the home or in an outpatient clinic. One Canadian study found that continence nurse advisors had a positive impact in improving management of UI in older persons [763].

Data suggest that continence nurse led services are effective for the general population, but there are no specific data for frail older people [764].

4. COLLABORATIVE PRACTICES BETWEEN ADVANCE PRACTICE NURSES AND PHYSICIANS

In many countries, publicly supported continence nurse advisors are not available. However, other models have developed that generally involve collaborative practices between nurses with special interest, advanced training, and expertise in continence care and physicians (usually a urologist, gynaecologist, or geriatrician). These collaborations can be vital for providing optimal continence care for the frail elderly because of the multi-component therapy required. Such nurses may provide reim-
bursable services in private offices and clinics; provide education, consultation, and/or direct services to nursing homes or other long term care facilities, and assisted living facilities; and assist with the assessment and management of UI to frail elders in their homes. The complexity of healthcare delivery systems and needs of medically complex frail older adults are acknowledged in calls for optimal continence care delivered through multidisciplinary teams [404]. An analysis conducted with data from the 2006 National Audit of Continence Care for Older People in England and Wales found that integrated services, those that included organisational structure and clinical care processes for continence care which met national quality standards, provided higher quality of care [268]. Reimbursement for advance practice nurses and their ability to provide direct care independently of a physician varies across countries, and in some case within countries (e.g., in the US their scope of practice can vary by state). Evidence from a randomised controlled trial of a nurse-led continence service (for women aged 40 years and over) revealed clinical and statistically significance decrease in the urinary symptoms of urgency, frequency and UI [765]. The nurses in this study were specially trained, used evidence-based interventions and behavioural techniques with motivation and reinforcement. The nurses also consulted with a medical team. Although this model was used in independently living women, it shows promise for use in community-dwelling frail older people. In some countries there are specially organisations for continence nursing (e.g., the US, Wound Ostomy Continence Nurses Society and Society of Urological Nurses and Associates; Canada, Canadian Continence Nurse Advisors; UK, Association for Continence Advice). Although little data on the effectiveness of these organisations in terms of improving patient care exist, they are becoming more widespread (e.g., Israel and Italy).

5. INSTITUTIONAL LONG TERM CARE

Long term care for the frail elderly is provided in a variety of types of institutional settings throughout the world. Continence care here is dependent upon many factors, including: type of resident (those requiring long-term skilled and personal care, short-term rehabilitation, post-hospitalisation care); physical environment; the organisational culture and leadership commitment to providing high quality care; the number, education, and motivation of direct care staff; access to physicians with interest in and understanding of continence care; and financial and regulatory incentives to provide appropriate continence care. Nursing home staffing continues to be a major barrier to translating research on prompted voiding and other interventions (see sections on Behavioural interventions and Environmental factors) into practice, and because resource constraints are stringent and will become more challenging with the rapid growth in the frail elderly population [766]. One study found that one staff member to five residents was necessary to implement combined toileting assistance with an exercise programme for physically dependent residents [470]. However, the residents’ ability to maintain continence or improve may depend not only on the number of staff available, but also on their knowledge, skill, and interest and how these staff members are deployed. A systematic review on the impact of nursing workload and staffing on establishing healthy work environments for example, found a positive association between the knowledge and level of staff, and patient outcomes. Specifically, a greater proportion of regulated staffing (i.e. registered nurses, enrolled nurses, practical or vocational nurses) is associated with improved outcomes related to the Functional Independence Measure score, the Short Form Health Survey (SF-36) vitality score, patient satisfaction with nursing care, patient adverse events (including atelectasis, pressure ulcers, falls, pneumonia, postsurgical and treatment infection and urinary tract infections) [767]. Moreover, improved patient outcomes in relation to falls, pneumonia, pressure ulcers, urinary tract infection, length of stay and postoperative infection rates are associated with increased hours of registered nurse employment. The section on Interventions with Long-term Care Staff above, reviews studies of interventions with nursing home staff to improve continence care. These interventions have generally met with limited success because they have not incorporated either contextual or patient-level factors into their interventions, but have merely concentrated upon facilitation [768].

Three broad strategies have been employed to improve the quality of continence care for frail elderly nursing homes residents. The first are standardised approaches to identification, assessment, and management of UI. One is the Resident Assessment Instrument for nursing facilities, whose use is mandated in the US and other countries [418].) The Resident Assessment Instrument combines information from the Minimum Data Set (including data on individual resident demographics, medical conditions, function, cognition, and care needs) with Resident Assessment Protocols for specific conditions and impairments. The continence section of the Minimum Data Set is generally accurate in identifying incontinent patients, but not for determining the type or severity of UI or determining especially smaller changes in continence over time [769]. The original version of the Resident Assessment Protocol for UI was partially validated in a sample of approximately 100 frail, incontinent patients in one large academically-affiliated US nursing home [770]. In other countries, such as Australia and the UK, the use of clinical assessment tools in nursing homes is not mandated. They are in certain cases however, linked to accreditation processes and funding, providing a financial incentive for nursing homes to document an assessment and care plan
that addresses residents' continence care needs. The National Audit of continence Care for Older People reported on the extent to which nursing homes adhered to a suite of continence assessment and management standards based on ICI and national criteria [265].

Another approach is national guidance directives, such as that for surveyors who conduct yearly quality evaluations of all US nursing homes. A revision of the US guidance to surveyors for UI and catheter use in 2005 attempted to replace the existing emphasis on nursing documentation of continence care plans with an emphasis on UI assessment and provision of patient-focused care [418]. However, a subsequent study found that both surveyors and nursing home staff did not understand this shift in emphasis, and that the dissonance between these two groups in basic UI knowledge and elements of the guidance was a barrier to any change in quality of UI care [427]. Despite the existence and dissemination of guidelines, several studies document an ongoing discrepancy between their recommendations and regulations and the continence care actually delivered in the US [277, 425, 458, 771] and UK [265, 772].

The second strategy has been the use of principles of continuous quality improvement and total quality management developed for business management [773]. The key elements of these approaches are education and involvement of direct care staff, identification of a “continence champion” and team to implement the programme, and the continuous collection and analysis of quantitative outcome data using principles of statistical quality control. Quality assurance programmes using UI quality indicators have also been proposed [263]. One study successfully used a computerised assessment and quality improvement software program and external oversight to maintain a 50% reduction in UI in eight diverse, geographically dispersed US nursing homes [440]. A second implemented a quality improvement programme in five diverse US nursing homes, but UI reduction was more modest (20-30%) in this effort to translate research into practice [484]. In a recent major quality improvement in NHs initiative, the Centres for Medicare and Medicaid Services (CMS) in the United States use publicly disclosed quality measures (QMs) for nursing homes. Low risk incontinence (i.e., percent of low risk long stay residents with loss of bladder or bowel control) was associated with the percent of residents readmitted and the percent of residents incontinent of urine on admission to the facility [774].

The third approach is a specialty practice exemplar model for continence care, with an academic nursing faculty member with expertise in the assessment and treatment of UI engaged in clinical UI practice in a long-term care facility (see Interventions with Long-term Care Staff, above): graduate nursing students working with this individual focus on the Resident Assessment Protocol for UI. UI assessment and management skills are transferred to the facility nursing staff members through several mechanisms, including staff education and improved continence care systems [398]. This approach to improving continence care in nursing homes can be facilitated through collaborative partnerships between academia and the nursing home sector. Proponents of this type of collaboration claim it has the potential to facilitate culture change in nursing homes; to transform the perceptions and images of nursing homes in academia and the community, as exemplary places for quality and care and quality of life; and to promote evidence-based care, interdisciplinary collaboration, and resident-centred care [775-777]. For example, they can also potentially support the development of clinical leaders to introduce change at the clinical interface [778].

The concept of using clinical leaders, and/or nurses with advanced knowledge and skill, to improve the evaluation and treatment of UI in nursing homes is not new [277, 453, 767, 779, 780]. Watson and colleagues for example report a quasi-experimental pre-post design to test the effectiveness of using nurse practitioners to translate the Agency for Health Care Research and Quality Urinary Incontinence Guideline into practice for residents from nursing homes in upstate New York. Although the intervention was inconsistently implemented, 8.4% of residents’ (n=25) became continent: largely due to treatment of reversible causes such as constipation [781].

6. OTHER INSTITUTIONAL SETTINGS

Other institutional settings that warrant attention in the context of models of care for improving the management of UI in frail older adults are: 1) acute care settings and 2) assisted living communities.

Acute care is a form of secondary health care which involves an active approach to managing a short-term, but urgent health problem. It is generally delivered by a range of health care professionals in a hospital setting. Older adults comprise the largest proportion of people admitted to acute care and as the population ages, the number of frail older adults requiring hospitalisation will increase. A recent prospective cohort study of 577 patients (mean age 82 +/- 6.9 years) admitted to general medical wards of three acute care hospitals in Brisbane, Australia, found UI rates of 43.8% (243/555) premorbid, 36.7% (176/479) during admission, and 35.3% (187/530) at discharge [782]. Moreover, of 438 patients at the time of discharge, 38 (12.8%) had new onset UI. One group of patients with a high risk for developing UI in hospital are female hip fracture patients. A secondary analysis of data from 6516 hospitalised women with a fractured hip revealed 21% became incontinent during hospitalisation [783]. Risk factors in this group included admission from a nursing home or other long-term care facility (odds ratio
confusion (OR 3.44, 95% CI 2.79–4.24), use of a wheelchair or device for walking (OR 1.53, 95% CI 1.29–1.83), and prefracture dependence on others for ambulation (OR 2.51, 95% CI 1.64–3.85).

Other research on UI in acute care draws attention to an overreliance on continence aids, and inadequate attention to identifying and addressing potentially contributing factors. For example, Ostaszkiewicz and colleagues conducted a point-prevalence survey of 447 hospitalised older adults in acute and subacute care settings in Australia and found 60% with a continence product or device, however, 50 (41%) patients with an absorbent pad denied having experienced UI or FI in the preceding 24 hours [430]. By contrast, 113 patients (16%) who reported UI or FI in the same period had no continence product or device. Hospital inpatient notes and admission notes also lacked information about patients’ continence status. Similar findings were reported for elderly patients admitted to hospitals in Israel [409] Switzerland, [408], and Italy [784]. Zisberg and colleagues [409] conducted a prospective cohort study of 352 patients aged 70 and older who were continent prior to admission to an acute care hospital. They found, 17.1% developed UI during their hospitalization, and in a multivariate analysis, the use of a urinary catheter or diaper were associated with the development of UI (4.26 95%CI 1.53-11.83 and 2.62 95%CI 1.17-5.87 respectively). Zurcher and colleagues [408] surveyed 78 elderly inpatients in a Swiss hospital and found 41 (51%) screened positive for UI, yet only 10 (24%) of nursing records documented the presence of UI. Moreover, the use of absorbent pads was the only intervention documented. The number of patients who declined to be asked about their continence status was minimal (n=5). Palese and colleagues also drew attention to a mismatch between UI and absorption use, which occurred for 34% of patients admitted to medical wards in two Italian hospitals [784]. Factors that contribute to the lack of screening and assessment of incontinence, and overreliance on containment strategies for UI in acute care include: healthcare practitioners’ lack of knowledge and skills, [428, 785-787] negative attitudes toward older adults with incontinence, or the belief that UI is not a priority [788, 789].

Whilst existing research indicates the need for UI to be treated as a potentially preventable complication of hospitalisation, it does not offer specific information about the continence status and continence care needs of hospitalised frail older adults as a specific subgroup. As incident UI is a marker for frailty, and functional decline, it is important to focus clinical and research attention on this vulnerable population [790, 791]. Dowling-Castronovo and colleagues provide a standard of practice protocol for managing UI in older hospitalised adults [792]. However to the best of our knowledge, there is no evaluative research on the use of these or other protocols for managing either daytime or night-time UI in acute care, especially in the frail elderly. There is a similar lack of published literature on models of care. Staff management protocols that involve using clinical champions, goal setting, self monitoring, and industrial quality control techniques, that have been trialled and evaluated in other settings (i.e. nursing homes), may apply to acute care.

Assisted living communities are social care residential models, in which older persons are provided primarily IADL assistance (meals, laundry, cleaning), and are becoming more common (primarily in the developed world). There is substantial variation in the functional status and medical care needs of their residents, the availability of nursing and physician care, reimbursement, regulation, and whether and how residents are allowed to age “in place” versus being transferred to nursing facilities should their care needs substantially increase. In some countries and localities, assisted living residents may substantially resemble the nursing home population. There are no data on the quality of management of UI for frail elderly residing in assisted living facilities, or intervention trials specifically in this population. The US National Association for Continence (www.nafc.org) has published a “blueprint” for continence care in assisting living facilities, based primarily on expert opinion.

7. RESEARCH RECOMMENDATIONS

1. Compare the efficacy of specific models of UI care for the frail elderly around the world.
2. Determine the factors associated with the effectiveness of care models in countries with different health care systems.
3. Develop and evaluate protocols for managing UI in frail elderly persons in acute care.
4. Differentiate frail from non-frail older adults in research on UI.
5. Replicate clinical trials and quality improvement initiatives to reduce urinary incontinence in a variety of healthcare settings with larger samples.
6. Identify specific models of care for UI in frail elderly persons in specific healthcare delivery settings: acute care, nursing home and assisted living, and primary care settings.
7. Determine system-level, group-level and individual-level quality indicators and outcomes for different models of care for UI in frail elderly persons.
8. Determine the factors associated with the effectiveness of care models in countries with different health care systems.
C. FAECAL INCONTINENCE

I. BACKGROUND

FI in older people is a distressing and social isolating symptom and is associated with a possible increased risk of morbidity,[320, 793] mortality,[794, 795] and dependency [793, 795-797]. Frailty, defined by having multiple comorbid chronic illnesses and/or limitations to physical activity, is an independent risk factor for FI [798, 799]. Many older individuals with FI will not volunteer the problem to their general practitioner or nurse, and regrettably, health care providers do not routinely enquire about the symptom.[800] This ‘hidden problem’ can therefore lead to a downward spiral of psychological distress, dependency, and poor health. The condition can especially take its toll on informal care providers of home-dwelling patients, [801] with FI being a reason for requesting nursing home placement [802].

Even when older people are noted by health care professionals to have FI, the condition is often managed with the use of absorptive or containment products, especially in the long-term care setting where it is most prevalent. Current surveys show that the level of awareness regarding appropriate assessment and treatment options is limited among primary care physicians [803]. The importance of identifying treatable causes of FI in frail older people, rather than just managing passively (e.g. pads provision without assessment) is strongly emphasized in national and international guidance,[320, 804] but audits show that adherence to such guidance is generally poor, with non-integrated services, and sub-optimal delivery by professionals of even basic assessment and care [268].

This section covers specific issues for frail older people with FI. Since frail older adults frequently have co-existing urinary incontinence, evaluation and management of urinary incontinence and FI should be considered simultaneously [805-809]. Healthy older people should be managed using the interventions covered in the Chapter 16 on the “Management of Faecal Incontinence.”

For the previous ICI report, the literature review covered the period 1966 to 2008. We identified new population-based studies on the prevalence and incidence rates of faecal incontinence specifically including frail, older adults (Table 11). Table 10 includes all studies published through December 2011, which met the following criteria: (1) sample representative of the general population (not a convenience sample or sample recruited from a specialty/primary care medical clinic or other setting in which there is a probable selection bias), (2) sample involving specific models of care for the older adult, and (3) sample of specific disease or co-morbid condition (i.e., home care, long term care).

The PUBMED.gov database was searched up to December 2011 using the following keywords:

(i) ‘anal, bowel, faecal, faecal’ and ‘incontinence’
(ii) constipation
(iii) ‘urinary’ and ‘incontinence’
(iv) laxatives, enemas, suppositories
(iv) other relevant phrases such as ‘comprehensive geriatric assessment’ ‘stroke’
(v) level of care, ‘nursing home,’ ‘institutionalisation’, long-term care, ‘acute care,’ ‘hospitalisation’

Additional articles were identified by examining reference lists, and the Cochrane other recent systematic reviews.

II. PREVALENCE AND RISK FACTORS FOR FAECAL INCONTINENCE

In 2007, the Centre for Disease Control commissioned the University of Minnesota to prepare a systematic review of the prevalence and risk factors associated with FI for the State of the Science Conference on the Prevention of Faecal and Urinary Incontinence [810]. Their inclusion criteria differed from ours and did not focus on the frail older adult. The studies identified in both of these publications were reviewed for this report.

1. PREVALENCE ESTIMATES FOR FAECAL INCONTINENCE

(FI) prevalence estimates for faecal incontinence vary widely: 2.2% to 25% in the general community-dwelling population, 9-30% in older, frail adults, 18% to 33% in acute care settings, and may approach up to 50% in long term care and institutionalised settings. Incident FI varies from 6% to 17% in community dwelling populations, with less information known about incident rates in specific care settings. The variability in the prevalence rates may be related to the case definition and the frequency of FI reported. Case definition may include flatal incontinence, as well as loss of solid and liquid stool. Often, passive FI, or seepage, is not differentiated from solid or liquid stool FI in prevalence studies. A few studies have also defined a category of soiling of underwear only. In this review, FI refers to the loss of solid or liquid stool or mucus. Studies are specified that use other definitions, such as flatal incontinence or anal incontinence and soiling.

2. PREVALENCE AND INCIDENCE ESTIMATES OF FI IN COMMUNITY-DWELLING OLDER ADULTS.

FI is strongly associated with aging in many studies, and studies only involving older adults have higher prevalence estimates. The National Health and Nutrition Examination Survey (NHANES) in

the United States (US) provides one of the best estimates of FI prevalence to date because it surveyed both sexes, all major races represented in the US, and a range of older adults by age decade (55-69 and 70 years of age and older) [811]. NHANES also provided separate estimates for different types of FI (e.g., solid, liquid, mucus, and flatus) and frequencies of stool loss. The age-adjusted prevalence of FI (defined as accidental loss of solid, liquid, or mucus incontinence in the month preceding the interview) in the non-institutionalised population of the United States is 8.9% of women and 7.7% of men, with higher rates in older adults (15.3% in women and 15.5% in men aged 70 years of age and older). Liquid stool incontinence was the most common type of FI reported in the NHANES data. Rates of FI in older, frail adults are not gender-specific, with recent studies suggesting equal rates of FI among older men and women [797, 798, 811-815], and differences in survey methods make it difficult to interpret observed differences [793, 811, 812, 816-818].

New additions to the literature include prevalence estimates of urinary incontinence and FI in populations receiving specialty services in the home, such as home health care/home visits by physicians and other care providers. Using the Outcome and Assessment Information Set (OASIS), a standardised and administrative assessment tool used to document patient needs in home care settings in the United States, urinary incontinence was identified in 27%-33% of home health care patients and 7%-9% had FI on admission to the home health agency/provider [819].

Rates of incident (i.e., rate of new onset) FI in non-institutionalised populations have been reported in two recent studies [817, 818]. Both studies surveyed older adults in the community and reported FI incidence rates after 4 and 9 years, respectively, from the initial survey period [817, 818]. Incident rates for FI occurring in the last year were 17% (95% confidence interval 13.7% to 20.1%) after 4-years in one study (n=557)[817] and 6.3% (95% confidence interval 4.5% to 8.6%) after 9-years in the other (n=683).[818] For FI occurring at least monthly, the incidence rate was 6% (95% confidence interval 4.0% to 8.3%) after 4-years [817]. Differing FI incidence rates may be due to the age range of those surveyed at baseline. In the Markland et al study, the average age of those surveyed was 77.7 years at 4-years, whereas the Rey et al study surveyed adults 50 years and older at baseline. FI incidence rates have also been reported in specific populations followed over varying time periods. Rates of incident FI in institutionalised older adults was 7.5% at 1-year (n=1186), [794] with another study finding an incidence rate of 5.4% 1-year after hospitalisation for an acute brain injury (n=1013),[820] and a smaller study finding a rate of 10.2% 5.5 years after a lateral sphincterotomy for an anal fissure (n=62) [821].

### 3. PREVALENCE ESTIMATES OF FI IN HOSPITALIZED OLDER ADULTS.

Like the variability of prevalence rates of FI in community-dwelling population, hospitalized older adult populations also vary depending on the type of acute care setting or hospital setting, type of populations being studied (i.e. those under surveillance for certain types of infections), and duration of the hospital stay. Rates of FI in hospital or acute care settings range from 18-33%. In one study, the rates of FI in the acute care setting for adults (mean age of 67 years) was 33% (50/152 with diarrhoea under surveillance for infections) [822]. In another study, FI (17.6%) was almost as common as urinary incontinence (19.7%) in 608 hospitalised adults (age range 4 years to over 80 years) [823]. Older age was associated with a 4-fold increase in FI in hospitalised adults [823].

### 4. PREVALENCE AND INCIDENCE ESTIMATES OF FI IN LONG-TERM CARE RESIDENTS.

Few studies were identified that reported prevalence rates of FI in nursing home or long-term care resident facilities. Data are often limited by the type of facility described or administrative data that report FI rates [805, 824-828]. Prior estimates of FI in long-term care or institutionalised older adults varied due to the type of facility and administrative data reporting. Recent FI prevalence studies confirm the prior high range of FI (>50% of nursing home residents having FI) reported in the literature [824, 825, 829]. Little is known about the FI incidence rate in this specific population of frail adults, with one study reporting a rate of 20% during a 10-month period after admission [794].

### 5. Faecal Incontinence in Older Adults – The “Hidden” Problem.

Recent evidence re-affirms that adults with FI do not seek care [830] and that health care practitioners are not likely to inquire or document discussions regarding FI [802,803]. Over 600 geriatricians responded to a US questionnaire on their beliefs, referral patterns, and perceptions on quality of care, and management practices for FI among older adults. Only 54.1% reported screening for FI and over 40% did not feel that FI could be managed conservatively. Only 32.9% believed nursing homes provide good care for FI and 27.1% believed that nursing home care conditions exacerbate FI [831].
Increasing awareness is important aspect of the identification, prevention, and treatment of FI in older adults [320]. Recent public campaigns with public and industry funding have sought to increase awareness of bowel control in the United States and United Kingdom (http://www.bowelcontrol.nih.gov/ and http://www.bowel-control.co.uk). Using appropriate terminology for FI for individuals that is consistent with health literacy levels may be an important factor. Terminology such as “bowel” or “bowel control” may be more appropriate than the term “faecal” or “faecal incontinence.” Barriers that prevent adequate identification and treatment include: social and cultural issues about discussing symptoms, perception that treatments may not exist, access to trained health care providers in the community, access to providers in long-term care settings, and access to training and treatment protocols. Given the high prevalence rates of FI in the hospital, home care, and long term care settings, health care practitioners should directly inquire or directly observe bowel control issues and document any findings. Other high risk groups of older adults that should be questioned about bowel control include older adults that have: mobility problems, cognitive impairment/dementia, prior pelvic/lower abdominal radiation exposure, prior anal or rectal surgery, urinary incontinence, chronic constipation, chronic diarrhoea, and co-morbid disorders such as diabetes and stroke.

6. RISK FACTORS ASSOCIATED WITH FI IN OLDER ADULTS.

Age has been established as a risk factor for FI in many population-based studies [797, 808, 811, 832]. Other factors that have been associated with increased rates of FI include: female gender, co-existence of UI, poor general health, physical limitations, cognitive impairment, stool consistency, prior colo-rectal surgery, and high body mass index [798, 833-836]. However, among population-based studies among older adults, risk factors specific to women (e.g. vaginal deliveries, parturition characteristics) are no longer significantly associated with FI when controlling for all other factors [811, 837]. Many diseases and co-morbid disorders are associated with FI and include: diabetes, dementia-related incontinence, irritable bowel syndrome, inflammatory bowel disease, systemic sclerosis, and neurological diseases, such as cerebrovascular disease [797, 818, 833, 838-842]. The association between faecal incontinence and loose stool consistency (diarrhoea) is robust in community-dwelling populations and nursing home studies [811, 817, 818, 826, 836, 837]. As supported by the epidemiological data, the aetiology of faecal incontinence remains multifactorial and treatment depends on the underlying mechanisms or specific co-morbid disorders known to impact bowel function.

III. THE AGEING LOWER BOWEL AND PATHOPHYSIOLOGY IN OLDER ADULTS WITH FAECAL INCONTINENCE

Chapter 4 covers the pathophysiology of FI. This section considers factors specific to frail older people.

1. QUALITY OF DATA

There have been few relevant new studies since the last consultation. The findings from physiological studies of the lower bowel in older adults tend to be variable due to a) a variety of different techniques used in measuring anorectal function, b) unclear definition of the normative range of manometric measures for older people, c) poor matching between cases and controls of clinical factors which may affect gut function (e.g. level of mobility), or inadequate clinical information, d) usually small subject numbers, e) few studies deal with subjects over 80 years, and f) improvements in imaging quality with endoanal ultrasound and MRI. Studies reviewed are cohort case-control to evaluate age-effect [843] [844] [845], young-old healthy subject comparisons [847, 848], and age- and sex-matched case-control studies of continent versus incontinent patients [849-852].

2. ANORECTAL FUNCTION IN HEALTHY OLDER ADULTS

Studies of age effect in healthy volunteers have shown a linear reduction with ageing in squeeze pressures (external anal sphincter tone) in women after the age of 70, and in men from the 9th decade onwards [844] Studies of normal men and women demonstrated a significant but similar linear decrease in anal resting pressure and maximum squeeze pressures in both men and women with increasing age [853] [854] [855]. Studies of asymptomatic females showed a significant decrease in both anal resting and squeeze pressures with age [856] [857] [858]. A study comparing young and old continent women found a decrease in anal resting pressure but no decrease in squeeze pressures between the two groups [852] Age beyond 70 years was associated with reduction in anal resting pressures (internal anal sphincter tone) in both sexes, but to a greater degree in women in some studies [843] [844] [848], but not confirmed in other studies as reaching statistical significance [850, 859] [860].

The internal sphincter thickness and diameter is significantly increased in older versus younger men and women [861] and in nulliparous older women [862]. In addition this was associated with a significant decrease in the external anal sphincter thickness in women [863] [864]. A study of men and women using endoanal MR imaging showed a
significant decrease in the external anal sphincter thickness in men but not women with age [865].

With ageing the enteric nervous system undergoes age-related degeneration. In patients older than 65 years there is >30% loss of enteric neurones when compared to people aged 20 to 35 years. This loss is associated with an increase in fibrous tissue deposition [866]. Increase in thickness of internal sphincter is related to an increase in collagen deposition [867] [868].

There was a significant increase in pudendal nerve latencies with age in women [857] and not men [869].

Rectal motility appears to be unaffected by healthy ageing [847], but there is an age-related increase in anorectal sensitivity thresholds [854] [870] [855]. Rectal compliance was not affected in one study [870] but reduced rectal sensation was associated with reduced rectal compliance in another [858]. Anorectal function in older adults with faecal incontinence.

One study demonstrated prolonged pudendal nerve terminal motor latency (>2.2ms) in 34% of women aged over 50 with FI, though no relationship was observed between pudendal neuropathy and anal resting or squeeze pressures. Advancing age was however related to declining anal resting pressures. [871] Another study similarly found an age-related increase in pudendal neuropathy in continent women, again unrelated to squeeze pressures [872]. Single fibre EMG in incontinent patients aged over 78 years showed an increase in polyphasic potentials in the external anal sphincter muscles compared with continent subjects after adjusting for age, indicating some local reinnervation of these muscles following neurogenic damage. [851] A study comparing anorectal function in young (mean age 42) and old (mean age 72) women with FI (patients with constipation and/or pelvic floor dysfunction excluded) showed that older women were more likely to have bilateral pudendal neuropathy, but less likely to have a sphincter deficit of >90 degrees, likely to have had a previous sphincteroplasty and thin perineal body, although the validity of this test is questionable (Committee 7). Anorectal physiology was similar aside from a trend toward lower resting tone in older women [846].

An examination of anorectal function in elderly medically frail incontinent patients and continent age- and sex-matched controls showed that individuals with FI had reduced anal resting pressures. Significantly lower anal resting pressures were found with decreasing mobility in FI elderly [850]. Lower anal resting pressure was correlated with a lower threshold for expulsion of a rectal balloon. Patients with FI and dementia were more likely to exhibit multiple rectal contractions in response to rectal distension, though the role of these ‘uninhibited’ contractions in causing incontinence was unclear [873].

A similar matched case-control study showed that elderly patients with rectal impaction and soiling had impaired rectal sensation (needing a larger volume before feeling the presence of a rectal balloon and the desire to void), lower rectal pressures during rectal distension, and impaired anal and perianal sensation (‘rectal dyschezia’) [849]. Resting anal and squeeze pressures were however unimpaired in these patients, and the rectoanal inhibitory response were well-preserved. The authors concluded that overflow FI is primarily due to locally secreted mucus from around an irritative rectal faecal mass leaking out, despite well-preserved anal sphincter integrity.

A study comparing 8 older incontinent women (mean age 71.6 SD 7.5) with 9 older continent women (mean age 71.6 SD 7.5) and 9 younger continent women (mean age 28.7 SD (7.3) found women with FI were more likely to have decreased maximum squeeze pressures and levator ani (LA) defects. (OR 14). LA defects were associated with 26% less force on maximal contraction. Levator and urogenital hiatus measurements on MRI were increased in older women irrespective of continence status. [874]. Older FI females tolerated lower balloon anorectal manometry volumes before urge to defaecate indicative of rectal hypersensitivity [852].

**SUMMARY OF EVIDENCE ON FAECAL INCONTINENCE AND THE AGEING GUT**

- Anorectal function in healthy older persons is characterised by a tendency towards an age-related reduction in internal anal sphincter tone (Level 2), and a more definite decline in external anal sphincter tone, especially in older women (Level 3). An age-related decline in anorectal sensitivity in women has been observed (Level 3), but rectal motility is well-preserved (Level 3).
- Ageing alone however, appears to have little impact on anorectal function until later old age – from the 7th decade upwards in women and even later in men (Level 3).
- Age-related internal anal sphincter dysfunction (reduced anal resting tone) is an important factor in FI in later old age (Level 3),
- Pudendal neuropathy is an age-related phenomenon in women with FI (Level 2), and a likely predisposing factor for FI (Level 3), although the validity of this test is questioned.
- Stool impaction predisposing to overflow is related to rectal dyschezia in frail older adults, a condition characterised by reduced tone, increased compliance and impaired sensation (Level 3).
- Overflow FI is due primarily to mucus secretion from around a rectal faecal bolus, rather than to impaired sphincter function (Level 3).
- Decrease in mobility is associated with anorectal dysfunction and is a predisposing factor for FI (Level 3),
RECOMMENDATIONS - PATHOPHYSIOLOGY OF FI IN OLDER PEOPLE

1. Overall, the physiological data suggests that FI should not be considered an inevitable consequence of ageing.

2. Older adults with FI should be evaluated for age-related reduction in internal and external sphincter function.

3. Older patients with FI require a digital examination to identify rectal stool impaction causing overflow.

4. Patients who are unaware of the presence of a large faecal bolus in the rectum may have rectal dyschezia, and should be considered at risk of recurrent impaction with overflow.

3. CAUSES OF FECAL INCONTINENCE IN OLDER ADULTS

Stool consistency is an important aspect of determining the cause and the associated factors for the evaluation of FI in an older adult [817, 818, 837]. Loose, as well as hard, stool consistency can be related to FI in frail, older adults [794, 825, 875]. Evidence shows that loose stool consistency and chronic diarrhoea are important contributing factors for FI [811, 817, 818, 826, 837]. Loose stool consistency and chronic diarrhoea can result from multiple causes, such as malabsorption syndromes (e.g., lactose intolerance, gluten sensitivity, and fat-malabsorption), acute diarrhoeal illnesses, microcytic colitis, irritable bowel syndrome – with diarrhoea predominant symptoms, and other causes of chronic diarrhoea. Any change in stool consistency along with other warning symptoms (weight loss, bloody stools, change in stool calibre, and painful defaecation) should prompt further evaluation for colorectal cancer. Potential reversible causes of loose stools may include: excessive laxative use, lactose intolerance, drug-related side-effects, bacterial overgrowth, and possible bowel obstruction with "overflow" FI. "Overflow" FI secondary to constipation and stool impaction is also important to consider in older adults, potentially more common in men than women,[876, 877] those with mobility problems, [825, 875, 878] and those that reside in nursing home settings [825, 878].

Overflow incontinence or FI that results from stool impaction can be difficult to diagnose, may be more common in certain frail, older populations, and should be evaluated and treated when suspected. Evidence suggests that constipation and symptoms of constipation are common among nursing home residents with FI [825, 878, 879]. However, the true prevalence of impaction and FI in nursing home residents is not clearly identified. Constipation (according to bowel movement frequency) and associated symptoms (straining and incomplete evacuation) were common among nursing home residents in a 4-site randomized controlled trial to improve FI and urinary incontinence among nursing home residents by giving a multi-component intervention involving toileting assistance, exercise, and dietary snacks [825]. At baseline, 81% of the 111 nursing home study participants had less than 3 bowel movements in 5 days. During the 2-day run-in period where toileting assistance was provided, the number of bowel movements per day increased from 0.3 ± 0.3 to 0.8 ± 1.0 with 11% found to have straining and 21% reporting problems with incomplete evacuation. The average stool consistency rating on the 7-point Bristol Stool Form Scale was 4.2 ± 1.5. Another study that identified factors associated with FI in different health care settings found that 70% of nursing home residents experienced "faecal loading" compared to 63% in rehabilitation wards, 57% in acute care wards, and 20% in the home care setting [878].

Urgency associated with bowel movements is also an important bowel-related factor that should be assessed in older adults. Many studies do not evaluate urgency as an independent risk factor. However, among the studies that evaluated a sense of urgency associated with bowel movements, urgency is consistently and strongly related to FI, having a negative impact on quality of life even after controlling for other known confounding factors [818, 880, 881].

Other bowel-related disorders or complications of prior anorectal surgery can contribute to FI in older adults who otherwise would be continent, especially when functional status, mobility and cognition become impaired. Other bowel related disorders that have been associated with FI in adults (but not limited to the frail older adults) include: haemorrhoids,[876, 882] posterior vaginal prolapse (rectocele),[837] inflammatory bowel disease,[883] irritable bowel disease,[837, 884] and a strong sense of urgency [880]. Types of prior anorectal surgery that contribute to FI include: haemorrhoid surgery,[876] fistula repair,[885, 886] sphincterotomy for anal fissures,[821] partial or total colectomy,[887] low anorectal resection and re-anastomosis for colo-rectal cancer,[888, 889] prostatectomy,[814] and prior pelvic/perineal radiation [814, 890]. All of these bowel-related disorders and prior surgeries should be part of the focused history in older adults with FI. More studies are needed to identify causal pathways for causing FI in the older adult.

Functional FI, as defined by mobility problems or restraints that restrict accessibility to the toilet despite normal bowel sensation and capacity, is also cited as a common reason for FI in epidemiological studies among community-dwelling older adults and those residing in nursing homes [326, 794, 798, 799, 807, 826-828, 891, 892].

Other causes of FI in older adults can be related to other diseases or co-morbid disorders, especially neurological disease, which increases the risk having FI.
Even after adjusting for age and gender, diabetes mellitus is associated with gastrointestinal symptoms including FI in population-based studies,[813, 840] nursing home residents,[892] and has been associated with impaired rectal sensitivity and sphincter weakness [838].

Neurological diseases that contribute to FI in older adults include cognitive impairment, stroke, traumatic brain injury, and sacral cord dysfunction. Older adults are living longer with significant neurological conditions. Cognitive impairment and dementia have been found to be independent risk factors with FI in older adult populations from epidemiological studies and among those in nursing homes [794, 807, 814, 826]. Having a stroke is an important risk factor for FI, with three and half times the rate of FI, compared to adults who did not have a stroke, in one population-based study [893]. FI affects 30-56% of stroke survivors in the acute period after having a stroke (1-30 days), with a lower prevalence (11%) of FI after 3-months, and 11-22% at 12-months following the initial stroke event [839, 894]. It is unclear whether the functional disability from having a stroke or the disruption in neurological pathways (sensory mechanisms) that promote continence, contributes more to FI among stroke survivors. Traumatic brain injury has also been linked with urinary incontinence and FI, but limited data exist on older adults from registry studies and single site studies [820, 895]. Spinal cord injury (depending on the level of injury) may result in impaired muscular strength of the external anal sphincter, delayed transit time, abnormal defaecation reflexes, and impaired sensation [896].

SUMMARY OF EVIDENCE ON PREVALENCE AND RISK FACTORS FOR FI IN FRAIL OLDER PEOPLE

Summarised below are key points that are specific to the frail elderly population.

- FI affects 1 in 5 older people (aged 65+) living in the community, and half of those reside in care homes [Level 1].
- The prevalence of FI increases with age alone, particularly in the 8th decade and beyond [Level 1].
- The prevalence of FI is higher in the acute hospital and nursing home setting than in the community [Level 1], thus the group most affected is frail older people.
- The prevalence of FI in frail older men is equal to or greater than in women [Level 2].
- This predominance of older men over women with FI is most striking among nursing home residents [Level 2].
- The prevalence of FI varies dramatically between institutions in nursing home studies [Level 2].
- FI usually coexists with urinary incontinence in frail older people [Level 1].
- Aside from age, the following are primary risk factors for FI in older people [Level 2]:
  - Stool consistency -- Loose stool
  - Bowel-related disorders, such has prior rectal surgery
  - Impaired mobility
  - Dementia
  - Neurological disease
  - Chronic medical conditions
  - Depression
- Loose stool is a primary cause of transient FI in older people (Level 2).
- Faecal loading and constipation are clinically linked to FI, but there is little epidemiological work assessing this association (Level 3).
- Physicians and nurses in primary care, acute hospital, and long-term health care settings do not have a high awareness of FI in older people (Level 2).
- Within nursing homes, there is a low rate of referral by nursing staff of residents to primary care physicians or continence nurse specialists for further assessment of FI (Level 2), and there is a tendency toward passive management (e.g. use of pads only without further evaluation) (Level 2). Faecal loading is often present in older care home residents with FI (Level 2).
- Older people may be reluctant to volunteer the symptoms of FI to their health care provider for social or cultural reasons, or due to a popular misperception that the condition is part of the aging process and therefore ‘nothing can be done about it’ (Level 2).
- FI is associated with reduced quality of life, and poor health perception (Level 2).

RECOMMENDATIONS - IDENTIFYING Fecal INCONTINENCE IN FRAIL OLDER PEOPLE

- Bowel continence status should be established by direct questioning and/or direct observation in:
  - all nursing and residential home residents
  - hospital inpatients aged 65 and over
  - people aged 80 and beyond living at home
  - older adults with impaired mobility
  - older adults with impaired cognition
  - older adults with neurological disease

Level 1 evidence is based on a single high quality study. Level 2 evidence is based on 2 or more lower quality studies. Level 3 evidence is based on observational studies or expert opinion.
An initial assessment can be undertaken by any suitably trained health care practitioner, often this will be by either a physician or clinical nurse specialist. In the majority of cases, a clinical evaluation will provide sufficient diagnostic information upon which to base further management. There are available tools which can assist in this process [447]. The use of formal testing is hampered by both lack of relevant data in frail older people and the poor correlation between symptoms and abnormalities [897, 898]. Evidence that the assessment of faecal incontinence in older people is poorly done despite the existence of guidelines has been a persistent finding throughout the history of this chapter [339, 772]. What actions need to be taken to ensure that older people receive assessments which are consistent with current guidelines remain to be defined. There is evidence from a survey of US physicians that the presence of FI makes a referral for nursing home placement more likely than if it is not present [37]. Self reports of bowel symptoms are reliable and reproducible in older people including those in long term care [899-901]. Documentation of the type of incontinence experienced is very important, particularly because of the association between faecal incontinence and loose stool [385]. Faecal urgency is closely associated with diarrhoeal illness whereas constant passive leakage of homogenous liquid stool or stained mucus is more characteristic of overflow incontinence around faecal impaction. People with anal sphincter dysfunction tend to lose small amounts of stool. Urgency faecal incontinence tends to predominate when there is underlying external sphincter weakness and those with internal sphincter weakness experience more passive leakage [902]. People with faecal incontinence due to dementia may pass normal stool, particularly after meals, in response to the gastrocolic reflex. Any assessment of faecal incontinence should also include an assessment for constipation. It is important to recognise the constipation subtype of rectal delay in older people, which is said to affect 21% of the community dwelling elderly and may lead to faecal impaction and overflow incontinence [903]. A prolonged evacuation and feeling of anal blockage with the need to evacuate manually are the hallmark symptoms. A majority of the constipated elderly have evacuation problems rather than low stool frequency [904]. Regardless, the clinical definition of constipation relies upon the finding of an excessive amount of stool in the rectum or colon. An objective assessment is especially important in the frail elderly as they may not be able to communicate their symptoms and may, despite constipation, still have regular bowel movements [905]. The frail older person may also have impaired rectal sensation and be unaware of the existence of a full rectum [906, 907] or be unwell, with confusion (or worsening confusion). Older people are also less likely than the young to report a reduction in bowel frequency, abdominal bloating or positional changes to achieve defaecation [908].

Digital rectal examination can assess to a reasonable degree anal sphincter tone and squeeze pressure and appears to be as good as sphincter ma-
nometry in discriminating continent from incontinent people, although not the frail elderly [909]. Constipated patients with an empty rectum on digital examination may have high impaction.

Radiographs of the abdomen should be requested to establish the diagnosis to assess the extent of faecal loading and to rule out an obstruction or sigmoid volvulus. As with any other person, a change in bowel habit with weight loss, anaemia, rectal pain and faecal incontinence should raise the suspicion of an underlying malignancy [910]. Colorectal cancer is associated with both constipation and use of laxatives, although this risk is likely to be complicated by underlying bowel habit. In a retrospective study of 4798 incident cases of colorectal cancer in people aged 30 – 84 from UK datasets, independent predictors in men and women included family history of gastrointestinal cancer, anaemia, rectal bleeding, abdominal pain, appetite and weight loss. Alcohol consumption and recent change in bowel habit were also predictors in men alone [911].

The single symptom of chronic constipation does not usually warrant colonoscopic investigation, however, in the frail elderly this may be considered as the index of suspicion may be higher. Given the increased difficulty of adequately preparing frail older people for either endoscopy or barium studies [912]; CT colonography may be considered as an alternative investigation where available [913]. Evaluation of the capacity to successfully toilet should include an assessment of mobility, visual acuity, manual dexterity and cognition. If acceptable to the older person, observing the process of transferring to the toilet, manage their clothing, redress and leave the lavatory is a good measure of ability. Caregivers should additionally be aware of the surroundings in which the frail older person lives in terms of access, lighting, distance and clutter. The design of commodes should also be considered in the light of the individual’s capabilities.

Faecal incontinence is also associated with the development of pressure ulcers in older people with impaired mobility although whether this is a causal association is still a matter for debate, [914, 915] however, an assessment of skin integrity and provision of appropriate pressure relief is important. A pelvic examination to rule out posterior compartment prolapse is also important given the association between FI and prolapse in older women [916, 917]. There are no bowel specific quality of life assessments validated for use in the frail elderly.

5. TREATMENT OF FI IN OLDER ADULTS.

a) Quality of data

New trials are included on the treatment of FI in frail, older adults. No trials were identified on the prevention of FI in high risk, older adults. Many studies that include older adults have small sample sizes, inadequate power to detect clinically meaningful differences in outcomes, and biased methodology. Given these limitations, FI treatments applicable to older adults were considered and include: multi-component treatments for FI, treatments aimed at specific populations of older adults (e.g. nursing home populations and stroke survivors), and percutaneous tibial nerve and sacral neuromodulation for FI. Issues related to surgery, bulking agents, biofeedback, containment, and skin care are discussed in other chapters.

b) Multi-component treatments for FI.

Given the multifactorial causes for FI in older adults, few studies existed in the literature involving multi-component interventions. In 2006, the Cochrane group reported that available trials for FI do not allow for a definitive assessment of the role of pelvic floor muscle training and/or biofeedback therapy in the treatment of FI. The Cochrane report also noted that insufficient data exists that pelvic floor muscle training or biofeedback is any better than other conservative measures such as medication or education [918]. Since the Cochrane report, a recent study by Heymen et al involved a run-in period to improve stool consistency among adults with weekly FI prior to randomization to pelvic floor muscle training or biofeedback [919]. Among the 168 community-dwelling participants (mean age was not reported), FI frequency decreased from 3.4 to 2.0 days/week (41% reduction) and 35 patients (21%) reported adequate relief at the end of run-in. FI severity scores, as measured with the Faecal Incontinence Severity Index (FISI), decreased from 36.9 at baseline to 31.0 at the end of run-in (p<0.001). The run-in phase controlled for the effects of improved medical management to normalize stool consistency and this produced adequate relief of FI for 21% of patients. The remaining participants (n=108, mean age 60 years) were randomized to pelvic floor muscle exercises alone or manometric assisted biofeedback. After 3 months, the participants who received biofeedback treatment had a great improvement in improvements in their FI severity scores (p=0.01) and fewer days with FI (p=0.083) [919]. An additional study comparing different methods of biofeedback concluded that active sensory training is more effective than sham training for participants with “idiopathic” FI [920]. Others have found that the additional of rectal balloon distension sensitivity training did not improve outcomes [921, 922]. Evidence for biofeedback treatment for improving FI in older adults with cognitive impairment or physical limitations/poor functional status was not found.

A systematic review in 2003 identified three trials that compared loperamide versus placebo without any trials among older adults; one in patients with ileoanal pouches, and two in patients with chronic diarrhoea [923]. No controlled studies were identified during this review using anti-diarrhoea medica-
tions for patients initially presenting with the primary complaint of faecal incontinence and there were no controlled studies investigating the treatment of faecal incontinence in older adult populations. In a double blind randomised crossover trial by Lauti et al [2008], fibre supplementation was used along with loperamide and specific diet recommendations in participants with the primary complaint of liquid and solid faecal incontinence [924]. Participants (n=63, mean age 59 ±15 years, 91% women) were randomised in a cross-over trial to loperamide along with fibre supplements and advice sheet on diet versus loperamide with an advice sheet on low residue diet and placebo fibre supplements. There was significant improvement in both groups from baseline to 12 weeks in FI severity without group differences between the two treatments. There were also no adverse events reported and very few participants reported dry mouth (specific amounts not reported). Expert opinion suggests that loperamide should be used with caution and close monitoring for faecal impaction in older adults, especially those with chronic co-morbid disorders.

c) Treatment of FI in nursing home settings.

Treatments for FI in nursing home settings also involved the treatment of constipation and faecal loading or faecal impaction. In a French study among 206 nursing home residents in 4 different homes, lactulose alone was compared to lactulose plus daily suppositories along with weekly tap-water enemas for reducing FI episodes. Although there were no differences between the two groups, residents that achieved complete rectal emptying also reduced the number of FI episodes by 35% while also reducing staff workload by 42% (soiled laundry counts). [879] Recently, Schnelle et al (2010) completed a multi-centre, multi-component intervention for improving FI and constipation in cognitively impaired 112 nursing home residents (mean age 86 ± 10 years) [829]. In this controlled trial in 6 nursing homes in the United States (n=112), the intervention was compared to a usual care control group. The intervention group received toileting assistance, exercise, and choice of food/fluid snacks every 2 hours for 8 hours/day for 3 months. Participants in the intervention group compared to the usual care control group had improvements in bowel movement frequency and the percentage of bowel movements in the toilet (p<0.01), but not the frequency of FI episodes determined by direct checks from research staff. Urinary incontinence episodes also improved with this intervention (p<0.05). Among the 29 nursing home residents who had anorectal manometry, a dyssynergic defeation pattern was identified in 89%. The authors concluded that this multi-component intervention improved some factors associated with FI in nursing home residents, but further work to improve stool consistency and treatments for dyssynergia may be warranted.

d) Treatment of FI in stroke survivors.

In outpatient and inpatient stroke survivors (n=146), Harari et al (2004) completed a randomised, controlled trial to improve FI and constipation symptoms with an intervention based on education booklet for the patient/caregiver along with treatment recommendations to the health care provider and compared this intervention to a usual care control group [925]. After 6-months and 1-year of follow-up, the intervention group compared to the usual care control group were more likely (p<0.05) to have ‘normal’ rated bowel movements on a 7-day bowel diary and more likely to have an increased bowel frequency (p<0.05). The intervention group was also more likely to alter their diet and fluid intake to control their bowels.

e) Sacral Neuromodulation/Percutaneous tibial nerve stimulation for FI in older adults.

Recent prospective multi-centre trial data on sacral neuromodulation with a surgically-implanted device shows significant improvements in FI episodes, symptoms, and quality of life [926]. In the larger, multi-centre studies with data at 2- and 3-years, the mean ages were 54.3 ± 11.3 and 60.5 years (range 30-88 years) without subgroup data on the older age participants [927-929]. Evaluating and selecting older adults and adults with specific neurological conditions who may benefit from permanent implantation is an important consideration [930, 931]. Data on sacral neuromodulation for FI and surgical outcomes including adverse events for frail, older adults is limited [932].

Percutaneous tibial nerve stimulation (PTNS) studies for FI have also reported benefits. Among the 8 small, prospective studies (largest study, n=32), involving a total combined sample size of 129 participants, have significant variation in the study population, with large mean age ranges (38 to 60 years), methodology, and outcome measures [933-940]. One prospective study involving 100 participants with a median age of 57 years found that “urge-related” FI and “mixed” FI were more likely to having improvements in a symptom score than those with “passive” FI [941]. Data from adequately powered randomized controlled trials for PTNS treatment for FI are currently ongoing and will add significantly to the existing evidence [942].

6. SUMMARY OF EVIDENCE ON THE TREATMENT OF FI IN FRAIL OLDER PEOPLE

1. Structured multi-component approaches to bowel care did not reduce the frequency of FI in the nursing home setting, but did improve bowel frequency and number of bowel movements in the toilet (Level 2)

2. Older people with FI may benefit from biofeedback-
3. Loperamide can reduce frequency of FI, particularly when associated with loose stool (once infection and other causes have been excluded) but should be used with caution (Level 2)

4. Additional fibre supplementation to loperamide may not improve FI outcomes (Level 2)

5. Multi-component structured nurse-led assessment and intervention can improve bowel symptoms and alter bowel-related habits in older stroke patients (Level 2)

6. More data are needed on the use of sacral neuromodulation in specific higher risk older age populations (Level 4)

7. RECOMMENDATIONS - TREATMENT OF FI IN FRAIL OLDER PEOPLE (ALL GRADE C)

1. Loperamide is a useful treatment in FI, in the absence of constipation, but should be used with caution in older adults

2. Causes of loose stool must be identified and treated.

3. All frail older people with FI should have structured multidisciplinary assessment and treatment of their bowel problem.

4. Patient and caregiver education (using verbal and written materials) should be undertaken to promote self-management and other coping mechanisms, and where appropriate self-management (e.g. reducing risk of constipation and impaction through dietary and lifestyle measures, advice on how to take loperamide). Advice on skin care, odour control, and continence aids is also important.

5. Greater emphasis needs to be placed on systematic and effective management of FI in older people backed up by sound communications between all health care providers, especially in the nursing home and acute hospital setting.

6. Education of health care providers with regards to heightening awareness of the problem plus methods of identification, assessment and management of FI in older people should be broad-ranging and include geriatricians, general practitioners, hospital physicians, hospital, community, general practice and long-term care nurses, and related disciplines (physiotherapists, occupational therapists, dieticians, pharmacists).

7. Cyclical national audit with provider accountability, of current practice in managing FI in older people is needed to lay the ground-work for standardised care, and provide a culture of continuous quality improvement. Such audit tools should be developed using standardised consensus methodologies

8. AREAS FOR FURTHER RESEARCH ON FI IN FRAIL OLDER PEOPLE

1. Trials of laxative and nonpharmacological treatment and prevention of faecal impaction and overflow are needed to optimise standards of prescribing and care.

2. Multicomponent interventions to treat FI in frail older people should be evaluated to assess effective ways of FI management in acute care settings

3. Multidisciplinary study assessing the feasibility and efficacy of a step-wise approach to the management of dementia-related FI in nursing home residents

4. Evaluation of case-finding methods for FI in different settings including the fundamentals of staff education, screening protocols, and patient’s educational information would be very informative.

5. Testing the feasibility of providing an integrative approach to assessment of FI in the frail older person, including a range of health and social care providers and different health care settings (acute, intermediate or sub-acute, long-term care and community) would be relevant to national implementation of bowel care improvement programmes.

6. Examination of the variability of FI rates between nursing homes within single nation states, (taking into consideration case-mix) will highlight problems areas both organisationally and clinically. Nursing home administrative factors such as resident: nurse staff ratios should be evaluated as a contributing factor to FI.

7. Further epidemiological studies are required to document causes of FI in frail older people in different health care settings. Such studies should include evaluation of unmet need for patients and caregivers.

8. Evaluation of the pathophysiological basis for high prevalence of FI in older men. Evaluation of potentially preventable causes of loose stools in institutionalised older people, and impact of their treatment on FI.

9. Nurse-led initiatives are needed to develop care pathways for assessing of bowel problems in frail older people with a view to establishing integrated service delivery.

10. Examine the research question, ‘Do educational interventions by health care providers to informal carers of home-dwelling older people with FI reduce carer burden and improve quality of life for patient and carer?’
REFERENCES

The present chapter would not have been possible without the work of the previous editors, Jean Hay Smith [2008] and Don Wilson [2000, 2004]. They produced the remarkable framework for the present review. Indispensable assistance was also provided by Victoria Mei Lee, Fiona Stewart, Sheila Wallace, and the Cochrane Incontinence Group. Finally, this chapter would not have been possible without the untiring dedication of Mr. Wayne Day.

I. INTRODUCTION

Conservative treatment is any therapy not involving surgical treatment of incontinence. In this chapter update, we cover studies that provide some comparison data between therapy and lifestyle interventions (also called lifestyle interventions), physical therapies, scheduled voiding regimens, complementary and alternative medicines, anti-incontinence devices, supportive rings/pessaries for pelvic organ prolapse (POP) and medications with a direct comparison with conservative management.

Conservative therapies are considered relatively low cost, non-invasive approaches, with minimal adverse effects that are typically guided by a healthcare professional and depend on user participation. It is generally accepted that conservative measures are part of the initial counselling at the primary care level of individuals suffering from either UI or POP. Conservative therapy is also indicated for those for whom other treatments are inappropriate, for example, those unwilling to undergo or unfit for surgery and women who plan future pregnancies (as these may adversely affect surgery). Other indications include individuals awaiting surgery or who wish to delay surgery and those whose symptoms are not serious enough for surgical intervention.

The research base on which to judge the effectiveness of conservative management is growing although some aspects such as lifestyle interventions and alternative and complementary medicines in particular, require considerably more well designed trials. In this chapter we add to what was known in the 2009 4th Edition ICI [1] and integrate the evidence since the last search on treatment of urinary incontinence and pelvic organ prolapse (POP). The updated literature search was conducted from 1 January 2008 to August 2011 of randomised controlled trials (RCTs). (Appendix 2 lists the details of the literature search).

Each section concludes with the level of evidence and factors affecting outcome. Separate chapters in this 5th Edition address incontinence in the elderly, children, pharmacological treatment, products for incontinence, those with neurological conditions and those suffering from faecal incontinence.

Where summary statistics are presented, the raw data from which these are derived can be found in the tables at the end of the chapter, in trial reports and systematic reviews cited in the chapter. The Chapter is intended as a stand alone document and adds to the comprehensive reports from previous ICI editions.

A. UI IN WOMEN

I. LIFESTYLE INTERVENTIONS

A number of lifestyle factors may play a role in either the development or resolution of UI. Few RCTs have been carried out to assess the effect of a specific lifestyle change on UI. This section will examine the evidence for the association and use of lifestyle interventions in the management of female UI. A summary of the search strategy and inclusion/exclusion criteria is given in Appendix 2.

1. PREVENTION

No RCTs assessing the effect of lifestyle interventions on UI prevention were identified.

2. TREATMENT

Where RCTs are available, these are reviewed. Where there are no RCTs for a particular lifestyle intervention, other types of evidence are considered giving priority to good quality cohort studies.

a) Weight loss

Three RCTs were identified on weight loss. Two specifically recruited incontinent women [2-4]. The third focused on the effect of intensive lifestyle intervention in overweight women with diabetes [5]; this intervention mainly comprised weight loss. Four prospective cohort studies [6-9] evaluated the effect of weight loss. Other study designs were
cross-sectional [10-16], retrospective cohort [17], or case-control studies [18]. The non-RCT evidence will not be reviewed here in light of the available RCT evidence.

1. Quality of Trials

Sample sizes for the three RCTs were 48 [2], 338 [3,4], and 1,957 [5]. Participant blinding was not possible in any of the three RCTs. Of 48 randomised in one trial, 40 remained in the study at the time of assessment [2]. The Subak [2009] study randomised 338 women, six month incontinence outcome data was available for 304 women (290 had diary data – the primary outcome measure). Participants were followed up at 12 and 18 months, at which time 96% provided urinary incontinence outcome data. In the large RCT with diabetes as the primary focus, 2191 women were enrolled and 234 were excluded because data about UI were not available; the number that dropped out before the endpoint is not detailed for this subpopulation of women.

All three trials used subjective and objective measures including urodynamics, urinary diary and 24 hour pad test. Follow-up periods were three months after completion of a very low calorie liquid diet and exercise [2], six months after completing an intensive group weight intervention programme that included lifestyle and behaviour changes [3], and a mean of 2.9 years after beginning the intervention [5]. In addition, the Subak study population [3,4] was followed up at 12 and 18 months, and is reported in a separate paper [19].

Results

In the 2005 RCT [2] involving 48 participants, median baseline weight (95 kg) and number of incontinent episodes (21 per week) were similar between the groups. Compared to controls (wait list) that did not participate in a weight loss programme, women in the weight loss (liquid diet) group lost 15kg (SD 7) (compared to 0kg (SD 4)) and experienced a 60% reduction in weekly incontinence episodes (compared to 15%).

The Programme to Reduce incontinence by Diet and Exercise (PRIDE) [4,19] randomised 338 overweight incontinent women in a 2:1 ratio to an intensive 6-month group weight intervention programme or usual care, consisting of four information sessions. Women in the intervention group lost a mean of 8% of their body weight from baseline compared with 1.6% in the usual care group after 6 months. Forty one percent of women in the intervention group decreased the weekly number of incontinence episodes by at least 70% compared to a 22% reduction in the usual care group. At 12 months weight loss in the intervention group was 7.5% of their body weight from baseline compared to 1.7% with 46% reporting 70% less incontinence in the weight loss group compared with 31% in usual care. By 18 months weight loss was 5.5% in the intervention group compared to 1.6% with 46% reporting 70% less incontinence episodes compared to 40% in the usual care group.

The RCT from the Diabetes Prevention Programme [5] reporting on 1957 participants found that overweight diabetic women assigned to intensive lifestyle therapy (consisting of low-fat diet, moderately intense exercise for at least 150 minutes per week and a behavioural and educational curriculum) were less likely to be incontinent compared to those assigned to placebo drug with standard lifestyle advice or metformin alone (38.3% versus 45.7% and 48.1%, respectively; \( p=0.001 \)).

Wing et al [2010a] [19] combined data from the Subak 2009 RCT and Wing (2010b) [20] follow-up of the same sample to determine the magnitude of weight loss associated with significant improvement in urinary incontinence. They combined the intervention and control groups into weight loss categories irrespective of randomisation group. Women who lost 5-10% of their body weight were 2-4 times more likely to achieve a 70% reduction in incontinence episodes compared with those who gained weight at 6, 12 or 18 months. Weight losses larger than 10% did not result in greater improvements in incontinence outcomes. It is important to note that individuals were not randomly assigned to weight loss categories therefore groups may have differed in other ways.

2. Summary

Obesity is an important independent risk factor for the prevalence of UI. Massive weight loss (15 to 20 BMI points) significantly decreases UI in morbidly obese women. (Level of Evidence: 2). Moderate weight loss maybe effective in decreasing UI especially if combined with exercise (seeB.1.2b(i)). (Level of Evidence: 1).

3. Recommendations

For morbidly and moderately obese women weight loss should be considered a first line treatment to reduce UI prevalence (Grade of Recommendation: A). Given the high prevalence of both UI and obesity in women, the dual issues of weight loss and prevention of weight gain (and exercise) should receive high research priority.

b) Physical activity

No RCTs exist in which moderate physical activity and its effect on UI is compared to no activity.

1. Quality of data

Two prospective studies assessed the risk of incident UI according to physical activity level, reported as metabolic equivalent task hours per week, in 2,355 women aged 54 to79 years [21] and 30,135 women 37 to 54 years at risk of incident UI [22]. Both
suggested that low levels of physical activity are predictive for the onset of UI in middle aged women or older. In the prospective study of women aged 37-54 repeated physical activity reports over 12 years were averaged to estimate long term activity levels. Over the subsequent 2 years 4081 incident cases were identified with monthly incontinence.

2. Results

In older women enrolled in the Nurses’ Health Study, total physical activity (i.e. top versus bottom quintile of metabolic equivalent task hours per week) was significantly associated with a reduced risk of new UI (OR 0.81) in analyses adjusted for confounders. Walking constituted about half of the total physical activity among the participants and was related to a 26% lower risk of developing UI. Total physical activity was not related to the incidence of UUI [21]. These findings were mirrored in younger women enrolled in the same study [22]: the risk of at least monthly UI decreased with increasing quintiles of moderate physical activity.

3. Summary

There is good prospective cohort information suggesting that moderate exercise decreases the incidence of UI in middle-aged and older women; this effect may be mediated by weight control (Level of Evidence: 3).

4. Recommendations

Epidemiological evidence is building for an association between moderate physical activity and a reduction in urinary incontinence. There is a need for randomised controlled trials to confirm causality.

c) Physical Forces (exercise and work)

No RCTs exist in which UI prevalence is compared between subjects assigned to heavy work or high impact activity versus sedentary activities.

1. Quality of data

Two trials have evaluated the difference in UI prevalence between 305 and 144 women, respectively, engaged in high versus low impact activities [23,24]. In another trial, Be (2001a) compared 572 athletes ages 15-39 years with 574 controls [25]. Caylet [2006] compared UI prevalence among 157 elite female athletes and 426 women from the general population between ages 18 and 35 [26]. Kruger [2007] conducted a case-control study exploring mechanisms by which athletes might be more likely to experience SUI and compared pelvic organ descent and pubovisceral muscle volume between 24 elite nulliparous athletes and 22 age and BMI matched controls [27]. Eliasson [2005] compared UI at 36 weeks gestation and one year postpartum between 665 primiparous women participating in high-impact, low-impact or no activity [28].

Several cross-sectional studies compared the prevalence of UI with the self-reported level of physical activity. The Norwegian EPICONT study compared both any and severe UI in 27,936 women according to three levels of high impact physical activity [13]. Another compared UI prevalence and severity in 3,364 women according to physical activity level as assessed by the International Physical Activity Questionnaire [29].

2. Results

Minimal SUI is common in young exercising women [23]. College athletes participating in high impact activities are more likely to report the symptom of SUI during exercise than those participating in low impact exercise [24]. In one trial no difference in UI prevalence was found between elite athletes and controls [25]. Another found that 28% of elite athletes reported UI compared to 10% of controls [26]. There was no difference in UI prevalence between physically active and sedentary controls. In the prospective study of pregnant and postpartum women, high-impact physical activity before pregnancy was associated with more urinary leakage one year postpartum compared to low-impact activity [28]. There is little available information on whether strenuous exercise or activity causes the condition of UI later in life. In a study of 104 women who were Olympians approximately 25 years prior to data collection, those who competed in gymnastics or track and field were not more likely to currently report daily or weekly UI than Olympians who competed in swimming [30].

The EPICONT study reporting on 27,936 women found no difference in either ‘any’ UI or severe UI in women that reported high impact physical activity one to two hours per week or three or more hours per week compared to those that reported exercised less than one hour per week (after adjusting for age, BMI, parity, coughing and wheezing) [13]. In contrast, Nygaard [2005] reported that UI with physical activity was more common among highly active than less active women (15.9% versus 11.8%; \(p=0.01\)) [29]. Additionally, after adjusting for age, parity, comorbidities and other factors, women with very severe UI were more likely to be less active than continent women. Danish nursing assistants, who are exposed to frequent heavy lifting, were more likely to undergo surgery for genital prolapse and/or UI than women in the general population; parity was not controlled for [31].

3. Summary

Strenuous exercise may unmask the symptom of SUI during provocation. There is currently no evidence that strenuous exercise causes the condition of UI. There are scant uncontrolled data that suggests that women engaged in occupations with heavy lifting may be predisposed to genital prolapse and/or UI (Level of Evidence: 3).
4. Recommendations

There is a paucity of data about the association of strenuous exercise and lifting and UI, this association should be investigated further.

d) Smoking

There are no RCTs investigating the effect of smoking on UI. There are no trials of the effect of smoking cessation.

1. Quality of data

One case-control study compared incontinent smokers with non-smokers [32], another compared smoking behaviour between continent and incontinent women [33]. Cross-sectional studies have evaluated multiple risk factors for UI, including smoking [10,13,16,34-37]. One case-control study evaluated smoking as a risk factor for failure of SUI surgery [38]. One trial of women planning surgery for SUI assessed the association between smoking and severity of UI, defined by mean number of incontinence episodes per day on a bladder diary [39]. An in vitro study assessed the effects of nicotine on bladder muscle contraction [40]. Sample sizes were 189 [32], 1761 [34], 160 [33], 199 [38], 7949 [10], 7338 [35], 3302 [36], 5,488 [37], 27,936 [13], and 83,355 [16].

2. Results

Smokers were more likely to report UI than non-smokers in some studies [13,16,33,35,36], but not others [10,34,37]. Amongst women with SUI, current smoking was positively associated with UI severity after adjusting for confounders [39]. After adjusting for age, parity, type of delivery, and prepregnancy BMI, smokers had a 1.3 fold higher RR (95% CI 1.0 to 1.8) of reporting UI at 16 weeks gestation than non-smokers [35]. The adjusted OR for moderate or severe UI among women reporting UI was 1.38 (95% CI 1.04 to 1.82) in current smokers, after adjusting for perimenopausal status, BMI, diabetes and ethnicity [36]. In the large population based study by Hannestad et al [13], smoking increased the odds of severe UI (OR 1.4, 95% CI 1.2 to 1.6) but not of mild UI. In the case-control study, after adjusting for confounders, smoking was a protective factor against recurrent UI after anti-incontinence surgery [38]. Incontinent smokers were found to have stronger urethral sphincters and lower overall risk profiles than incontinent non-smokers [32]; therefore, the authors proposed that more violent coughing promotes anatomic defects, which allow UI.

Two studies have reported that nicotine produces phasic contraction of isolated bladder muscle probes in vitro [40,41]. However, Milsom (1993) reported an apparent paradoxical local estrogenic effect of nicotine on the vagina, resulting in a decrease in vaginal pH and an increase in lactobacilli [42].

3. Summary

Data suggest that smoking increases the risk of more severe UI (Level of Evidence: 3). Smokers may have a different mechanism causing their UI than non-smokers.

4. Recommendations

Further prospective studies are needed to determine whether smoking cessation prevents the onset, or promotes the resolution, of UI.

e) Dietary factors

1. Diet

No RCT was identified that addressed dietary changes for urinary incontinence alone.

However, a randomised cross over trial examined the effect of a soy-rich diet on urogenital changes including urge incontinence [43]. The study recruited 36 women to undergo two 12 week diet periods, a soy rich diet and a control diet (soy free).

The recent BACHs study group (Boston Area Community Health Survey) [44] undertook an epidemiological, cross sectional, population based study of 2060 women aged 30-79 and used a validated food frequency questionnaire to collect data on dietary intake as well as collecting data on lower urinary tract symptoms (LUTS). In a prospective questionnaire study, Dallosso (2004a) studied the impact of dietary risk factors on the one-year incidence of SUI in women [45] and OAB symptoms [46,47]. Participants completed a 130-item validated food frequency questionnaire.

2. Caffeine

No new studies on caffeine and incontinence were found. One RCT [48] assessed the effects of a caffeine reduction intervention upon frequency, urgency and UUI for those who consumed more than 100mg caffeine daily. The experimental group received bladder training and a caffeine-fading method to decrease caffeine intake to less than 100mg per day, while the control group also received bladder training but no caffeine reduction information. Another RCT [49] used a crossover design to evaluate the effect of caffeine restriction and of increasing and decreasing fluid intake on urinary symptoms over a four-week period in women with urodynamic SUI or DO.

3. Fluid Intake

In one RCT, women with UI were randomly assigned to one of three groups: increase fluid intake by 500 cc, maintain fluid intake at baseline level, or decrease by 300 cc. Participants kept fluid intake and output diaries for five weeks [50]. Another study [51] recruited 24 people to a crossover trial in which they were asked to increase or decrease their fluid intake. Individuals were randomised into two groups,
the groups amended their fluid intake over 4 day blocks, group 1: drinking 25% more (group 2: 25% less) than baseline for 4 days followed by 2 days of normal drinking, 4 days drinking 50% more (group 2: 50% less) than baseline (2 days normal drinking) followed by 4 days drinking 25% less (group 2: 25% more) than baseline (2 days normal drinking) and finally 4 days drinking 50% less (group 2: 50% less) than baseline. Any changes in frequency, urgency, nocturia and incontinence episodes were then recorded according to randomised group and stage. Participants completed a 4 day frequency volume chart and a validated ICIQ-OAB.

In a large postal survey, 6037 men and women responded to questions about tea, soft drink and alcohol consumption, as well as whether or not they had UI [52].

4. QUALITY OF DATA

It was not feasible to blind participants in any of the RCTs. Dropout rates were: 8% [43], 22% [48], 37% [49], and 45% [50].

5. RESULTS

(a) Diet: One RCT found no statistical difference in urinary incontinence following a soy-rich diet [43]. Non-RCT data showed that after adjusting for age, physical functioning, SUI at baseline, obesity, smoking and certain dietary factors, the incidence of SUI at one year was increased in women consuming more total fat, saturated fatty acids and monounsaturated fatty acids, as well as those that consumed more carbonated beverages, zinc or vitamin B12 at baseline [45,46]. The incidence of SUI was reduced in those that ate more vegetables, bread and chicken at baseline [46]. Higher intake of vitamin D, protein and potassium were also associated with decreased risk of onset of OAB in women [47]. The 2011 BACHS study [44] found that greater total energy intake was associated with LUTS. The same data source was used to test the hypothesis that carotenoid, vitamin C and calcium intakes were associated with UI in women, they found that high dose vitamin C and calcium were positively associated with incontinence whilst vitamin C from food and drinks were negatively associated with incontinence.

(b) Caffeine: One RCT found a clinical effect of decreasing caffeine, while the other did not. Bryant (2002) reported that women in the intervention group decreased daily caffeine consumption to a mean of 96.5mg, compared to 238.7mg in the control group. The experimental group had statistically significant reduction in urgency episodes (61% versus 12%); the number of Incontinence episodes decreased as well (55% compared to 26% in the controls) but this was not statistically significant. In contrast, while Swithinbank (2005) found no effect of decreasing fluid intakes (see below) or changing from caffeine containing to decaffeinated drinks.

(c) Fluid intake: In an RCT, 32 women were assigned to one of three groups: increase fluid intake by 500cc over baseline, decrease by same amount, or maintain baseline level [50]. While non-adherence to the protocol made results difficult to interpret, the authors reported that 20 women who had fewer incontinent episodes at the end of the trial attributed this to drinking more fluids. Another RCT that used a cross-over design found that when fluid intake was decreased, 39 women with SUI decreased the number of incontinence episodes; similarly, 30 women with DO significantly decreased voiding frequency, urgency and incontinence episodes [49]. Fluid manipulation [51] with a decrease in normal intake by 25% led to a significant reduction in frequency (23%), urgency (34%) and nocturia (7%) but not urinary incontinence. Increases in fluid consumption led to symptom worsening.

After adjusting for age and gender, no association was found between UI and consumption of alcohol [52]. After adjusting for age and fluid intake, consumption of wine, beer or spirits did not increase the incidence of either SUI or OAB (there was a trend towards less SUI in beer drinkers; OR 0.75 (95% CI 0.56 to1.01) for weekly drinkers versus those that drank beer less than monthly) [46]. Similarly, in a large cross-sectional study, there was no association in either unadjusted or adjusted analyses between alcohol consumption and UI [11].

6. SUMMARY

Indications from epidemiological data suggest diet may play a role in urinary incontinence (Level of Evidence: 3). Evidence is building on the role of macronutrient intake and reduction of UI. Fluid intake may play a minor role in the pathogenesis of UI. Caffeine consumption may play a role in exacerbating UI. Small clinical trials do suggest that decreasing caffeine intake improves continence. (Level of Evidence: 2).

7. RECOMMENDATIONS

Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not less than one litre a day (Grade of Recommendation: B). Further RCT’s to assess the role of diet in urinary incontinence are warranted.

A reduction in caffeine intake is recommended for those with incontinence symptoms (Grade of Recommendation: B). Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.

1) Constipation

No published RCTs were found which assessed the effect in adults of regulating bowel function on UI. An observational study compared the self-report of straining as a child with urogaenaecological symptoms as an adult [53]. Population-based studies assessed multiple risk factors for UI [54,55].
1. QUALITY OF DATA

Sample sizes range from 73 for the observational study [53] to 213 in a study correlating the surrogate measures of perineal descent and pudendal neuropathy [56] to 1154 and 1051 in the population-based studies [54] respectively.

2. RESULTS

In a small observational study, 30% of women with SUI and 61% of women with uterovaginal prolapse reported straining at stool as a young adult, compared to 4% of women without urogynaecological symptoms [53]. In a large population-based study of 1154 women over age 60 years, those with UI were slightly more likely to report constipation than those who were continent of urine (31.6% vs 24.7%) [54]. After adjusting for demographic and obstetric confounders, women who reported straining at stool were more likely to report UI and urgency [55]. There appears to be an association between straining and pudendal nerve function. The mean pudendal nerve terminal motor latency increased after straining, correlated with the amount of descent, and returned to resting by four minutes after a strain [57]. Others found evidence of pudendal neuropathy in only 25% of women with abnormal perineal descent; in this large group of patients with defecating dysfunction no relationship was seen between neuropathy and pelvic descent, leading to the conclusion that pelvic descent and neuropathy may be two independent findings [56].

3. SUMMARY

There is some evidence to suggest that chronic straining may be a risk factor for the development of UI. (Level of Evidence: 3). There are no intervention trials that address the effect of resolving constipation on UI.

4. RECOMMENDATIONS

Further research is needed to define the role of straining in the pathogenesis of UI. If the association holds, public education, particularly of parents and paediatricians, is needed to make an impact on the common problem of straining due to constipation in children.

g) Other

There are many other lifestyle interventions suggested either by healthcare professionals or the lay press for the treatment of UI, including reducing emotional stress, wearing non-restrictive clothing, utilising a bedside commode, decreasing lower extremity oedema and treating allergies and coughs. There is no evidence to support these interventions for UI; support for these interventions is all anecdotal in nature.

3. OTHER LUTS

No data was found.

4. FACTORS AFFECTING OUTCOME

No data was found.

II. PELVIC FLOOR MUSCLE TRAINING (PFMT)

Pelvic floor muscle training (PFMT) remains a key factor in the prevention and treatment of UI. Because pelvic floor muscle (PFM) integrity appears to play an important role in the continence mechanism (see report from Committee 4: Pathophysiology), there is a biological rationale to support the use of PFMT in preventing and treating UI in women [58]. The role of PFMT in the treatment of UUI came later, when it was recognized that PFM contraction can also be used to occlude the urethra to prevent leakage during detrusor contraction, as well as inhibit and suppress detrusor contraction.

1. RATIONALE AND PRINCIPLES

a) Biological rationale for PFMT for SUI

The biological rationale for using PFMT to treat SUI is at least three-fold.

First, in healthy continent women, activation of the PFM before or during physical exertion seems to be an automatic anatomic response [59-61]. This PFM ‘reflex’ contraction is a feed-forward loop and might precede bladder pressure rise by 200-240 milliseconds [62,63]. An intentional and effective PFM contraction, prior to and during effort or exertion, compresses the urethra and increases the urethral pressure, preventing urine leakage [64]. Supporting this rationale, both ultrasonography and MRI studies have demonstrated the cranial and forward movements of the PFM during an active contraction and the resulting impact on the position of the urethra [65,66]. This active contraction of PFM during activities that cause SUI leakage has been referred to in various ways including counterbracing, perineal pre-contraction, PFM functional training, stress strategy, and the “knack” [67,68]. Miller assessed effectiveness in an RCT and demonstrated that a voluntary PFM contraction before or during coughing can reduce leakage after only one week of training in middle-aged and older women with SUI and in pregnant women with de novo SUI. Performing a rapid, strong, and well-timed PFM contraction seems to actively prevent urethral descent during an intra-abdominal rise in pressure [69]. Thus, the timing of a PFM contraction could be an important factor in the maintenance of urinary continence. Active, volitional contraction of PFM to occlude the urethra during physical activity is now routinely combined with PFM exercise to improve strength and tone. However, the optimal strength required to compress the urethra and prevent urine leakage has yet to been determined.

Second, the bladder neck is supported by a strong, toned PFM (resistant to stretching), limiting its
downward movement during effort and exertion, thereby preventing urine leakage [64,70]. Intensive strength training may reinforce structural support by permanently elevating the levator plate to a higher position inside the pelvis and enhancing the hypertrophy and stiffness of the connective tissues [70]. Anatomical and dynometric differences of the PFM have been demonstrated between continent and incontinent women [71-73]. Women with SUI and MUI demonstrate less PFM passive force (tone), maximal strength, rapidity of contraction and endurance as compared to continent women [74,75]. In a pre and post PFM training study using an MRI reconstruction method, a significant reduction in the internal surface area of the levator ani was observed after PFMT; this suggests an increase in passive tone of the levator ani, which in turn is indicative of the state of PFM tone [76]. Increased urethral stability at rest and during effort following 14 weeks of supervised PFMT and behavioural modification has been noted [77]. Thus, a growing body of evidence supports the rationale that PFMT improves PFM tone, facilitates more effective automatic motor-unit-firing of the PFM, and thus prevents PFM descent and urine leakage during increased intra-abdominal pressure [78]. Finally, morphological and functional changes after PFMT indicated a relationship between improved PFM coordination and increased PFM mobility and also to striated urethral sphincter hypertrophy [79]. Therefore, PFMT could also contribute to continence through a direct action on the urethral sphincter. However, more research is needed to confirm these results.

Finally, there is some evidence that contraction of the transversus abdominus (TrA) muscle is associated with co-activation of the PFM. This has been demonstrated by US, EMG and MRI studies [80-84]. However, a TrA muscle contraction does not appear to elevate the PFM in all women [85] and when it does, it does not appear to be as effective as a direct PFM contraction [83,84]. More research is needed to better understand the relationship between the TrA and the PFM muscles as well as the effect on incontinence of rehabilitating the interaction between TrA muscle and the PFM.

Given the above biological rationale, in treating SUI the objective behind PFMT is to improve the timing (of contraction), strength and stiffness of the PFM and perhaps urethral sphincter function.

b) Biological rationale for PFMT for UUI

PFMT can also be used in the management of urgency and urge urinary incontinence (UUI). In 1975 Godec observed that a detrusor muscle contraction can be inhibited by a PFM contraction that has been induced by electrical stimulation (ESstim) [86] and Burgio demonstrated that a detrusor contraction can be inhibited by a voluntary PFM contraction [87]. During urine storage, bladder distension produces low-level vesical afferent firing, which in turn stimulates the pudendal nerve outflow to the external urethral sphincter thereby increasing intraurethral pressure, an effect he termed a ‘guarding reflex’ for continence [88]. It is also posited that Barrington’s Micturition Centre’s excitatory loop switches on when bladder pressures are between five to 25mmHg, while the inhibitory loop is predominantly active above 25mmHg [89]. Inhibition involves an automatic (unconscious) increase in tone for both the PFMs and the urethral striated muscle.

Thus, voluntary PFM contractions may be used, often as part of a broader urge suppression strategy, to treat UUI. Generally, patients are instructed not to rush to the toilet in response to any urge sensation, because it can trigger detrusor contraction and increase intra-abdominal pressure. The strategy involves remaining still, repeatedly contracting PFMs, and waiting for the urge to pass. After inhibiting the urgency to void and the detrusor contraction, the patient can learn to reach the toilet in time to avoid urine leakage. However, the number, the duration, the intensity and the timing of the PFM contraction required to inhibit a detrusor muscle contraction is not known.

This focus on urge suppression strategies, often combined with PFM exercise, is commonly called behavioural training. Behavioural training also involves teaching the concept of using volitional PFM contraction to occlude the urethra and prevent urine loss during uninhibited detrusor contraction. Further, patients can also be taught to be more vigilant about PFM tone when they begin to sense bladder fullness and consciously maintain resting tone rather than allowing the pelvic floor relaxation that immediately precedes and coordinates with detrusor contraction.

c) Principles of skeletal muscle strengthening

The aim of any strengthening programme is to alter muscle morphology by increasing the cross-sectional area, increasing the number and frequency of motor neuron excitations, and improving tone and stiffness. When muscles engage in intense, repetitive tasks that exceed the normal demands of daily activities this stimulates an increase in the muscle fibre size (hypertrophy), which in turn increases muscle bulk. However, hypertrophy is not immediately evident as a training response. An increase in strength is evident long before visible hypertrophy. Early improvements in strength result from neural adaptation, including a greater number of activated motor units, an increased rate of motor unit excitation, more synchronised motor unit firings and more persistent activation of type II motor units [90-92]. Hypertrophy begins only after a minimum of eight weeks of regular and intense strength training [93]. With increased overload, hypertrophy may continue for some years.

There are four principles of strength training: specificity, overload, progression and maintenance [78].
Strength training is specific to the muscle(s) being trained and requires overload (that is, exposing the muscle(s) being trained to a gradual increase in resistance, repetitions or repetition speed). Progression is the extension, through increased resistance, intensity and volume of training, of the initial exercise programme. Finally, maintenance refers to the extent to which the muscle is able to maintain a continued level of strength. In order to achieve an effective strength training programme, the American College of Sports Medicine recommends that all these elements be addressed [94].

d) Principles of behaviour change

PFMT is a treatment that involves changing an individual's behaviour and teaching new skills. Because its effectiveness depends on the active patient participation, including adherence to instructions, clinicians are faced with the challenges of changing the individual's behaviour. Some are self-motivated, but most require assistance. In general, models of healthcare behaviour change rely on providing information and education. But these are usually inadequate in the case of interventions like PFMT that typically take effect gradually and require several weeks at least to reach optimal efficacy.

Much of human learning follows the principles of operant learning, in which behaviour is a function of antecedents and consequences. Antecedents include education, motivating techniques, as well as daily reminders including cues to exercise PFM or to use them volitionally to prevent urine loss with physical activities or in response to urge. Most learning occurs through the consequences of behaviour, i.e., by trial and error and feedback. Thus, people learn how to contract and relax PFMs not only through instructions, but also through various modes of feedback. This can include visual or auditory feedback loops provided by a therapist verbally or through biofeedback, in which physiological parameters are measured and fed back using various instruments. Operant learning principles include the concept of positive reinforcement: positive results reinforce behaviour and it is more likely to be repeated. Behaviours that do not produce the desired results tend to be abandoned. Herein lies the challenge for clinicians using PFMT, to help the patient sustain their efforts for long enough to achieve a result, whether it is a change in muscle strength or improvement in symptoms. Even when they result in short-term improvements, patients in PFMT tend to have difficulty sustaining regular exercise long-term, partly because discontinuing the exercise regimen does not result in immediate regression.

Learning is mediated by individual characteristics, including disposition, attitudes, beliefs, and experiences. Several models of behaviour change have evolved that are relevant for addressing health behaviours. According to one widely-adopted model, Social Cognitive Theory, people will engage in a new behaviour when they believe it will lead to positive outcomes and they believe they are capable of performing the behaviour (concept known as self-efficacy). Factors that may affect the ability to learn new skills and change daily habits fall into several domains, including social, cognitive, physical, emotional, behavioural, and environmental. Clinicians have the opportunity potentially to influence any of these by making an effort to understand the patient's daily life, assessing barriers to change during treatment, and assisting patients with overcoming the impediments they encounter. It is generally accepted that clinicians should promote realistic expectations of treatment and outcome, individualize treatment protocols, and follow-up with patients to assess adherence, monitor progress, encourage persistence, and facilitate long-term behaviour change.

This section presents the evidence for the use of PFMT in the prevention and treatment of UI in women. Questions addressed are:

a) Is PFMT effective in the prevention of UI?
b) Is PFMT better than no treatment, placebo or control treatments in the treatment of UI?
c) Is one type of PFMT programme better than another in the treatment of UI?
d) Is PFMT better than other treatments in the treatment of UI?
e) Does the addition of PFMT to other treatments add any benefit in the treatment of UI?
f) What factors might affect the outcome of PFMT in the treatment of UI?
g) What is the effect of PFMT on other lower urinary tract symptoms?

In this section, the pre-specified primary outcomes of interest were 1) self-reported UI (for prevention studies), 2) self-reported cure or 3) cure and improvement in UI symptoms (for treatment studies). Secondary outcomes of interest were 1) quality of life (prevention and treatment studies) and 2) leakage episodes and amount (treatment studies) [95].

2. PREVENTION AND TREATMENT (PREGNANT AND POSTNATAL WOMEN ONLY)

This subsection specifically considers PFMT for the prevention and treatment of UI in pregnant and postnatal women (called childbearing women in this section). As the physiological changes of childbearing can affect PFM function, it is possible that the effect of PFMT might differ in this group compared to non-childbearing women.

A 2008 Cochrane review in this area analyzed data from 15 trials in 6,181 participants [96]. An additional 6 randomised trials published between 2008 and 2011 were identified and also reviewed.
for this subsection (total 21). Similar to methods used in the Cochrane review, trials in this section have been grouped in 3 areas: 1) trials of PFMT for prevention of UI (performed in women without UI symptoms when randomised); 2) trials of PFMT for treatment of UI; and 3) trials of PFMT for the prevention and treatment of UI (participants with and without UI symptoms enrolled). Trials were further separated into those beginning during pregnancy (antenatal) or postnatal.

As in the recently updated Cochrane review, the primary outcome of interest was self-reported UI [97]. Secondary outcomes included condition-specific quality of life (e.g. King’s Health Questionnaire (KHQ), Incontinence Impact Questionnaire (IIQ), or any other quality of life or health status measure (for example Short Form-36); symptom severity; number of leakage episodes; measures of pelvic floor muscle function; and economic analyses. Other outcomes of interest included adherence measures.

a) Is PFMT effective in the prevention of UI in childbearing women?

There are three grades of prevention: primary, secondary and tertiary. Primary prevention aims to remove the causes of a disease. Secondary prevention focuses on the detection of asymptomatic dysfunction and provides treatment aimed at stopping its progression. Tertiary prevention focuses on existing symptoms to prevent the progression of the disease through treatment. This subsection addresses the question of PFMT effectiveness for primary and secondary prevention of UI in childbearing women. Clinically it can be difficult to effectively screen trial participants to ensure that a disease process is altogether absent (for primary prevention studies) or present, although asymptomatic (for secondary prevention). Trials investigating prevention of UI usually enroll people purely on the basis of the absence of symptoms. Thus, the trials in this section likely represent a combination of primary and secondary prevention effects.

The 2008 Cochrane review [96] included 5 trials addressing prevention of UI in childbearing women [98-102]. Two of the studies were combined prevention/treatment studies, but published or unpublished data were available for women who were continent at recruitment [98,101]. In the study by Sampselle (1998), 54 of 72 women were continent based on a standing stress test at 20 weeks gestation. After drop outs, unpublished data were available from 37 previously continent women (16 PFMT and 21 controls). Markved (2003) [101] published data for 207 of 301 women who were continent before pregnancy and at 20 weeks gestation. After dropouts, data were available from 193 previously continent women (94 PFMT and 99 controls). Neither study was powered to detect differences in the previously continent subgroup and the subgroup sizes were small.

One new prevention trial published in 2010 was found [103] and two combined prevention/treatment trials of antenatal PFMT with UI outcomes were published since 2008, but outcome data specific to the women who were continent at baseline were not presented [104,105]. Thus, these two trials and their results are included in the section below on combined prevention/treatment trials.

Five studies [98,99,101-103] recruited nulliparous or primiparous women during pregnancy, and one recruited “pregnant women” [100]. Reilly (2002) recruited primigravid women without a pre-pregnancy or current history of UI, but with bladder neck hypermobility at 18 to 20 weeks gestation. Primigravidae were recruited at 18 [98], 20 [101,103] and 28 weeks [102] gestation.

In all six trials, PFMT began during pregnancy while controls received the usual antenatal care, which may have included advice on PFMT from their maternity caregivers [98,99,101,103] or were asked not to do PFMT [100,102]. There were some variations in the PFMT parameters (intensity and supervision):

- Eight to 12 near-maximal voluntary PFM contractions, held for six to eight seconds, followed by three to four fast contractions at the end of each contraction, twice daily from 20 weeks gestation [101,103]. Also a weekly [101] or monthly [103] exercise class from weeks 20 to 36.
  - Eight to 12 PFM contractions, held for six seconds with a two second rest, three sets twice daily, from 18 weeks gestation. Also individual PFMT with physiotherapist during monthly visit [99].
  - Up to 30 near-maximal PFM contractions per day from 20 weeks of gestation [98].
- 10 PFM contractions; held for eight seconds each followed by three fast one second contractions; a six-second rest between contractions; for up to 20 weeks. PFMT taught one-on-one with physiotherapist. Weekly clinic appointments (one hour each) for eight weeks, then weekly phone calls [102].
- PFMT not described. Participants were seen twice monthly throughout pregnancy, and every three months postpartum for one year [100].

Correct voluntary PFM contraction was checked prior to training in four [98,101-103].

1. Quality of data

Allocation concealment appeared adequate in four trials [98,99,101,102] and the outcome assessors were blind in five of the six trials [98-101,103]. Dropout rates varied, including 4% [101,102], 14% [99], 36% [98] and as high as 53% [103]. Stothers (2002) did not report any losses to follow up.

Outcomes were measured at various times: 28 and 35 weeks gestation and six weeks postpartum.
Results

Pooled data described in this section are reported from the 2008 Cochrane review [96].

(a) Late pregnancy (34 weeks or later): Pooled data from three trials [98,101,102] showed that women in the antenatal PFMT group were 56% less likely to report UI than the controls. Statistically significant heterogeneity was observed in this comparison. The point estimates in all three studies favoured PFMT but these differed considerably. A possible reason for the more pronounced difference between PFMT women and controls in the study by Gorbea Chavez (2004) is that the comparison group was asked not to do PFMT, whereas in the other two controls had usual care that might have included PFMT. In another trial [103] a lower proportion of women in the PFMT group at 36 weeks gestation reported UI compared to controls, but the difference was not statistically significant.

(b) Early postpartum (up to 12 weeks): Pooled data from two trials showed that PFMT women were around 50% less likely to report UI, compared to the controls (RR 0.50 95% CI 0.31 to 0.80) [98,102].

(c) Mid postpartum (three to six month postpartum): In the pooled analysis, PFMT women were still statistically significantly less likely than controls to report UI, although the difference in risk had reduced to about 30% (RR 0.71 95% CI 0.52 to 0.97) [98-101]. Similar to their results at 36 weeks of pregnancy, Mason et al [103] found fewer women in the PFMT group compared to controls reported SUI symptoms at three months postpartum, but this difference was not statistically significant. Loss to follow-up was high, and this outcome was assessed in only 47% of those with baseline data.

(d) Late postpartum (up to one year postpartum): Too few participants (n=44) were available in 1 trial [98] to determine if there was a difference in prevalence of UI between PFMT women and controls at 12 months postpartum.

(e) Long term (more than one year): At four year follow up, Reilly (2002) reported seven of 42 PFMT women and 26 of 58 controls had symptoms of SUI. However, this apparent benefit for the PFMT group was not seen in a later 8 year follow up study [106]. In that report, 164 (71%) of the initial 230 participants with postnatal data were analyzed, and SUI was reported by 35.4% in the PFMT group versus 38.8% in the control group; 70% of those assessed had had one or more additional deliveries during the follow-up period.

Regarding secondary outcome measures, five of the six trials reported symptom severity data such as frequency or amount of urine leakage. None of the measures, or the ways in which they were reported, were common to the four trials. In general, the data suggested that PFMT women with symptoms of UI might have demonstrated less severe symptoms than the controls. Only Stothers [2002] noted adverse events; two of the 43 PFMT women withdrew due to pelvic floor pain.

Only three trials reported treatment adherence data. Gorbea Chavez (2004) reported that 84% of PFMT women attended seven or eight of the eight physiotherapy appointments. In another, nearly half the women in the PFMT group exercised for 28 days or more; postpartum similar proportions of women in the intervention and control groups were doing occasional or no PFMT (28% and 34% respectively [99] Mason [2010] reported that just 64% of women assigned to the PFMT group attended at least one class, but women in the intervention group reported performing more exercises in a 3-day diary at both 36 weeks of pregnancy and three months postpartum than did controls.

Summary

Pregnancy and birth appear to be important factors associated with the development of UI in women. Therefore, all women who have had a child or children might be considered ‘at risk’ of developing UI at a later date.

Continental pregnant women having their first baby who participated in a more ‘intensive and supervised’ PFMT programme than the PFMT provided as part of usual care were less likely to experience UI from late pregnancy up to six months postpartum (Level of Evidence: 1). There was not sufficient evidence available to demonstrate whether this benefit persists at 12 months postpartum; results from a single trial suggest the benefit of PFMT is not maintained eight years after treatment or with subsequent deliveries (Level of Evidence: 2). There was no evidence investigating the preventive effects of PFMT in pregnant, previously continent, multiparous women.

RecommenDations

Continental, pregnant women having their first baby should be offered a supervised (including regular health professional contact) and intensive strengthening antepartum PFMT programme to prevent postpartum UI (Grade of Recommendation: A). The usual or standard approach to PFMT in pregnancy (which is commonly verbal or written instruction without confirmation of correct contraction or supervision of training) needs to be reviewed.

Additional trials with longer-term follow-up (greater than 12 months postnatal) are needed to determine long-term benefits of antenatal PFMT. Further,
large, good-quality RCTs are needed to investigate the effect of antepartum PFMT on preventing postpartum UI in multiparous women.

b) Is PFMT effective in the treatment of UI in childbearing women?

Four studies which addressed the treatment of existing UI after delivery [107-110] were identified and all were included in the 2008 Cochrane review [96]. One study recruited incontinent women during pregnancy [110], while the other three recruited women three months or more after delivery. All four studies recruited a mix of primiparous and multiparous women.

The control groups in three [107,108,110] received standard care, which included ante and postpartum advice on PFMT, whereas the control group in Dumoulin’s (2004) study received, in lieu of training, relaxation massages at the same frequency as the PFMT treatments.

The PFMT interventions varied as follows:

- intervention group received either PFMT, or PFMT with vaginal cones, or vaginal cones (VC). PFMT comprised 80 to 100 PFM contractions per day (a mix of fast and slow), with three home visits by a nurse, healthcare visitor or continence advisor. The VC group received 15 minutes per day of cone therapy while the combined PFMT/VC group received both interventions [107].
- as above supplemented by instruction from a physiotherapist on four occasions [108].
- PFMT with biofeedback + electrical stimulation (EStim) with or without deep abdominal training. PFMT comprised weekly sessions supervised by physiotherapists for eight weeks with 15 minutes of EStim and 25 minute of PFM exercise with biofeedback including strengthening and motor relearning exercises [109].
- four one to one and half hour sessions with a physiotherapist (three antepartum and one at six weeks postpartum) but details of the PFMT programme were not given [110].

1. Quality of data

Random allocation concealment was adequate in three of the four trials [107-109] and outcome assessors were blind in two [108,109].

In one trial losses to follow-up were high in all intervention groups (51% PFMT; 63% PFMT/VC; 41% VC). In two others losses to follow-up were 30% [111] and 38% [110]. In contrast, Dumoulin’s (2004) trial (which included weekly contacts with a physiotherapist for eight weeks) reported a 6% loss to follow-up. Outcomes were measured outcome 12 months after delivery [107,108], and then 24 to 44 months post-delivery, and six years after the index delivery [111]. Dumoulin (2004) reported outcome nine weeks after intervention began. However as women were recruited at varying lengths of time following delivery (all more than three months postpartum) the data are presented alongside those from Glazener (2001), and Wilson (1998), as long-term post-natal data.

2. Results

In the one study of antepartum PFMT for treatment of UI, no statistically significant difference was reported in the prevalence of UI between PFMT and control groups at 35 weeks, eight weeks postpartum, six months and 12 months postpartum [110].

Pooled data from the three trials of postpartum PFMT found women were about 20% less likely to have UI after treatment compared to the controls (RR 0.79, 95% CI 0.70 to 0.90) [96]. Statistically significant heterogeneity was observed. The treatment effect in the study by Dumoulin (2004) was much greater than that in the other two studies. Possible reasons are that the controls in the study by Dumoulin (2004) were asked not to do PFMT, whereas controls in the other two studies received usual care and both interventions and control groups were also doing PFMT (a mean of 20 versus five PFM contractions per day in Glazener 2001), and 86 versus 35 in Wilson 1998). Another difference was the intensity and supervision of the PFMT intervention; Dumoulin (2004) used a more intensive PFMT programme with adjunctive EStim and BF and physiotherapy appointments once a week for eight weeks, whereas in the other two studies [107,108] women had three or four appointments with a health professional over approximately six months and were asked to do PFMT on their own.

All four treatment trials reported some data on symptom severity such as frequency or amount of urine leakage. None of the measures, or the ways they were reported, was common to the four trials. The data suggested that PFMT women with symptoms of UI might have less severe symptoms than the controls, but this was not a consistent or clear-cut finding. Dumoulin (2004) stated that none of the women in the PFMT group reported any adverse events.

Three trials reported some data related to treatment adherence, one for antepartum PFMT [110] and two for postpartum PFMT [107,108]. In the antepartum study, at 36 weeks gestation 37% of the PFMT women were exercising intensively compared to 14% of the controls. Mean number of PFM voluntary contractions per day at 12 months postpartum were 20 [108] and 86 [107] per day in PFMT women, and 5 and 35 respectively per day in the controls.

Glazener and colleagues followed up women six years after the index delivery. The effect of PFMT on UI was not sustained. At six years, 100 out of the 263 in the intervention group and 99 out of the 253 in the control group experienced UI at least once
per week [111]. However, the women had had an average of 1.5 deliveries since the index delivery.

3. SUMMARY

To date, only one trial has investigated the effect of PFMT for the treatment of UI in pregnant women [110]. This was a moderate-size study that did not report allocation concealment or blinding of the assessors, and did not describe the type of PFMT programme employed. In the absence of any detail on the PFMT programme it is impossible to judge if the intervention had the potential to be effective.

Postpartum women with UI who were randomised to PFMT taught and supervised by a health professional were less likely to be continent than controls (standard care or relaxation massage) six to 12 months following delivery (Level of Evidence: 1). Of the three trials, the one that used an intensively supervised strength training programme demonstrated the greatest treatment effect. It is unclear if the benefit of PFMT is maintained over time or with subsequent deliveries (Level of Evidence: 2).

For women who have persistent symptoms of UI at three months postpartum PFMT is a more effective treatment than standard postnatal care or relaxation therapy to women with persistent UI symptoms three months after delivery (Grade of Recommendation: B). An ‘intensive’ PFMT programme (in terms of supervision and exercise content) is likely to increase the treatment effect (Grade of Recommendation: A).

There is a need for at least one large, pragmatic, well-conducted and explicitly reported trial with long term follow-up (five plus years) of postpartum PFMT that investigates the effect of ‘intensive’ treatment followed by periodic refresher sessions.

c) Is PFMT effective in the mixed prevention and treatment of UI in childbearing women?

Ten trials are included in this section. Of these trials, some women did and some women did not have UI at the time of recruitment, i.e. the effect of PFMT included a mix of prevention and treatment. Eight [98,101,112-117] were included in the 2008 Cochrane systematic review [96] and two were more recently published [104,105].

In six, nulliparous or primiparous women were randomised to either supervised antepartum PFMT or usual antepartum care [98,101,104,105,113,116]. The other four randomised nulliparous women during pregnancy [114] or postpartum [112,115,117] to either postpartum PFMT [112,115,117] or usual postpartum care or no PFMT [114].

Two new studies were added [104,105]. Ko (2011) recruited nulliparous women at 16–24 weeks gestation. Women in the PFMT group met individually with a physical therapist for instruction, and correct contraction was assessed by observing inward movement of the perineum during contraction. The individual therapy was similar to that used by Reilly (2002) described above, including three sets of eight contractions repeated twice daily. Additional group therapy occurred weekly in 45 minute sessions over a 12 week period. Controls were excluded if they reported previous use of PFMT, but were not specifically discouraged to do PFMT during pregnancy; otherwise they received usual prenatal care. Be’s study (2011) differed in that the primary aim was to assess the effect of regular exercise on weight gain in pregnancy. Primiparous, sedentary women within the first 24 weeks of pregnancy were recruited and randomised to aerobic fitness classes including group instruction and practice of PFMT or usual care (not described). Women in the exercise group were asked to attend two to three 1-hour aerobic fitness classes weekly for at least 12 weeks. The PFMT included verbal instruction and group performance of three sets of eight to twelve contractions, holding six to eight seconds each in sitting, kneeling and standing positions. No individual assessment of the ability to perform a correct contraction was included. In addition, the exercise group was given a PFMT pamphlet that recommended a regimen of three sets of eight to twelve PFM contractions daily.

Hughes (2001) recruited nulliparous women at 20 weeks gestation and women randomised to PFMT attended one individual appointment then, between 22 and 25 weeks gestation, a group PFMT session (maximum six women) with a physiotherapist. No details of the training parameters were reported. Women with no palpable voluntary PFM contraction or a flicker of contraction were randomised. Controls received the usual community antepartum care. In another trial [116], women in the PFMT group were trained to use an Epi-No device (an inflatable vaginal balloon connected to a pressure gauge for visual feedback), 15 minutes daily; for three to six weeks. Controls received no device. The authors’ primary interest was in improving the elasticity of the PFM for delivery rather than continence outcomes.

(b) Postpartum PFMT versus usual care or no PFMT: Chiarelli (2002) only included women who had had forceps or ventouse deliveries, or had delivered a baby weighing 4000g or more. Ewings (2005) only included women who had already experienced UI and who were at high risk of UI following childbirth
in accordance with the SIFCRAFT risk scale. The control groups received the usual postpartum care, which included: an invitation to postpartum classes taught by physiotherapists [115], standard ante and postpartum care [112], no PFM re-education from two to 10 months postpartum [114] and verbal promotion of PFM exercises supplemented by a leaflet [117]. In PFMT groups, women were visited by a midwife or physiotherapist on the postnatal ward and were advised to train as follows:

- PFMT exercises as often as remembered and contractions integrated with daily living activities, plus midstream urine stop. Correct PFM contraction was checked on a second visit at eight weeks postpartum [112].
- PFMT exercises with three to six-second holds, three times a day. A variety of adherence strategies were employed (e.g. red stick-up dots, home or hospital visit after eight weeks).
- PFMT programme including 12 visits with a physiotherapist between two and 10 months postpartum, including a 20 minute BF training session and a 15 minute EStim session [114].
- PFMT taught one to one with physiotherapist in hospital in addition to an invitation to attend PFMT class at two and four months postpartum; 21 of 284 women participated in the first class (18%) and only 5 (4%) attended both [117].

1. **Quality of data**

(a) Antepartum PFMT versus usual care: Three of the six trials had adequate random allocation concealment [98,101,113]. In the others women were allocated at random but it was not clear if allocation was adequately concealed [104,113,116]. Assessors were blinded in four of the six trials [98,101,104,105]. Sample sizes varied: 72 [98], 105 [104], 144 [116], 300 [105], 301 [101], and 1169 [113]. Dropout rates were 14% at 6 weeks postpartum [104], 4% [101] at three months postpartum and ranged from 0% [105] to 34% [113] at six to seven months postpartum. At 12 months, the drop-out rate was 36% [98].

(b) Postpartum PFMT versus usual care or no PFMT: Random allocation concealment was adequate in three trials [112,115,117] but inadequate in Meyer (2001) where alternate assignment was used. Blinding of outcome assessment was adequate in one [115]. Sample sizes were large and varied: 1,800 women [112]; 720 [115]; 234 [117], and 107 [114]. Outcomes were measured at Both the Sleep (1987) and Chiarelli (2005) trials measured outcomes at three months [112,115]; 6 months [117], or 10 months [114]. Lost to follow up ranged from 6% to 19%.

2. **Results**

(a) Antepartum PFMT versus usual care: As reported by Hay-Smith and colleagues in 2008 [96] pooled data from three trials [98,101,113] showed that women who were randomised to antepartum PFMT had about 10% less risk of UI in late pregnancy. Statistically significant heterogeneity was observed in this comparison. While the point estimates in all three studies favoured PFMT these differed considerably between the trials; the study by Hughes (2001) carried considerable weight in the pooled analysis, most likely because it was the largest study. One of the differences between the studies by Mørkved (2003) and the other two in this analysis was the PFMT intensity and supervision as reported previously, being more ‘intense’ in the former. Ko (2011), used a similarly more intense PFMT programme, and also found significantly less UI in the PMFT women at 36 weeks gestation compared to controls (34% vs. 51%, p<0.01). Bø (2011) found no difference in the prevalence of UI in the exercise and control groups in late pregnancy.

In the pooled analyses from Hay-Smith (2008), the prevalence of UI was not statistically significant between PFMT and control groups in the early, [98] mid, [98,101,113] or late postpartum period [98,116]. At 6 weeks and 6 months postpartum, Ko (2011) found less UI in the PFMT compared to control group (25% vs. 35% and 16% vs. 27%, respectively); this difference was of borderline significance (p=0.06 at 6 weeks and p=0.04 at 6 months postpartum). Bø (2011) found no difference in the prevalence of UI in the exercise and control groups in the early postpartum period.

Symptom severity such as frequency or amount of urine leakage was reported in three trials, but PFMT was not found to be superior to control or vice versa at the primary endpoint for each study [98,112,113]. In another, statistically significant lower Urogenital Distress Inventory Short Form (UDI-6) and IIQ Short Form (IIQ-7) scores in the PFMT group were noted compared to controls at all end-points (late pregnancy and three days, six weeks and six months after delivery, suggesting less bother related to urinary symptoms and less functional impact from UI in the treatment group [105].

Some adherence outcomes were included for four of the six trials: 81% of the PFMT women attended more than half of the weekly classes [101]; 85% and 62-90% of the PFMT women reported performing PFMT at least 75% of the time at 35 weeks gestation and at 1 year postpartum [98]; >80% of the PFMT women attended every group session, and at 36 gestational weeks, 87% reported PFMT practice at least 75% of the time [105]; or 40% of the exercise group attended >80% of the weekly exercise classes [104].

(b) Postpartum PFMT versus usual care or no PFMT: There was no statistically significant difference in the prevalence of UI in women randomised to postpartum PFMT or control in the mid [112,115,117] or late postpartum period [114,115]. Statistically significant heterogeneity was observed in the combined
data for the mid postpartum period, with one study favouring PFMT [115], one neither PFMT nor control and one favouring the control condition [117]. Some potentially important clinical differences were noted between the studies. Firstly, Chiarelli (2002) recommended a PFM strength training programme; neither of the other two studies described their PFMT programme, so it is not possible to determine whether the latter studies could have had an effect or how different the PFMT and control conditions were. Further, Sleep (1987) noted only a moderate difference in the proportion of PFMT women and controls doing some PFMT at three months postpartum while at three months postpartum Chiarelli reported that about half the controls were doing PFMT and an even greater proportion of the PFMT group were exercising. A second difference was that Chiarelli recruited women at potentially increased risk of postnatal UI, such as those who had a large baby or a forceps delivery.

3. SUMMARY

The effect of antepartum PFMT or postpartum PFMT, in groups of women where some did and some did not have prior UI symptoms, varied by study with some showing a benefit on UI prevalence whereas others did not (Level of Evidence: 2). The characteristics of the three trials, all methodologically robust, that demonstrated some effect were:

(a) For antepartum PFMT: pregnant women having their first baby and used intensively supervised strengthening PFMT programmes; PFMT reduced UI prevalence in late pregnancy and three to six months postpartum [101,105], but this was not evident six years after the index delivery [101].

(b) For postpartum PFMT: primiparous and multiparous women at potentially greater risk of postpartum UI after a large baby or forceps delivery, and used a strengthening PFMT programme; PFMT reduced UI prevalence at three months postpartum but not at one year [115].

4. RECOMMENDATIONS

Health providers should carefully consider the cost/benefit of population based approaches to health professional taught antepartum or postpartum PFMT, that is, health professional instruction to all pregnant or postnatal women regardless of their current or prior continence status (Grade of Recommendation: B).

Where a population approach is used, the ‘best’ evidence to date suggests the following: (a) an intervention comprising of a daily home PFMT and weekly physiotherapist-led exercise classes for 12 weeks, starting at 20-24 weeks gestation for pregnant women having their first baby, and (b) an individually taught strengthening PFMT programme that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000g or more) (Grade of Recommendation: C)

3. PREVENTION (OTHER WOMEN)

Hay-Smith and colleagues [96] have previously reviewed trials of PFMT for the prevention of UI in pregnant, postnatal or childbearing women. No trials investigating the primary/secondary prevention effects of PFMT for UI in non-childbearing women were found. These results were considered in section B.2.1. Prevention of post prostatectomy UI is considered in Section D.2.1.

a) Is PFMT effective in the prevention of UI?

No trials investigating the prevention effects of PFMT for UI in non-childbearing women were found.

4. TREATMENT (WOMEN)

a) Is PFMT better than no treatment, a placebo or a control group treatment?

The recommendations in this section are based on the updated 2011 Cochrane Review [97]. Primary outcomes were 1) patient-reported cure or improvement in symptoms and 2) symptom bother (level of distress) and an incontinence-specific quality-of-life assessment. Secondary outcomes of interest included the number of leakage episodes and pad and paper towel testing. For a comprehensive background to the rationale for treatment of urinary incontinence with PFMT see Dumoulin 2010 [118].

There were 25 RCTs comparing PFMT with no treatment for women with UI identified, of which 7 were excluded: one included women with symptoms of geriatric syndrome that could have influenced the results [119], three compared supervised with unsupervised PFMT [120-122], one abstract that did not clearly state “RCT” [123] and two due to the sham PFMT consisting of strong isometric hip abductor contractions [124,125]. According to EMG, dynamometric and MRI studies, both hip abductions and external rotations result in a synergic contraction of the PFMs [61,74,126,127]. Thus, in all likelihood, these two trials probably compared a direct versus an indirect approach to PFMT.

1. STUDIES INCLUDED IN THE ANALYSIS

Among the 18 RCTs, three were not considered in the final analysis because they lacked adequate data [68,128,129].

Of the remaining 16, 12 recruited women with SUI exclusively [67,130-140] and one included women with SUI, with or without UUI. However, only one trial was found for women with mixed urinary incontinence (MUI) and it was thus analysed with the SUI studies [141]. One included older women with UUI with or without SUI (with urge as the predominant type) [142]. The remaining two recruited women with a range of diagnoses [119,143].
2. PFMT details

Twelve of the 16 studies provided adequate detail about the type of PFMT program used. In all 12, PFMT was taught by a health professional and in eight, a correct voluntary PFM contraction was confirmed prior to training [67,119,130,134,136,139,140,142,143]. Based on the description of the programmes, two trials had PFMT programmes that clearly targeted coordination [67] or strength training [134]. It was more difficult to categorise the other PFMT programmes, because they were either a mixed (i.e. strength and endurance or strength and coordination) programme or did not provide enough information on the exercise parameters. All PFM exercise programs are presented in Table 1.

3. Control group details

Among the 15 studies, the ‘control’ groups received no treatment in eight [67,130,131,135,136,139,140], a placebo drug [142], sham ESTim [132], sham PFMT with placebo drug in one [137], a non-active control intervention such as the use of an anti-incontinence device [134], advice on incontinence pads [132] and general education on healthy aging [119,138,140].

Our ability to consider the combined results from individual studies was limited by: 1) lack of consistency in the choice of outcome measures chosen by the researchers; and in the older studies 2) poor reporting of outcome data (i.e. mean reported without a measure of dispersion) hence some data could not be used in the pooled analysis.

4. Quality of Data

In three trials published as conference abstracts, the brevity of the reporting made it difficult to assess data quality [131,135,137]. Only three trials reported adequate random allocation concealment [119,134,140]: 9 reported using blinded outcome assessors [67,119,128,133-135,140-142].

5. Results

There were 16 RCTs comparing PFMT with no treatment, placebo, sham or other non-active control treatments. Two reported data on subjective cure and both found that women in a PFMT group were statistically and significantly more likely to report cure [134,142]. However, the effect size was quite different in the two trials. In the trial exclusive to women with UI, the PFMT group were about 17 times more likely to report a cure compared to the controls [134], whereas in the study of PFMT women with urge-predominant UI, the women were only about two-and-half times as likely to report a cure [142].

With regard to an individual-perceived cure or improvement, two trials in women with urodynamic SUI [132,134] suggested a greater likelihood of cure or improvement than the single study in women with UUI with or without urodynamic SUI [142]. In five, psychometrically robust questionnaires were used to assess symptom impact. Be (1999) used the Bristol Female Lower Urinary Tract Symptoms (B-FLUTS) questionnaire, but only reported the lifestyle and sex-life results. Women in the PFMT group were less likely to report that UI symptoms interfered with activities or were problematic post-PFMT. Schagen van Leeuwen (2004) reported a mean change in the Incontinence Quality of Life (I-QoL) score, but it was not clear if the difference, which favoured the PFMT group, was important as the reported means lacked a measure of dispersion. Two used QOL in Persons with Urinary Incontinence I-QoL score and reported a mean change in the QOL favouring PFMT over control [140,143]. Another found a significant difference favouring the PFMT group when the scores for incontinence-related limitations and impact on daily life were compared [139].

Six studies used urinary diaries to count leakage episodes: three days [134,143], seven days [140,144]; and 14 days [141,142]. Effect size was greatest in the Lagro-Janssen’s (1991) trial; however, the treatment effect may have been overestimated due to inadequate concealment of random allocation. The point estimates in the other trials were similar and all were statistically significant [134,141-143]. Ultimately, PFMT women experienced approximately 1 to 1.5 less leakage episode per 24 hours as compared to the controls.

Three other studies measured incontinence frequency [119,136,138] with either a four-point ordinal scale (1 = urine loss once a day to 4 urine loss once a month) [136] or a six-point leakage scale to document cure (0 = no urine leakage to 5 = every day) [119,138]. Kim’s 2007 study, the post-treatment scores were significantly better for the PFMT group post-treatment compared to the control, while in the 2011 trial 44.1% reported a cure in the PFMT group versus 1.6% in the control group immediately after intervention, a statistically significant difference.

One new trial was added to the section [143] making a total of 9 trials reported on pad and paper towel tests. Eight used “short office-based pad tests” and one used a paper towel test [67] Five involving women with SUI [130,131,134,136,140] dichotomised the short pad test data as either “cured”/“not cured” [134,136,140]; or “cured and improved”/“not improved” [130,131,136]. Four of the five found that “cured” or “cured and improved” was statistically and significantly more likely in the PFMT group. One older trial was small and did not find a statistically significant difference (fewer than 10 participants per group) [130,131]. Four reported data as mean and SD [128,134,140,143], and two others as a mean change in pad weight from baseline [135,143]. The two trials in women with urodynamic SUI, found that PFMT women had, on average, about 30g [134] and 12g [140] less urine loss than the controls. In a study of women with unspecified urinary incontinence,

PFMT women had about 5g less urine loss compared to the controls; however, the wide confidence intervals included the possibility of no difference [128]. Sari (2009), evaluating women with SUI and MUI, reported PFMT women had about 14g less urine loss compared to the control. Finally, Bidmead (2002) found women with SUI in PFMT group reported a pad weight change of 13g more than controls, based on a baseline comparison.

The only trial indicating a 24-hour home-based pad test [134] reported data as mean and SD. PFMT women reported about 28g less leakage than the controls but with wide confidence intervals that included the possibility of no difference. The only trial reporting a paper towel test [68,145] for either a moderate or a deep cough reported data as mean wet area with SD: the wet area for PFMT women as compared to the controls was approximately 20cm² less on a medium cough and 21cm² less on a deep cough. However, in both cases, the wide confidence intervals included the possibility of no difference.

Five trials have published long-term follow-up results ranging from three and six [141], seven [119], nine [130], 12 months [138], and one and five years [144]. Burns (1993) found that those experiencing mild leakages were more likely to have a return of symptoms in contrast with those experiencing moderate to severe leakages and were more likely to continue excising in order to continue to improve. Henalla (1989) reported 18% who returned the nine-month questionnaire had recurrent symptoms. Five years post-trial, Lagro-Janssen (1991) contacted 101 of the 110 women included in their original trial. Data from the 88 consenting women showed that the proportion of continent women (about 25%) was similar after five years, but the number with severe incontinence and those reporting leakage episodes increased from 3% to 18%. Two thirds of women (67%) remained satisfied with the outcome and did not want further treatment. Kim documented cure at 10 months (2011) and 12 months (2007) post-treatment, according to bladder diary. In the 2007 trial, 55% in the treatment group were cured at 12 months compared to 9.3% in the control; this suggests a greater likelihood of continence after one year in the PFMT group; at 10 months, 39.3% were cured at 7 months in the treatment group compared to 1.6% in the control group [119].

6. SUMMARY

PFMT is better than no treatment, a placebo drug or an inactive control treatment for women with SUI, UUI, or MUI (Level of Evidence: 1). Women treated with PFMT were more likely to report a cure or improvement and a better quality of life; they also indicated fewer daily leakage episodes and had less urine leakage on the pad and paper towel test than those in the control group in immediately after treatment and in the long term. The effect of PFMT in Women with SUI does not seem to decrease with increased age: in trials with older Women with SUI it appeared both primary and secondary outcome measures were comparable to those in trials focused on younger women. Moreover, the treatment effect appears to be enhanced where PFMT is based on sound muscle training principles such as specificity, overload progression, correct contraction confirmed prior to training, and use of the Knack (Level of Evidence: 4).

7. RECOMMENDATIONS

Supervised PFMT should be offered as a first-line conservative therapy for women of all ages with SUI, urge or MUI (Grade of Recommendation: A).

b) Is one type of PFMT programme better than another?

As discussed in the last section, PFMT is more effective than no treatment, placebo or inactive control treatments for women with urinary incontinence, which leads to another question: What is the most effective PFMT programme? A number of factors can influence the outcome of a PFMT programme such as the way in which it is taught and/or supervised, the parameters of the actual exercises, and adherence to the training regime. In this section, different approaches to PFMT were considered based on a Cochrane systematic review [97]. The review compared the effects of different approaches to PFMT on the management of female SUI, urge, and MUI. From 34 potentially eligible trials thirteen were excluded: 2 because they were still on going and 11 due to inadequate information. The interventions from the 21 included trials are described in detail in Table 2.

Among the included trials the following variables were compared:

1. Supervision of training: amount of contact with health professional [146-151].
2. Supervision of training: individual versus group supervision [146,147,149,152-154].
3. Exercise programme: direct versus indirect exercises [124,125,150,152,153,155].
4. Exercise programme: generic versus individualised exercises [154].
5. Exercise programme: submaximal versus near maximal contractions [156].
6. Exercise programme: daily versus 3 times per week [157].
7. Exercise programme: addition of upright exercise position [158].
8. Exercise programme: addition of strength training to motor learning [159].

Footnotes PFM = Pelvic floor muscle, VPFMC = voluntary PFM contraction, PFMT = PFM training, HP= Health professional Set = one episode or sequence of PFM contractions or training, including length of time of holding contraction, positions while performing contractions and number of repetitions of contractions.

11. **Exercise programme**: addition of adherence strategy [162, 163].

12. **Exercise programme**: addition of biofeedback: clinic biofeedback [120, 141, 164-166]; home biofeedback [136, 167-169].

1. **Quality of data**

Of the 21 trials, one was a conference abstract [124] rendering it difficult to assess. Ten of the remaining 20 trials provided sufficient detail of the methods to generate a randomisation to ensure they were genuinely random [134, 148 - 150, 152 - 154, 156, 157, 170]. Of the remaining 10 trials, 3 were clearly not random [147, 162, 163]. The final 6 provided sufficient detail to ensure that allocation was concealed [125, 134, 150, 153, 159, 161].

Overall, in regard to random allocation and concealment, 6 trials were considered to have a low risk of bias [125, 146, 150, 153, 159, 161] and 4 had a high risk; in the remaining 11, the risk of bias was unclear.

Only three trials clearly stated that the outcome assessment was blinded for one or more of the outcomes of interest [150, 155, 159] and 2 stated that a lack of blind outcome assessment was a limitation [129, 157].

None of the included trials was large and nearly two-thirds (13/21) were mid-sized, with only 20 to 50 participants per group. Four had fewer than 20 participants per comparison group [147, 155, 156, 160]; one of which was reported as a pilot study [155]. The largest trial randomised 120 women to each of two trial arms: 240 participants in all [153].

2. **Results**:

**Comparison 1. Supervision of training: amount of contact with health professional**

Subgroup 1.1: additional group supervision

Four trials shared similarities in terms of the amount of time and frequency of the extra health professional contact: [146-149]. All four recruited women with urodynamic SUI. Three provided the same home-based PFMT programme and individual supervision to both trial arms, then investigated the effect of adding an additional supervised group exercise session (a 45-minute weekly exercise class [146]; a 50-minute twice-weekly exercise class [149]; a weekly group session [147]. The fourth also added a 45-minute twice-weekly exercise session [148]; however, it was unclear if this was offered individually or as a supervised group exercise session.

Subgroup 1.2: additional phone calls

Ng (2008) recruited women with MUI, offered the same home-based PFMT programme in both trial arms, and investigated the effect of adding twice-weekly phone call subsequent to the initial face-to-face contact with a health professional [151]. This was the only trial included in the second subgroup.

Subgroup 1.3: individual supervision versus no supervision (different PFMT)

In the trial of women with SUI or MUI, both arms differed in the amount of health professional contact and the type of PFMT programme used [150]. This was the only trial in the third subgroup.

- **Cure/no cure**: There was no statistically significant difference in the number of women reporting “no cure” comparing PMFT with and without additional group supervision, subgroup 1 [23, 149]. As well, for subgroup 1.3, no difference was found between the supervised and unsupervised groups [150]. Ng [151], subgroup 1.2, reported the odds ratio (95% confidence interval) for the difference between the groups for their responses to 2 items from the BFLUTS (i.e., whether they did or did not have symptoms of SUI or urgency incontinence). For both items, the participants in the ‘phone call group’ (subgroup 1.2) had lower odds of reporting either SUI or urgency incontinence, suggesting that more women in the phone call group were asymptomatic.

- **No improvement/Improvement**: Women receiving additional group supervision (subgroup 1.1) were less likely to report incontinence [23, 147-149]. Hung (2010) found women in the supervised group (subgroup 1.3) were less likely to report no improvement [150].

- **Leakage episodes**: Only one of the 4 trials investigating the effect of ‘additional group supervision’ (subgroup 1.1) measured leakage episodes [147]; similarly those receiving additional supervision reported fewer leakage episodes per day. Based on the Leakage Index [23, 146], leakage was less in the group receiving additional supervision. Hung (2010), subgroup 1.3, also measured leakage episodes and found no differences between the supervised and non-supervised groups.

- **Pad and paper towel tests**: All 4 trials investigating the addition of group supervision used pad tests (90-second [146]; 20 minute [150] one-hour [148]; 24-hour [149]). Due to missing data, it was not possible to estimate differences between the treatment groups; where it was possible to calculate differences, these were not statistically significant.

**Comparison 2. Supervision of training: individual versus group**

Six trials were included in this comparison; however, each had at least one other difference between
trial arms (i.e., between the subjects and the controls within each trial), hence caution is required in interpreting the data.

Subgroup 2.1: individual versus individual+group supervision

The 3 trials in this subgroup (which were also included in Comparison 1, subgroup 1.1) used the same PFMT programme in both trial arms, supplemented with group supervision in one (in terms of frequency and total time) and individual supervision in the other [146,147,149]. Trials included women with SUI only.

Subgroup 2.2: individual versus group supervision (different PFMT)

The 3 trials in this subgroup differed in both supervision and the PFMT programmes [152-154]. Women with SUI [155] or mixed incontinence were included [152].

- **No cure/Cure**: There was no statistically significant difference in the number of women reporting ‘no cure’ between the group and individual supervision arms [146,149] in subgroup 2.1.

- **No improvement /Improvement**: In subgroup 2.1, women who received group supervision were more likely to report ‘improvement’ in their incontinence [146,147,149]. In subgroup 2.2, difference between group and individual supervision was found [154].

- **Leakage episodes**: In addition to the group versus individual supervision comparison, two trials measured leakage episodes; one used a different PFMT programme between the trial arms [154] and the other used the same programme for both [147]. De Oliveira [2009] indicated no difference between groups while Konstantinidou [2007] reported that the women who had received group supervision indicated fewer leakage episodes per day.

- **Pad and Paper towel test**: All 3 trials in subgroup 2.1 used pad tests (90-second [146]; and 24-hour [147, 149]). The differences, where they could be calculated, were not statistically significant. All 3 trials in the subgroup 2.2 used a 1-hour pad test; and one used a standardised bladder volume rather than maximum bladder capacity [154]. The overall pattern was one of no difference between the groups.

Comparison 3. Exercise programme: direct versus indirect exercises

This comparison encompassed four subgroups.

Subgroup 3.1: PFMT versus sham/imitation

The first comprised 2 trials in women with SUI that compared PFMT versus sham or imitation PFMT treatments [124,125].

Subgroup 3.2: PFMT versus the ‘Paula method’

The second subgroup included 2 trials comparing PFMT versus the ‘Paula method’ in women with SUI [153] or SUI and mixed incontinence [152].

Subgroup 3.3: PFMT versus the ‘Sapsford’ approach

The third subgroup contained a single trial that compared PFMT with the ‘Sapsford’ approach in women with SUI or mixed incontinence [150].

Subgroup 3.4: PFMT versus Pilates

The fourth subgroup also comprised a single trial; a pilot study that compared PFMT versus Pilates in women with SUI [155].

- **No cure/Cure**: No difference between ‘direct’ PFMT and the ‘Sapsford’ approach was found in the single trial in subgroup 3.3 [150].

- **No improvement/Improvement**: The pooled data from the two trials in subgroup 3.1 (PFMT versus sham/imitation) did not show a statistically significant difference in favour of either trial arm [124, 125]. In contrast, Hung [2010] in subgroup 3.3 found that women in the ‘Sapsford’ approach group (with more health professional contact) were more likely to report improvement. Savage [2005], subgroup 3.4, did not report on improvement but, instead indicated there was no difference between the groups in terms of satisfaction.

- **Leakage episodes**: Hung [2010], subgroup 3.3, found no difference between the trial arms (median 0 leaks per day, IQR 0 to 0.3, in both groups). In terms of a less than 50% reduction in leakage frequency, neither Ghoniem [2005], subgroup 3.1, nor Liebergall [2009], subgroup 3.2, found differences between groups in weekly or more frequent incontinence episodes.

- **Pad and paper towel test**: Four trials reported pad test data: 20 minute [150]; 1 hour [152,153]; or type not known [124]. The data of two [150] subgroup 3.3, and subgroup 3.2 [124], could not be used to calculate an estimate of effect. Neither of Liebergall’s studies [152,153] found a difference in the mean change from baseline.

Comparison 4. Exercise programme: generic versus individualised exercise

This comparison included one study [154] in which women were randomised to either individualised PFMT provided on a 30-minute twice-weekly clinical visit or to a generic PFMT programme offered through a 45-minute twice-weekly group exercise class.
• No cure/ Cure: No data was reported.
• No improvement/ Improvement: No difference between the generic and individualised exercise trial arms was reported [154].
• Leakage episodes: There were no differences in the number of leakages between the generic and individualised exercise trial arms in a 24-hour trial period [154].
• Pad and paper towel test: There was no difference in a 1-hour pad and cough test between the trial arms [154].

Comparison 5. Exercise programme: submaximal versus near maximal contractions

One study assigned women with SUI to PFMT programmes that were the same in all aspects with one arm adding either near maximal PFM contractions or submaximal contractions [156]. Both groups received the same amount of contact from health professionals.

• Not cured/ Cured: No data was reported for this outcome.
• No improvement/ Improvement: No data was reported for this outcome.
• Leakage episodes: No statistically significant differences reported between the exercise groups for leakage episodes in a 24-hour period [156].
• Pad and paper towel test: Pad weight (10-hour pad test) did not differ between the groups.

Comparison 6. Exercise programme: daily versus 3 times per week.

A new trial [157] compared PFMT programmes that were the same in all aspects except one group was asked to do daily exercise and the other 3 times a week. Both groups had the same amount of contact with health professionals.

• Not cured/ Cured: There was no statistically significant difference between the groups in terms of the number of women who reported ‘no cure’.
• No improvement/ Improvement: None of the women in either group indicated any significant difference in improvement.
• Leakage episodes: No data was reported.
• Pad and paper towel test: There was no difference between the groups on a 1-hour pad test.

Comparison 7. Exercise programme: addition of upright exercise position

Two PFMT programmes were compared that were the same in all aspects except one group was asked to exercise only in the supine position while the other alternated exercise sets between the supine, sitting and standing positions [158]. Both groups had the same amount of contact with health professionals.

• No cure/ Cure: No data was reported for this outcome.
• No improvement/ Improvement: No data was reported for this outcome.
• Leakage episodes: There was no statistically significant difference between the exercise groups for leakage episodes in a 24-hour period.
• Pad and paper towel tests: There was no difference between the groups for the mean change in pad weight gain on a 1-hour pad test.

Comparison 8. Exercise programme: addition of strength training to motor learning

Women with SUI or MUI took part in two motor-learning PFMT programmes that were the same in all aspects except one group undertook additional strengthening in PFMT. Both groups had the same amount of contact with health professionals.

• No cure/ Cure: There was no difference between the groups in terms of the number of women who reported ‘no cure’.
• No improvement/ Improvement: There was no difference between the groups in number who reported ‘no improvement’. There were no differences in other self-reported improvement outcomes: satisfaction with treatment, comfort with continuing the training and desire for further treatment although in this last, the women in the motor learning PFMT group were less likely to want to continue.
• Leakage episodes: There was no statistically significant difference between the groups for the number of leakage episodes per day.
• Pad and paper towel tests: There was no difference between the groups on either a paper towel test or a 24-hour pad test.

Comparison 9. Exercise programme: addition of abdominal muscle exercise

Sriboonreung (2011) compared two PFMT programmes that were the same in all aspects except one group was asked to undertake additional abdominal muscle exercises (these were not described in further detail) [157]. Both groups had the same amount of contact with health professionals.

• No cure/ Cure: There was no statistically significant difference between the groups in terms of the number who indicated ‘no cure’.
• No improvement/ Improvement: There was no statistically significant difference between the groups.

1127
Leakage episodes: No data were reported.

Pad and paper towel tests: There was no difference between the groups on a 1-hour pad test.

Comparison 10. Exercise programme: addition of intravaginal resistance device

One new trial was added to this section [161] for a total of three which compared two PFMT programmes that were the same in all aspects except one group used an intravaginal device design to increase the resistance to the PFM contraction [129,160,161]. The resistance devices included a spring-loaded device with two limbs [161] an intravaginal balloon [160], and a vaginal dilator [129]. In all three, each arm had the same amount of contact with health professionals. The women in one study had SUI [Ferguson 1990] and in the others SUI or MUI [Delgado, 2009; Wells, 1999].

No cure/Cure: There was no statistically significant difference between the groups in terms of the number of women who indicated ‘no cure’ [129,161].

Not improved/Improvement: There was no statistically significant difference between the groups in terms of the number of women who indicated ‘no improvement’ (129,161).

Leakage episodes: No statistically significant difference between the two treatment groups was found [129].

Pad and paper towel tests: All three reported pad test data (30-minute and 24 hour [160,161] or unspecified duration [129]. None of these found statistically significant differences between the treatment groups.

Comparison 11. Exercise programme: addition of adherence strategy

Adherence strategies such as audiotape [162] or small chiming (alarm) device [163] have been tried. The PFMT programmes were [163] or appeared to be [162] the same for both trial arms. Both trial arms in each study had the same amount of contact with health professionals.

No cure/Cure: No data was reported for this outcome.

No improvement/Improvement: The group using the devices was less likely to report ‘no improvement’ post treatment.

Leakage episodes: No statistically significant difference was found between the groups for the number of leakage episodes in 24 hours [163].

Pad and paper towel tests: The average amount of leakage on a 1-hour pad test was less in the groups using the devices post treatment.

Comparison 12 Teaching programme: Addition of biofeedback

No new studies were found that compared biofeedback alone to PFMT plus biofeedback in either the home or clinic. Three studies were excluded based on the BF group differing from the no BF group in terms of treatment intensity (e.g., number of clinic visits) [122,171,172] or supervision (i.e., group versus individual teaching) and absence of between group analyses [173].

Five trials used clinic based BF in the treatment of predominantly SUI symptoms [141,164,165], predominantly UUI [120], or OAB with UUI [166]. In four, the home PFMT programme was the same in both groups, with the addition in one arm of clinic BF once every two weeks [120], once a week [141,165], twice a week [166] or three times a week [164].

Treatment durations in both arms were four [164,165], eight [120,141] and 12 weeks [166]. In one, there was more supervisory HP contact with the BF group than with the PFMT alone group [165]. Of the five clinic based BF trials, three had adequate random allocation concealment [120,141,164,166] and three had blinded outcome assessors [120,164]. Three randomised between 25 and 74 women to each group [120,141,165,166], while others randomised less than 25 women per group [164,165]. Withdrawals or losses to follow up were none [164,165], less than 10% [141], less than 15% [120,165,166]. All women were assessed post-treatment; further follow up was conducted at three and six months [141] or at three months and two to three years [165].

There were no new home based trials added to this section so there remains a total of four. Random allocation concealment was adequate in just one [167], and outcome assessors were blind for some or all of the outcomes in two [167,168]. The number of women allocated to the comparison groups was 20 or less [136,168], 40 women in the BF group and 20 in the PFMT [169] or 50 or more per group [167]. Two had complete data sets on trial completion [136,168], one reported 9% withdrawal [167], and 33% dropped out of another [169].

With regard to clinic BF, two of the five trials reported significantly better outcomes with the addition of BF to PFMT. Based on pad weight in women with urodynamic SUI at one to two years after treatment, five of 19 women in the BF group and none of the 14 women in PFMT reported cure [165]. However, the BF group had 4 treatment sessions whereas the PFMT group had 2-3 sessions. In women with OAB there were changes in the total score on the KHQ with the addition of BF, but no statistically significant differences between the groups on any of the nine subscales [166]. Patient-reported cure or improvement was 50% for the BF
group and 38% for PFMT alone; a statistical comparison was not reported [166].

Three trials, including the two largest trials, reported significant improvements in incontinence with PFMT with or without BF, but no significant differences between groups [120,141,164].

For the home BF trials, only one reported a significant effect for the addition of BF [168]. In the others, including the largest trial [167] both groups had significant improvements, but no differences between groups.

A 2011 Cochrane review on feedback or biofeedback to augment PFMT [174] included 24 trials involving 1,583 women and concluded that women who received PFMT with BF were significantly more likely to report that their UI was cured or improved compared to those who received PFMT alone. However, this review included trials in which the treatment groups differed on parameters other than BF, and the authors caution that women in the BF groups commonly had more contact with the health provider. Thus, more research is needed to determine whether differences are due to BF or other differences such as intensity, approach, or contact with the health professionals.

With regard to clinic based BF, studies were inconsistent. The larger trials indicated no statistically significant differences between BF assisted and non-BF groups for self-reported cure, cure/improvement, or leakage episodes per day or quality of life (Level of Evidence: 1). This pattern appeared to be consistent across trials that recruited women with SUI, UUI, or MUI. There were a similar number of trials addressing the effect of home BF, but fewer data. In a single robust trial there were no statistically significant differences between home BF and non-BF groups for self-reported cure, cure/improvement, or quality of life for women with urodynamic SUI (Level of Evidence: 2).

Clinicians should provide the most intensive HP led PFMT programme possible within service constraints because HP taught and supervised programmes are better than self-directed programmes, and more HP contact is better than less (Grade of Recommendation: A). Although studies are inconsistent, there does not appear to be a clear benefit of adding clinic (Grade of Recommendation: A) or home based BF (Grade of Recommendation: B) to a PFMT programme.

Cautiously, we conclude that voluntary PFM contractions are better than exercises that facilitate co-contraction of the PFM muscles (e.g. crossing the ankles and pulling the legs apart). Further, ‘indirect’ methods (e.g. the ‘Paula method’ or ‘Sapsford’ approach) did not appear to be better than direct PFM contractions, noting that some study data were confounded by differences in the amount of contact time with health professionals. Moreover, and tentatively, we found there was no benefit from adding intravaginal devices to increase resistance in PFMT.

This review underlines the fact that existing evidence is insufficient to make any robust recommendations about the best approaches to PFMT, beyond the fact that the amount of health professional contact may influence women’s perceptions of their improvement.

5. IMPLICATIONS FOR RESEARCH

Comparisons of PFMT approaches are, de facto, comparisons of two active treatments. Therefore, it is difficult to determine which approach is best, unless (a) the differences in outcome are large or (b) the trials are powered to find small to moderate differences in outcomes that would be indicative of the need for larger trials. Although finding the best approach to PFMT has been identified as a high priority research area, large, costly trials may not be the best use of research funds, particularly where the difference in outcomes between two active treatments is expected to be small. Therefore, the highest research priority should be to investigate the effect of supervision on PFMT. In addition to clinical effectiveness, this is an important question because of resource implications, both financial and human, for health-service delivery.

6. RECOMMENDATIONS

Clinicians should provide the most intensive supervision-led PFMT programme possible within service constraints because supervised PFMT programmes are better than those with little or no supervision. (Grade of Recommendation: A).

c) Is PFMT better than other treatments?

Trials were considered for inclusion in this section if they compared PFMT with another stand-alone intervention, e.g. vaginal cones, bladder training, drug therapy. Of note is that there are 37 RCTs comparing PFMT with another stand-alone treatment but few recent studies since the last update. For this review, four were excluded, two as conference abstracts [175,176], one reported in two conference abstracts with inconsistent data [177], and one compared PFMT and vaginal cones versus EStim [178].

The 33 trials addressed the following comparisons:

- PFMT versus vaginal cones (VC) [107, 122, 134, 140, 169, 175, 179-183]
• PFMT versus EStim (EStim) [130, 132, 134, 140, 166, 184-188]

• PFMT versus bladder training (BT) [128, 189, 190]

• PFMT versus drug [125, 130, 131, 142, 188, 191-193]

• PFMT versus surgery [194]

(a) PFMT versus VC: Eleven trials compared PFMT with VC [107, 122, 134, 140, 169, 175, 179-183, 185]. The details of the VC and PFMT programmes for each trial are presented in Table 4.

(b) PFMT versus EStim: 10 trials compared PFMT with EStim in women with UI [186] SUI [134, 184, 185], urodynamic SUI [130, 132, 140], mixed UI [187] or OAB [166, 188]. There were different PFMT and EStim protocols in each study.

Two trials used interferential current, two to three times weekly, 30 minutes, 10-50Hz to PFMT (weekly PFM exercise courses and daily home exercises), for four to six weeks [185] or 20 minutes weekly for 10 weeks, 0-100Hz, at maximal tolerated intensity to PFMT (five PFM contractions with five second holds, hourly, every day for 12 weeks) [130]. Another applied external (extra-vaginal and lumbar) electrodes to deliver an unknown type of current (10 minutes, three times weekly, intensity increased until noticeable PFM contraction and patient added voluntary PFM contraction) versus PFMT (no details given), for six weeks [132].

The remaining trials all delivered the stimulation using a vaginal electrode. The comparisons were, in approximately ascending order of duration of EStim:

• 20 minutes, twice weekly, biphasic symmetric intermittent current at 10Hz, pulse duration 400 microseconds, duty cycle 10 seconds on and five off, maximum tolerated intensity, versus PFMT (no details given), for 12 weeks [166]

• 20 minutes, twice per week, biphasic intermittent current at 10Hz, pulse duration 1 millisecond, unidentified number of seconds of contraction and, duty cycle, at maximal tolerated intensity up to 100 mA [188]

• 20 minutes, three times weekly, biphasic intermittent current at 50Hz, pulse duration 0.5 millisecond, 5 second contraction, duty cycle one to two, at maximal tolerated intensity up to 100 mA [140]

• 30 minutes, three times weekly, biphasic intermittent current at 50Hz, pulse duration one millisecond, two second contraction, duty cycle one to two, at maximal tolerated intensity up to 100 mA (for predominant SUI) or the same stimulation at 20Hz (for predominant UUI), versus PFMT (no details given), for eight weeks [186]

• 30 minutes daily, biphasic intermittent current at 50Hz, pulse duration 0.2 milliseconds, individualised duty cycle depending on ability to hold PFM contraction, at maximal tolerated intensity up to 120mA, versus PFMT (three times daily, eight to 12 near-maximal PFM contractions with six second hold and six to eight second rest, with three to four fast contractions at the end of every contraction in addition to weekly exercise class), for six months [134]

• up to 60 minutes, twice daily, asymmetric balance biphasic intermittent current at 12.5 and 50Hz, pulse duration 300 microseconds, five second contraction time with two second ramp up and one second ramp down, duty cycle one to two, intensity to 80mA, versus PFMT (daily, 60 slow and quick PFM contractions), for four months [187]

• six to eight hours per night, intermittent current at 12, 20 or 50Hz, versus PFMT (six to eight times daily, five to 10 maximal PFM contractions with five second hold and five seconds rest, and one sub-maximal contraction with 30 to 40 second hold), for six months [184].

Amount of HP contact was the same for both groups in two trials [130, 140], greater for EStim in two [132, 185], and greater for PFMT in another [134, 188]. Any differences were not clear in the other four trials.

(c) PFMT versus BT: Three trials compared PFMT with BT in women with SUI [190], SUI and/or DO [189] or UI [128]. BT comprised a voiding schedule with weekly progression [128, 189, 190]. Wyman (1998) also included urge inhibition techniques (affirmations, distraction and relaxation). Sherburn trial added to voiding schedule, education on normal bladder control and voiding parameters, skin care, pad usage, fluids and fluid intake, optimal toileting position, voiding dynamics, and relaxation, distraction and breath control as part of the deferral strategies.

In the three trials BT was compared with:

• PFMT with clinic based BF, and a twice daily home PFMT programme of five fast (three second holds) and 20 sustained (10 second holds with 10 second rests) PFM contractions, PFM contraction for urge suppression and with increases in intra-abdominal pressure [Wyman, 1998].

• PFMT with clinic based BF, and daily home PFMT of 30 PFM contractions for strength and endurance (12 second holds) [Yoon, 2003].

• PFMT with weekly group class, and daily home PFMT prgram. The PFMT exercise class included intensive PFMT, combining motor control, strength, endurance, power and functional training in a variety of different body positions [Sherburn, 2011].
Treatment duration, and amount of HP contact, was the same in both arms of all three trials, with treatment duration ranging from eight (Yoon, 2003), 12 (Wyman, 1998), and 20 weeks (Sherburn, 2011).

(d) PFMT versus drug therapy: Eight trials compared PFMT to drug therapy in women with SUI [125, 130, 131, 191, 192] or UUI [142, 188, 193, 195, 196]. The trials for SUI used several different drugs. In two, premarin (conjugated equine oestrogens) 2g per night for six or 12 weeks was compared to PFMT [130, 131]. In one of these [130], the PFMT was comprised of a daily home programme of five PFM contractions with five second holds per hour; in the other [131] PFMT was not described. Another trial compared phenylpropanolamine hydrochloride for four weeks versus six months of PFMT (90 to 160 PFM contractions with 10 second hold and 10 second rest distributed throughout the day) [192]. Ishiko [2000] compared clenbuterol (20mg bid) versus PFMT (10 minutes daily), for 12 weeks [191]. One study compared duloxetine (4mg bid, plus sham PFMT) versus PFMT (four times weekly, three sets of 10 six to eight second contractions and two sets of 10 one to two second contractions) for 12 weeks [125].

Three trials on UUI used oxybutynin(193) [142,188,193]. Doses and PFMT programs varied: oxybutynin chloride (2.5mg tid, progressed to maximum 5mg tid) versus PFMT with urge suppression strategies for eight weeks [142]; extended-release oxybutynin (5mg/day) versus PFMT (plus lengthening voiding intervals and urge strategies) for 3 months [193]; and oxybutynin chloride (5mg bid, progressed to maximum 5mg tid) to PFMT (and to functional electrostimulation) for 12 weeks [188].

Four trials had approximately the same amount of HP contact in drug and PFMT groups [125,130,142,191]; in one, this was not clear [130]. Wells [1991] assessed treatment effect after four weeks in the drug group, and six months in the PFMT group. Kafri [2007] provided 5 sessions for the PFMT group, but not for the drug group. Arruda [2008] provided two sessions per week with physiotherapist for the PFMT group and visits every 4 weeks for the drug group.

(e) PFMT versus surgery: Only one trial, published in 1986, has compared PFMT to surgery [197]. The surgical technique was based on the type of defect identified: Burch colposuspension for anterior suspension defects and vaginal repair for posterior bladder descent. Women with both defects had a combined Burch and vaginal repair procedure. No details on the PFMT parameters were provided; women had five or more group sessions with a physiotherapist.

1. Quality of Data

(a) PFMT versus VC: Adequate allocation concealment was reported by five: [107,122,134,140,180]. Three indicated that outcome assessors were blinded [134,140,183]; only some of the outcome assessments were blinded in two [107,122]. Sample sizes ranged from fewer than 40 women [107, 134,140,169,175,179,180,182,183], 50 [181] to 79 per group [122]. There were dropouts in both the PFMT and VC groups in all trials except Gameiro’s (2010) [181] where no details were provided or in Cammu’s (1998), in which all of the dropouts were from the VC group. Dropout rates were higher in the VC groups for several [169,175,179,180,183]; conversely, they were higher in the PFMT group for others [107,122,134,140,182]. Only one trial reported any follow-up beyond the post-treatment evaluation, and this, at 6 and 12 months post treatment [181].

(b) PFMT versus EStim: Of the eight trials, three reported adequate random allocation concealment and blinding of outcome assessors; samples sizes ranged from 10 to 20 and 35 women per group. Four trials appeared to have no dropouts [130,132,184,187]. Others reported 5% [186], 10% [140], 12% [134,188], 13% [166] and 19% [169]. All women were assessed post treatment; follow up was at nine months and one year [130] and four years [184].

(c) PFMT versus BT: Adequate random allocation concealment was reported in one trial [190]; outcome assessors were blinded in two [128,190]. Samples sizes ranged from 15 to 20 women [128], 43 to PFMT and 41 to BT [190] to 70 women per group. Dropouts were approximately 4% for Wyman (1998) and 12% for Yoon (2003) and 8% for Sherburn (2011). All women were assessed post treatment, and Wyman (1998) followed-up three months later (i.e. six months after treatment began).

(d) PFMT versus drug therapy: Random allocation was concealed in two of the eight trials [125,196]. Outcome assessors were blinded in two [125,142]. Five trials randomised 25 or fewer participants per group [130,131,188,191,193]; one randomised approximately 50 per group [125]. The two largest randomised about 80 [192] or 85 women per group [142]. Dropout rates were: 0% [130], 14% [142], 15.9% [193], 16% [191], 16.9% [196], 25% [192] and 36% [125]. Drop out ratios were not reported in two [131,193]. Most trials assessed outcomes immediately post-treatment and three had longer follow up of nine months [130], one year [188], and 21-month [193] although in this last trial most participants had discontinued drug therapy after active intervention.

(e) PFMT versus surgery: It was not clear if allocation was adequately concealed, or if the outcome assessors were blinded. Approximately 25 women were in each comparison group with no dropouts at four months (post treatment assessment). There was further long-term follow-up at one year, then four to eight years [197].

2. Results

(a) PFMT versus VC: The comparative results in seven of the 11 studies were inconsistent. For cure,
one trial favoured PFMT [134]. Six favoured neither PFMT nor VCs [107, 122, 140, 179, 182, 183]. Pooled data from these eight trials showed statistically significant heterogeneity.

For cure/improvement, pooled data in six of the 11 trials showed no statistically significant differences. In four, PFMT was better than VCs in terms of daily leakage episodes. And, two others [140,181] no significant differences in terms of incontinence-specific quality of life measures (I-QoL) and the number of incontinence episodes were found.

Three reported adverse effects associated with cones such as the inability to use them, pain, vaginitis, bleeding, a sense of unpleasantness [134,180] or inconvenience [183].

(b) PFMT versus ESTim: Pooled data from three trials of women with SUI found self-reported cure was more likely with PFMT [134, 184, 187], although only one found a statistically significant difference when data from the trials was considered individually [134]. It was not clear if the cure data reported by Hofbauer (1990) were derived from a symptom scale or a voiding diary; these data were therefore excluded. Pooled data from three trials in women with also found self-reported cure/improvement was more likely in PFMT women [134,184,185]; again only Bø (1999) found a statistically significant difference when trial data were considered individually. At 6 months, QOL (as measured with I-QoL Questionnaire) increased significantly both in the PFMT group 28.4% and in the ESTim group 32.4% but there was no significant difference between the groups [140]. Leaking episodes and quality of life ([Social Activity Index]) were not statistically significant in one study [134]. At nine months post treatment, Henall (1989) found that three out of 17 PFMT women and one out of eight in the ESTim group reported recurrent symptoms. Side effects related to ESTim included vaginal irritation and/or bleeding [134,184,187].

Spruijt [2003] [186] recruited women with SUI, UUI or MUI and Wang (2004) [166] women with UUI. Neither found a statistically significant difference between the groups for self-reported cure/improvement although Wang indicated women in the PFMT group had statistically significantly fewer leakage episodes per day. ESTim produced “physical and emotional stress” in the elderly women in the Spruijt trial. On the KHQ there were no statistically significant differences in general health perception, incontinence impact, role limitation, physical limitation, social limitation, and personal relationship, but the ESTim group had statistically significant better scores for emotions, sleep/energy and severity measures. In the Arruda (188) study [188], 52% and 76% of the women randomised to the ESTim and PFMT groups, respectively, claimed to be satisfied after 12 weeks of the study treatment period. Further, there was a significant decrease in the urge-incontinence episodes, the daily number of urinary pads. However, there was no significant difference in any of these measures between the groups.

(c) PFMT versus BT: Wyman [1989] [189] recruited women with SUI, UUI or MUI. While more women in the PFMT group reported symptomatic improvement or fewer leakage episodes the difference was not statistically significant post-treatment or three months later. Sherburn recruited women with SUI. Women in the PFMT group reported significantly lower amounts of leakage on the stress test, improved symptoms and bother and greater perception of change after 5 months than the BT group (Sherburn, 2011). No adverse event data were reported in either trial. Yoon (2003) [128] did not report any data for the outcomes of interest.

(d) PFMT versus drug: Neither of the two trials comparing vaginal oestrogens versus PFMT in women with urodynamic SUI reported data for the outcomes of interest [130,131]. Of those that responded to a follow-up questionnaire at nine months, three out of 17 PFMT women and three women using oestrogens reported recurrent symptoms. Adverse events were not reported in either trial.

Two older trials that compared an adrenergic agonist and PFMT in women with SUI or MUI were previously reported in ICI 2009. No significant differences between groups were reported [129,191].

Duloxetine had a significantly greater impact in decreasing incontinence episodes than PFMT (57% versus 35% median decrease between drug and PFMT respectively) [125]. However post-treatment data collection began immediately after treatment initiation, before the effects of PFMT could be expected to occur. There were no significant differences between the treatments with respect to Incontinence Quality of Life (I-QoL).

In the three trials that compared PFMT to oxybutynin, PFMT groups had similar or better outcomes on most parameters. In the largest of these, a comparison of PFMT and oxybutynin in older women with DO or DO with urodynamic SUI, women in the PFMT group had significantly greater reduction in incontinence episodes compared to those in drug treatment and fewer incontinence episodes per day [142]. Women in PFMT were more likely to report that they were “much better” but cure rates did not differ significantly. Side-effects were common among women in the drug group, particularly dry mouth.

One trial reported that the PFMT group had better outcomes for voiding frequency, but not for incontinence episodes [193]. Follow-up at 21 months showed that the PFMT group maintained or improved their voiding frequency, whereas the drug group regressed to baseline levels. However, most participants had discontinued the drug. Similarly, another trial reported that subjective symptom improvement was almost identical in the PFMT and
drug groups (77%, 76%, respectively) [188]. Changes in incontinence episode frequency favored the PFMT group, but were not significantly different.

(e) PFMT versus surgery: At four months PFMT women with urodynamic SUI were less likely to report cure than women who had surgery, although there was no statistically significant difference in the proportions reporting cure/improvement. At 12 months, 10/24 from the PFMT group were satisfied with initial therapy, versus 19/26 randomised to surgery. Long-term data (four to eight years) were not presented by group allocation. Adverse events were associated with surgery: new UUI, retropubic or pelvic pain, or dyspareunia [197].

3. Summary

In the 11 trials that compared PFMT with VCs in women with SUI, no consistent pattern emerged in the data. Further, data on self-reported cure in eight of the trials were inconsistent and there was no difference in the pooled data from six trials for self-reported cure/improvement. Notably, there were in fact fewer daily leakage episodes with PFMT in the pooled data from three trials (Level of Evidence: 1).

PFMT with EStim in women with SUI was compared in six trials. Pooled data demonstrated that self-reported cure and cure/improvement were more likely in PFMT than in EStim groups (Level of Evidence: 1). It is worth noting that only one trial individually demonstrated a statistically significant difference in these outcomes and there was more health professional contact in the PFMT arm. There were no statistically significant differences between PFMT and EStim groups for leakage episodes or quality of life, based on a single trial on MUI (Level of Evidence: 2). In the one trial that recruited women with SUI, UUI or MUI self-reported cure/improvement rates were not statistically significantly different (Level of Evidence: 2). Self-reported cure and cure/improvement rates and satisfaction were not statistically significantly different in the 2 trials in women with UUI, although PFMT women had fewer leakage episodes per day, and women in the EStim group had better quality of life in three of the nine domains measured on the KHQ (166). (Level of Evidence: 2). Some women reported adverse events attributable to ES.

PFMT and BT was reported in three but only two included data of interest. In women with SUI, symptomatic improvement, leakage episodes and quality of life were statistically significantly better in the PFMT group (Level of Evidence: 2). In contrast the study that recruited women with SUI, UUI and MUI did not find statistically significant differences between the groups (Level of Evidence: 2).

There is insufficient evidence to determine if PFMT is better than vaginal oestrogens. Neither trial that compared an adrenergic agonist with PFMT in women with SUI or MUI found a difference in self-reported cure/improvement and adrenergic side effects were bothersome (Level of Evidence: 2). One trial of PFMT versus oxybutynin in women with DO or DO with urodynamic SUI found women doing PFMT were more likely to report improvement and have fewer leakage episodes per day after treatment (Level of Evidence: 2). Many women taking oxybutynin reported drug-related side effects. One trial compared a serotonin-norepinephrine reuptake inhibitor (duloxetine) with PFMT and while women who took the drug had fewer leakage episodes, there was no difference in terms of quality of life between the two groups and drug side effects were sufficient to discontinue treatment in some women. (Level of Evidence: 2).

Based on one trial it seemed self-reported cure was more likely after surgery than PFMT for women with urodynamic SUI, but no statistically significant difference in the proportion of women reporting cure/improvement (Level of Evidence: 2). There was insufficient detail about the PFMT programme to make a judgment about how effective it might have been.

4. Recommendations

For women with SUI:

- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised (Grade of Recommendation: B).
- PFMT is better than BT as first line conservative therapy (Grade of Recommendation: B).
- PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug (Grade of Recommendation: C).
- PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive (Grade of Recommendation: C).

For women with SUI or MUI:

- PFMT is better than VC as first line conservative therapy (Grade of Recommendation: B).

For women with UUI or MUI:

- PFMT and BT are effective first line conservative therapy (Grade of Recommendation: B).
- PFMT is better than oxybutynin as first line therapy (Grade of Recommendation: B).

For women with UUI:

- PFMT and BT are effective first line conservative therapy (Grade of Recommendation: B).

Larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. In planning comparisons researchers should consider carefully the potential impact of dif-

1133
different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies. A comparison of surgery and PFMT might be least useful, because PFMT is usually first-line therapy with surgery reserved for those in whom PFMT was unsuccessful or is not the treatment of choice.

d) Does the addition of PFMT to other treatments add benefit?

In this section, the effects of PFMT combined with therapy A versus therapy A alone, are compared to address the additive benefit of PFMT. Nine RCTs were found, and three were excluded: no useable data [198]; men and women and the data were not reported separately [199] and a combination BT/ PFMT programme [200].

(a) PFMT/VC versus VC: Two trials, in women with urodynamic SUI [201] or SUI [107], compared combined PFMT/VC versus VC. In both arms of each study the recommended VC regime was twice daily for 15 minutes, with cone weight progressing from 20g to 70g [201] or 100g [107]. Both PFMT programmes asked women to do 100 PFM contractions per day with 10 contractions 10 times a day [201], or a combination of fast and slow contractions [107]. Treatment duration was 12 weeks in both arms of both studies.

(b) PFMT/EStim versus EStim: No new trials have been published on the topic since the last review. In women with urodynamic SUI, EStim (10 minutes, three times weekly, sufficient intensity to provoke a visible contraction to which the patient added their own PFM contraction, extravaginal and lumbar electrodes) was compared to PFMT/ES (daily PFMT home programme (not specified) and a twice weekly exercise class plus the same ES programme) [132]. Treatment duration was six weeks in both arms.

(c) PFMT/BT versus BT: No new studies were found. In women with urodynamic SUI, or urodynamic SUI with DO, Wyman (1998) compared BT (progressive voiding schedule, advice on urge inhibition techniques such as affirmations, distraction and relaxation) to PFMT/BT (twice daily PFMT, maximum of 10 fast contraction with three second holds and 40 sustained contractions with 10 second holds in addition to bladder training as above). The combined PFMT/BT group began with BT and added PFMT in the 3rd week of the intervention. Women in both groups received the same preliminary education programme and treatment duration was 12 weeks in both arms [189].

(d) PFMT/drug versus drug: Two previously reported trials compared PFMT/drug (beta(2)-adrenergic agonist (clenbuterol); duloxetine) [125,191]. Two new trials compared PFMT/drug to drug alone in women with UUI [202,203]. One was a two-stage, multi-site RCTI [203]. In Stage 1, women received tolterodine (4 mg/day) versus tolterodine plus PFMT with urge suppression strategies (behavioural training) for 4 visits over 10 weeks. Stage 2 involved drug discontinuation. PFMT included 3 sessions of 15 exercises daily, starting at 2-seconds duration and progressed to 10 seconds. The other trial [202] was a single-site study of individually-titrated, extended-release oxybutynin (initiated at 5 mg/day and escalated as tolerated to a maximum of 30mg/day) with proactive management of side effects versus oxybutynin plus PFMT with urge suppression strategies for 4 visits across approximately 8 weeks. PFMT was also 3 sessions of 15 exercises daily, starting at an individualized duration and progressed to a maximum of 10 seconds.

1. Quality of data

(a) PFMT/VC versus VC: Adequate allocation concealment and some outcome assessment was blind in one [107]. Neither of these was clearly reported in the study by another [201]. Sample sizes were approximately 20 women in each comparison group. Dropouts ranged from 63% of the women in the PFMT/VC group compared to 41% in the VC group [107] to 30% of the PFMT/VC group versus 9% in the VC only group [201].

(b) PFMT/EStim versus EStim: It was not clear if random allocation concealment was adequate or whether assessors were blind [132]. There were only 11 women in each comparison group. There did not appear to be any dropouts.

(c) PFMT/BT versus BT: In one, it was not clear if random allocation concealment was adequate; outcome assessors were not blinded [189]. There were 68 women in the BT group and 67 in combination therapy with fewer than 10% dropouts after 12 weeks of treatment. Further follow-up was reported at six months and approximately three years after study entry.

(d) PFMT/drug versus drug: Although adequate allocation concealment and blinded assessors where used in three trials [125,202,203] it was not clear in another [191]. Sample sizes varied from 18 women in the drug group and 23 in the combination therapy group [191] with 27% and 17% dropouts respectively, principally because of drug-related side effects. In another, approximately 50 women with SUI were assigned to each group, 30% of whom dropped out of both treatment groups. Burgio (2008) randomised 307 women with urge-predominant UI and had a drop out rate of 8.8% at the end of active treatment (10 weeks). Burgio (2010) randomised 64 women with urge-predominant UI before being stopped for futility and had a drop out rate of 9.4%.

2. Results

(a) PFMT/VC versus VC: In this comparison, neither of the two trials identified any statistically significant differences between the groups (for patient reported cure, improvement as measured by a Visual Analogue Scale or pad test) and all of the confidence intervals were wide [107,201].
(b) PFMTES versus ES: Although Hofbauer (1990) [132] reported cure/improvement, it was not clear whether this was based on data from a symptom scale or a urinary diary. There were no data reported for the other outcomes of interest.

(c) PFMT/BT versus BT: No statistically significant difference was found in one early study [189] between combination versus single therapy in the number of women reporting they were much better or in the number of leakage episodes per day; however more in the combination group reported they were much better at six months post treatment. With regard to quality of life the combination therapy group had statistically significantly better scores on UDI and IIQ after treatment, but there was no statistically significant difference in either measure six months after treatment had begun. Approximately three years later, a similar number in each group had sought further treatment for UI (19 of 48 BT, 18 of 48 PFMT/BT). Of the women who had not sought further treatment, fewer were free of leakage episodes in the BT group (four of 22 in BT versus eight of 16 in the combination group). Adverse events are not mentioned.

(d) PFMT/drug versus drug: Ghoniem [2005] [125] reported that the combined treatment was not significantly different from the drug-only-treatment in terms of frequency of incontinence episodes, quality of life (IQOL) and Patient Global Impression of Improvement Scale. Ishiko (2000) [191] did not report data for any of the primary outcomes of interest; 10/13 in the drug group, and 17/19 in the combination therapy group had no leakage episodes per week post treatment, and some reported drug-related side effects sufficient enough to withdraw from treatment.

A higher proportion of women in the combined therapy group had a successful outcome, defined as at least 70% reduction in frequency of UI episodes [203]. The combined therapy group also had greater subjective improvement, greater patient satisfaction and greater reductions in symptom distress on validated questionnaires. In another study [202], the groups were so similar on an interim analysis and power calculation that recruitment was stopped early for futility. With the individualized, escalating dose titration and proactive management of side-effects, the drug alone group achieved an 88.5% reduction of incontinence episodes, leaving little room for added benefit.

3. Summary

There were few trials addressing the effect of adding PFMT to another therapy, and only five of the eight studies reported useful data. There appears to be no benefit of adding PFMT to VC or duloxetine respectively in women with SUI [107,125] (Level of Evidence: 2). There may be benefit to adding PFMT to BT for women with urodynamic SUI or SUI with DO in the short term (three months), but it is not clear if this benefit persists at six months or more [189] (Level of Evidence: 2). There is not sufficient evidence to be sure if there is any benefit in adding PFMT to ES. There is a single trial indicating added benefit of PFMT when drug therapy is administered with the usual intensity.

4. Recommendations

For women with SUI or MUI a combination of PFMT/BT may be better than BT alone in the short-term (Grade of Recommendation: C), and a combination of PFMT/drug may be better than drug alone. If a woman is taking duloxetine or using VC, it may not help to add PFMT (Grade of Recommendation: C). However, these recommendations are based on single trials of variable quality and larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. Further, these studies examine the effects of combining therapies as an initial approach. Less is known about the effects of combining therapies in a stepped fashion when women do not achieve the desired outcomes with a single therapy.

5. Other LUTS

Seven trials included above reported data for other LUTS, e.g. frequency, nocturia, bladder pain but no new trials were added to this section for the update.

The effect of a PFMT programme on frequency, nocturia and urgency in women with MUI improved self report of symptom bother both frequency and nocturia significantly more in the PFMT group, while urgency persisted [204].

Three trials investigating different type of PFMT programs reported whether women had nocturia [147,150,152,153]. There were few data and some missing, making it difficult to observe a difference between PFMT programs.

A secondary analysis looked at the effect of PFMT versus drug therapy on nocturia in older women with UUI or MUI [142]. The PFMT group reduced nocturia by a median of 0.5 episodes per night; this was significantly more effective than drug treatment.

One trial addressed PFMT versus EStim on urgency symptoms and nocturia in women with DO. There was a significant decrease in urge incontinence episodes in both groups, but no difference between groups. Further, there was a reduction in nocturia frequencies in the EStim group [188].

Finally, one new trial [202] studied the effect of drug therapy alone and combined with PFMT on urgency and 24-voiding frequency in women with urgency – predominant incontinence. Urgency decreased significantly although there was no difference between the two groups.
6. FACTORS AFFECTING OUTCOME

Apart from differences in effect attributed to PFMT or comparison interventions, other factors may affect outcomes. Of particular interest is the effect of older age; this and other factors are considered here.

a) Age

Firstly we looked for trials included above that specifically recruited older women; there were six. The average age of women in these trials was between 60 and 70 years [120,141,142,192], or over 70 years [186,190] compared with a mean age of 40 to 55 in most other included studies. It was not possible to compare the data from older women with data from younger women for the following comparisons: PFMT versus EStim [186], PFMT versus drug [142,192] and PFMT versus BT [190].

For three comparisons (PFMT versus no treatment [141], PFMT versus placebo/sham/control [120,142], BF assisted PFMT versus PFMT alone [141]), there were no clear differences in the size or direction of effect when the data from the trials in older women were compared with data from other trials. The recommendations arising from these comparisons appear to apply to older women. Namely, that PFMT should be offered, as first-line therapy, to all women with SUI, UUI, or MUI.

Secondly, the methods of included trials were checked for use of regression or other methods to investigate association between baseline characteristics (specifically age) and outcome. The literature search also located some papers that reported secondary analysis of data from the included trials. Papers that reported an association between age and outcome, but did not describe the methods of testing association are not discussed here.

Two reports detailed the testing of independent associations between patient characteristics (including age) and outcome [126,205]. In one data was used from PFMT groups in three RCTs [120,121,142]. The individual trials restricted entry to women 55 years and older [120,142] or 40 years and over [121]. In multivariate analysis, age was not a significant predictor of reduction in leakage episodes for PFMT women with SUI, UUI or MUI. In another trial, Hay Smith (2006) investigated the associations between leakage on paper towel test and patient characteristics using data from a trial that compared two approaches to PFMT for Women with SUI [126]. Older age was associated with more leakage in univariate models, but was not significant in multivariate analysis.

One further trial [189] used correlation methods, and one [206] categorised women as successes or failures, to investigate the association between age and outcome. In a secondary analysis [207] of the trial by Wyman [1998] there were no statistically significant correlations between age and reduction in leakage episodes or change in PFM activity after PFMT or BT in women with SUI, UUI or MUI. Bø (1992) characterised participants in the intensive PFMT group as treatment responders or non-responders. Treatment responders were statistically significantly older than borderline responders; there were no non-responders.

Considering the number of included trials, there were few that restricted entry to older women and/or investigated the association between age and treatment outcome. Only two studies have used the most appropriate methods to test independent associations. More research is needed to investigate the association between age and treatment outcome. Neither study using multivariate models found an association between age and outcome, nor was there a reported correlation in another. The two studies that categorised women as treatment successes or failures had conflicting results.

Summary

There is no good evidence to date to suggest that ‘healthy’ older women with UI do benefit less from PFMT compared to younger women.

b) Other

Aside from age, other factors have the potential to mediate treatment outcome, e.g. baseline UI severity, duration of symptoms and co-morbid conditions. All reports were checked for the methods used to address association between baseline characteristics and treatment outcome. Some appeared to be based on researcher observation; these data are not discussed here. Seven reports of interest were found [118,126,141,171,192,205-208]. A wide range of patient characteristics were considered in these papers; it is not clear whether it is more important to know which baseline characteristics might be predictors of outcome, or which ones might not. To eliminate long lists of non-significant associations, a pragmatic choice was made to report only significant associations although this creates a false impression of some consistent associations. None of the variables discussed here has demonstrated a consistent association with outcome, and all are worthy of further investigation.

Two reports addressed independent associations between patient characteristics and outcome [126,205]. Burgio (2003) used data from PFMT groups in three RCTs [120,121,142]. In multivariate analysis of data from PFMT women with UUI or urge predominant MUI, a 75% reduction in leakage episodes was more likely if women did not use protection (e.g. pads) prior to treatment. Continence (100% reduction in leakage episodes) was more likely if women had fewer incontinence episodes at baseline and had a lower educational level, but less likely if they had prior UI surgery. For PFMT women with SUI or stress predominant MUI a 75% reduction in leakage episodes was less likely if women had previously been evaluated for UI or had
more than 10 leakage episodes per week pre-treatment. Hay-Smith (2003) investigated the associations between patient characteristics and two outcomes (leakage on paper towel test, self-reported improvement) using data from a trial that compared two approaches to PFMT for Women with SUI. In multivariate models increasing parity was associated with less improvement in leakage symptoms and more risk of leakage on a paper towel test. Shorter symptom duration and higher body mass index were both associated with more improvement in symptoms. Leakage once or more per day was associated with greater risk of leakage on a paper towel test; the reverse was true for women with a history of constipation.

There was no statistically significant correlation between any of the baseline characteristics listed and the two outcomes (reduction in leakage episodes or change in PFM activity) in a secondary analysis [207].

Treatment responders had statistically significantly longer symptom duration, higher body mass index, stronger PFM, and were more motivated (clinician judgement) than borderline responders; there were no non-responders [206].

Two studies examined PFM characteristics as possible predictors of successful response to PFMT [118, 208]. Yoo [2011] reported on biofeedback assisted PFMT. In multivariable regression, the only factor predictive of successful treatment response was change in mean amplitude of tonic contraction after the 8th treatment session. Dumoulin [2010] studied PFM function variables measured by dynamometer in women with postpartum SUI. Treatment success (20-minute pad test volume < 2g) was associated with lower pre-treatment passive force and greater pre-treatment PFM endurance.

Few studies investigated the association between patient characteristics and treatment outcome and no consistent pattern emerged from the available data. Even fewer studies used appropriate methods. More research is needed to test for independent associations between patient characteristics and outcome. Given the few data available, and the methodological limitations of some papers, any patient characteristic described above that was associated with outcome should be considered as a possible rather than established prognostic factor.

**SUMMARY**

It is not clear if there are any reliable predictors of PFMT outcome. Too few trials have appropriately investigated the association between patient characteristics and outcome to be sure.

**III. WEIGHTED VAGINAL CONES (VCS)**

Weighted vaginal cones (VCs) were developed as a method for testing PFM function and to provide progressive muscular overload during PFM strengthening exercises [182,209]. In theory, when a cone is inserted into the vagina, the sensation of ‘losing the cone’ provides strong sensory feedback that prompts the PFMs to contract to prevent the cone from slipping out. Women start in a standing position with a weighted cone held inside the vagina for at least one minute, incrementally adding time and increased cone weight whilst standing or walking. The goal is to walk around for 20 minutes without losing the cone; the gradual increase in cone weight maintains muscle overload over the course of the exercise programme.

There are various cone weights and sizes (Figure 1). However, the effectiveness of the VC training method is unclear. Of note is that the PFM contraction is not the only reason the cone is retained and because orientation of the vagina is not completely vertical, some women can retain the cone without actually contracting the pelvic floor. Radiology has also demonstrated that the cones can rest in a transverse position [210,211]. Depending on the axis of the vagina, women need to produce different force intensities to retain the cone. Thus, using VCs as a measure of PFM function does not appear to be a valid method. Finally, some women may find it impossible to insert the cones due to a narrowed vaginal opening or, conversely, to retain it due to an enlarged vaginal opening, prolapse, or an insufficient PFM contraction, one incapable of holding even the lightest cone.

This section examines the evidence for VCs in the prevention and treatment of UI in women. Questions addressed:

- Are VCs better than no treatment, placebo or control for the prevention of UI?
- Are VCs better than no treatment, placebo or control for the treatment of UI?
- Are VCs as effective as other treatments for the treatment of UI?
- Are VCs combined with PFMT better than PFMT alone for the treatment of UI?

**1. PREVENTION**

No trials investigating either the primary or secondary prevention effects of training with VCs for women with UI were found. The literature search revealed two reviews on the prevention of UI [159,212]. Of these, only Hay-Smith (2002) considered VC prevention trials; however, none of the trials measured the effect on UI, only PFM activity. Because no continence-related outcomes were measured, these trials are not reviewed here. Further, the most recent Cochrane review of VCs did not address prevention [213], and our search did not reveal any new RCTs on VCs as a preventive treatment.
2. TREATMENT

The literature search revealed one systematic review that specifically addressed the effects of VCs in the treatment of UI in women [213]. One new trial [181], the review and three RCTs from ICI 2009 form the basis of this subsection [122, 140, 181, 183].

a) Are VCs better than no treatment, placebo or control treatments?

Four RCTs compared VCs with control treatments for women with UI [107, 122, 134, 140]. Details of the VC programmes for each trial are presented in Table 3.

1. QUALITY OF DATA

All four reported adequate allocation concealment, randomisation and blinding of outcome assessors. Dropout rates were 3% [122], 12% [134], 14% [140], and 40% [107]. In one, the VC group experienced more dropouts (42%) than the control group (22%) [107]. In another, participants in the VC group reported abdominal pain, vaginitis or bleeding and 14 reported problems with self-motivation and difficulty in using the cones [134]. Williams did not report any side effects for either treatment group other than the fact that 2.5% of the women in each of the trial arms reported urinary tract infections (UTI). Wilson [1998] and Castro [2008] did not report any side effects in either group.

2. RESULTS

Women in the VC groups were more likely to report they were cured than the controls (RR 1.98, 95% CI 1.21 to 3.23). The pooled data for self-reported improvement/cure from two trials [122, 134] showed statistically significant heterogeneity. Individually, one trial favoured the VC group [134] while the other favoured neither group [122]. VC participants scored better than the controls on the Leakage Index but showed no statistical differences on the Social Activity Index [134]. Further, Castro (2008) [140] reported better incontinence-related QOL in VC participants as compared to the controls on the IQoL questionnaire.

3. SUMMARY

The evidence from these four RCTs suggests that VCs are better than control treatments for subjective reporting of cure or cure/improvement and QoL impact in the treatment of SUI (Level of Evidence: 1). However, VC treatment may be inappropriate in some cases due to potential reported side effects.

4. RECOMMENDATIONS

For women with SUI, VCs with supervised training sessions by a trained health professional can be offered as a first-line conservative therapy to those who can and are prepared to use them (Grade of Recommendation: B); VCs may be inappropriate in some cases due to inability to insert or retain the cone or because of side effects and discomfort. Trained health professional assessment is recommended (Grade of Recommendation: D)

b) Are VCs as effective as other treatments?

VCs have been compared with PFMT and EStim, but not with other therapies such as drug treatment, BT or surgery.

(a) VCs versus PFMT

This comparison has been addressed in Section B2.3c. The details of the VC and PFMT programmes for each trial are presented in Table 4.

(b) VCs versus EStim

Five trials compared VCs with EStim [134, 140, 201, 214, 215]. The details of the VC and EStim programmes for each trial are presented in Table 5.

1. QUALITY OF DATA

(a) VCs versus PFMT: See Section B2.3c.

(b) VCs versus EStim

Among the five trials, two [134, 140] reported adequate randomisation, allocation concealment and blinding of outcome assessors; blinding was unclear in the other three [201, 214, 215]. Dropout rates were higher in the VC groups for [201, 214, 215] but higher in the EStim groups for three [134, 140, 201].

2. RESULTS

(a) VCs versus PFMT See Section BII4c.

(b) VCs versus EStim

There was no statistically significant difference between VCs and EStim in the pooled data between two trials [134, 140] in terms of self-reported cure nor in the pooled data [134, 215] for cure/improvement.

</tbody>
</table>

*Footnotes: VCs = vaginal cones, Estim = Electrical stimulation*
No differences were reported on the I-QoL questionnaire or in the number of leakage episodes on a 7-day bladder diary evaluation (mean and standard deviations: cones 1.5 ± 1.8 vs. EStim 2.3 ± 5.5) [140]. Ba [1999] also found no differences in daily leakage episodes on a 7-day bladder diary.

Discomfort or side effects between EStim and VC are reported to be similar [140,214]. One study described women who were unable to use the VCs because of vaginal size [215] and another reported tenderness and bleeding, discomfort or motivational and other difficulties in using the EStim [134]. In the VC group, one participant reported abdominal pain, two vaginitis and one bleeding; 14 reported motivational problems and difficulty using the cones.

3. SUMMARY

Overall, the pooled data for VCs and EStim demonstrated no statistically significant differences between the groups in terms of a self-reported cure, a cure/improvement, incontinence-specific QOL measures or the number of leakage episodes (Level of Evidence: 1). Additionally, both the VC and EStim groups reported adverse events.

4. RECOMMENDATIONS

VCs and EStim seem equally effective in the treatment of SUI and MUI, but the side effects and discomfort caused by the VCs and EStim limit their utility in clinical practice (Grade of Recommendation: B).

c) Are VCs combined with PFMT better than PFMT alone?

Two trials compared a combined PFMT/VCs to PFMT alone (107,216). Details of the PFMT/VCs and PFMT are presented in Table 6. None of the outcomes used in the two trials overlapped.

1. QUALITY OF DATA

Allocation concealment was clear in one and some outcomes had blinded assessors [107,216], but neither of these variables was clearly reported the other [216].

2. RESULTS

No statistically significant differences were detected for either cure or cure/improvement after 12 weeks in either study. Dropout rates in both trials were higher in the combined PFMT/VCs group.

3. SUMMARY

The limited available evidence suggested no benefit from adding VCs to PFMT for women with SUI (Level of Evidence: 2).

4. RECOMMENDATIONS

If this combined intervention proves to be of interest to women, then more research is needed to confirm or refute the advantages of adding VCs to PFMT.

3. OTHER LOWER URINARY TRACT SYMPTOMS (LUTS)

Two trials included in the VC section reported data on other LUTS: urgency and nocturia [122], nocturia [181]. In the Williams [2006] study, there were no differences between VC, control and PFMT group after intervention for urgency or nocturia. Gameiro [2010] however, noted a significant reduction in nocturia after treatment in both VC and PFMT groups, but no significant difference between groups.

4. FACTORS AFFECTING OUTCOME

None of the trials above addressed the effect of age or other factors on the outcome of VC training. Nonetheless, it is worth noting that in the 22 trials included in this section, on average, 24% of the women being treated with VCs (range 0 to 63%) withdrew or dropped out. Although few trials examined the causes of attrition, among those that reported causal factors low compliance, motivational problems, unpleasantness, aesthetic dislike, discomfort, and bleeding were indicated although no one reason predominated.

IV. ELECTRICAL STIMULATION (ESTIM)
