In their systematic review published in 1996, Black and Downs drew attention to the deficiencies of the literature available at the time (Black & Downs, 1996, Downs & Black, 1996) [2,3]. In particular they highlighted the difficulties posed by case definition and the uniformity of surgical technique both between and within surgical teams, the problem of variations in outcome measures used, the handling of confounding variables, the generalisability or external validity of the results, and the lack of statistical power in most studies. Most systematic reviews published since on the topic of surgery for incontinence in general or relating to individual surgical procedures have made similar comments regarding the quality of available evidence. Hence recommendations must be made not only on the amount of evidence available, but on the quality of that evidence. Several systems for grading the quality of studies have been proposed, including that initially presented by Black and Downs (Black & Downs, 1996, Downs & Black, 1996) [2,3], and that proposed by the GRADE group (Grading of Recommendations Assessment, Development and Evaluation) in their publications (Atkins et al., 2004a, Atkins et al., 2004b, Atkins et al., 2005) [4,5,6] and on their website, http://www.gradeworkinggroup.org. A recent series of articles in the BMJ explain the GRADE system in more detail (Guyatt et al., 2008a, Guyatt et al., 2008b, Guyatt et al., 2008c) [7,8,9].

The duration of follow-up is another factor affecting the validity of comparison between studies of efficacy and safety. In the first edition of this consultation, it was suggested that short term surgical follow-up should be considered as being up to 3 months, medium term from 3 to 12 months, and long term over 12 months (Mattiasson et al., 1999) [10]. There are occasions when case reports or short-term trial follow up and the early presentation of outcomes may be not only appropriate but also indeed mandatory. If serious unexpected adverse events come to light during early experience with procedures, colleagues and patients must be made aware. Where significant differences in efficacy or safety outcomes become apparent before the end of a study, it may be ethically unacceptable to continue randomisation. It is unlikely however that these factors are at play in the majority of studies of less than a year follow-up. In a recent review on long-term studies of pelvic floor dysfunction Hilton found that of 127 papers published in the last 25 years on
incontinence or pelvic organ prolapse (POP) which included the phrase ‘long term’ in their title or abstract, follow-up periods ranged from 1 to 14 years, with a mean of 59.5 months in those investigating surgical treatments (Hilton, 2008) [1]. Whilst highlighting some of the difficulties inherent both in undertaking and interpreting long-term studies, he argued for longer-term studies of high quality, and for a change in definition of ‘long-term’ to imply outcome at 5 years or more (Hilton, 2008) [1].

a) Search strategy

This section is based on electronic searches of Medline, EMBASE, CINHAL, the Cochrane database of systematic reviews, and the NICE website (www.nice.org.uk) references included in identified reviews were evaluated separately. Hand searching of recent (Jan-Apr 2008) issues of American, European and British journals in urology, gynaecology and urogynaecology was undertaken, to capture recent publications not yet included in the online databases. ICS, IUGA, AUA and AUGS conference proceedings for 2007 were also reviewed. It was assumed that trials presented earlier than this would be in press if they were of sufficient quality and maturity to justify inclusion; hence older abstracts have not been considered here. A total of 5331 references were identified; excluding duplicates, there were 3650 unique references. Of these 762 were of relevance to this review of non-tape procedures. Search terms used included the following:

URINARY INCONTINENCE; URINARY INCON- TINENCE, STRESS/; ((stress$ or mix$ or urg$ or urine$) adj3 incontinen$); SURGICAL PROCEDURES, OPERATIVE/; SURGICAL PROCEDURES, MINIMALLY INVASIVE/; UROGENITAL SURGICAL PROCEDURES/; GYNECOLOGIC SURGICAL PROCEDURES/; UROLOGIC SURGICAL PROCEDURES/; UROGENITAL SYSTEM/su [Surgery]; URINARY TRACT/su [Surgery]; URETHRA/su [Surgery]; VAGINA/su [Surgery]; BLADDER/su [Surgery]; LIGAMENTS/su [Surgery]; ((urethra$ or vagina$ or bladder$) adj surg$); (colposuspension$ or colpo suspension$) or vescicosuspension$ or urethrosuspension$ or urethrocystosica$ adj3 susp$; (urethrocystopexy$ or cystourethropexy$ or urethrocervicopexy$); (bladder$ adj3 buttress$); colpoplication$; burch$; (marshall$ or marchetti$ or krantz$ or mkm$); (paravagina$ or pubococcygeal$) adj3 repair$; (obturator$ adj3 shelf$); ((bladder$ or neck$ or needle$) adj3 susp$); ligament fixation$; (pereyra$ or stamey$ or raz$ or gitte$) adj3 (susp$ or procedure$); colporraph$; ((anterior$ or vagina$) adj3 repair$); (pacey$ or kelly$ or kennedy$); SURGICAL MESH/; (slings$ adj3 (procedure$ or operat$)); ((bladder$ or surgical$ or synthetic$ or biological$ or autologous$) adj3 (slings$ or tape$ or mesh$)); ((urethra$ or suburethra$ or midurethra$ or mid urethra$ or transurethra$ or trans urethra$ or transurethra$ or midurethra$ or midurethra$ or suprapubic$ or supratubular$ or suprapubic$ or pubovaginal$ or pubo- vaginal$ or transvaginal$ or intravaginal$ or lyodura$) adj3 (sling$ or mesh$ or implant$) bologna$; ingelman sundberg$; ‘PROSTHESSES AND IMPLANTS’/; INJECTIONS/; ((urethra$ or suburethra$ or midurethra$ or mid urethra$ or transurethra$ or periurethra$ or endourethra$ or endo urethra$) adj3 (inject$ or agent$ or bulk$)); injectable$; (injection$ adj3 ther$); (bulk$ adj3 agent$) contig$; COLLAGEN/; macroplastique$; exp SILICONES/; microparticulate$; HYALURONIC ACID/; hyaluronan ther$; act balloon$; CARBON$; carbon particle$ POLYTETRAFLUORETHYLENE/; BIOCOMPATIBLE MATERIALS/; URINARY SPHINCTER, ARTIFICIAL/; ((artificial$ or prosthete$) adj3 (urinary or genitourinary or urethra$ or bladder$) adj3 sphincter$); limit to humans; limit to female.

Relatively little high-level evidence has been published on the basis of new research since the last consultation; where available, level 1 and 2 evidence has been included in this update. Systematic reviews had already been published by the Cochrane Collaboration (Moehrer et al., 2000, Bezerra et al., 2001, Glazener & Cooper, 2001, Pickard et al., 2003, Glazener & Cooper, 2004) [11-15], and others have been developed or updated since (Bezerra et al., 2005, Lapitan et al., 2005, Dean et al., 2006a, Keegan et al., 2007) [16-19]. The National Institute for Health and Clinical Excellence (NICE) in England has published a clinical guideline on all aspects of urinary incontinence in women, including sections on surgical treatment (National Institute for Health & Clinical Excellence, 2006b, based on systematic reviews undertaken by the National Collaborating Centre for Women’s and Children’s Health (National Collaborating Centre for Women’s & Children’s Health, 2006). NICE has also published guidance on a number of individual procedures through its Interventional Procedures Programme (National Institute for Health & Clinical Excellence, 2003, 2005a, b, 2006a). http://www.nice.org.uk

b) Anterior colporrhaphy.

The term ‘anterior colporrhaphy’ tends to be used generically to describe procedures for both anterior vaginal wall prolapse and for SUI. When used to treat SUI, in addition to the reconstruction of the pubocervical fascia, it is conventional to use some form of plicating sutures to support and/or elevate the urethra and/or bladder neck. Many variations have been described often lending eponymous titles to the procedures e.g. Kelly, Kennedy, Pacey. The heterogeneity of procedures adds to the difficulties of evaluation of anterior colporrhaphy or vaginal repair procedures as a group. The place of anterior colporrhaphy in management of POP is covered elsewhere.

1194
Case series indicate a wide range of continence rates following anterior colporrhaphy, ranging between 31% and 100% (Jarvis, 1994) [20] [EL=3]. Accepting variation in the procedures undertaken, the duration of follow-up considered, and the outcomes reported, cohort studies that include anterior colporrhaphy consistently show it to be associated with lower cure rates than the comparators (usually colposuspension or Marshall-Marchetti-Krantz procedure (MMK)); cure rates reported from cohort studies are 21% to 70% (National Collaborating Centre for Women's & Children's Health, 2006) [EL=3]. Accepting variation in the procedures undertaken, the duration of follow-up considered, and the outcomes reported, cohort studies that include anterior colporrhaphy consistently show it to be associated with lower cure rates than the comparators (usually colposuspension or MMK); cure rates reported from cohort studies are 21% to 70% (National Collaborating Centre for Women's & Children's Health, 2006) [EL=3].

Several reviews of greater or lesser degrees of rigour have included anterior colporrhaphy; these include the previous editions of this chapter (Jarvis et al., 1999, Smith et al., 2002, Smith et al., 2005), and those of Jarvis (Jarvis, 1994) [20], Black (Black & Downs, 1996, Downs & Black, 1996) [2,3], the American Urological Association (Leach et al., 1997) [24], Cochrane (Glazener & Cooper, 2001) [13], and NICE (National Collaborating Centre for Women's & Children's Health, 2006, National Institute for Health & Clinical Excellence, 2006b).

Many randomised trials are presented (with published abstracts) or published (as full peer-reviewed papers) on several occasions, usually with increasing duration of follow-up. The 10 trials reported in the Cochrane review of anterior vaginal repair appear as 27 abstracts or papers (Glazener & Cooper, 2001) [13]. Two of these trials, despite being undertaken over 20 years ago, have not yet appeared as full papers (Quadri et al., 1985, Stanton et al., 1985b) [25,26]; the latter are therefore not included in the more recent NICE report.

Ten randomised trials are considered here (Table 1), comparing anterior colporrhaphy with pelvic floor muscle training (Klarskov et al., 1986) [27], colposuspension (Bergman et al., 1989a, Bergman et al., 1989b, Bergman & Elia, 1995, Berglund & Lalos, 1996, Liapis et al., 1996a, Liapis et al., 1996b, Berglund et al., 1997, Kammerer-Doak et al., 1999, Klutke et al., 1999, Colombo et al., 2000, Lalos et al., 2000) [28,30], needle suspension, (Bergman et al., 1989a, Bergman et al., 1989b, Bergman & Elia, 1995, Klutke et al., 1999, Di Palumbo, 2003) [28-30,37,39], MMK (Liapis et al., 1996b) or TVT (Meschia et al., 2004) [40] (some studies having 3 intervention arms).

Excluding cases that may have appeared in more than one report, 967 women were included in these studies, 346 undergoing anterior colporrhaphy. Cure rates of 31% to 88% are reported, with anterior colporrhaphy consistently showing what are both statistically and clinically poorer outcomes than surgical comparators [EL=1].

Few trials provide follow-up beyond 12 months, although mean follow-up is provided at periods between 1 and 14 years in different studies. Where serial outcome is provided the results indicate lack of longevity. Subjective outcomes fell from 80% at 1 year to 60% at 5-7 years in one study (Berglund & Lalos, 1996, Lalos et al., 2000) [31,38] [EL=2], and combined subjective and objective cures fell from 80% at 3 months to 63% at 1 year and 37% at 5 years in another (Bergman et al., 1989a, Bergman & Elia, 1995) [28,30] [EL=2].

The view of the first edition of this consultation was that the major indication for bladder buttress in contemporary practice must be the patient who prefers to sacrifice some chance of becoming continent for a reduced risk of complications (Jarvis et al., 1999) [21]. Subsequent editions found no new literature to justify a change to that view (Smith et al., 2002, Smith et al., 2005) [22,23].

The previously expressed view of the American Urological Association was that anterior repairs are the least likely of the four major operative categories (anterior repair, suburethral sling, colposuspension, long needle suspension) to be efficacious in the long-term (Leach et al., 1997) [240]. The Cochrane review of anterior vaginal repair, whilst finding insufficient data to allow comparison with physical therapies, needle suspension, suburethral slings or laparoscopic retropubic suspensions, felt that there was evidence to indicate that anterior vaginal repair was less effective than open abdominal retropubic suspension in the treatment of primary urodynamic stress incontinence (SUI). The beneficial effect of the abdominal approach...

</table>
appeared to be longer lasting, whether or not the women had associated prolapse, and there appeared to be a greater need for repeat surgery for incontinence after vaginal repair. Although there was a higher incidence of prolapse after abdominal operations, this did not require surgical correction more often. Since postoperative surgical morbidity, quality of life measures, and economic outcomes were poorly reported, the alternative treatments could not be compared in other ways. They concluded that the use of anterior vaginal repair in the treatment of urinary incontinence should be restricted to women deemed unsuitable for alternative treatments (Glazener & Cooper, 2001) [13] [EL=1]. Given the recent developments in less invasive surgical approaches to SUI, it seems unlikely that one could identify a group of women who are suitable for anterior colporrhaphy yet who would be deemed unsuitable for some more effective alternative. Although we were not able to identify studies directly comparing of anterior colporrhaphy with mid-urethral tape procedures in the treatment of overt stress urinary incontinence, one randomised trial compared anterior colporrhaphy (including endopelvic fascial plication) with tension-free vaginal tape (TVT) in 50 women with stage II anterior wall prolapse and ‘occult SUI’ (Meschia et al., 2004) [40]. They found both subjective (96% vs. 64%; p=0.01) and objective (92% vs. 56%; p=0.01) continence rates to be significantly higher following insertion of TVT, with no increase in post-operative voiding problems or irritative symptoms [EL=2]. The recent NICE guidance makes a high level recommendation that anterior colporrhaphy should not be used for the treatment SUI (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b) [EL=1]. We found no new high quality evidence published on anterior colporrhaphy since this latter review; indeed we found no new evidence of any level that considered the place of anterior colporrhaphy in the treatment of SUI incontinence in the absence of POP.

**Summary**

Anterior colporrhaphy is comparable in effectiveness to needle suspension, and less effective than open colposuspension in the treatment of SUI; its effectiveness deteriorates substantially with time [EL=2]. Although the evidence is less robust, it appears to be less effective than the minimally invasive mid-urethral tape procedure (TVT) in the management of ‘occult’ SUI [EL=2].

**Recommendation**

**Anterior colporrhaphy should not be used in the management of SUI alone. [Grade A]**

c) **Open colposuspension (Figure 2)**

The general reviews of incontinence surgery cited earlier all included open colposuspension of the Burch type (Burch, 1961, Burch, 1968) [41,42] amongst their considerations (Jarvis, 1994, Black & Downs, 1996, Downs & Black, 1996, Leach et al., 1997, Jarvis et al., 1999, Smith et al., 2002, Smith et al., 2005, National Collaborating Centre for Women’s & Children’s Health, 2006)[20,23, 24,21-23]; the Cochrane database includes a specific review of the procedure (Lapitan et al., 2005) [17]. The latter includes details of 39 trials 12 of which were available only as abstracts, although otherwise there was virtually complete overlap with the systematic reviews from which the NICE guidance was formulated (National Collaborating Centre for Women’s & Children’s Health, 2006). One of those studies previously only available in abstract form has recently been published (Carey et al., 2006) [43], and two others have further publications with health economic considerations or longer term follow-up (Dumville et al., 2006, Ward et al., 2008)[44,45].

There have been only two newly published randomised trials including colposuspension since previous systematic reviews (Albo et al., 2007, Sivasloglu et al., 2007)[46,47]. In total we examined 33 published randomised trials, seven trials comparing open colposuspension with the anterior colporrhaphy, (Bergman et al., 1989a, Bergman et al., 1989b, Bergman & Elia, 1995, Berglund & Laos, 1996, Liapis et al., 1996a, Liapis et al., 1996b, Berglund et al., 1997, Kammerer-Doak et al., 1999, Klutke et al., 1999, Colombo et al., 2000, Laos et al., 2000)[28,38], four with the MMK procedure (Colombo et al., 1994, Liapis et al., 1996b, Quadri et al., 1999, McCrery & Thompson, 2005) [48,33,49,50], six with needle suspension (two of which also had an anterior colporrhaphy arm) (Mundy, 1983, Bergman et al., 1989a, Bergman et al., 1989b, German et al., 1994,

![Figure 2: Open colposuspension illustrating sutures elevating para-urethral fascia towards Cooper's ligament](image)
Open colposuspension has been shown to be an effective surgical treatment for stress incontinence.

In common with other procedures there is some loss of efficacy with time.

Recommendations:

Open retropubic colposuspension can be recommended as an effective treatment for primary stress urinary incontinence, which has longevity. [Grade A]

Although open colposuspension has to a large extent been superseded by the less invasive mid-urethral tapes, it should still be considered for those women in whom an open abdominal procedure is required concurrently with surgery for SUI. [Grade D]

d) Marshall-Marchetti-Krantz (MMK) procedure

Only level 3 evidence relating to the MMK procedure was consider in the last edition of this consultation (Smith et al., 2005) [23]. Fifty eight papers, predominantly retrospective case series, published between 1951 and 1998 were reviewed, including 3238 patients. Cure rates were largely subjectively defined and averaged 88%. In many studies it was not possible to say whether procedures were carried out for primary or recurrent SUI; those that did specify gave success in 92% in primary procedures and 84% in recurrent cases (Smith et al., 2005) [23].

The MMK procedure itself has not been subject to formal Cochrane review, although two studies were identified where MMK was considered as a comparator in the review of open colposuspension (Colombo et al., 1994, Liapis et al., 1996a) [48,32], and one where the index procedure was of the MMK type rather than Burch type (Henriksson & Ulimsten, 1978) [84]. (Lapitan et al., 2005) [17]. The systematic review underlying the NICE guidance on urinary incontinence (National

Collaborating Centre for Women’s & Children’s Health, 2006) identified two further RCTs comparing MMK with open colposuspension (Quadri et al., 1999, McCrery & Thompson, 2005) [49,50]. We have not identified other level 1 or 2 evidence relating to MMK (see table 3). The Cochrane review found that whilst results at early follow-up were not significantly different, both subjective and objective cure were significantly better after the Burch procedure than after MMK at one to five years after surgery (RR 0.44; 95%CI 0.25 to 0.77) (Lapitan et al., 2005) [17] [EL=1]. One of the additional studies identified in the review underlying the NICE guidance showed significantly better subjective and objective results from MMK at 1 year (negative stress test 93% vs. 53%; p=0.02) (Quadri et al., 1999) [49] [EL=2]; the other showed significantly better subjective outcomes from colposuspension at a mean follow-up of 2 years (59% vs. 49%; p=0.02) (McCrery & Thompson, 2005) [50] [EL=2]; neither reported longer term outcome.

Other longer term follow up data are limited, and of poor quality. Six studies looking specifically at long-term outcome found cure rates averaging 58% at periods between 4 and 15 years (McDuffie et al., 1981, Colombo et al., 1998, Czaplicki et al., 1998, Luna et al., 1999, Hegarty et al., 2001, Demirci et al., 2002) [85-90]. Two studies showing trends over time in 204 and 81 patients respectively reported cure in 90% at year one, 86% and 57% at five years, and 72% and 28% at 10 years (McDuffie et al., 1981, Czaplicki et al., 1998) [85,87] [EL=3].

Summary:

Although short-term results indicate comparable cure rates to colposuspension, there is limited evidence that longer-term outcome is poorer following MMK [EL=1], and declines further over time [EL=3]. The previous edition of this consultation found no reason to support the continued use of MMK over colposuspension; there is no new evidence to indicate a change in this view.

Recommendation:

The MMK procedure is not recommended for the treatment of SUI. [Grade A]

e) Needle suspension procedures (Figure 3)

Several endoscopic and non-endoscopic bladder neck needle suspension procedures have been described since the original report of Pereyra (Pereyra, 1959) [91]; modifications include those described by Stamey (Stamey, 1973) [92], Gittes (Gittes & Loughlin, 1987) [93], and Raz (Raz et al., 1992) [94]. The procedures have been considered appropriate for either primary or recurrent SUI in particular where open retropubic suspension procedures were unsuitable, such as in frail or elderly women or where colposuspension may be technically difficult because of poor vaginal mobility.

Notes: patient numbers are given as –no. followed up or analysed /total no. recruited (analysed no. in index group: analysed no. in comparator group)
or capacity, from atrophic change, previous surgery, or radiotherapy.

The review by Jarvis was based largely on low level evidence, with only seven out of the 213 surgical studies reviewed being randomised. He identified data from 3553 women undergoing endoscopic or non-endoscopic bladder neck needle suspension with an average subjective cure rate of 79% and objective cure rate of 71% (Jarvis, 1994) [20] [EL=2].

The Cochrane review of needle suspension procedures (Glazener & Cooper, 2004) [15] and the systematic review underlying the NICE guideline on urinary incontinence (National Collaborating Centre for Women’s & Children’s Health, 2006) both included the same ten RCTs describing six different needle suspension procedures, 1983, (Palma et al., 1988, Bergman et al., 1989a, Bergman et al., 1989b, Hilton, 1989, Stein & Weinberg, 1991, German et al., 1994, Bergman & Elia, 1995, Athanassopoulos & Barbalias, 1996, Gilja et al., 1998, Klutke et al., 1999, Di Palumbo, 2003) [95,28,29,96,29,97,52,30,53,54,36,39]. We did not identify any more recent high level evidence relating to this group of procedures (see Table 4). No studies were identified comparing needle suspension with sham treatment or non-surgical treatments; one small study compared with a sling procedure, seven with colposuspension, and three with anterior repair; two others compared different needle suspension procedures or different sutures. The needle suspension procedures were found to be less effective than colposuspension based on subjective outcome within one year of surgery (RR for failure 1.70, 95% CI 1.11 to 2.60); and after the first year (29% vs. 16% failure; RR for failure 2.00, 95% CI 1.47 to 2.72); there were no clear differences between the procedures for any of the other outcome measures examined, although the confidence estimates around estimates were wide. The performance of needle suspension and anterior colporrhaphy appeared similar in terms of subjective cure rates after 12months (RR 0.86, 95%CI 0.64 to 1.16) and voiding dysfunction, whether the women had prolapse in addition to stress incontinence or not [EL=1].

Only low level evidence is available to judge long-term outcomes. Cure rates of 31%-68% have been reported at 4-5 years (Hilton & Mayne, 1991, Bergman & Elia, 1995, Reid & Parys, 2005) [98,30,99] and 20%-33% at 10 years (Trocmak et al., 1995, Mills et al., 1996) [100,101]. Unpublished results from the Leeds group showed 80% cures at 1 year (n=186), declining to 45% at 2 years, 18% at 4 years, and to only 6% at 10 years (n=17) (Jarvis et al., 1999) [21] [EL=3].

A later development of the needle suspension procedures, introduced in an attempt to improve the longevity of results, was the use of bone anchors for the suspensory sutures. Bone-anchored cystourethropexy has not been subject to RCT, although two versions, the ‘Vesica®’ and ‘In-Tac®’ procedures, have been reviewed by the NICE Interventional Procedures Programme (National Institute for Health & Clinical Excellence, 2003). They highlighted the poor long-term outcomes, and concluded that current evidence of the safety and efficacy of bone-anchored cystourethropexy is not adequate to support the use of this procedure in routine clinical practice [EL=2].

Although we found no new high level evidence regarding needle suspension procedures, there is continuing concern not only about long-term efficacy, but also about long-term complications which continue to emerge. These include suture migration into the urinary tract, and chronic infective complications from the implanted buffers and/or bone anchors (Goldberg et al., 2004, Gregorakis et al., 2006, Smith & Rovner, 2006) [102-104]; osteomyelitis of the pubic bones has been reported to occur in 1.3% in one series (Goldberg et al., 2004) [102] [EL=3].

**Summary:**

High level evidence indicates that needle suspension procedures are as effective as anterior colporrhaphy, but less effective than colposuspension even in the short-term [EL=1]. Long-term studies indicate lack of longevity even of the initial modest results; long-term complications remain a concern [EL=3].

**Recommendation:**

**Endoscopic and non-endoscopic bladder neck needle suspension procedures, with and without bone-anchors are not recommended for the treatment of SUI. [Grade A]**

**f) Paravaginal repair**

The paravaginal defect repair was first described by White in the early part of the 20th century, as a vaginal procedure (White, 1909, 1912) [105,106]. It has since

</table>
been described using either abdominal (Richardson et al., 1976) [107] or laparoscopic approaches (Richardson et al., 1997) [108]. There is little high level evidence on these procedures, and the available studies are often confounded by the use of combined procedures.

Only one RCT has been published which included abdominal paravaginal defect repair in a comparison with open colposuspension in women with SUI and grade 1 urethrocystocele (Colombo et al., 1996) [55]. Although this study was included in the Cochrane review of colposuspension, it was felt that this study was too small, and the data insufficient to draw conclusions. Thirty six women were recruited, and although no sample size calculation is included in the paper, recruitment was terminated when it was felt no longer ethical to randomise patients. The majority of women in both groups also underwent hysterectomy during the laparoscopic procedure (Scotti et al., 1996, Bruce et al., 1999) [109,110], 70% to 93% following the laparoscopic procedure (Ostrzenski, 1998, Miklos & Kohli, 2000) [111,112], and 43% to 89% following the vaginal procedure (Mallipedi et al., 2001, Clemons et al., 2003)[113,114]. Only one small series has been published more recently, indicating a cure rate of 93% for prolapse and 80% for SUI in 20 women treated by abdominal paravaginal repair alone compared to cures in 100% of 10 women treated by paravaginal plus incontinence surgery, at a mean follow-up period of 40 months [EL=3].

Several small case series with limited follow-up and largely subjectively defined outcome were reviewed in the last edition of this consultation. Cure rates of 80% to 94% were found following the abdominal procedure (Scotti et al., 1998, Bruce et al., 1999) [109,110], 70% to 93% following the laparoscopic procedure (Ostrzenski, 1998, Miklos & Kohli, 2000) [111,112], and 43% to 89% following the vaginal procedure (Mallipedi et al., 2001, Clemons et al., 2003)[113,114]. Only one small series has been published more recently, indicating a cure rate of 93% for prolapse and 80% for SUI in 20 women treated by abdominal paravaginal repair alone compared to cures in 100% of 10 women treated by paravaginal plus incontinence surgery, at a mean follow-up period of 40 months [EL=3].

Summary:

There is limited evidence that abdominal paravaginal defect repair is less effective than open colposuspension [EL=2].

Recommendation:

Paravaginal defect repair is not recommended for the treatment of SUI alone. [Grade A]

9) Laparoscopic colposuspension (Figure 4)

The Cochrane review of laparoscopic colposuspension has been updated since the last edition of this consultation; it now includes details of 22 RCTs that including laparoscopic colposuspension (Dean et al., 2006a) [18], 14 more than their initial review (Moehrer et al., 2000) [11]. Of these 22 trials, ten compared laparoscopic colposuspension with open colposuspension (Su et al., 1997, Burton, 1999, Summitt et al., 2000, Fathy et al., 2001, Morris et al., 2001, Cheon et al., 2003, Ankardal et al., 2004, Ankardal et al., 2005, Carey et al., 2006, Kitchener et al., 2006) [69,115,116,70,117,71,118,72,43,74], and eight with minimally invasive mid-urethral slings (Persson et al., 2002, Ustun et al., 2003, Maher et al., 2004, Paraiso et al., 2004, Valpas et al., 2004, Mirosh & Epp, 2005) [119-124]; the remainder examined different aspects of the laparoscopic technique (one vs. two sutures (Persson & Wolner-Hanssen, 2000) [125], sutures vs. Mesh (Ross, 1996, Zullo et al., 2001, Ankardal et al., 2005) [126,127,72] and transperitoneal vs. extraperitoneal approach to laparoscopy (Wallwiener et al., 1995 [128]). Seven compared laparoscopic colposuspension with Tension-free Vaginal Tape®, and these have been published separately (Dean et al., 2006b) [129]. Seven were only available as abstracts at the time of the systematic review underlying the NICE guidance on urinary incontinence, and hence were not considered in their report (National Collaborating Centre for Women’s & Children’s Health, 2006). Eight of the ten studies comparing laparoscopic colposuspension with open colposuspension were included along with eight retrospective cohort studies in a recently published meta-analysis (Tan et al., 2007) [130]. We identified two further RCTs on laparoscopic colposuspension (Piccione et al., 2001, Ustun et al., 2005) [131,73]; in addition one study previously only in abstract form has recently been published (Carey et al., 2006) [43], and two have further publications with longer-term follow-up (Jelovsek et al., 2008) [132] or cost-effectiveness data (Valpas et al., 2006) [133]. Details of the 15 published studies (22 papers) are given in table 5.

</table>
Studies included in the Cochrane review had different lengths of follow-up, although eight studies had follow-up in the region 6 to 18 months. In comparison with open colposuspension they found subjective cure rates to range from 58% to 96% in the open and 62% to 100% in the laparoscopic group within the 18 months follow up, with a non-significant 5% lower relative subjective cure rate for laparoscopic colposuspension (RR 0.95, 95% CI 0.90 to 1.00) (Dean et al., 2006a) [18] [EL=1]. The two studies with follow-up at five years or beyond unfortunately remain unpublished and available in abstract form only. Both these studies were relatively small, and their results are inconsistent, one finding better subjective outcome from the laparoscopic procedure (Morris et al., 2001) [117], and one favouring the open procedure (Burton, 1999) [117]; the methodology of this latter study in particular has been questioned [EL=2].

Overall, the objective cure rate as judged by cough stress testing or pad test within 18 months was statistically significantly lower following laparoscopic colposuspension (RR 0.91, 95% CI 0.86 to 0.96) [EL=1]. Between 18 months and five years there was no significant difference (RR 1.01, 95% CI 0.88 to 1.16); again however, there was heterogeneity with one small trial greatly favouring open procedure (Burton, 1999) [115] and the other favouring laparoscopic (Morris et al., 2001) [117] [EL=2]. When objective cure was judged by urodynamic investigations there was a significantly higher success rate following open colposuspension (RR 0.91, 95% CI 0.85 to 0.99).

Cost effectiveness was assessed in only one trial (Dumville et al., 2006, Kitchener et al., 2006) [44,74]. This study showed that whilst laparoscopic surgery produced greater quality adjusted life years (QALYs), there was an additional cost when compared to open surgery. The differential mean cost was GBC 372 (95% credibility interval [CrI]; 274–471), and at 6 months QALYs were slightly higher in the laparoscopic arm relative to the open arm (0.005; 95% CrI: −0.012 to 0.023). The cost of each additional QALY in the laparoscopic group or incremental cost-effectiveness ratio (ICER) was £74,400 at 6 months, but reduced to £9,300 by 24 months, in view of a further increase in QALYs, but no additional costs (assumed) (Dumville et al., 2006) [44] [EL=1]. Earlier studies have shown TVT™ to be dominant in cost effectiveness terms over both open (Manca et al., 2003) [134] and laparoscopic colposuspension (albeit using a mesh technique) (Valpas et al., 2006) [133] [EL=1].

In comparison with minimally invasive mid-urethral slings there was no statistically significant difference in subjective cure rates within 18 months (RR 0.91, 95% CI 0.80 to 1.02) [EL=1]. The definition of objective cure varied widely between studies, although overall the objective cure rate was higher for minimally invasive mid-urethral slings than laparoscopic colposuspension (RR 0.92, 95% CI 0.85 to 0.99) [EL=1].

Studies comparing different laparoscopic techniques found that two sutures either side of the bladder neck resulted in higher subjective (RR 1.37, 95% CI 1.14 to 1.64) and objective (RR 1.42, 95% CI 1.14 to 1.77) cure rate than one (Persson & Wolner-Hanssen, 2000) [125] [EL=2], and that sutures resulted in higher subjective (RR 1.28, 95% CI 1.11 to 1.47) and objective (RR 1.20, 95% CI 1.07 to 1.35) cure rate than mesh (Ross, 1996, Piccione et al., 2001, Zullo et al., 2001, Ankardal et al., 2005) [126,131,127,72] [EL=1].

The conclusion from the Cochrane review was that the currently available evidence suggests that laparoscopic colposuspension may be as effective as open colposuspension two years postoperatively (Dean et al., 2006a) [18]. The systematic review specific to laparoscopic colposuspension and TVT™ concluded that the evidence so far appears to favour the latter as the minimal-access technique of choice for USI (Dean et al., 2006b) [129]. In both cases however the authors indicated that the place of laparoscopic colposuspension in clinical practice could not be clearly defined without further long-term results.

It should also be noted that much of the published research in this area is from individuals with enthusiasm and skill in laparoscopic surgery; their results should not necessarily be seen as being generalisable to the urogynaecological/urological community at large. The NICE guidance includes amongst its recommendation that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI in women, but that the procedure should be performed only by an experienced laparoscopic surgeon working in a multidisciplinary team with expertise in the assessment and treatment of UI (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b); this same point is emphasised in the meta-analysis from Tan and colleagues (Tan et al., 2007) [130] [EL=4].

**Summary:**

Laparoscopic colposuspension shows comparable subjective outcome, but poorer objective outcome than both open colposuspension and TVT™ in the short to medium term; longer term outcomes are unknown [EL=2]. It may not be good value for money when compared with open colposuspension in the short term (i.e. first 6 months following surgery), but it could be a cost-effective alternative over 24 months [EL=1]; other comparisons however suggest that minimally invasive mid-urethral tape procedures may be dominant in health economic terms.
Urethral bulking agents have been used for the treatment of SUI in women for the past 3 decades. A variety of substances have been reported to be safe and effective in this context including bovine glutaraldehyde cross linked (GAX) bovine collagen (Contigen®), polytetrafluoroethylene (Teflon®), polydimethyl-siloxane elastomer (Macroplastique®), porcine dermal implant (Permacol®), carbon-coated zirconium beads (Durasphere®), non-animal stabilized hyaluronic acid/dextranomer NASHA/Dx (Zuidex®), calcium hydroxyapatite (CaHA; Coaptite®), ethylene vinyl alcohol (Uryx®; Tegress®) and autologous tissues such as fat, chondrocytes, and myoblasts. Each of these different agents has variable biophysical properties that influence tissue compatibility, tendency for migration, radiographic density, durability and safety. The ideal urethral bulking agent has not yet been identified.

Most urethral bulking agents are injected transurethrally or periurethrally, in a retrograde fashion under direct cystoscopic guidance although implantation devices have been developed which potentially obviate the need for this. There is no universally accepted injection route, technique, equipment or anaesthetic regimen. The optimal location for injection has not been defined and reported injection locations have included anywhere between the mid-urethra and the bladder neck. The optimal volume of material for injection during a single session, ideal site orientation for injection, or the optimal number of reinjection sessions for any given agent (until clinical “failure” has been determined) has not been defined. Long term success may not correlate with the endoscopic appearance at the conclusion of the injection session or certain preoperative urodynamic parameters.

The exact mechanism by which urethral bulking agents exert their effects on continence has not been defined although an obstructive effect or an improved hermetic effect has been suggested (Dmochowski & Appell, 2000) [135]. Although initially it was thought that urethral bulking agents would be most effective in patients with intrinsic sphincter deficiency (ISD) alone, subsequent reports have suggested clinical efficacy in patients with urethral hypermobility (Herschorn et al., 1996, Steele et al., 2000, Bent et al., 2001) [136,137,138].

The Cochrane review of periurethral injection therapy has been updated since the last edition of this consultation (Keegan et al., 2007) [19] and now includes 12 RCTs including bulking agents in at least one arm; this is five additional trials over the previous review (Pickard et al., 2003) [14], although five do not exist as full peer-reviewed publications and are available only as conference abstracts. One double blind study compared autologous fat with a placebo (Lee et al., 2001) [139]. Two studies compared injection with open surgery; one collagen therapy with bladder neck suspension, sling or Burch colposuspension (Corcos et al., 2005) [140], the other silicon particles with pubovaginal sling (Maher et al., 2005) [141]. Eight studies compared two different bulking agents; two compared GAX collagen with silicon particles (Macroplastique®) (Anders et al., 2002, Appell et al., 2005) [142,143]; two compared GAX collagen with carbon particles (Durasphere®) (Lightner et al., 2001, Andersen, 2002) [142,145] two compared with calcium hydroxyapatite (Coaptite®), coaptite with collagen (Dmochowski et al., 2002a, Appell et al., 2005) [146,143]; one study compared GAX collagen with ethylene vinyl alcohol (Uryx®) (Dmochowski et al., 2002b) [147]; a single study compared porcine dermal implant (Permacol®) with silicon injection (Macroplastique®) (Bano et al., 2005) [148] and one study compared periurethral and transurethral injection techniques (Schulz et al., 2004) [149]. We identified only one further RCT comparing calcium hydroxyapatite with bovine dermal collagen (Mayer et al., 2007) [150] (see table 6).

The Cochrane group felt the available trials were small, generally of only moderate quality, and the limited data available were not suitable for meta-analysis in view of the wide confidence intervals around all estimates.

The study comparing urethral bulking with a saline placebo (Lee et al., 2001) [139] found cure or improvement in 21% in both groups 3 months after the final injection (RR 0.98; 95% CI 0.75 to 1.29), with no significant change from baseline in UI score or in pad weight. One woman died from fat embolism (EL=1).

The two studies comparing urethral bulking with conventional surgery found significantly better objective outcome in the surgical groups, although not in subjective cures or patient satisfaction (Corcos et al., 2005, Maher et al., 2005) [140,141] [EL=2].

</tbody>
</table>
All results from studies comparing different agents had wide confidence intervals. Silicone particles (Anders et al., 2002, Ghoniem et al., 2005) [142, 151], calcium hydroxyapatite (Dmochowski et al., 2002a, Appell et al., 2005, Mayer et al., 2007) [146, 143, 150], ethylene vinyl alcohol (Dmochowski et al., 2002b) [147], and carbon spheres (Lightner et al., 2001, Andersen, 2002) [144, 145] gave improvements equivalent to collagen [EL=2]. Porcine dermal implant gave improvements comparable to silicone at six months (Bano et al., 2005) [148] [EL=2]. A comparison of periurethral and transurethral methods of delivery of the bulking agent found similar outcome but a higher rate of early complications in the periurethral group (Schulz et al., 2004) [149] [EL=1].

Many published case series exist in the literature describing each of the bulking agents mentioned here: 50 of these are reviewed in the systematic review forming the basis of the NICE guidance (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b). The methodological problems surrounding these are even greater than those of the RCTs described, and they provide little useful additional data to inform practice.

Several periurethral bulking agents have been associated with the formation of periurethral pseudocysts (Abdelwahab & Ghoniem 2007., Hartanto et al 2003., Sweat & Lightner 1999., Petrou et al 2006., Hagemeier et al 2006., Madjar et al 2006) [152, 153, 154, 155, 156, 157]. These collections may result in a variety of symptoms including pain, voiding dysfunction and urinary retention. Definitive treatment consists of transurethral resection, transvaginal needle aspiration or transvaginal resection.

Summary:
The evidence of benefit from urethral bulking agents is limited, and appears to be temporary. The only placebo controlled randomised study found similar symptomatic improvement with both placebo and autologous fat [EL=1]. Greater symptomatic improvement was observed after conventional surgery, although these advantages may need to be seen against likely higher risks [EL=2]. There is no evidence that any one bulking agent has advantage over any other [EL=2]. There are no available data comparing urethral bulking agents with non-surgical treatments or with other minimal access surgical techniques.

Recommendations:
If urethral bulking agents are to be used, women should be made aware that repeat injections are likely to be required to achieve efficacy, that efficacy diminishes with time, and is inferior to that of conventional surgical techniques; they should also be aware of alternative minimally invasive procedures. [Grade B] Newly developed

---

i) ‘Traditional’ sling procedures (Figure 5)
The term ‘traditional’ sling procedures is used here, in line with the terminology used in the latest Cochrane review, (Bezerra et al., 2005) [16] to distinguish open sling procedures more usually placed at the region of the bladder neck, from the newer minimal access mid-urethral tape procedures.

Sling procedures have been in use since the beginning of the twentieth century. Many variations in the technique have been described although it is unclear which of these materially influence the outcome. The majority of sling procedures have involved a combined abdomino-vaginal approach, although totally abdominal procedures are described. Suspended or ‘sling on a string’ methods have been developed in order to reduce the invasiveness of the procedure, and to shorten the length of sling material. As with needle suspension procedures, bone anchoring has been used as an alternative form of sling suspension.

Sling materials vary widely, and whilst perhaps having only limited effect on initial efficacy, may have considerable impact on the longevity of procedures,

Figure 5 : The Aldridge sling employing rectus sheath fascia
or the associated morbidity. Materials may be synthetic or biological; the latter include autograft (rectus fascia, fascia lata, round ligament, dermis, vaginal skin, and gracilis, levator, and rectus muscles), allograft (fascia, dermis and dura mater) and xenograft (porcine dermis and small intestinal mucosa, bovine fascia and pericardium). Both biological and synthetic sling materials are analysed together in the Cochrane review, although these were considered separately in the systematic review underlying the NICE guidance on urinary incontinence (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b). NICE has also published a non-systematic review of biological sling procedures under its Interventional Procedures Programme (National Institute for Health & Clinical Excellence, 2006a).

The Cochrane review included 13 RCTs describing a total of 760 women of whom 627 were treated with sub urethral slings; four of these are available only in abstract form and remain unpublished as full peer-reviewed papers. Five of the trials compared sub urethral slings with open abdominal retropubic suspension (Henriksson & Ulfsten, 1978, Enzelsberger et al., 1996, Sand et al., 2000, Demirci & Yucel, 2001, Fischer et al., 2001) [84,56-58,158], and one compared sub urethral slings with Stamey needle suspension (Hilton, 1989) [96]. In six trials, different types of sub urethral sling were compared with each other (Barbalias et al., 1997, Lucas et al., 2000, Shin et al., 2001, Arunkalaivanan & Barrington, 2003, Kondo et al., 2003, Viseshsindh et al., 2003) [159-164]. Nine different sling materials were included (Teflon, polytetrafluoroethylene, prolene, porcine dermis, lyophilised dura mater, fascia lata, vaginal wall, autologous dermis and rectus fascia). There were no comparisons of sub urethral sling with anterior repair, laparoscopic retropubic suspension, urethral bulking agents or artificial urinary sphincter. One trial compared surgery (including slings) with anticholinergic medication. The systematic review underlying the NICE guidance on urinary incontinence (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b) included three further RCTs comparing pubovaginal sling with TVT ((Lucas et al., 2004, Bai et al., 2005, Wadie et al., 2005) [165,60,166] and open colposuspension (Bai et al., 2005) [60], or other sling procedures (Lucas et al., 2004) [165]. We identified a further publication of longer-term outcomes from one of the included RCTs (Guerrero et al., 2007) [167] and one new study (Tennstedt & Urinary Incontinence Treatment Network, 2005, Albo et al., 2007, Mallett et al., 2008, Richter et al., 2008) [61,46,62,63]. Hence material from 15 RCTs is considered here (see table 7).

In comparison with open colposuspension the objective cure rate from sling operations was not significantly different within the first year (RR 0.19; 95% CI 0.02 to 1.53) or on longer follow-up (RR 0.49; 95%CI 0.17 to 1.42) [EL=1]. Other outcomes were not analysable in the Cochrane review. The most recent, and by far the largest and most rigorous RCT of colposuspension and fascial sling randomised 655 women of whom 520 were assessed at 24 months; this was not included in the Cochrane review. This showed significantly better combined subjective and objective outcome in terms of any incontinence 38% vs. 47% (p=0.01) and SUI 49% vs. 66% (p<0.001) from the sling procedure; adverse events in general (47% vs.63% (p<0.001) and voiding difficulty in particular (14% vs. 2%, p<0.001) were more common in sling group (Albo et al., 2007) [46] [EL=1].

Only one small trial is available to allow comparison between sling (porcine dermis) and needle suspension (Stamey) in a group of women unsuitable for abdominal colposuspension because of vaginal narrowing secondary to either previous interventions or atrophic change (Hilton, 1989) [96]. Although there were no differences in objective cure rates at 3 or 24 months, peri-operative complications (RR 4.50; 95% CI 1.28, 15.81) and length of hospital stay (RR 13.00; 95% CI 5.00, 21.00) favoured the needle suspension procedure [EL=2].

In the Cochrane review, trials comparing rectus fascia with other materials heavily weighted the comparison different types of sling (Bezerra et al., 2005) [16]. Failure rates were similar both in the short (RR 0.96; 95% CI 0.59, 1.55) and long-term (RR 0.69; 95% CI 0.41, 1.16).

1. Synthetic slings

A silicone sling material reinforced with woven polyethylene terephthalate (Dacron®) was described by Stanton and colleagues (Stanton et al., 1985a) [26]. No high level evidence relating to procedures utilising this material was identified; three case series reported outcomes in 124 women (Stanton et al., 1985a, Korda et al., 1989, Duckett & Constantine, 2000) [26,168,169]. The subjective cure rate was 79% at mean follow-up of 15 months in one series, and both subjective and objective cure rates were 83% at 3 months in another. Intra-operative complications were common, including haemorrhage requiring blood transfusion (6%) and vaginal, bladder or urethral perforation (7% each). The need for sling adjustment or removal because of sinus or fistula formation was found in all series, and sling removal was required in 5 out of 7 patients (71%) in one series (Duckett & Constantine, 2000) [169] [EL=3].

Three small controlled trials evaluated a polytetrafluoroethylene (PTFE – Gore-Tex®) sling in comparison to open colposuspension (Sand et al., 2000, Culligan et al., 2003) [57,59], rectus fascial sling (Barbalias et al., 1997) [159], and vaginal wall

</table>
sling (Choe et al., 2000) [170] (total n = 124). In a RCT against open colposuspension, although the groups were different at baseline in terms of the proportion with detrusor overactivity (DO), cure rates with PTFE were not significantly different from open colposuspension at 2.5 years (objective 100% vs. 85%; subjective 84% vs. 93%) (n = 36) (Sand et al., 2000, Culligan et al., 2003) [57, 59] [EL=2]. In a RCT against fascial sling the combined objective and subjective cure rates were 88% and 81%, respectively, at 6 months (Barbalias et al., 1997) [159]. A quasi-randomised comparison with vaginal wall sling gave no statistical analysis, but found combined subjective and objective cure in 95% vs. 75% at mean follow-up of 22 months (Choe et al., 2000) [170] [EL=2]. Again, the need for sling removal is common, reported in up to 31% (median 8%) in a review of case series within the systematic review underlying the NICE guidance on UI (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b) [EL=3].

Only low level evidence is available to evaluate slings made of polyester (Mersilene®). Four case series evaluated a Mersilene® sling with follow-up from a mean of 2 years to 5 years (Kersey, 1983, Kersey et al., 1988, Guner et al., 1994, Young et al., 2001) [171-174]. Subjective cure rates across the studies ranged from 50% to 96% (median 84%). The objective cure rate in 52 women followed-up at 5 years in one study was 94%, compared to 95% at 1 year (although this only represented a quarter of the women treated) (Young et al., 2001) [174] [EL=3].

2. BIOLOGICAL SLINGS

Nearly all RCTs of biological slings compare the autologous rectus fascial sling procedure with a range of other surgical interventions. RCTs evaluating dura mater and porcine dermal slings were also identified.

i) Rectus fascial sling

One RCT compared autologous rectus fascial sling with periurethral silicone injection in women with stress UI secondary to ISD in whom conservative treatment had failed. At 6 months, no significant differences were seen between groups in subjective cure or satisfaction, QOL (UDI-6, IIQ). Significantly more women undergoing sling surgery were objectively cured on the basis of urodynamic assessment (81% vs. 9%; p=0.0001), but duration of the procedure, catheterisation, inpatient stay, and time to return to normal activities were significantly longer. A survey of two-thirds of the women at 5 years found no statistically significant differences between groups in urinary symptoms or in satisfaction with surgery (n = 45),557 [EL=2].

Open continence surgery (a suspension procedure in 46% and fascial sling in 54%) was compared with periurethral collagen in women with stress or mixed UI in a further RCT. Again there were no significant differences in patient satisfaction or QOL (SF-36, IIQ) between groups at 1 year. Using intention-to-treat analysis there was no significant difference in continence rates at 1 year (52% collagen, 55% surgery); if only the 89% of women who underwent the randomised intervention were considered, the continence rate with surgery was significantly higher (72% vs. 53%; p=0.01). The incidence of adverse effects was significantly higher in the surgery group: urinary retention 13% versus 2%, transient voiding difficulty 36% versus 17%, UTI 6% versus 0% (n = 133) (Corcos et al., 2005) [140] [EL=2].

Three RCTs have compared autologous rectus fascial sling with TVT involving a total of 284 patients (Bai et al., 2002, Lucas et al., 2004, Wadie et al., 2005) [175,165,166]. Cure rates at 12 months (symptom-free +/- negative stress test in the different studies) were 83%, 87%, and 88% following TVT and 81%, 82% and 93% following rectus fascial sling; one of these trials also had a colposuspension arm, which had a 12 month cure rate of 88% (Bai et al., 2002) '175', and one a porcine dermis sling arm with a cure rate of only 53% (Lucas et al., 2004) [165] [EL=1/2]. One quasi RCT compared autologous rectus fascial sling with a self-fashioned polypropylene sling in 50 women, with similar findings (Kuo, 2001) [176] [EL=2].

One RCT compared rectus fascial and PTFE slings in women with stress UI, 92% of whom had had prior continence surgery. Combined objective and subjective cure rates were 81% and 88%, respectively, at 6 months. No complications were reported in the fascial sling group, whereas urethral erosion, recurrent UTI and de novo DO were very common with PTFE (n = 48) (Barbalias et al., 1997) [159] [EL = 1].

Rectus fascial and vaginal wall slings were compared in one RCT and two non-randomised retrospective studies (Kaplan et al., 1996, Visesshindhu et al., 2003, Rodrigues et al., 2004) [177,164,178]. All were considered to be of poor quality. The RCT reported high subjective cure, and satisfaction rates (80–100%), with median follow-up of 7 months (n = 26). (Viseshshindhu et al., 2003) [164] [EL=2]. The non-randomised studies reported similar ‘success’ rates with both interventions, ranging from 80% to 97%, with follow-up of 21 months, and 70 months versus 45 months (n = 232, n = 79) [EL=2].

One RCT compared two techniques of fascial sling in 168 women with urodynamic stress UI 89% of whom had had prior continence surgery. Women underwent a standard fascial sling procedure or a ‘sling on a string’ (a shorter sling mounted on each end with a nylon thread). At 1 year, subjective cure rates were 84% using both techniques. Satisfaction and changes in IIQ scores were also similar in both groups, whereas improvements in UDI scores were greater with the standard approach (adjusted for differences in baseline
et al. (Lucas et al., 2000) [160]. A further follow-up of women in this study was recently reported at 5 to 7 years (Guerrero et al., 2007) [167]. There were no significant differences in symptoms of SUI or UUI between groups, with 40%-53% vs. 36%-51% reporting SUI in sensitivity analysis [EL=1].

Case series of autologous rectus fascial sling were reviewed within the systematic review underlying the NICE guidance on urinary incontinence (National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence, 2006b). Ten series including a total of 1280 women were considered. Studies had a mean or median duration of follow-up between 2 and 6 years; in three studies, maximum follow-up of 15–18 years was reported. Subjective cure rates ranged from 26% to 97% (median 81%); and cure that included subjective and objective elements 73% to 95%. Satisfaction rates of 86% and 92% were reported in two studies.

**ii) Dura mater sling**

One RCT compared dura mater sling with open colposuspension in 72 women with SUI after hysterectomy. The combined objective and subjective cure rates were 92% versus 86%, at about 3 years. Significantly more women in the sling group had voiding difficulty or retention postoperatively, both of which were common, and more women developed rectocele in the colposuspension group. Bladder perforation and de novo urgency were common in both groups. Time to spontaneous voiding was significantly longer in the sling group (n = 72) (Enzelsberger et al., 1996) [56] [EL=1].

**iii) Porcine dermis sling**

One small RCT compared a porcine dermis sub urethral sling with the Stamey needle suspension procedure in 20 women with stress UI who were considered unsuitable for colposuspension. At 2 years, subjective cure rates were 90% versus 70%. Intraoperative blood loss and postoperative infection were significantly more common in the sling group. Other common complications in both groups were bladder injury and de novo DO (n = 20) (Hilton, 1989) [96] [EL=2].

One RCT comparing porcine dermis sling (Permacol®) with TVT™ found no significant differences operating time, hospital stay, complication rates, or subjective cure at 1 year (85% vs. 89%) (Arunkalaivanan & Barrington, 2003) [162] nor in cure (88% vs. 82%) or satisfaction at 3 years, assessed by mailed questionnaire (77% vs. 80%) (Abdel-Fattah et al., 2004) [179] [EL=1]. One can only speculate why this study found comparable results between Permacol® and TVT™, whereas the 3-arm trial cited above found such significantly poorer results from Permacol® to require the premature curtailment of recruitment (Lucas et al., 2004) [165].

**iv) Autograft vs. allograft vs. xenograft**

Seven non-randomised studies compared the outcomes of autologous and allograft slings in a total of 786 women with SUI; one also compared both interventions with a xenograft material (porcine dermis). All were retrospective reviews, each with differences in duration of follow-up for the interventions evaluated (between 3 months and 3 years), with drop-out rates of 4% to 34%; between 16% and 82% in different studies underwent other concomitant surgeries; all were considered to be of poor quality (Wright et al., 1998, Brown & Govier, 2000, Soergel et al., 2001, Flynn & Yap, 2002, O’Reilly & Govier, 2002, Almeida et al., 2004, McBride et al., 2005, Simsiman et al., 2005) [180-187] [EL=2].

Four of these studies compared autologous with allograft (cadaveric) fascia lata. Three of these studies reported similar results for all outcomes (subjective cure, satisfaction, and UDI-6, IIQ-7 and SEAPI scores) (Wright et al., 1998, Brown & Govier, 2000, McBride et al., 2005) [180,181,186]; the fourth study reported significantly higher cure rates in the autologous group (Almeida et al., 2004) [185] [EL=2].

In three studies that compared autologous rectus fascia or fascia lata with allograft fascia lata, two found a significantly higher cure rate in the autologous group(Soergel et al., 2001, Simsiman et al., 2005) [182,187]; the other found no significant differences in cure rate, although satisfaction rates were higher in the autologous group after 2 years follow-up(Flynn & Yap, 2002) [183]. In the study with a xenograft arm, cure rates were significantly higher with autograft material (Simsiman et al., 2005) [187] [EL=2].

**Summary:**

The conclusion of the Cochrane review was that data on sub-urethral sling operations remain too few to adequately address the effects of this type of surgical treatment. They highlight the fact that many studies fail to address appropriate outcome measures to address the broader effects of the surgery, such as general health status and health economics. They also emphasise that reliable evidence on which to judge whether or not sub-urethral slings are better or worse than other surgical or conservative management is currently not available.

Autologous rectus fascial sling is the most widely evaluated biological sling, which is an effective treatment for SUI and has longevity [EL=1]. Limited data suggest that pubovaginal sling using porcine dermis is also effective [EL=1], although data relating to other biological slings are few, and generally of poor quality. There is limited evidence that rectus fascial sling may be as effective as or more effective than open colposuspension, although adverse events and voiding difficulty in particular may be more common [EL=1]. There is no high level evidence of a
difference in efficacy between biological and synthetic sling materials, although adverse events may be more common following the use of synthetic materials for 'traditional' sling procedures [EL=3]. There is no high level evidence of a difference in efficacy between different biological sling materials, although those studies that find a difference all favour autologous materials [EL=2].

**Recommendations:**

Autologous fascial sling is recommended as an effective treatment for stress urinary incontinence, which has longevity. [Grade A]

Further high quality research is required to clarify the place of 'traditional' sling procedures in relation to other procedures, and to establish the optimum sling materials. [Grade D]

### 2. MID-URETHRAL TAPES

The Tension-free Vaginal Tape (TVT) procedure for treatment of female urinary stress incontinence was first introduced by Ulmsten et al. in 1996. The development of the TVT operation was an attempt to support the middle portion of the urethra instead of restoring anatomy and correct urethral hypermobility at the bladder neck.

The idea of supporting the "mid-urethra" derived from discoveries of several research projects conducted during the last thirty years. Zaccharin already in 1968 [581] and DeLancey in 1994 [582] showed that the pubourethral ligaments inserted at the mid-urethra and that the urogenital diaphragm also was more close to the middle portion of the urethra than the bladder neck.

Owman et al. 1978 found that the most densely innervated portion of the urethra was the middle part and Huisman in 1983 [583] in histological studies showed that the mid-urethra had the most abundant vascularisation.

When Westby et al. 1982 [584] in radiographic studies showed how the urine stream was interrupted at the mid-urethra on holding in continent women and Asmussen et al. 1983 [585] showed that the maximal urethral closure pressure was situated at the mid-urethra it became apparent that focus on the mid urethra might bring improvement in the performance of incontinence surgery.

Prospective observational cohort studies revealed that placing a macroporous, monofilament polypropylene tape at the mid urethra resulted in cure rates between 80-90 % in primary cases of stress incontinence (Ulmsten et al 1996, Ulmsten et al 1998, Nilsson 1998, Ulmsten et al 1999, Nilsson et al 2001) [188-192], in recurrent cases (Rezapour and Ulmsten 2001, Kuuva and Nilsson 2003) [193, 194], in mixed incontinence cases (Rezapour and Ulmsten 2001) [607] and in an unselected group of women including primary, recurrent and mixed incontinence as well as women with intrinsic sphincter deficiency (Nilsson and Kuuva 2001) [195]

a) RCT:s comparing TVT with traditional incontinence operations (Figure 6)

Only around 12 randomized clinical trials comparing TVT with traditional incontinence procedures have been published in peer reviewed journals. Five of these compare TVT with open colosuspension (Ward et al. 2002, Liapis et al. 2002, Wang et al 2003, Bai et al. 2005, El-Barky et al. 2005) [65,64,66,60,68], four compare TVT with laparoscopic colposuspension (Persson et al. 2000, Ustun et al. 2003, Parasol et al. 2004, Valpas et al. 2004) [119,120,122,123], two compare TVT with a fascial sling (Bai et al. 2005,Wadie et al. 2005) [60,166] and one compares TVT with no treatment (Campeau et al. 2007) [196]. These articles are listed in Table 1. A limitation to the conclusions that can be drawn from the results obtained in these studies is the fact that most of the trials include only 23 -50 patients in each arm with no mention of power calculations. The trials by Ward et al. 2002, 2004, 2008 [65,67,64] and Valpas et al. 2004 [123] enrolled a greater number of patients and included power calculations, but neither reached the required number of patients.

*Figure 6: The tension free vaginal tape (TVT)*
b) TVT vs Colposuspension

Four of the studies comparing TVT with open colposuspension used objective outcome measures for defining cure: 1 hour pad test (Ward et al. 2002, 2004, 2008, Liapis et al. 2002, Wang et al. 2003) [65,67,45,64,66], cystometry (Ward et al. 2002) [65] and a stress test (Ward et al. 2002, 2004, Bai et al. 2005) [65,67,60]. The study by El-Barky et al 2005 [68] only used subjective outcome measures. None of these studies found any statistical differences in objective cure rates between the two operations. The cure rate varied between 63 and 87 % in the TVT groups and between 51 and 90 % in the open colposuspension groups. The time period of follow-up was between 3 and 24 months in all five trials except the 5 years extension of the Ward et al. 2008 study. This five years report is, however, hampered by a 58 % lost to follow-up in the TVT group and a 67 % lost to follow-up in the colposuspension group. Subjective cure was mostly poorly defined and validated quality of life questionnaires was only used in the Ward et al. 2002 [65] study finding no difference in subjective cure between the TVT and the colposuspension groups.

Operation time, hospital stay and time for resuming normal activity was significantly shorter in the TVT groups (Ward et al. 2002, Liapis et al. 2002, El Barky et al. 2005) [65,64,68]. The percentage of intra-operative bladder perforations was significantly greater in the TVT group in than the colposuspension group, 9 % and 3 % respectively, in the Ward et al. 2002 study while El Barky et al. 2005 reported no perforations in the colposuspension group and two in the TVT group (< 0.05). Wound infections were more common in the colposuspension group (<0.05).

Significantly more patients experienced delayed voiding in the colposuspension group in the Ward et al. 2002 [65] study and in the 2 years follow-up report of the same study there were significantly more patients in the colposuspension group needing intermittent self catheterization (<0.0045) and surgery for pelvic organ prolapse (<0.0042) than in the TVT group.

c) TVT vs Fascial sling

The study by Bai et al. 2005 [60] actually compared TVT with both open colposuspension and a fascial sling and found that at 3 and 6 months follow up there was no difference in cure rate between the operations, but at 12 months the fascial sling operation had a significantly higher cure rate of 92.8% than the colposuspension and TVT operations, 87.8% and 87.0% respectively. No difference in cure rates was found between the TVT and the fascial sling operations in the study by Wadie et al.2005 [166]. In an interesting study by Campeau et al. 2007 [196] elderly women over the age of 70 years were randomized either to immediately receive TVT surgery or had to wait for 6 months for surgery. Follow-up at 6 months by different quality of life questionnaires revealed highly significantly (<0.0001) higher quality of life in the operated women, even though 22.6% experienced bladder perforation and 12.9% urinary retention as a result of the surgery.

d) TVT vs laparoscopic colposuspension

Laparoscopically performed colposuspension has been compared with the TVT operation in four randomized trials (Persson et al. 2000, Ustun et al. 2003, Paraiso et al. 2004, Valpas et al. 2004) [119,120,122,123] and with modified mid-urethra tape procedures as the transobturator route of tape placement (TOT) and tape placement retropubically by an abdominal approach (SPARC) in two trials: TOT by Sivaslioglu et al. 2007 and SPARC by Foote et al. 2006197.

In the studies comparing TVT, TOT or SPARC with laparoscopic colposuspension objective cure was assessed by a pad test in 2 of the six studies (Persson et al. 2000, Valpas et al. 2004) [119,123], by a stress test in four of the studies (Ustun et al. 2003, Paraiso et al. 2004, Valpas et al. 2004, Sivaslioglu et al. 2007) [120,122,123,47] while the criteria for cure or improvement was rather unclear in the study by Foote et al. 2006 [197]. The trial by Valpas et al. 2004 [123] with the greatest number of patients enrolled showed a significantly higher objective and subjective cure rate in the TVT group than in the laparoscopic colposuspension group (<0.0001), while the other studies showed similar cure rates for both procedures ranging between 72.9% and 96.8% in the TVT groups and between 58.8% and 87% in the laparoscopic colposuspension groups.

Although laparoscopically performed colposuspension is regarded as a less invasive operation than the open colposuspension the mid-urethra tape procedures had significantly shorter operating time (<0.001), hospital stay (<0.001) and time for resuming normal activity (<0.01 -0.001) than the laparoscopic colposuspension.

e) Metanalyses of TVT vs other procedures

Novara et al. 2007 [586] published a meta-analysis of randomized controlled trials comparing Tension-free mid-urethral slings with other surgical procedures for treatment of stress incontinence. They concluded by meta-analysis that the TVT procedure outperformed the Burch colposuspension and that the efficacy of the TVT was similar to pubo-vaginal slings. A review by Dean et al. 2006 [18] including seven randomized trials comparing laparoscopic colposuspension with TVT found an overall objective cure rate within 18 months of follow-up to be significantly higher in the TVT group.
f) RCTs comparing TVT with modifications of the retropubic tape placement

The favorable results obtained with the TVT operation have resulted in several modifications of the procedure and the use of different tape materials. These retropubic modifications have been poorly clinically evaluated and only seven randomized studies comparing these with the TVT have been published. Three trials compare the TVT with the Supra Pubic Arc Sling (SPARC) which utilizes a polypropylene tape material, but differs from the TVT by approaching the mid-urethra from an abdominal incision (Tseng et al 2004, Adonian et al. 2005, Lord et al. 2006). [198,199,200] The study by Lord et al. including 147 TVT and 160 SPARC cases showed a significantly higher subjective cure rate in the TVT group. They also found that the SPARC procedure was significantly more often associated with tape erosion and was more difficult to adjust with the need of tape loosening in the operating theater than the TVT procedure (<0.002). Tseng et al.[198] reported a 12.9 % of bladder perforation in the SPARC group with none in the TVT group. The difference was not statistically significant in this small study with only 31 patients in each group, but the authors stated it to be clinically significant.

One study compares TVT with an allogenic graft material made from acellular porcine collagen, the Pelvicol. Arunkalaivanan et al.[162] report on the results in two articles, the 12 months results in 2002 and the 36 months results in 2004. Outcome was assessed in both reports by a postal questionnaire and found no difference in subjective cure rate between the groups of 68 TVT operations and 74 Pelvicol operations.

Three trials compare TVT with the Intra Vaginal Sling (IVS) procedure, which utilizes a multifilament, miniporous polypropylene tape material (Rechberger et al. 2003, Lim et al. 2005, Meschia et al. 2006) [201-203]. In the study by Meschia et al. including 95 patients in each group the objective cure rate was 85% for the TVT and 72% for the IVS and the subjective cure rate was 87% and 78% respectively, with no difference between groups. There was a 9% erosion rate during the 2 years of follow-up in the IVS group, with none in the TVT group. Rechberger et al found no difference between the groups in their 13 months follow-up of 50 patients per group. Lim et al. [77] compared TVT with both IVS and SPARC, with 65 patients in each group. The subjective cure rates between 6 and 12 months of follow-up were 87.9% in the TVT group, 81.5% in the IVS group and 72.4% in the SPARC group, the differences not being significant. They found a significantly greater rate of tape protrusion in the SPARC group compared to both TVT and IVS (<0.04). Most concerning is the report by Balakrishnan et al. 2007 [587] in which they followed the subgroup of IVS patients of the Lim et al [202]. study for up to 30 months and found that 13% had sling erosions requiring sling removal and that of the 29 patients (47%) of the initial IVS group who were seen 12 to 34 months post-operatively 24% experienced sling erosion with sinus formation and requiring sling removal.

The meta-analysis by Novara et al. 2007 [586] concludes that the TVT is more effective than both the IVS and the Sparc.

g) RCT:s comparing TVT with transobturator tape placement (Figure 7)

The retropubic placement of the mid-urethra tapes has been associated with the risk of bladder injury, the rates varying between 0.8% and 21 % in different reports (Wang 2004, Andonian et al. 2005) [204,199]. Two systematic registries on the rates of complications associated with the TVT operation have been published, one from Finland including the first 1455 operations performed nation-wide and one from Austria including 2795 operations (Kuuva and Nilsson 2002, Tamussino et al. 2001) [205,206].

The rates of bladder perforation were 3.8% and 2.7% respectively. To avoid bladder injuries Delorme in 2001 [588] introduced a modified tape procedure in which the tape was brought to support the mid-urethra from inside the thighs through the obturator foramen on both sides, the so called outside-in transobturator tape procedure (TOT). De Leval in 2003 [589] further modified the procedure to be an inside-out procedure called the Tension-free Vaginal Tape-Obturator (TVT-O).

The original retropubic TVT has been compared with the inside-out TVT-O in six randomized trials (Zullo et al. 2007, Meschia et al.2006, Liapis et al. 2006, et al. Laurikainen et al 2007, Araco et al. 2008, Rinne et al. 2008) [207,203,208,209,210], and with the outside-in TOT in two trials (Andonian et al. 2007, Porena et al. 2007) [212,213] Wang et al. 2006 [590] compared the TOT with SPARC and found no difference in cure rate or rates of complications between the group of 31 TOT patients and 29 SPARC patients.
Five of the studies comparing TVT with TVT-O included power calculations either for detection of differences in cure rates and complication rates (Meschia et al. 2006, Laurikainen et al. 2007, Rinne et al. 2008) [203,209,211], or only for detection of differences in complications (Zullo et al. 2007) [207]. The study by Liapis et al [208] reported no power calculations. No differences in the overall objective or subjective cure rates were seen between the TVT and the TVT-O procedures during follow-up periods of 6 to 12 months. The only statistically significant difference in objective cure rate was seen in the Araco et al. [210] report where a stratification between mild and severe stress incontinence had been made. They found a significantly higher cure rate in the TVT patients with severe stress incontinence than in the TVT-O patients with the same condition: 100% versus 66% cure respectively (<0.001).

Somewhat contradictory results concerning complications arise from the trials. The reports by Meschia et al.[203] and Laurikainen et al., [209] including 3-4 times more patients than the reports by Zullo et al. [207] and Liapis et al. [208] show either no differences in the overall number of complications or a significantly higher rate of overall complications in the TVT-O group (Laurikainen et al.). It is not clear from the Zullo et al. study, which showed a higher complication rate for the TVT, how the overall complication rate was calculated.

The two trials comparing TVT with TOT (Porena et al. 2007, Andonian et al.2007) [213,212] found no difference in cure rates between the procedures. There were no differences in complication rates between the procedures in the Porena et al. report, while Andonian et al. reported significantly greater rates of complications in the TOT than in the TVT group.

Two trials have compared the inside-out procedure (TVT-O) with the outside-in procedure (TOT). But and Faganelj 2007 [591] included 60 patients in each group and found no difference in subjective cure rate between the procedures at 4 months follow-up, 90.7% for the TVT-O and 88.7% for the TOT respectively. Lee et al. 2008 [592] concludes that in their underpowered study no differences in objective or subjective cure rate was seen and no differences in complication rates.

h) Metanalyses
The meta-analysis by Novara et al 2007 [586] found overlapping cure rates with the retropubic and transobturator procedures. A meta-analysis by Latthe et al. 2007 [593] also arrived at equal cure rates for both the retropubic and transobturator route of mid-urethra tape placement the follow-up period though being only 2-12 months. There seems to be no difference in complications between the TVT procedure and the transobturator procedures.

CONCLUSION
There is evidence that the retropubic TVT is more effective than the Burch colposuspension and equally effective as traditional fascial sling operations (Level 1/2).

Operation time, hospital stay and time to resume normal daily activity is shorter with the TVT than with colposuspension. Post-operative voiding problems and need for urogenital prolapse surgery are more commonly associated with colposuspension, while bladder perforation is more commonly associated with TVT (Level 1/2).

TVT is more effective than the IVS and the SPARC procedure (Level 1/2).

Retropubic and transobturator placement of monofilament tapes at the mid-urethra perform equally at a short term follow-up of 6 to 12 months and overall complication rates are comparable (Level 1/2) (Table 7 a).

II. CONFOUNDING VARIABLES

1. AGE
Although there is extensive historical reporting of efficacy and low morbidity associated with various sling technologies, the affect of age on outcomes is relatively undefined. The affect of aging on the lower urinary tract includes a higher rate of detrusor overactivity, as well as, urge incontinence and intrinsic sphincteric deficiency. In addition, older patients are more likely to have had prior interventions, and may, therefore, may have a higher rate of peri-urethral fibrosis and/or other abnormalities in the area tissues surrounding the lower urinary tract. The presence of multiple co-morbidities may also affect overall surgical outcome, including creating the possibility for increased complication and prolonged post-operative course. Variable rates of success have been reported by numerous authors [214,215,216].

When evaluating mid-urethral slings in older women, the definition of age is controversial. The most extensive study of older patients is that of Gordon [217], who evaluated 460 consecutive women undergoing transvaginal tape (TVT). By characterization of age (greater than 70 years), 157 (34%) were considered to be elderly. These patients underwent pre-operative and three-month post-operative urodynamic outcomes, as well as symptom appraisal. All patients were followed for at least twelve months, with a mean follow-up of 26 months. In the older age population, there was a greater prevalence of mixed incontinence (31%), when compared to the younger patients (23%). In addition, concomitant pelvic organ prolapse surgery was undertaken in a greater percentage of the older patients (84%), when

</table>
Intra-operatively, the rates of blood loss between older and younger patients were similar, although there were fewer bladder perforations encountered in the elderly patients. Post-operative complications such as wound infection and urinary tract infection were similar between the two groups but older patients experienced age-related problems at a greater rate, including pulmonary embolism (two), DVS thrombosis (one), pneumonia (one), and cardiac arrhythmia (two). There was no increased risk of device erosion or extrusion in the older patients. There was also no significant difference between the two groups in post-operative voiding dysfunction although one patient in the older group did require urethrolysis. Failure to cure SUI was not encountered to any greater extent in the older population and rates of post-operative urge incontinence were also similar. A higher rate of de novo urge incontinence was encountered in the older patients (18% versus 4%). Small studies have documented the higher rates of de novo urgency in older patients [218].

In one study the authors analyzed the potential influence of urethral hypermobility (as defined as Qtip test < 30 degrees) [219]. Of those patients with no hypermobility, 71% were cured, compared with 62% of patients with hypermobility. They identified a similar post-operative outcome, but with a somewhat extended post-operative outcome, as compared to the younger population. Considering the overall impact of voiding dysfunction and other complications in overall quality of life, Walsh, using King's Health Questionnaire, noted that younger patients (defined as less than 70 years) experienced a greater improvement following stress incontinence surgery than older patients (defined as 70 years and older) [219]. In addition, older patients had a higher rate of pre-operative detrusor overactivity than younger patients (24% versus 8%), and also had a higher rate of post-operative voiding dysfunction (as defined by a positive Q-tip test) [219].

2. RACE

There are clear differences in the prevalence of SUI among racial groups (Dooley, Kenton et al. 2008) [594], (Anger, Saigal et al. 2006) [221] however whether these differences have implications in the treatment of SUI, especially the surgical treatment of SUI, is unclear. Racial disparities in the US may exist among patients undergoing surgery for SUI. In one study in US women over the age of 65, Caucasians and Hispanics were more likely to be diagnosed with SUI and undergo sling surgery for the condition as compared to non-whites (Anger, Rodriguez et al. 2007) [232]. One other study suggested that US Caucasians are 5x more likely to undergo SUI surgery than blacks (Waetjen, Subak et al. 2003) [223]. However, non-whites are approximately twice as likely to suffer complications as a result of the surgery (Waetjen, Subak et al. 2003) [223] (Anger, Rodriguez et al. 2007) [222]. Whether this is due to actual racial differences or other factors such as disparities in health care services is unclear. Race does not appear to be related to symptom severity or bother in those undergoing SUI surgery (Kraus, Markland et al. 2007) [224] and does not appear to be independently associated with quality of life outcomes (Ragins, Shan et al. 2008) [595] or surgical outcomes (Daneshgari, Moore et al. 2006) [226].

There is little data on whether a particular surgical approach is more effective or is associated with more morbidity in any given racial group as compared to another. The small amount of underpowered data available suggests that race does not independently predict for failure following SUI surgery (Richter, Diokno et al. 2008) [63].

3. OBESITY

There are no prospective randomized studies that have examined obesity as an independent variable across different anti-incontinence surgical procedures or within the same procedure. Obesity has been studied only retrospectively in case series as a risk factor for success or morbidity in stress incontinence surgery (Level 4 evidence).

There are no prospective, randomized trials that suggest superiority of one surgical technique over another in the obese population. Recent studies have focussed on complication rates and outcomes from mid-urethral tapes; the analysis of the influence of obesity is therefore divided into mid-urethral tapes and other surgeries.

a). Other surgeries

Several studies have suggested increased failure rates among obese patients undergoing needle bladder neck suspensions (O’Sullivan DC et al 1995) [227], (Lo TS et al 2003) [228], (Varner RE et al 1990) [596] or retropubic suspensions (Alcalay M et al 1995) [82], (Brieger G & Korda A 1992) [230] (Kjolhede 2005) [231]. In contrast a retrospective study of anti-incontinence surgery in 198 women demonstrated that overall continence did not correlate with obesity in patients undergoing anterior colporrhaphy, anterior colporrhaphy with needle bladder neck suspension or Burch colposuspension although cure rates were markedly better in those in the Burch colposuspension cohort overall (Zivkovic F et al 1999) [597]. One small case series suggested that fascial slings are effective in the morbidly obese patient (Cummings JM et al 1998) [233]. In this study, 2/4 patients failed bladder neck suspension surgery whereas there were no failures in the 12 patients undergoing fascial slings.

b). Mid-urethral tapes

1. COMPLICATIONS OF SURGERY

A review of the influence of obesity on pelvic floor disorders (Jerod Greer W et al 2008) [234] identified seven studies which compared the complications of tension free vaginal tape (TVT) surgeries between 251 obese and 700 non-obese patients. Bladder injury was the only complication reported consistently enough for metaanalysis in six of the studies. The overall perforation rates were 1.2% in the obese group and 6.6% in the non-obese group (p=0.015 ; OR 0.277, 95% confidence interval 0.098-0.782). Only one of the studies demonstrated a difference in TVT complications (Skriapas et al 2006) [235]. A higher risk of immediate post-operative complications was reported in morbidly obese women (BMI>40) compared to non-obese women (BMI<30) : 48.4% in the morbidly obese compared to 38.5% in the non-obese. Complications observed in the morbidly obese but not in the non-obese included minor wound haematoma (n=2), deep vein thrombosis (n=2), pneumonia (n=1) and cardiac arrhythmia (n=1) whilst there was no differences in blood loss, operating time, hospital stay or length of time catheterised post-operatively. Jerod Greer W et al also noted that although TVT surgery on the obese patient is perceived to be more difficult by surgeons there is no evidence from a review of seven additional TVT studies that complications such as blood loss and visceral injuries is higher in obese patients. Even when a significantly longer operating time was reported this was not associated with a higher complication rate (Rogers R et al 2006) [236].

2. EFFICACY

Although several studies comparing outcome from TVT in obese and non-obese women report similar efficacy Jerod Greer et al 2008 found that metanalysis of seven studies which included 453 obese and 1,186 non-obese women revealed a significant difference in cure rates (81% vs 85% =<0.001 ; OR 0.576, 95% confidence interval 0.426-0.779). Most of these studies are limited by their length of follow up (6-24 months).
Longer term follow up might be expected to reveal a progressive increase in the difference in cure rate between the obese and non-obese. Furthermore, Hellberg et al 2007 [598] reported that the failure rate appears to rise more when the BMI is >35 compared to >30.

There are no studies, prospective or retrospective, that have suggested obesity has a positive or favourable influence on outcome in stress incontinence surgery.

4. PSYCHIATRIC ILLNESS

Despite the obvious association between psychological or personality factors and satisfaction with treatment, minimal research has been done on the influence of such factors on subjective or objective surgical success. Black et al. found women undergoing stress incontinence surgery in the United Kingdom to be demographically similar to the general population, although mental health status was not specifically compared (Black NA et al 1996) [237]. Baseline symptom impact correlated positively with mental health, symptom severity, poorer socioeconomic status, and youth.

In a study of 45 women who underwent retropubic cystourethropexy or pubococcygeal repair, baseline lower neuroticism correlated with subjective and pad test cure at one year (Berglund A et al 1997) [34]. Higher extraversion correlated with subjective but not objective cure. Depression decreased in women objectively cured, but not those improved/failed; the decrease in depression in those subjectively cured did not reach statistical significance. Baseline somatic anxiety, psychic anxiety, and psychasthenia (obsessive-compulsive) characteristics were higher in women subjectively failed/improved than those cured or than a reference group. The multiple comparisons and small sample size in this study make some chance associations likely. The same subjects analyzed in a different study showed the cured group to have a higher baseline degree of social integration than the improved group (Berglund A et al 1996) [31]. No differences were found in baseline or follow-up intimate relationship measures.

Öbrink et al. detected above-average levels of neuroticism and depression in women who reported failure of their continence surgery without objective urine loss at 10 to 20 year follow-up (Öbrink A et al 1979) [238]. Below-average levels were found in women with objective but not subjective failure. In 63 women who underwent a Burch procedure, symptomatic improvement was associated with fewer sleep disturbances and less tension (Rosenzweig BA et al 1991) [240]. Subjectively persistent incontinence was associated with more depression and sleep disturbance.

There is Level 3 evidence that psychological factors impact on subjective and objective surgical outcomes in different ways. No data inform psychological interventions to improve the outcome of persistent incontinence or its impact.

5. ACTIVITY

There is no evidence on the influence of post-operative activity on the cure rate or risk of recurrence of stress incontinence after surgery.

6. PREVIOUS CONTINENCE SURGERY

As indicated in the review of procedures above, cure rates following surgery for SUI vary between 20% and 100%; for many procedures, whilst initial results may be good, long-term outcomes indicate variable recurrence rates. The mechanisms underlying initial failure and later recurrence may be quite different, although it would be counter-intuitive if prior surgery were not a significant confounding factor in the outcome of second-line treatment for SUI. The majority of studies reporting on surgery for SUI are however limited to primary cases; many others do not specify whether cases were primary or recurrent, or are inadequately powered to undertake subgroup analysis in this respect. In the review published by Jarvis less than half the reported patients were specified as primary or recurrent (Jarvis, 1994) [20]. Jarvis was however able to extract some useful data on the outcome of surgery recurrent SUI, and found that the objective results for traditional sling (mean 86.1%; 95% CI 82.4-89.8%), colposuspension (mean 82.5%; 95% CI 76.3-88.7%) and endoscopic needle suspension procedures (mean 86.4%; 95% CI 72.4-100%) were better than other procedures, with sling having the narrowest confidence intervals (Jarvis, 1994) [20].

The previous consultation suggested that women should be advised that other procedures for recurrent stress incontinence have been shown to have a lower success rate than the same procedures used in primary SUI (although it was also pointed out that preliminary data on the TVT procedure suggested similar cure rates in both primary and recurrent cases) (Smith, et al., 2005) [23]. Amaye-Obu & Drutz undertook a retrospective review of 118/198 women treated for recurrent SUI over a 12 year period. Overall, they found similar subjective and objective cure rates for the various procedures examined, but found the cure rate following colposuspension was lower in women with more than one previous unsuccessful procedure, whereas the results following slings were maintained in women who had undergone 2 previous failed operations (colposuspension 81%, 25% and 0%, sling 77%, 73% and 38%, for 1, 2, and 3 previous unsuccessful procedures respectively) (Amaye-Obu & Drutz, 1999) [241] [EL=3]. It should be noted that the number of patents with >2 previous procedures in this series was very small.
a) Open colposuspension for recurrent SUI

Case series reporting the outcome of colposuspension for the treatment of recurrent SUI after previous surgical treatment have shown variable results, with an objective cure rate at median follow-up of 9 months of 81% and 86% in two studies (Maher, et al., 1999, Bidmead, et al., 2001) [80,81], but 61% and 65% at 5-15 years in two studies using a Kaplan-Meier analysis (Alcalay, et al., 1995, Thakar, et al., 2002) [82,83] [EL=3]. The latter study in particular found no correlation between outcome and age, past hysterecestomy, number of previous incontinence procedures, parity, body mass index or blood loss at operation (Thakar et al, 2002) [83].

b) Laparoscopic colposuspension for recurrent SUI

As noted above, one small RCT reported in abstract form only compared laparoscopic colposuspension and TVT in the treatment of recurrent SUI found similar success, complication and re-operation rates, although TVT was associated with reduced operating time, hospital stay and return to normal activity (Maher, et al., 2004) [121] [EL=2].

- Traditional sling procedures for recurrent SUI

Despite the supportive conclusions of Jarvis (see above) (Jarvis, 1994) [20], and the fact that the biological slings have traditionally been seen by many as treatment of choice for recurrent SUI, the Cochrane review on traditional sling procedures reported that the data on sub urethral sling operations remain too few to address the effects of this type of surgical treatment. They felt that reliable evidence on which to judge whether sub urethral slings are better or worse than other forms of management was not currently available; in particular they made no comment on the application of sling procedures in the management of recurrent SUI (Bezerra, et al., 2005) [16] [EL=1]. In the review of procedures we have identified a number of recently published RCTs examining the effect of sling procedures; none however adequately address the question of sling procedures for recurrent SUI.

Since the last consultation a number of small case series have been published describing a variety of sling procedures applied to women with recurrent SUI. Petrou & Frank reported 86% subjective cures following repeat pubovaginal sling; it should be noted however that 3/14 women suffered significant post-operative complications, and only 50% were considered objectively cured at mean follow-up of 17 months (Petrou & Frank, 2001) [242] [EL=3]. Kane & colleagues reported 92% (12/13) subjective and objective cures following a bone-anchored pubovaginal sling procedures at median 2 year follow-up(Kane, et al., 1999) [243] [EL=3]. A retrospective series of 72 fascia lata slings found 90% subjective cures at minimum follow-up of 6 months (Breen, et al., 1997) [244] [EL=3]. Finally, a series of in-situ vaginal wall sling procedures was compared with a historical control group of traditional polytetrafluoroethylene sling operations in the treatment of recurrent SUI; both objective (35% vs. 88%) and subjective (61% vs. 93%) were significantly poorer in the index cases(Su, et al., 1999) [245] [EL=3].

c) Mid-urethral tapes for recurrent SUI

In the previous consultation very limited data were available on the use of tape procedures in the treatment of recurrent SUI. Two cohort studies reported comparable cure rates in recurrent SUI to those in primary cases at mean follow-up of 9 months (Rardin, et al., 2002) [246] and 4 years respectively (Rezapour & Ulmsten, 2003) [193] [EL=3]. Since then only one RCT and a number of case reports have addressed the issue of mid-urethral tapes in the management of recurrent SUI.

One small RCT comparing laparoscopic colposuspension and TVT in the treatment of recurrent SUI found similar success, complication and re-operation rates, although TVT was associated with reduced operating time, hospital stay and return to normal activity (Maher et al, 2004) [121] [EL=2]; this study is still only available in abstract form.

In a prospective series of 51 women treated with TVT for recurrent SUI, the objective cure rate was reported to be 90% and subjective cure rate 80% at a two-year follow-up (Kuuva & Nilsson, 2003) [194]. Liapis et al reported a small series with 12 month follow-up; the overall cure rate was 70%, although they described greater success in those with urethral hypermobility (90%) than those with a fixed urethra (33%) (Liapis, et al., 2004) [239] [EL=3].

The use of repeat TVT has been reported to be successful in patients with persistent or recurrent SUI after an initial TVT procedure (Riachi, et al., 2002, Villet, et al., 2002) [247,248] [EL=3]. Other small case series or reports have examined the effect of shortening the original tape, claiming comparable success rates to those reported from re-operation (Villet et al, 2002, Lo & Lee, 2004, Paick, et al., 2004, Nam, et al., 2007) [248,249,250,251] [EL=3].

One case series described five patients with SUI persisting or recurring after transobturator tape procedures successfully managed by a retropubic tape (Moore, et al., 2007) [252] [EL=3].

Summary

The role of previous continence surgery as a confounding factor is poorly understood, and further high level evidence is needed in this area.

It is received wisdom that most continence procedures when used in recurrent stress incontinence will have a lower success rate than the same procedures used...
in primary SUI. It has been suggested that results may be even poorer following several failed procedures. There is limited low level evidence to support this latter contention [EL=3].

Short-term follow-up suggests that the results of open (and laparoscopic colposuspension) in recurrent SUI may in fact be comparable to those in primary cases; long term results from ‘survival analysis’ suggest a greater fall off in cures following the application of colposuspension in recurrent SUI [EL=3].

Previous meta-analysis has suggested that the results from traditional slings are as good as or better than other procedures. In primary SUI (or series where the surgical history is not specified) slings appear to have longevity. Limited low level evidence suggests high success rates in recurrent SUI; high level evidence and long-term follow-up are not available in this patient group [EL=3].

Limited low level evidence suggests that TVT is associated with a similar success rate in recurrent SUI to that seen in primary cases [EL=2/3].

This seems to apply whether TVT is applied following a previously unsuccessful TVT, other mid-urethral tape procedures, or other forms of continence surgery [EL=3].

There are not sufficient data on tape shortening or re-tensioning to evaluate these procedures.

**Recommendation**

**Women undergoing surgery for the treatment of recurrent SUI should be aware of the uncertain log-term outcomes. [Grade B]**

Whilst only limited low level evidence is available currently, colposuspension, traditional biological slings and retropubic mid-urethral tape procedures are recommended in the management of recurrent SUI. [Grade B]

8. SEVERITY AND DURATION OF SYMPTOMS

Severity of SUI is difficult to measure accurately. It is tied to many factors including ambient physical activity of the patient, urethral function, and voiding frequency among others. Commonly utilized objective and subjective severity measures include pad tests and/or pad counts, urethral function tests, questionnaires, voiding diaries, quality of life scores, and bother indices. In the few prospective trials that have measured outcomes using a variety of different measurements, surgical success rates vary widely depending on the parameter (Ward, Hilton et al. 2004; Albo, Richter et al. 2007) [67,46]. Each of these outcomes is associated with significant limitations as an isolated measure and furthermore these parameters only modestly correlate with each other (Albo, Wruck et al. 2007) [46]. When comparing outcomes across SUI procedures, baseline severity is rarely considered and may not be comparable across trials leading to confounding factors when trying to compare procedures.

Symptom duration, especially as regards SUI treatment, is rarely reported in intervention trials. The inherent problem in reporting this data is recall bias by the patient in remembering the duration of symptoms prior to intervention. Therefore, whether duration of SUI symptoms correlates with surgical success or morbidity is unclear.

9. DETRUSOR OVERACTIVITY AND STRESS INCONTINENCE

The previous edition of this consultation found only level 3 evidence to support their conclusion that women who have detrusor overactivity (DO) pre-operatively are less likely to have a favourable outcome from surgery for SUI.
Much of the data on the effect of symptomatic urge urinary incontinence (UUI) on the outcome from surgery for SUI is based on women with overactive bladder syndrome (OABS), rather than on the pre-operative urodynamic finding of DO. There are no prospective randomised trials which compare the outcome of surgery in women with and without DO. Early case series of colposuspension in DO reported cures rates as low as 24-43% (Stanton, et al., 1978, Milani et al, 1985, Lose, et al., 1988) [277,254,261] [EL=3]. Colombo et al performed a retrospective cohort study and compared 44 stress incontinent women with DO with a matched group of women with stress incontinence and a stable bladder (Colombo, et al., 1996) [55]. They reported a cure rate of 95% in the stable group compared to 75% in the unstable group two years after surgery [EL=3].

Choe et al. demonstrated a comparable outcome after sling procedures performed in stress incontinent patients with or without OABS, although only 26% of in their mixed incontinence group actually had DO (Choe, et al., 2008) [267] [EL=3]. A number of studies have examined slightly different aspects of detrusor function in urodynamically mixed incontinence. In a retrospective study of 98 women treated by colposuspension, or needle suspension procedures, Pow-Sang et al demonstrated that ‘high pressure’ DO was associated with a poorer outcome than in patients with stable bladders or those with ‘low pressure’ overactivity (Pow-Sang, et al., 1986) [262] [EL=3]. A retrospective review of 36 women who underwent a sling procedure for stress incontinence and Valsalva induced DO revealed a cure rate of stress incontinence of 92% and urge incontinence of 75% (Serels, et al., 2000) [263] [EL=3]. Koonings et al. demonstrated that in women with mixed incontinence where bladder contraction is preceded by urethral relaxation, there is a more than 90% chance that bladder overactivity will disappear after successful operation for stress urinary incontinence (Koonings, et al., 1988) [264] [EL=3].

We have only identified a further four evidence level 3 studies published since the last consultation, and these are summarised as follows. In a cohort study of 340 women treated by traditional bladder neck sling or minimally invasive mid-urethral sling, Botros et al found that more patients in the mid-urethral sling group had resolution of their DO (38% vs. 15%, p<0.001), and fewer developed de novo overactivity than in the bladder neck sling group (29% vs. 62%, p=0.002) (Botros, et al., 2005) [265] [EL=3].

In a retrospective cohort study of 51 women undergoing TVT for combined urodynamic stress incontinence and DO, Duckett & Tamilselvi found resolution of overactivity in 47% and subjective cure of urge symptoms in 63% at a minimum of six months follow-up; stress incontinence was objectively cured in 92% (Duckett & Tamilselvi, 2006) [266] [EL=3].

In a series of 192 women undergoing sub urethral sling procedures, patient satisfaction was reported by 98% of 106 with normal detrusor function pre-operatively, 82% of 50 with underactive or acontractile detrusor function, and 75% of 36 patients with pre-operative DO (p<0.05) (Kuo, 2007) [599] [EL=3].

Choe et al. reported a retrospective cohort of 549 women treated by TVT; 180 had OABS in addition to SUI pre-operatively; 132 of these were seen for follow-up at 3 months. Based on a 3-day frequency-volume chart and a questionnaire responses complete resolution of OABS was seen in only 24%. Perhaps surprisingly, the rate of resolution was significantly higher in those with DO preoperatively than in those with stable bladders (37% vs. 18%; p=0.021) (Choe, et al., 2008) [267] [EL=3].

Summary

It has long been accepted that women who have detrusor overactivity pre-operatively are less likely to have a favourable outcome from surgery for SUI than those with pure USI [EL=3]. The rate of resolution of stress incontinence in women with mixed USI and DO is not significantly from that seen in those with pure USI [EL=3]. Rates of ‘cure’, or resolution of OABS or urodynamic findings ranging from 24% to 90% have been reported in women with mixed USI and DO [EL=3].

This wide range of treatment effect may be due to differences in surgical techniques or in methodology and outcome assessment [EL=4].

Although a number of women may develop new symptoms of OABS or so-called de novo DO following surgery for USI, such surgery should not be considered contraindicated in women with mixed symptoms of SUI and OABS or mixed urodynamic findings of USI and DO, provided that patients are fully counselled about possible outcomes [EL=4].

Recommendations

Surgery for USI should not be considered contraindicated in women with mixed symptoms of SUI and OABS or mixed urodynamic findings of USI and DO. [Grade B]

All patients undergoing surgery for stress urinary incontinence should be appropriately counselled to allow realistic expectations of outcome; this is particularly important in those with mixed symptoms or mixed urodynamic. [Grade B]
10. URETHRAL OCCLUSIVE FORCES

The influence of urethral function defined by leak point pressure or maximum urethral closure pressure is difficult to define on account of the large variation in outcome measures employed. Furthermore, other variables such as urethral mobility are often not controlled. Intrinsic sphincteric deficiency (ISD) is usually defined as a leak point pressure of < 60 or maximal urethral closure pressure (MUCP) of < 20. Rezapour reported a four-year outcome follow-up for patients undergoing TVT with ISD [193]. Of the 49 patients, only eight had immobile urethras. None of the patients with immobile urethras were cured, although three were noted to be improved. Paic also reported lower cure rates in patients with low leak point pressures, given no substantial differences in urethra hypermobility [250]. Urethral hypermobility has been predictive of mid-urethral sling success by some authors [269], whilst low leak point pressures have not been predictive of success by other authors [270,271]. It would appear that a low leak point pressure is less predictive of outcome on this data when compared to the presence or absence of urethral hypermobility.

11. SURGEON’S EXPERIENCE

Several factors independent of the patient characteristics might affect the outcome of incontinence surgery. Such are the experience of the surgeon as a surgery performing physician, experience of the surgeon in performing a given procedure, experience of the team and the hospital within which the surgery is performed. These issues have not been studied within randomized trials or in a prospective way.

In a report by Gormley et al (2002) [272] no effect of surgeon’s grade of experience or teaching status of the hospital was seen when performing pubovaginal sling procedures. There are a few reports looking at the learning curve of surgeons performing the TVT operation. The overall impression is that bladder perforations and retention symptoms occur more often during the first 15 to 50 TVT operations than later on. In a nationwide report on the introduction of the TVT procedure in Finland, where the learning curve of every single surgeon was included it was found that performance improved after the first 15 operations (Kuuva and Nilsson 2002) [273] Groutz et al (2002) [274] reported a dramatic decrease in the rate of bladder perforations from 40% in the first 10 patients to 10% in the next 10 patients and in the last 10 of a total of 30 patients operated on by a newly trained experienced urogynaecologist no further bladder perforations occurred. Lebret et al (2001) [275] reported a similar decline in the rate of bladder perforation from 22% in the first 50 patients to 8% in the next 50 patients. McLennan et al (2005) [276] analyzed the bladder perforation rate in 278 TVT operations performed by 23 residents performing a mean number of 12 operations each and found a linear decrease in perforation rate from 34% in the first 5 patients to 26% in the last five of 15 patients.

There is no robust literature on how many procedures need to be performed to maintain skills nor is there evidence on whether surgical skill or experience influences the cure rate rather than the complication rate although a correlation might be expected.

III. STRESS INCONTINENCE WITH PROLAPSE

1. URINARY INCONTINENCE AND PROLAPSE

Women who present with urinary incontinence as their primary symptom may also have pelvic organ prolapse which may be symptomatic or asymptomatic. The decision as to whether the prolapse should be treated surgically at the same time as the incontinence is determined by the symptoms and bother the prolapse produces to the patient and the influence that the prolapse surgery may have on the outcome of the surgery for the incontinence. The following clinical scenarios may present:

a) Stress urinary incontinence with prolapse
b) Urgency incontinence with prolapse
c) Prolapse with urinary incontinence (See Prolapse Chapter)

Where the prolapse is symptomatic it will be a matter of subjective opinion whether the incontinence or the prolapse is more significant (rather than a pathological diagnosis). If the treatment selection is based on subjective assessment it follows that the outcome from treatment must be based on subjective rather than objective measures.

a) Stress incontinence with prolapse

Women who present with stress incontinence commonly have deficient support of the anterior vaginal wall. Significant prolapse is generally defined anatomically as the presenting part of the prolapse reaching to within a cm of the hymenal remnant. Symptomatic prolapse may be more or less prominent. Milani et al (Milani 1985) [254] (Level 3) noted that the presence of vaginal prolapse preoperatively led to a lower cure rate of stress incontinence with either the Burch colposuspension or the MMK procedure; the greater the severity of the prolapse, the greater the reduction in cure rate. In a RCT Colombo et al (Colombo 2000) [37] compared Burch colposuspension with anterior colporrhaphy in women with stress urinary incontinence and Grade 2-3 anterior vaginal wall prolapse and found that the Burch colposuspension was better in controlling stress incontinence but that cystocele recurred in 34% of
patients. The cure rate for cystocele with anterior colporrhaphy was high (97%) but stress incontinence cure rate was very low. The authors concluded that neither operation was recommended for combined stress incontinence and advanced cystocele.

Gordon (Gordon et al 2001) [600] prospectively followed 30 patients short-term who underwent TVT at the same time as surgery for severe genitourinary prolapse. No patients had postoperative symptoms of stress incontinence despite 3 patients (10%) having positive postoperative stress tests. De novo detrusor overactivity occurred in 13% of subjects. A RCT compared types of anti-incontinence procedure performed with prolapse surgery, endopelvic fascia plication and TVT. (Meschia 2004) [40] (Level 1). This study included 50 women and demonstrated that adding a TVT results in higher 2-year objective continence rate than endopelvic fascia plication at the urethrovesical junction (92% vs. 56%, respectively; p<.01). The subjective cure rates were 96% for TVT compared to 64% for suburethral plication. Time for resumption of spontaneous voiding, rates of urinary retention, de novo urge incontinence, and complications did not differ between the groups. Despite negative cystometrograms, de novo urge incontinence symptoms were reported in 12% of the TVT group compared to 4% of the suburethral plication group (p=.66). Although not statistically significant, the authors recommend that data from a larger series are required to define the risk: benefit ratio between TVT and endopelvic fascia plication.

The TVT procedure combined with vaginal reconstruction resulted in 85% to 95% cure rates for urodynamic stress incontinence in a prospective cohort (Huang 2003) [278] and case series (Partoll 2002)279. Huang et al (Huang 2003) [278] reported urinary urgency and voiding dysfunction rates of 10% and 11%, respectively. Voiding difficulties and post void residuals of > 100 ml were treated with urethral dilatation. The authors did not report any cases of long-standing urinary retention.

b) Urgency incontinence with prolapse

The effect of anterior vaginal wall prolapse on bladder function and the influence of surgical repair are much debated. Digesu et al (2007) [280] reported on a 12 month prospective cohort study of ninety three women who had a standard anterior fascial repair for cystocele. Post-operatively, urinary frequency resolved in 60%, urgency resolved in 70% and urge incontinence resolved in 82% illustrating that anterior repair appears to resolve the majority of overactive bladder symptoms. Similar findings were reported in a prospective cohort study of prolapse repair in elderly women by Foster RT Sr et al (2007) [281]. They also noted that vaginal reconstructive or obliterator surgery produced a similar improvement in urinary symptoms at 12 months after surgery.

CONCLUSIONS

There is Level 2/3 evidence that when prolapse repair surgery is performed at the same time as a TVT to treat stress incontinence, the cure rate for the stress incontinence is not adversely affected.

There is Level 3 evidence that treatment of prolapse by constructive or obliterator surgery improves overactive bladder symptoms.

IV. COMPLICATIONS OF SURGERY FOR STRESS INCONTINENCE

1. EVIDENCE
2. INCIDENCE OF COMPLICATIONS
3. PREVENTION OF COMPLICATIONS
4. OPERATIVE EXPERIENCE
5. CHOICE OF APPROACH
6. OTHER RISK FACTORS
7. COMPLICATIONS RELATED TO SUI SURGERY
a) Intraoperative
   1. URINARY TRACT INJURY
      i) Urethra
      ii) Bladder
      iii) Ureter
   iv) Bleeding and vascular injury
v) Bowel injury

   3. NERVE INJURY
   4. BONE ANCHOR RELATED COMPLICATIONS
   5. SEXUAL DYSFUNCTION
   6. OTHER POSTOPERATIVE COMPLICATIONS
   8. PERIURETHRAL BULKING AGENTS
1. EVIDENCE

There are very few randomized, prospective studies adequately powered to assess differences in complications between operative procedures. Because the reported incidence of most complications is quite low, adequate powering of randomized clinical studies would necessitate extraordinarily large numbers of patients. Current literature does not permit such an analysis although national registries may be one such source of this information in the future. Most of the available evidence is from case series, non-cohort comparative trials or underpowered randomized trials. Meta analysis and underpowered clinical trials may give some information on the incidence of particular complications, but comparing the relative risk of complications across various procedures of a similar nature is difficult and may be misleading based on available data.
The field of incontinence surgery, and especially stress urinary incontinence (SUI) surgery has rapidly transformed over the past several years. The types of SUI procedures being performed has evolved from transvaginal needle suspensions and retropubic suspensions to various types of slings, most commonly the midurethral polypropylene slings. This shift has implications for the types of complications seen in contemporary practice. Therefore the emphasis in this section will be in review of the midurethral sling procedure and its many derivatives. It is important to note that much of the data regarding these complications is immature. It is possible that over time the incidence of various types of complications or unforeseen additional types of complications may occur.

2. INCIDENCE OF COMPLICATIONS

The overall incidence of intraoperative and postoperative complications is difficult to ascertain. Much of the available literature derives from a single centre experiences, national registry data, case series or case reports. In addition, the reporting of surgical complications by individual investigators is not mandatory, is often selective, and is defined by the investigator. Furthermore, the incidence and type of complications reported in the literature are, for the most part, derived from academic medical centres. Complications arising in community practices may be wholly different. Central databases such as the FDA MAUDE website are voluntary and accurately determining complication rates based on such data is not possible for a variety of methodological reasons.[282]. In addition, there is no generally accepted standard categorization, or nomenclature for the reporting of surgical complications for urinary incontinence (UI) surgery although it has been suggested [283,24]. One such paradigm was developed by the AUA SUI Guidelines Panel which divided complications into 6 categories: transfusions, general medical, intraoperative, perioperative, subjective, and those complications requiring surgery [24]. Unfortunately this taxonomy has not been widely adopted. A system for the grading of severity of surgical complications has also been developed [284] and utilized in the UI literature [46] but it does not provide a mechanism for classification of specific complications in the genitourinary tract. Complications vary in severity and associated morbidity (i.e. a postoperative UTI vs. transvaginal erosion and extrusion of a synthetic sling material are not equivalent in severity but are weighted equally in the overall complication rate of a given procedure) As a result of these deficiencies an omission of the reporting of a given complication by an investigator is considered consistent with its lack of occurrence. Whether this method of accounting reflects accurately on the trial or on clinical practice is not clear. Finally, the definition of exactly what constitutes a complication is unclear. There are particular complications that are dichotomous or categorical: they either occur or they do not (e.g.: bowel injury, urinary tract injury, sling extrusion). However, other potential complications such as bladder outlet obstruction and dyspareunia are graded on a spectrum and not well defined. This lack of standardization permits considerable variability in the reporting of complications. For example, excessive bleeding is considered by most surgeons to be a complication but some bleeding is commonly encountered in the performance of most anti-incontinence procedures. However, the quantity of bleeding that must occur for it to be considered a complication is not standardized. Bleeding as a complication has been defined variably in the literature as a volume of blood loss (e.g. >200cc), development of a postoperative hematoma, peri- or postoperative hypotension, the requirement for transfusion, or even hemorrhagic shock and death.

Notwithstanding the limitations noted above, the incidence of complications varies widely between studies. Case reports and case series likely underestimate the actual incidence of some complications especially major complications [285]. In some series for certain groups of patients undergoing UI surgery, the complication rate may approach 40-50% if UTI's and urgency symptoms are defined as complications [286,287]. The AUA SUI Guidelines Panel reported that each of the 6 categories of complications occurred in 2-16% of patients across the 4 types of procedures covered in the meta-analysis: slings, retropubic suspensions, transvaginal sus-pensions and anterior repair. In a review of midurethral sling procedures, Boustead et al noted that the complication rate in published series ranged from 1-40% [288]. Taub et al used the Nationwide Inpatient Sample (a national database in the US) of over 147,000 patients who underwent surgery for SUI from 1988 to 2000 and found an overall complication rate of 13% [289]. Waetjen et al estimated a complication rate of 18% from the 1998 National Hospital Discharge Survey and the 1998 National Census including data on over 135,000 patients undergoing surgery for SUI [223]. On review of a sampling of the Medicare database from 1999-2001, Anger et al found that 12.5% of patients undergoing a sling developed a surgical or urological complication in the first 3 months following surgery [221].

3. PREVENTION OF COMPLICATIONS

Although most complications related to the surgical treatment of female urinary incontinence are treatable and, for the most part reversible, the optimal scenario is to prevent or minimize the potential for an adverse outcome. Certain preoperative factors may influence the risk of intraoperative or postoperative complications. Most have not been studied in a controlled fashion.
4. OPERATIVE EXPERIENCE
Operative experience with a given procedure has been cited as an important factor contributing to the risk of complications. Proper training and subsequent maintenance of skills is important not only in optimizing outcomes, but in minimizing complications. The number of cases necessary to gain competence with a given procedure is unknown and likely varies with the nature of the surgery, the learning environment and the skill of the surgeon. For the experienced and practicing surgeon, the NICE guidelines from the UK recommend that a minimum of 20 cases per year per surgeon for each incontinence procedure is necessary to maintain skills [290] this document further states that if fewer than 5 of a particular procedure are done by an individual surgeon per year, then local clearance and oversight, or alternatively referral to another centre may be necessary [290].

Kuuva et al reviewed a nationwide database on midurethral slings and noted that operative complications varied inversely with surgical experience (Level 3) [273] These authors reported that the risk of bladder perforation during a transvaginal midurethral sling varied with the experience of the operating surgeon in doing the procedure. Surgeons performing more than 80 procedures had almost 50% fewer perforations than those with less than twenty cases experience and these authors also noted that complications decreased per surgeon after completing 15 procedures. McClennan et al reported that the risk of perforation of the urinary bladder during TVT decreased with increasing surgical experience in a residency training program (Level 3) [276]. In a prospective Dutch study of TVT procedures, there was an increased risk of complications in teaching hospitals as compared to non-teaching hospitals as well as an increased risk of complications during a surgeon's second 10 procedures as compared to their first 10 procedures or >20 procedures (Level 2) [291]. Alternatively, Anger et al, in review of a large national database found no correlation between surgical experience and risk of surgical complications in patients undergoing SUI surgery (Level 3) [601].

5. CHOICE OF APPROACH
The relative risks of each complication between the various types of surgery being performed, especially within a single category such as midurethral slings, regardless of approach (e.g. the risk of bleeding in a transobturators vs. suprapubic vs. transvaginal approach), is difficult to assess due to the small number of randomized controlled trials between procedures and the relative low frequency of the event (complications). In a large meta-analysis in 1997, the AUA SUI Guidelines Panel reported that slings and retropubic suspensions were associated with a higher risk of complications such as bleeding and obstruction than anterior repairs and needle bladder neck suspensions (Level 1) [24].

There are few prospective randomized trials comparing complications. Ward and Hilton compared Burch to TVT and found that the risk of intraoperative complications such as bladder perforation was higher in the TVT group whereas the risk of postoperative complications such as delayed voiding was greater in the Burch group (Level 1) [65]. The Urinary Incontinence Treatment Network (UITN) completed a randomized controlled trial comparing Burch colposuspension to autologous rectus fascia pubovaginal sling (Level 1) [46]. There was no overall difference in total serious adverse events between groups (13% vs. 10%, p=0.20, sling vs. Burch, respectively) but surgical interventions for the treatment of voiding dysfunction only occurred in the sling group (19 interventions in the sling group vs. none in the Burch group). Overall adverse events (including most commonly UTIs) occurred more often in the sling group. (63% vs. 47%, p<0.001, sling vs. Burch, respectively). A small prospective study compared autologous fascial sling to TVT in 53 patients with SUI and found no difference in complications between the groups at 6 months follow-up (Level 2) [166].

There have been a few randomized trials comparing some combination of TOT (transobturator), TVT (transvaginally placed retropubic tape), and SP (suprapubically placed retropubic) urethral tapes. Zhu et al found no difference in complication rates or urinary retention in 56 women randomized to either TVT or TOT (Level 2) [292] as did Lee et al with 120 patients quasi-randomized to either procedure [293]. Laurikainen and colleagues noted that a TOT approach was associated with more complications than TVT but this difference was not considered clinically significant by the authors [209]. However, Liapis et al noted more overall complications in patients undergoing TVT (11/46) as compared to TOT (2/43) in a randomized trial between these two procedures [208]. At a median follow-up of 9 months, Wang et al noted no significant difference in complications between 60 patients randomized to TOT or SP urethral tapes although there was a non-significant trend for increased thigh pain and vaginal extrusion in the TOT group (Level 2) [591]. In a prospective trial, David-Montefiore et al found similar complication rates in patients randomized to TVT (8/42) or TOT (5/46) although the types of complications differed between the groups (see below) [294].

With respect to a transobturator approach, two studies have demonstrated equivalently low complication rates between the outside-in vs. inside-out approach (Level 2) [295,296].

6. OTHER RISK FACTORS
There are many patient factors which may potentially impact on the risk of complications in a given patient including aetiology and type of urinary incontinence, age, medical co morbidities, preoperative sexual function, the presence of associated conditions such
as vaginal prolapse, and prior abdominal, pelvic or anti-incontinence surgery. In one prospective study of over 800 patients undergoing TVT, Schraffordt Koops et al noted an overall 6.2% incidence of complications and identified several risk factors including menopausal state, previous prolapse surgery (but not prior incontinence surgery), mode of anaesthesia, and having the procedure done in a teaching hospital (Level 2) [291].

Identifying preoperative patient risk factors such as prior surgery, age, and obesity that consistently predict for intraoperative and postoperative complications has also been difficult. Much of the existing literature is conflicting (Level 3) [297]. For example, some authors have found that prior pelvic or incontinence surgery predicts for intraoperative bladder injury during midurethral sling (Level 2-3) [286, 298,206,257], while others have not (Level 2) [301]. This variability may be due to the type of prior SUI surgery: prior retropubic surgery such as Burch or MMK may lead to retropubic scarring and a risk of bladder injury whereas a prior transvaginal operative such as a Kelly plication wherein the retropubic space is not violated, may not [257]. Advanced age is not a contraindication to anti-incontinence surgery.

However surgery in the advanced elderly (>80 y.o.) may be associated with some increased morbidity as compared to the “young” elderly (Level 3) (65-80 y.o) [299] and may be associated with higher rates of postoperative urge incontinence, bladder outlet obstruction and surgical failure as compared to younger patients (Level 3) [300]. Rogers et al demonstrated no increased risk of intraoperative or postoperative complications in obese patients (BMI>30) as compared to the non-obese patients undergoing a variety of SUI surgeries in a prospective nested cohort study.(Level 2) [301] This supports the conclusion of other prior studies [233,302]. One study noted that individuals with a BMI>26.5 were at increased risk of bladder perforation during TVT but that overall outcomes were not affected [303].

7. COMPLICATIONS RELATED TO SUI SURGERY

a) Intraoperative Complications

1. URINARY TRACT INJURY

During SUI surgery, the urethra, bladder or, much more rarely, the ureters may be injured. The key to the management of each of these injuries is immediate recognition and repair. Long term sequelae resulting from unrecognized urinary tract injury can be devastating to the patient.

i) Urethra

Intraoperative urethral injury during UI surgery is rarely reported. It may occur during the initial transvaginal dissection, during trocar placement for midurethral sling procedures, needle placement for transvaginal suspensions, or during cystocele repair. Failure to recognize the injury or failure to repair it properly risks urethrovaginal fistula, erosion of sling material into the urethral lumen postoperatively, infection, and other potential problems (Level 4). The risk of urethral injury may be as high as 4 fold greater in the transobturator approach as compared to the TVT/retropubic approach [290] however this data is based on a single literature review and thus indirect comparisons and not randomized control trial data.

In the event of a planned synthetic sling in the setting of a concomitant intraoperative urethral injury, it is probably advisable to repair the urethra and abort the sling procedure until the urethra is completely healed (Level 4).

An autologous sling may be considered a safer alternative than a synthetic sling at the time of a urethral injury as an anti-incontinence procedure but there is little data to support this notion (Level 4). The urethra is rarely injured during retropubic surgery as the middle and distal thirds are protected by the symphysis pubis.

ii) Bladder

The potential for bladder injury may vary with the choice of operative approach. Albo et al reported a trend toward more bladder injuries in the colposuspension group as compared to the sling group (10/329 vs. 2/326, colposuspension vs. sling respectively) in the UITN study [46]. The risk of bladder injury during midurethral sling is probably higher with a retropubic approach as compared to a transobturator approach although randomized trial data are minimal in this regard (Figure 8).

Figure 8 : Mesh erosion into the bladder following TVT
In one literature review, the risk of bladder injury may be as much as 6 fold higher in the TVT/retropubic approach as compared to the transobturator approach [290]. The incidence of bladder perforation during TVT has been reported in 0-8% of patients (Level 3) [273,317,291,206,65]. Hodroff et al reported an overall bladder perforation rate of 6.7% in 445 patients undergoing a SP midurethral tape procedure and Deval et al reported an incidence of 10.5% in 104 patients (Level 3) [304, 286]. Davila et al reported no bladder perforations in over 200 patients undergoing a TOT sling (Level 3) [305].

Barber et al retrospectively compared over 200 patients undergoing TVT to a similar number of patients undergoing TOT (Level 3) [306] and found that the incidence of bladder perforation in the TVT group was 5% while there were no such injuries in the TOT group. Several small prospective RCT’s have reported a trend towards a greater risk of bladder perforation during TVT as compared to TOT (Level 2) [209, 208,307]. Nevertheless, there are multiple reports of bladder injury during transobturator midurethral slings [308,309] and thus this potential complication must be considered.

The relative risk of bladder perforation with a transvaginal vs. suprapubic approach to retropubic midurethral slings is, as of yet, unclear. While one retrospective study noted a high bladder perforation rate with a suprapubic approach (29% vs. 4%, suprapubic vs. transvaginal, respectively) (Level 3) [310], others have not (Level 2) [200].

In one small randomized prospective trial comparing transobturator to retropubic midurethral slings, bladder perforation was noted only in the retropubic cases (4/42, 9.5%) whereas vaginal injury was noted only in the transobturator cases (5/46, 10.9%) [294].

Redo incontinence surgery may be associated with a higher risk of urinary tract injury in patients undergoing midurethral sling surgery. Jeffry et al reported a bladder perforation rate during TVT of 71.4% vs. 7.6% in patients with prior surgery vs. those without (Level 3) [298]. Likewise, in patients undergoing SPARC, Deval et al reported a 36.6% vs. 7.5% urinary tract injury rate in those with vs. those without a history of prior surgery (Level 3) [286]. The risk of bladder perforation in the Austrian TVT national registry was 4.4% in patients with prior surgery but only 2% in those without prior surgery (Level 3) [206]. However, LaSala et al reported that prior abdominal hysterectomy or BMI >26.5, but not prior anti-incontinence surgery, was associated with an increased risk of intraoperative cystotomy during TVT (Level 3) [303]. Nevertheless, in one series, the surgical results in those with an intraoperative bladder perforation during TVT appear to be no different from those without such a complication provided that the perforation is recognized intraoperatively and corrected (Level 3) [303]. It is possible that the type of prior surgery has a significant impact on the risk of bladder perforation with such operations as Burch colposuspension in which there is considerable dissection in the retropubic space posing a potentially greater risk than prior anterior repair where no such dissection is performed (Level 3) [257].

iii) Ureter

Ureteral injury during incontinence surgery is very uncommon. The ureter may be kinked or obstructed during Burch or MMK procedures or during bladder neck sling procedures. With the advent of midurethral slings, these injuries are rare given the expected location of the sling at the level of the midurethra. In the UITN trial of Burch vs. autologous fascial sling, there were 2 ureteral injuries and both occurred in the Burch group [46].

iv) Bleeding and vascular injury

The risk of bleeding during SUI surgery can be minimized, but not entirely eliminated by good operative technique. Multiple blood vessels traverse the deep pelvis including large venous channels in the retropubic space.Named vessels in the obturator fossa, along the pelvic sidewall including the iliac vessels, and within the vascular pedicle of the bladder are at risk for injury especially during vaginal incontinence surgery due to lack of direct visualization of these structures during passage of trocars or needles (Figure 9).

Major vascular injury can quickly lead to life threatening haemorrhage if not recognized intraoperatively and may result in large retropubic hematomas postoperatively [311,312]. Leach et al reported bleeding complications requiring transfusion in 5% of colposuspensions, 4% of slings, 3% of needle suspensions and 3% of anterior repairs. (Level 1) [24]

Figure 9 : Abdominal wall haematoma after laparoscopic surgery
These differences were not statistically significant. In a series of over 5000 midurethral slings reported on by the Austrian Working Group for Urogynaecology, bleeding problems were reported in 2.7% of cases (Level 3) [313]. Only 0.8% of patients required intervention for bleeding with the vast majority of cases managed conservatively without operative intervention. Less than 1% of patients required transfusions. Kuuva et al reported a 1.9% incidence of bleeding >200cc in over 1400 TVT cases (Level 3) [273]. RCT’s comparing TOT to TVT and SP urethral tapes show no significant difference in bleeding complications between approaches (Level 2) [307,208,209]. There was no significant difference in complications related to bleeding between the colposuspension group and the sling group in the UITN report from Albo et al (3/329 vs. 1/326, p=0.62, colposuspension vs. sling respectively) [46].

**v) Bowel injury**

There exist multiple reports of bowel injury during urinary incontinence surgery [314,308,304]. Fortunately this is a rare and very infrequently reported complication. Bowel injury may occur during the retropubic dissection for a Burch or MMK especially in reoperative surgery, during entry into the retropubic space during an autologous pubovaginal sling, or during passage of needle passers or trocars during midurethral slings. These can be devastating complications leading to sepsis, abscess and even death [308].

**b) Postoperative complications**

1. **VOIDING DYSFUNCTION AND URINARY RETENTION**

Bladder outlet obstruction (BOO) may occur following SUI surgery. This presents as prolonged complete urinary retention, persistently elevated post-void residual urine volume or, as variably bothersome and poorly categorized lower urinary tract symptoms including combinations of recurrent urinary tract infections, obstructive symptoms and urinary urgency or urge incontinence.

Historically the prevalence of postoperative voiding difficulties lasting greater than 4 weeks occurs in 3-7% of patients undergoing Burch procedures, 4-8% of those undergoing transvaginal needle suspensions and 3-11% of pubovaginal slings [24]. Permanent urinary retention was estimated to be <5% across all procedures by these same authors.

The prevalence of voiding dysfunction, including urinary retention and de novo urgency and urge incontinence, following midurethral slings ranges from approximately 2%-25% (Level 2-3) [315-317, 320,367,318,319,295,286,206,205]. Surgical intervention for voiding dysfunction and urinary retention has been reported in 0-5% of patients undergoing midurethral slings (Level 2-3) [304, 206,319,295,367]. Randomized prospective studies have shown short term voiding difficulties following TVT appear less likely than following Burch (Level 1) [85] and pubovaginal slings (Level 2) [168]. Dietz found TOT to be less “obstructive” than TVT based on flow rates and ultrasound (Level 3) [321]. In one multicenter retrospective study, transobturato slings had fewer “obstructive” complications than retropubic midurethral slings (Level 3) [322] and another retrospective study compared TVT to TOT and found that fewer patients in the TOT group required urethralysis or anticholinergic medications in the postoperative period implying less obstruction (Level 2) [306]. Alternatively, one randomized trial comparing SP midurethral tapes to TOT demonstrated no difference in postoperative voiding dysfunction (Level 2) [204].

The diagnosis of urethral obstruction following SUI surgery is difficult and based on a combination of clinical parameters. In some patients, cystoscopy and videourodynamics may be helpful. However, there is no universally agreed method of making a diagnosis of postoperative urethral obstruction which prevents a true assessment of the incidence of this complication.

Management options for prolonged postoperative voiding difficulties include repeated voiding trials, initiation of intermittent urethral catheterization, and incision of the sling or urethralysis. As many cases of postoperative voiding dysfunction will spontaneously resolve, the ideal timing for surgical intervention has not been defined. Early intervention may result in high rates of recurrent SUI in patients in whom the voiding dysfunction may have resolved spontaneously given enough time. Alternatively, subjecting the patient to ongoing irritative lower urinary tract symptoms, UTI’s or CIC due to ongoing obstruction is not optimal. Some authors have recommended conservative therapy for postoperative voiding dysfunction for up to 3 months prior to attempting surgical revision [323]. However, a prolonged time to intervention for BOO may be associated with long term, potentially irreversible bladder dysfunction even following successful urethralysis [324, 325].

Transvaginal sling incision is often successful in reversing obstruction from a pubovaginal or midurethral sling (Level 2) [326-328]. For patients who fail transvaginal incision, or who underwent a non-sling procedure as the cause for their BOO, a urethralysis may be performed [329,330]. Via a transvaginal or retropubic approach [221,329,331], the retropubic space is entered and the urethra is sharply dissected off the posterior surface of the symphysis pubis and freed from the surrounding scar. The limbs of the sling or other retropubic attachments are isolated and divided in the retropubic space. Lateral attachments to the pelvic sidewall are incised as needed for those who previously underwent a Burch or paravaginal repair. A transvaginal, suprameatal approach to urethralysis has also been described and may be
particularly applicable to those patients previously undergoing an MMK [331].

Recurrence of SUI symptoms following urethrolysis or sling incision may occur in 15-20% of patients [328,332].

2. **VAGINAL EXTRUSION AND URINARY TRACT EROSION**

Vaginal extrusion refers to the finding of exposed sling material in the vaginal cavity postoperatively, whereas erosion implies the finding of material within the lumen of the urinary tract at some time interval postoperatively (Figure 10) which was clearly documented as not being within the urinary tract at the time of surgery. Both extrusion and erosion may lead to long term voiding dysfunction despite removal of the sling material.[333].

Extruded material may be located in the midline at the incision line or at the anterolateral vaginal wall. Midline extrusions imply wound dehiscence or defective healing whereas lateral extrusions may be due to an unrecognized vaginal wall perforation or injury at the time of sling placement (Level 4) [334].

Extrusion of material may be related to surgical technique, host factors, wound healing, infection, or the physical properties of the implanted material such as pore size or monofilament vs. multifilament construction [335,336]. Pore size or the specific weave of a mesh may be related to the intrinsic ability of a material to resist infection by allowing migration of host fibroblasts and macrophages into the interstices of the mesh to eliminate bacteria [336]. Certain woven mesh products may have a pore size or interstices below a critical size which may predispose to infection.

There is a paucity of randomized trials comparing monofilament to multifilament (polyfilament) mesh. One randomized trial found 9 extrusions in a multifilament sling group as compared to none in the monofilament group (TVT) (Level 2) [203] and another trial reported higher extrusion rates with a multifilament as compared to two other monofilament products [588]. A case control study comparing a monofilament to a multifilament mesh reported a several fold increase in urethral erosions in the multifilament group as compared to the monofilament group [337]. However, Rechberger et al noted no difference in extrusion rate in an RCT comparing monofilament to multifilament mesh. (Level 2) [201]. Several case series have suggested that the risk of extrusion with multifilament or other types of treated mesh is significant and may occur in 9-20% of cases (Level 4) [338-342,588]. The reported rate of mesh extrusion from case series using monofilament sling materials has been reported as between 0-5% [291,273,203,65,343,304].

Extrusions should be treated expeditiously. Some small extrusions may heal with conservative management including the application of topical oestrogen creams (Level 4) [343]. The size of an extrusion which can be managed non-operatively is not well defined nor is the time frame after which surgical intervention should be pursued. Larger extrusions can be managed with copious irrigation and secondary closure in the operating room. Some patients with large extrusions which are unable to be secondarily closed or who have already failed secondary closure should undergo excision and removal of the extruded sling (Level 4).

Urinary tract erosion may occur with synthetic, biologic or autologous materials [344,345]. The risk of sling erosion into the urethra is extremely low. In several national databases, the urethral erosion rate for TVT has been reported to be less than 1% [346,273,206,291]. One retrospective series demonstrated no urethral injuries with TOT-I or TOT-O [334].

This complication is managed operatively. Whether urinary tract erosion occurs as a result of a “missed” urinary viscus perforation at the time of surgery, or occurs as a result of migration of the material into the urinary tract sometime following surgery, is unclear. Patients may complain of irritative lower urinary tract symptoms, recurrent UTI’s, haematuria, dysuria as well as pelvic pain. The definitive diagnosis of urinary tract erosion is usually made endoscopically and treatment may involve endoscopic [347,348] or open removal of the eroded mesh.

3. **NERVE INJURY**

Several nerves traverse through the deep pelvis as well as superficially within the lower abdominal soft
tissues. These nerves are at risk for injury during female incontinence surgery during positioning of the patient or during the surgical procedure.

Lithotomy position may result in stretch or compression injury to the femoral nerve as can retractor placement during retropubic UI surgery. Femoral nerve compression may occur at the level of the inguinal ligament due to flexion of the hip joint [349]. This results in sensory changes to the anterior thigh or in more severe cases weakness of hip flexion. Severe abduction and external rotation of the thigh should be minimized during positioning to avoid this complication. The peroneal nerve can be injured by direct compression while in the lithotomy position. Lateral direct pressure on the peroneal nerve between the stirrup at the lateral aspect of the knee joint and the fibular head for a prolonged period of time may result in a peroneal nerve palsy and foot drop [349]. This injury may also occur with compression of the fibular head against the stirrup holder, especially candy cane stirrups as the leg rotates externally after placement in the holders.

The ilioinguinal and iliohypogastric nerves may be injured by sling harvest during autologous rectus fascia pubovaginal sling, trocar placement or dissection [350,357].

4. Bone anchor related complications

Bone anchors (BA) were popularized as an alternative method of suture fixation during stress urinary incontinence surgery such as pubovaginal slings and transvaginal needle bladder neck suspensions. Rackley et al estimated the prevalence of BA related infections in female pelvic reconstructive procedures as approximately 0.6% [351]. However, the complications associated with BA’s can be devastating including pelvic abscess and osteomyelitis of the symphysis pubis. There are numerous reports of bone anchor related complications associated with female incontinence surgery in the urologic, gynaecological and orthopaedic scientific literature [352-355]. Once diagnosed, osteomyelitis related to BA’s requires operative exploration and removal of the bone anchor.

5. Sexual Dysfunction

Postoperative female sexual dysfunction (FSD) was reported in between 2-8% of female patients undergoing SUI surgery in the AUA Female SUI Guidelines Panel [24]. The difference between procedures was not statistically significant. There are several questionnaires that have been utilized to assess FSD [356]. Use of these disease-specific questionnaires may yield a higher incidence of FSD than previously reported in many series which may be up to 20% [356,357] however not all contemporary series report such findings [358].

Dyspareunia is one form of sexual dysfunction and it may occur following UI surgery. Vaginal anatomy is altered by SUI surgery. The vaginal axis can be shifted changing the angulation of the vaginal canal. Circumferential narrowing of the vagina may occur due to excessive trimming of vaginal wall during prolapse surgery or as a result of aberrant scarring. Dissection along the anterior vaginal wall may result in nerve injury and neuroma formation. Sling erosion may also result in dyspareunia. Other poorly understood factors contributing to postoperative sexual dysfunction may exist. For example in some series 4-5% of patients following TVT or IVS slingplasty experienced decreased libido [359,356]. The reason for this decreased libido is unclear.

6. Infection and UTI

Multiple cases of pelvic abscesses have been reported with anti-incontinence surgeries including midurethral slings [360,361,363,282,364-365]. These consist mostly of case reports (Level 4).

There is inconsistent reporting of the prevalence urinary tract infection following anti-incontinence surgery. This may be due to issues with definitions and cause and effect.

7. General Medical complications and other postoperative complications

The incidence of significant morbidity from non-urinary tract medical conditions is unknown. As with any surgical procedure, there exists an undefined risk due to anaesthesia, associated cardiac and pulmonary morbidities such as postoperative myocardial infarction or pulmonary embolus. Older age and medical co morbidities may be associated with an increased risk of general medical and non-urological complications in older patients undergoing UI surgery as compared to younger patients [300].

Likewise the risk of death is unknown as this is an exceedingly rare complication in UI surgery. The AUA SUI Guidelines Panel estimated the risk of death following anti-incontinence surgery as 5/10,000 cases based on data from hysterectomy series [24].

Urinary fistula following SUI surgery is quite rare. Nevertheless, an unrecognized and unrepaird intraoperative injury to the ureter, bladder or urethra may result in ureterovaginal, vesicovaginal or urethropalvaginal fistula.

De novo vaginal prolapse may occur following anti-incontinence surgery and has been associated with colposuspension procedures including vault prolapse and posterior vaginal wall prolapse.

8. Periurethral bulking agents

(Figure 11)

In general, the morbidity associated with periurethral injectable agents is low. UTI, short term voiding dysfunction including urinary retention and haematuria
have been reported with all of the periurethral injectable agents. Stothers et al looked at complications related to intraurethral bovine collagen injection in a large series of patients (Level 3) [366]. In 337 patients injected with intraurethral collagen, approximately 20% of patients had at least one minor complication. The most common reported complication was de novo urge incontinence in 12.6%, followed by haematuria in 5% and urinary retention in 1.9%. Other bulking agents have demonstrated similar adverse event trials (Level 2) [148,144,150,149].

With respect to approach, periurethral injection has been noted to be associated with more complications including urinary retention and postoperative voiding dysfunction as compared to transurethral injection of bulking agents in one randomized trial of a dextran/hyaluronic acid compound (Level 2) [149,144].

Randomized controlled trials have compared bovine collagen to carbon coated beads as well as calcium hydroxylapatite. Lightner et al demonstrated a similarly minimal long term complication rate between collagen and carbon coated beads with a higher incidence of short term urinary retention and urgency in the carbon coated bead group (Level 1) [144]. Mayer et al noted no difference in short or long term complications in a randomized prospective trial comparing collagen and calcium hydroxylapatite (Level 1) [150]. Finally, there was no significant difference in short or long term complications in a randomized trial comparing porcine collagen to silicone (Level 2) [148].

Periurethral bulking agents including silicone [140] and collagen [141] have been compared to surgery in 2 randomized prospective trials. In both trials morbidity due to surgery was significantly greater than that associated with the injectable agent (Level 2).

Distal and systemic migration of polytef [368,369], and carbon coated beads [370] has been reported. The long term ramifications of these synthetic materials in the lymph nodes, lungs, brain and other organs are unknown. One bulking agent has been noted to have a high rate of erosion into the urethral lumen and has been recently withdrawn from the US marketplace.[371]

**V. SURGERY FOR DETRUSOR OVERACTIVITY**

The presumed aetiology of overactive bladder is detrusor overactivity [372]. Symptomatically, only 1/3 of patients with overactive bladder have associated urinary incontinence [373]. Many of these patients can be successfully treated with a combination of non-surgical measures including behavioural modification, pelvic floor physiotherapy and pharmacological therapy (see chapter on Conservative Management of Urinary Incontinence). Surgical therapy of non-neuropathic overactive bladder incontinence is generally reserved for those patients who have failed an adequate trial of these measures [374,375]. Overall, there are few studies on the surgical therapy of non-neurogenic detrusor overactivity urinary incontinence.[376,377]

Surgical interventions for urinary incontinence related to neurogenic detrusor overactivity incontinence are covered elsewhere (see chapter on Neuropathic Bladder).

### 1. ENDOSCOPIC APPROACHES

#### a) Endoscopic bladder transaction

Endoscopic bladder transaction is modelled after an open procedure, designed, in part to denervate the bladder by circumferential endoscopic incision proximal to the bladder neck. There are few reports of its use and this procedure is now rarely, if ever, performed.

**Level I evidence:** There is no Level 1 evidence regarding this modality in the therapy of non-neurogenic detrusor overactivity incontinence.

**Other evidence:** Parsons et al reported endoscopic bladder transaction as an effective technique of treating symptomatic bladder instability (Level 4 evidence) [378]. Subsequent reports (Level 4 evidence) [379,380] have been less favourable.

#### b) Hydrodistension or Bladder Overdistension

Bladder overdistension was originally described by Helmstein et al for the treatment of bladder cancer [381] but has also been cited as potential therapy for the treatment of some types of voiding dysfunction, including interstitial cystitis. Several reports have described its application towards the treatment of...
detrusor overactivity. In practice, this procedure is performed under general or regional anaesthesia and utilizes a hydrostatic column of fluid under high pressure infused into the urinary bladder and left indwelling for a variable period of time. The mechanism by which this therapy purportedly treats detrusor overactivity is not well understood.

**Level I evidence:** There have been no randomized controlled trials, double blind trials or cohort studies which have examined the effects of bladder overdistension for non-neurogenic detrusor overactivity incontinence.

**Other Evidence:** There are only a few reports on hydrodistention for the therapy of detrusor instability or non-neurogenic detrusor overactivity incontinence. The existing literature consists of primarily small retrospective case series with brief follow-up and subjective outcome parameters (Level 4 evidence).

Of the few favourable reports on hydrodistention for urinary incontinence, Ramsden reported that 41/51 patients (80.4%) had substantial improvement or were free of urinary symptoms at a follow-up of 13 months [382]. Dunn et al noted that 19/20 patients with urge incontinence or severe urgency and frequency were either improved or cured following bladder distention [383]. Corroborative objective outcomes data such as pad tests or voiding diaries were lacking in both of these studies. In contrast, Delaere and colleagues reported on 63 patients with involuntary bladder contractions on uroflowmetry and urge incontinence undergoing prolonged bladder distention [384].

Results were tabulated according to symptomatic outcome. Continence was not a primary outcome measure. At 1 year follow-up 11% of patients were cured and 21% improved. Whitfield noted that none of 11 patients with detrusor instability treated with a classical Helmstein balloon bladder overdistension “reverted” to a normal cystogram although 6/11 noted some symptomatic improvement [385]. Poor results were also seen by Pengally and colleagues in whom only 4/46 patients noted symptomatic improvement following hydrodistention [386]. Of the 43 patients undergoing postoperative urodynamics in this study, none had “conversion” to a stable detrusor on uroflowmetry.

Long-term follow-up studies demonstrating an objective or durable response to this modality of therapy for detrusor overactivity incontinence are lacking. Outcome measures have included mostly subjective patient assessments done in a retrospective fashion. Validated general or disease specific quality of life instruments have not been utilized to assess outcomes in these patients.

Bladder rupture, haematuria, infection, voiding dysfunction, and urinary retention are potential risks of bladder overdistention.

c) **Transvesical Phenol Injection**

Transvesical phenol injection is performed by endoscopic injection of a 5%-6% aqueous phenol solution in the region of the trigone of the bladder. The mechanism by which phenol exerts its favourable effects is purported to be via chemical denervation (neurolytic agent) [387].

**Level I evidence:** There are no randomized, double blind, placebo controlled studies that have examined the efficacy of subtrigonal phenol or compared it to another therapy for detrusor overactivity incontinence.

**Other evidence:** Several uncontrolled studies have examined the effects of subtrigonal phenol injection for the treatment of both non-neurogenic and neurogenic detrusor overactivity (Level 4 evidence). Initial studies suggested that this therapy was safe and effective in the short term with response rates of between 58-83% [388-391]. Better response rates were seen in neurogenic as compared to non-neurogenic voiding dysfunction, especially in patients with multiple sclerosis [389,390]. In one study, neurogenic bladder patients had a markedly greater response rate (82%) as compared to younger (<55 years old) non-neurogenic patients (14%) [391]. Subsequent studies with longer-term follow-up have not reproduced these results. Chapple and colleagues reported that only 4 out of 24 patients derived any ongoing benefit from phenol injection at 6 months follow-up [392], whereas Ramsay and colleagues reported a subjective response rate of only 14% in 41 patients at a mean follow-up of 13.7 months [393]. Wall et al reported a 29% initial response rate with all patients eventually failing at up to 4 years follow-up [394]. A similar long term failure rate was seen by Rosenbaum et al where only 1 out of 60 patients maintained a satisfactory result at 2 years [395].

Overall an 11.3% complication rate has been attributed to subtrigonal phenol injection including urinary retention, fistula and significant haematuria [392].

**Recommendation:**

Current evidence suggests that women with refractory non-neurogenic detrusor overactivity do not gain long term benefit from endoscopic bladder transaction, bladder overdistension, or transvesical phenol injection. Clinical use of these modalities is not recommended for this indication. (Grade C)

2. **OPEN SURGICAL INTERVENTIONS**

a) **Ingelman-Sundberg Denervation**

In 1959 Ingelman-Sundberg described an operation for the treatment of urge incontinence that selectively divided the preganglionic pelvic nerves near the inferior surface of the bladder through a transvaginal approach.
This involved considerable dissection near the cervix and bilateral transection of the pelvic nerves in this region.

**Level I evidence:** There have been no randomized controlled trials, double blind trials, sham-controlled studies, or cohort studies which have examined the effects of Ingelman-Sundberg denervation for the treatment of non-neurogenic detrusor overactivity incontinence.

**Other evidence:** Hodgkinson et al reported good results with this procedure in a case series of 23 patients, with 12 patients subjectively cured and an additional 9 improved (Level 4 evidence) [396]. The results of a modified Ingelman-Sundberg procedure by Cespedes and colleagues suggested a 64% cure of urge incontinence in carefully selected patients at a mean follow-up of 14.8 months [397]. In this case series (Level 4 evidence) the authors preselected the 25 patients based on a satisfactory clinical response to a transvaginal injection of local aesthetic in the region of the trigone. Westney and colleagues reported long term results with the same modified Ingelman-Sundberg procedure in a case series of 28 women (Level 4 evidence) [398]. Using the same preselection criteria as Cespedes et al, these authors noted a 54% cure of urge incontinence and a 68% cure/improved rate at a mean follow-up 44.1 months.

One randomized prospective trial compared 96 patients with mixed urinary incontinence treated with a transobturator midurethral sling (TOT) alone vs. those treated with a TOT combined with an Ingelman-Sundberg procedure. Objective surgical response rate was significantly higher in the TOT plus Ingelman-Sundberg group than in the TOT alone group (84.8% vs. 62.8%; p=0.019) [399]. Complications in both groups were similar although operative times were longer in the combined surgery group.

Complications associated with the Ingelman-Sundberg procedure have included ongoing voiding dysfunction, bleeding, and transient urinary retention.

**b) Sacral rhizotomy**

This procedure is primarily performed in the neuropathic bladder population and is discussed further elsewhere (See chapter on Neuropathic bladder).

**c) Enlargement (augmentation) cystoplasty**

1. **Enterocystoplasty**

Augmentation cystoplasty has been used for many years with varying degrees of success for refractory detrusor overactivity and related incontinence. Indications for enterocystoplasty (other than non-neurogenic detrusor overactivity) include small capacity bladders due to fibrosis, tuberculosis, radiation, or chronic infection, neurogenic detrusor overactivity, poor bladder compliance, as well as others [400-403]. Virtually any portion of the GI tract can be utilized for enterocystoplasty with each segment having its own unique favourable properties as well as inherent complications [403,404]. There is no ideal segment for all cases. Incorporation of bowel into the lower urinary tract results in decreased bladder contractility and an interval increase in the volume to first involuntary bladder contraction during cystometry. Technically, the surgeon must be aware that the selected bowel segment should contain a suitable length of mesentery to reach into the deep pelvis for a tension free anastomosis between bowel and bladder. During enterocystoplasty, there is no general agreement on whether it is more favourable to bivalve the bladder sagittally or transversely. However, it is ideal to create the broadest possible opening in the bladder and thereby create the widest possible anastomosis between bladder and bowel resulting in the most spherical configuration possible. The bowel is divided and detuberalised on its antimesenteric side prior to anastomosis to maximally reduce peristaltic contractions. The goal of enterocystoplasty is to create a high capacity, low-pressure reservoir during the filling/storage phase of the micturition cycle. When successful, and properly combined with other concomitant reconstructive procedures (i.e. ureteroneocystostomy, slings, artificial urinary sphincters, etc.), enterocystoplasty protects the upper urinary tract from pressure-related injury, infection and reflux while ideally providing complete urinary continence.

**Level 1 evidence:** There have been no randomized controlled trials, double blind or sham-controlled trials or cohort studies which have examined the effects of enterocystoplasty for the treatment of non-neurogenic detrusor overactivity incontinence or directly compared it to another therapy for the same indication.

**Other evidence:** There are only a small number of reports in the literature that have examined the results of enterocystoplasty in adult patients with non-neurogenic detrusor overactivity incontinence. These include only case series (Level 4 evidence). One series comprised solely females [405] with the remaining series including both males and females as well as varying numbers of neuropathic bladder patients [379, 406-412] (See Table 8). Outcome measures have included mostly non-validated questionnaires and subjective patient assessments. Validated general or disease specific quality of life instruments have not been widely utilized to assess outcomes in these patients.

Awad et al reported on a series of 51 female patients undergoing augmentation cystoplasty for refractory non-neurogenic bladder related incontinence [405]. 18% of patients continued to have disabling symptoms of urinary incontinence, and only 53% of patients classified themselves as “happy” with the outcome of the surgery. One series noted a deterioration in
outcomes over time [376]. In this mixed series, symptomatic improvement was reported in 83% of non-neurogenic patients at 3 months postoperatively, but decreased to just 58% at last follow-up (mean follow-up 38 months). In contrast, 92% of neuropathic bladder patients in this series reported a “good” or “moderate” result at last follow-up. Similarly, Herschorn and colleagues reported a very high degree of patient satisfaction in a series composed of only neuropathic bladder patients with all 59 patients reporting that they were delighted, pleased or mostly satisfied with the surgery [377]. The reasons for apparent superior patient satisfaction in neuropathic patients as compared to non-neuropathic patients are unclear.

d) Auto augmentation

As an alternative to enterocystoplasty especially in children with neuropathic bladder, auto augmentation of the bladder was initially described by Cartwright and Snow [413,414]. Auto augmentation may be performed by incision (detrusor myotomy) or excision (detrusor myomectomy) of a portion of the detrusor muscle. Either technique purportedly creates an iatrogenic bladder mucosal “bulge” or pseudodiverticulum and an increase in the storage capacity of the bladder with a concomitant decrease in storage pressures. The reported advantages of detrusor auto augmentation over enterocystoplasty is the avoidance of complications related to the use of bowel in the urinary tract including malignancy, mucous formation, stones, surgical morbidity related to opening and reanastomosis of the GI tract, and metabolic acidosis [375,415, 403].

Level I evidence: There have been no randomized controlled trials, double blind trials or cohort studies which have examined the effects of enterocystoplasty as a treatment for non-neurogenic detrusor overactivity incontinence.

Other evidence: There are few studies on auto augmentation in the adult non-neurogenic population (See Table 8). One small study of 5 patients with urge incontinence showed promising results in all patients at the initial postoperative visit, but clinical deterioration and failure occurred in 4 of the 5 patients at 3 months follow-up [416] (Level 4 evidence). Mean bladder capacity increased but mean volume to first unstable bladder contraction decreased. 4 of the 5 patients continued to have involuntary bladder contractions on cystometry. One retrospective study compared detrusor myomectomy to enterocystoplasty in 61 patients [412]. The population under study included both men and women with neurogenic and non-neurogenic voiding dysfunction. These authors reported comparable clinical success for the two procedures however there was a 22% incidence of serious complications in the 27 patients undergoing enterocystoplasty, compared to only 3% of the 33 patients undergoing detrusor myomectomy.

Long term follow-up of auto augmentation in children with neurogenic bladder has demonstrated disappointing results [417,418]. This has been attributed to eventual fibrosis of the pseudodiverticulum [415]. In an attempt to improve long-term outcomes with this procedure and create a biological “backing” and blood supply for the pseudodiverticulum, a number of variations of this procedure have been described. These variations have included the use of demucosalized bowel segments, stomach, peritoneum and rectus abdominis muscle [415,419-423]. Long-term follow-up demonstrating favourable clinical results with these variations is lacking.

e) Tissue engineering

Various tissue engineering techniques have been utilized in an attempt to create a suitable alternative to enterocystoplasty or autoaugmentation [424,425]. Many of these techniques rely on the use of native urologic tissues either partially or fully. Techniques have included the use of foetal tissues as well as collagen matrices overgrown with transplanted cells especially autologous cells.

Level I evidence: There have been no randomized controlled trials, double blind trials or cohort studies which have compared tissue engineered bladders in humans to any other technique for the treatment of non-neurogenic detrusor overactivity.

Other evidence: There are no published trials using tissue engineering techniques for bladder reconstruction in humans in the non-neurogenic detrusor overactivity population. One case series of 7 patients with neurogenic bladder due to myelome-ningocele demonstrated modest success with tissue engineered autologous bladder constructs (Atala, 2006) [426] (Level 4).

f) Urinary diversion

Urinary diversion away from the bladder is rarely needed for the treatment of non-neurogenic detrusor overactivity. This is usually reserved for patients who fail other surgical measures or who have intractable detrusor overactivity and desire a simplified method of management such as an abdominal urostomy. An ileovesicostomy (“chimney”) procedure or Bricker bilateral ureteroileostomy may be considered depending on the clinical circumstances including the presence or absence of native vesico-ureteral reflux (Leng, 1999) [412]. There are no studies that have examined these techniques in the treatment of non-neurogenic detrusor overactivity incontinence.

CONCLUSIONS

Prospective, randomized, placebo (or sham) controlled trials of surgical therapy for detrusor overactivity incontinence are lacking. There is a need to critically assess these procedures in an evidenced based manner and compare them to each other as well as non-surgical therapies using a variety of outcome measures including quality of life parameters. (Table 8)

Recommendations

Augmentation enterocystoplasty should be reserved for patients who fail all forms of conservative therapy and are willing to accept the potential perioperative, and postoperative morbidity associated with the procedure as well as the potential need for permanent intermittent urethral catheterization. Women with non-neurogenic detrusor overactivity incontinence should be advised that, in the long term, only 50% of women are satisfied with the outcome from this procedure. (Grade C)

VI. COMPLICATIONS OF SURGERY FOR DETRUSOR OVERACTIVITY

1. AUGMENTATION CYSTOPLASTY

Complications associated with enterocystoplasty are significant and include those related to factors derived from the bowel segment being in direct contact with the urine as well as other operative and perioperative morbidity. Short and long term complications of enterocystoplasty have been recently reviewed by Greenwell et al and are summarized in Table 9 [402]. Especially clinically relevant is the potential need for long-term clean intermittent catheterization in these patients. This possibility must be discussed with the patient preoperatively as patients should be willing and able to accept permanent clean intermittent catheterization (CIC) as a method of bladder emptying. Inability or unwillingness to perform CIC in those in whom it is necessary can lead to life threatening complications such as pouch perforation, urosepsis and death. Mucous build-up in the augmented bladder may also be troublesome but can be controlled by a number of measures [427]. Malignant transformation is a long-term risk of bladder augmentation and requires ongoing lifetime surveillance [428-430].

VII. NEUROMODULATION

Sacral nerve stimulation (SNS) involves the stimulation of the sacral nerves to modulate the neural reflexes that influence the bladder, sphincter and pelvic floor. The initial experience with sacral nerve stimulation for use in bladder dysfunction was reported by Tanagho and Schmidt (1981) [431]. Since then, SNS using the Interstim (Medtronic, Minneapolis, Minnesota, U.S.A.) has been an invasive therapy that was approved by the FDA in 1997 for treatment of refractory urge incontinence. Use has been extended to include significant urgency, frequency and idiopathic urinary retention. World-wide, the number of implants passed 10,000 in 2003 with more than 70% of the implants in the U.S.

a) Surgical Methods

Implantation of SNS consists of two steps: a) Stage I, or the trial stage – This involves the placement of a stimulation lead next to the dorsal root of S3 for a time period between 1-4 weeks. If the patient’s symptoms under the existing list of indications for SNS improves more than 50 %, then the patient is a candidate to undergo the second step; b) Stage II or Permanent Step – In this step the permanent neurostimulator is implanted in the soft tissue of the buttock of the patient.

b) Reports of RCT on three indications of UI, U/F and UR

The initial report on the efficacy of SNS on treatment of refractory urinary urge incontinence was reported in 1999 (Schmidt 1999) [432](Level 2- as no placebo or sham control was used). This study reported the treatment of 76 patients with refractory urgent urinary incontinence from 16 contributing worldwide centres. The patients were randomized to immediate implantation and a control group with delayed implantation for a six-month period. At six months, the number of daily incontinence episodes, severity of episodes, and absorbent pads or diapers replaced daily due to incontinence were significantly reduced in the stimulation group compared to the delayed group. Of the 34 stimulation group patients, 16 (47 percent) were completely dry, and an additional 10 (29 percent) demonstrated a greater than 50 percent reduction in incontinence episodes. The interesting finding was that during the therapy evaluation, the group returned to the baseline level of incontinence when the stimulation was inactivated. Complications
were site pain of the stimulator implantation in 16 percent, implants infection in 19 percent, and leak migration in 7 percent.

The use of SNS in urgency frequency was reported in 2000 (Hassouna 2000)\(^{433}\). Similar to the previous design, 51 patients from 12 centres were randomized into an immediate stimulation group and a control group (25 and 26 patients respectively) ((Level 2- as no placebo or sham control was used)). Patients were followed for one, three and six months, and afterwards at six-month intervals up to two years. At the six-month evaluation, the stimulation group showed improvement in the number of voiding episodes (16.9 + 9.7 to 9.3 + 5.1) volume per void (118 + 74 to 226 + 124 ml) and degree of urgency (the rank 2.2 + .6 to 1.6 + .9). In addition, significant improvement in quality of life was demonstrated, as measured by SF-36.

Use of SNS for urinary retention was published in 2001 (Jonas 2001)\(^{434}\), and in this study 177 patients with urinary retention refractory to conservative therapy were enrolled from 13 worldwide centres between 1993 and 1998 (Level 2- as no placebo or sham control was used). Thirty-seven patients were assigned to treatment and 31 to the control group. The follow-up was done at one, three, six, twelve and eighteen months. The treatment group showed 69 percent elimination of catheterization at six months and an additional 14 percent with a greater than 50 percent reduction in catheter volume per catheterization. Temporary inactivation of SNS therapy resulted in significant increase in residual volume, but the effectiveness of central nervous stimulation was sustained for 18 months after implantation.

In 2000, a follow-up report of some of these patients was published (Siegl 2000)\(^{435}\) (Level 3). This report showed follow-up results after three years in all the indications. Fifty-nine percent of 41 had urinary urge incontinence. 46 percent of these patients were completely dry. After two years, 56 percent of the urgency frequency patients showed greater than 50 percent reduction in voids per day, and after 1-1/2 years, 70 percent of 42 retention patients showed greater than 50 percent reduction of catheter volume per catheterization.

The results of the use of SNS in the U.S. population were published in 2002 (Pettit 2000)\(^{436}\) (Level 3). This publication showed the data collected from the U.S. patient registry. The report included the use of SNS in 81 patients with all three indications: 27 for urgent continence, 10 with urgency frequency and 10 with urinary retention. In this report, 27 from 43 patients with urgent continence, 10 out of 19 with urgency frequency and 10 out of 19 with urinary retention showed improvement of more than 50 percent.

The results of an Italian registry was published in 2001 (Spinelli 2001)\(^{437}\) (Level 3). This report included the reports of 196 patients – 46 males and 150 females – for idiopathic urinary retention. 50 percent of patients stopped catheterization and another 13 percent catheterized once a day at one year after implantation. At the 12-month follow-up, 50 percent of patients with hyper-reflexia had less than one incontinence episode daily and the problem was completely solved in 66 patients. Of the patients with urgent continence, 39 percent were completely dry and 23 percent had less than one incontinence episode daily.

In Norway, the results of users of this modality were published in 2002 (Hedlund 2002)\(^{438}\) (Level 3). The author reported the first three years of experience with 53 patients: 45 women and 8 men. This study showed similar results to previous studies.

c) Urinary Retention

Aboseif et al 2002 reported on the use of SNS in functional urinary retention (Level 3). 32 patients were evaluated and underwent temporary PNE. Those who had a least a 50% improvement in symptoms during the test period underwent permanent generator placement. All patients who went to permanent generator placement were able to void spontaneously. There was both and increase in voided volume (48 to 198ml) and decrease in post void residual (315ml to 60 ml). 18/20 patients reported a greater than 50% improvement in quality of life.

d) Other Indications

Use of SNS for other off-labelled applications has been reported in the form of abstracts. The off-labelled usage has included use of SNS in neurogenic bladder; interstitial cystitis, and chronic pelvic pain. All these results are limited case series reports. (Level 5)

e) Complications

The reported complications of SNS includes infection, revision of stage I or II, lead migration, and undesirable stimulus. Changes in other visceral functions (sexual function; bowel function) has also been reported.

Stoller in 1987 reported that stimulation of the peripheral tibial nerve in pig-tailed monkeys was able to inhibit bladder overactivity (Gillon 1989)\(^{439}\) (Level 3). This initial work led to its use in patients with refractory overactive bladder.

1. Results

In 2000 Klinger et al performed a prospective trial on 15 patients with urgency-frequency syndrome. They underwent 12 weeks of stimulation with the SANS device (Level 3). Ten patients responded with a reduction in voiding frequency per day (16 to 4) and daily leakage episodes (4 to 2.4). The only complication was one haematoma at the puncture site.
Govier et al (2001) [440° (Level 3) in a multicenter study reported the efficacy of SANS in 53 patients. All patients had refractory OAB and were seen at 5 different sites in the U.S. The patients completed a 12-week stimulation. 71% of the patients had at least a 25% decrease in daytime or night time frequency. No adverse effects were noted.

Level 2-3 evidence suggests that sacral neuromodulation may provide benefit in the treatment of patients with refractory urinary incontinence, urgency/frequency and idiopathic, non-obstructive urinary retention.

The mechanism of action of neuromodulation remains unknown.

The predictors of outcome and patient response to neuromodulation remain unknown.

Longer term and independent observational studies are needed to examine the longevity of the neuromodulation and identification of the most appropriate patient who should undergo this treatment.

2. COMPLICATIONS OF NEUROMODULATION

Several complications related to sacral neuromodulation have been well documented. Overall, the reported surgical revision or removal rate has been reported to be as high as 16-32% [441, 442]. Seigel et al reported on adverse events in 219 patients with pain at the stimulator site being the most common (Table 10) [443]. This is the most frequently reported complication in many series [442, 444]. Generally relocation of the device into another buttock or lower abdominal site will improve the pain.

| Table 10. Adverse events related to Interstim implantation in 219 patients* |
|-----------------|-----------------|
| Pain at the stimulator site | 15.3% |
| New pain | 9.0% |
| Lead migration | 8.4% |
| Infection | 6.1% |
| Transient electric shock | 5.5% |
| Pain at the lead site | 5.4% |
| Changes in bowel function | 3.0% |

*adapted from: [454]

Several recent studies have reported longer-term results of sacral neuro-modulation in a prospective fashion. van Kerrebroeck, et al reported a five-year prospective study using validated tools for urge incontinence, urinary frequency and retention. 17 centres were included, worldwide, with 163 patients of whom 87% were female. Of these patients, 152 eventually underwent permanent implantation of the InterStim device. Of those undergoing implantation, 96 (63.2%) had urge incontinence and 25 (16.4%) had urgency and frequency. Voiding diaries were collected post-insertion, annually, with clinical success being defined as 50% or greater improvement in primary voiding dysfunction variables. At five years, urge incontinence leaking episodes decreased from a mean of 9.6 (plus or minus 6) to 3.9 (plus or minus 4) episodes per day. For those patients with urinary urgency, mean voids decreased from 19.3. (plus or minus 7) per day to 14.8 (plus or minus 7.6) whereas mean voided volume increased from 92.3. (plus or minus 52.8 ) to 165.2 (plus or minus 147.7). All changes were noted to be statistically significant according to the authors’ findings, with no life-threatening or irreversible adverse events being recorded. However, 279 device- or therapy -related adverse events in 102 patients were noted. Overall, 23.7% of patients during the study period required device exchange (36 patients). An additional twelve (7.9%) required re-positioning of the pulse generator, and ten (6.6%) required a lead and pulse generator replacement, and finally, ten (6.6%) required only lead re-positioning. An additional eleven patients (7.2%) required either permanent or temporary explantation, due to a variety of indications. The authors concluded that neuromodulation provided long-term benefit for urge incontinence, urinary frequency and urinary retention. (Level 3 evidence)

A second long-term outcomes report for neuro-modulation was published by van Voskuilen [446]. This was a single institution study and was a retrospective assessment of all patients implanted. There were 149 patients, including 107 subjects with urgency and frequency and/or urge incontinence as indication for implantation. Mean follow-up was 64.2 months (standard deviation 38.5). 194 adverse events were recorded, including six infections, with one explantation for infection. 129 re-operations were performed, with 21 complete explantations. There was a "learning curve" with time such that incidents of re-operations decreased substantially after 1996, correlating with improved experience with the device. This also correlated with a more "proactive" approach toward adverse events, including earlier diagnosis and intervention. Revision rates decreased overall from 4.25 in 1990, the first year of the study, to 0.00 from 2001 through the end of study, in 2003. The most common adverse event encountered in this population was pain with stimulation, followed by undesirable changes in voiding function, 64 and two, respectively, and pain at the IPG site, which was 41. There were also ten cases of lead migration and six cases of device-related failures.

Based upon a stringent review of the literature, a recent NICE guidance stated that sacral nerve stimulation was recommended for patients with detrusor overactivity who had failed conservative treatments. The NICE guideline concluded that approximately two-thirds of the patients achieved continence or at least substantial improvement of...
symptoms over periods ranging from 3-5 years, with approximately one-third of the patients requiring a re-intervention due to device-site or infection related complications.

Barizzelli reported a systematic review of the literature and acknowledged a similar finding [447]

Recommendation

Evidence Level: Sacral neuro-modulation appears to have benefit for patients with urge incontinence, as well as urgency and frequency. (Level 1, 2, and 3)

Recommendation Level A.

4 NICE guidelines reference

VIII. URETHRAL DIVERTICULUM

Search of Medline for urethral diverticulum (UD) and female resulted in 576 published articles from 1952 to 2008. Despite case reports dating to 1786 (Hey), most studies consist of case series and consist of small numbers without control groups or comparison of differing interventions.

Diagnosis of UD was first advanced by Davis and Cian when they introduced the Double Balloon Positive Pressure Urethrography technique in 1956. Recently, longer term follow up studies post intervention and advances in imaging such as magnetic resonance imaging (MRI) has led to increased clinical awareness and diagnosis of this condition. (Daneshgari 1999) [448] (Figure 12).

The important clinical topics concerning UD are:

1. CLASSIFICATION
2. IMAGING MODALITY USED FOR CHARACTERIZATION AND DIAGNOSIS
3. INDICATIONS FOR CONCOMITANT PROCEDURES SUCH AS ANTI-INCONTINENCE PROCEDURES,
4. USE OF INTERPOSITIONING TISSUES.
5. OUTCOME MEASURES AND COMPLICATIONS OF UD REPAIR

1. CLASSIFICATION

Leach (Leach et al. 1993) [449] originated a classification system designed to accurately describe the characteristics of urethral diverticulae. The system utilizes the acronym LNSC3, which represents descriptive parameters for L = Location, N = Number, S = Size, C1 = Configuration, C2 = Communication, and C3 = Continence. In a series of 61 patients, urethral diverticulae were most commonly single in number (90 percent) and shape (62 percent). The location of the diverticulum swelling (62 percent), and ostium (60 percent) was mid-urethra. Fifty-six percent of the patients were incontinent (Leach et al 1993) [449].

Leng and McGuire divided diverticulae based on the integrity of the periurethral fascia, although diverticulae were described generally as primary diverticulae consisting of a mucosal layer only with narrow neck ostia bound by intact periurethral fascia. In contrast, pseudodiverticulae are often multi-layered with wide mouthed ostia on cystoscopic examination in association with a periurethral fascia defect. Rupture or erosion of the periurethral fascia often correlates with a history of prior suspension or a recurrent urethral diverticulae (Leng and McGuire 1998) [450]. These authors introduced the possibility that recurrence rates were influenced by global defects in the periurethral fascia thus potentiating de novo diverticulum formation or recurrence even after successful initial intervention.

2. IMAGING MODALITY USED FOR CHARACTERIZATION AND DIAGNOSIS

Optimal imaging modality for diagnosis of UD continues to be discussed in the literature. However, increasing data supports the definitive role of MRI examination in defining these lesions. The existing modalities include:

a) Voiding Cysto Urethrogram (VCUG) /Double Balloon Retrograde Urethrography
b) Ultrasound
c) MRI

The value of concomitant cystoscopy during the evaluation process lacks any significant evidence although this practice appears to be widely used.

Figure 12: Urethral diverticulum
Similarly, the use of urodynamics (with or without fluoroscopy) while very commonly done in naturalistic settings, has not been adequately studied to assess contribution to the overall assessment of UD.

a) Voiding Cysto Urethrogram (VCUG) /Double Balloon Retrograde Urethrography

In 1928, Norris and Kimbrough were the first to utilize cysto urethrography to define female bladder and urethral anatomy. A variation of this technique was repeated by Davis using a specialized double balloon catheter. Reported sensitivity for these techniques has ranged widely from 44 to 100 percent (Ganabathi 1994; Jacoby 1999; Golomb 2003 Level 3) [451-453]. Other authors have argued for the value of VCUG combined with urodynamics to assist in structural and functional analysis of the entire lower urinary tract. (Rufford, 2005, Level 4)[454]

b) Ultrasound

In 1977, Lee and Keller reported the use of abdominal ultrasound to identify urethral diverticulae (Lee 1977) [455] (Level 3). This modality may be used when a high clinical suspicion exists and when urographic results are negative. Diverticulae appear as anechoic or hypo echoic (to periurethral tissue) cavities with enhanced through transmission. Newer higher frequency ultrasound probes associated with intraluminal probe use may further enhance the utility of this technique. (Yang, 2004, Level 4) [456]. Ultrasound has been shown to have 100% sensitivity as compared to other modalities for the diagnosis of UD. (Gerrard, 2003, Level 3) [457].

c) MRI (Figure 13)

MRI has the advantage of multiplanar capabilities and excellent soft tissue definition. These qualities allow for differentiation between urethral diverticulae and other periurethral masses. Both T1 rated and T2 weighted images have been used or could be used for diagnosis of MRI. The T2 weighted images allow a high signal intensity of the urine, and collections within the urethral diverticulae making it a preferred method of imaging for urethral diverticulae (Level 3). The multiplanar capability of the MRI allows for a) identification of multiple urethral diverticulae; and, b) surgical planning for repair of the urethral diverticulae. Neitlich et al. applied a high-resolution fast stain echo MRI technique using a torso multicoil resulting in an examination time of 15 minutes. This study prospectively compared double balloon urethrography with MRI imaging of the urethra for detection of urethral diverticulae with a resultant sensitivity of 25 and 100 percent respectively. (Neitlich 1998 Level 2) [458] Another study evaluated diverticulae preoperatively with MRI classifying them simple, « U » shaped, or circumferential based upon MRI appearance. Recurrence after resection was significantly higher in « U » shaped (33%) or ring lesions (60%) then in the simple group (0%).(Han, 2007, Level 2)459 MRI has also been shown to alter surgical management in some patients (15% of 27 patients). (Foster 2007, Level 4) [281]. Attempts at refining MRI technique using endo cavity techniques may improve detection and characterisation of these lesions. (Lorenzo, 2003, Level 3) [460].

There is no Level 1 evidence to support the optimal imaging modality. There are differences in the calculated sensitivity of each imaging modality between the various recorded studies. Moreover, the results of the studies are limited by differences in the patient population, study techniques, and interpretive skills of the radiologists.

3. TREATMENT

Surgery for stress incontinence may be successfully performed along with urethral diverticulectomy. Leach (Leach and Bavendam 1987) [461] described simultaneous needle bladder neck suspension in 22 women with stress incontinence (Level 3). At the main follow-up of 20.5 months, 77 percent were totally continent and no significant complications were noted. Four of the five failures were secondary to ISD. Swierzewski (Swierzewski and McGuire 1993) [462] performed simultaneous autologous rectus fascia vaginal sling and urethral diverticulectomy in 14 women (Level 3). All were cured of the stress continence and one developed severe detrusor overactivity. The diverticulae recurred in one patient. More recent reports suggest that when an anti-incontinence procedure is not performed at time of diverticulectomy, rates of symptomatic incontinence are high with 49% of women reporting de novo SUI, and when incontinence was pre-existent, a 73% rate of persistence (Lee, 2008, Level 3) [485].

Use of labial (Martius) fat pad, vaginal wall bipedicled...
flap and autologous fascia in forms of pubovaginal sling has been used as interpositioning techniques for repair of UD. All reported cases are case series (Level 3). In several series, use of perivesical fascia as the interpositioning layer has been reported.

The optimal outcome of repair of UD is a) absence of UD recurrence; b) relief of symptoms; and c) absence of complications. A wide range of measured outcomes is reported in the literature in mostly in form of case series (Level 3). The potential complications of the UD repair are reported as either short term (bleeding, urinary tract infection) or long term (urethrovaginal fistula, urethral pain syndrome, urinary incontinence, recurrent diverticulum). Recurrence of UD has been reported as long as 5 years after surgery. Presence or absence of additional pathologies such as neoplasm (squamous cell carcinoma, clear cell carcinoma, nephrogenic adenoma, vaginal leiomyoma), malakoplakia, and calculi formation within the UD has also been reported as an outcome measure. The incidence of concomitant pathology is reported in less than 5% of large series (Kochakarn 2000) [463].

In 1875, Tait was the first to report complete excision of a urethral diverticulae (Tait 1875) [464]. The following approaches have been reported in the literature for urethral diverticulum.

1. Endoscopic Approach – This technique uses a transurethral marsupialisation. (Davis 1970; Lapides 1979) [465,466].

2. Packing/Obliterative Procedures – The diverticulae cavity is packed with oxidized cellulose followed by closure of the diverticulum and vaginal wall. (Ellik 1957) [467].

3. Open Marsupialisation – The Spence technique, which is essentially a meatotomy, is often performed for distal diverticulum connecting the posterior aspect of the urethral wall. (Spence 1970) [468].

4. Open Diverticulectomy – This technique uses mostly vaginal exposure to a) identify the diverticulum, b) dissect the diverticulum, c) repair the defect in the periurethral fascia. This technique has been the most widely used technique and the most widely reported in the literature. For the majority of the cases, a single closure of the periurethral fascia suffices for repair; however, use of additional inter-positioning tissues such as Martius fat pad has been reported.

5. Retropubic approach for ventrally based proximal diverticulae – This is used for very proximal and ventrally positioned proximal diverticulae, which are not the most common type of presentation for diverticulum.

6. Supra-Urethral meatus Approach to Ventrally Based Diverticulum – In this approach for urethrolysis, a semi-circle incision is made above the urethral meatus thereby gaining an approach to the ventral urethral space.

7. Transvaginal resection with periurethral fascia dissection and layered closure (most common)

8. Urethral transection with circumferential dissection. (Rovner, 2003, Level 3) [469].

All the reported surgical techniques are case series (Level 3), and there is no published report of comparing the techniques or the outcomes in a prospective, randomized manner. One series reports the longest follow up of transvaginal resection. Sixty four women were followed up to twenty years, with recurrence in 11, urinary tract pain in 11, dyspareunia in 14, urinary urgency in 39 (12 with urge incontinence), and 24 with de novo stress incontinence. This report underscores the importance of assessing all functional outcomes of UD interventions. (Ljungqvist, 2007, Level 3) [470]

IX. NON-OBSTETRIC URINARY FISTULAE

I. INTRODUCTION

In developing countries birth trauma remains the aetiology for the majority of fistulae. (Arrowsmith 1996) [471]. In developed countries, modern obstetric care has substantially limited the risk of vesicovaginal fistulae and fistulae are usually the result of complications of gynaecological or other pelvic surgery. Evidence for fistula evaluation, timing of corrective intervention, methods of and adjuncts to correction, and associated management strategies is based on clinical series and / or case studies (Levels 2, 3 and 4) and lacks definitive randomized control analysis.

2. SPECIFIC AETIOLOGIES

In developed countries the most common cause of vesicovaginal fistula is routine abdominal or vaginal hysterectomy. At least 75% of genitourinary fistulae are subsequent to this cause (Jonas 1984, Symmonds 1984, Lee 1988, Tancer 1992) [472-475]. Fistulae occurring after hysterectomy are thought to be due to unrecognized direct bladder trauma, tissue necrosis caused by inadvertent suture placement though the bladder wall (probably most common and arising from suture placement at time of vaginal vault reconstruction), or thermal injury from electrocautery either as an isolated factor or in association with direct surgical injury. Tissue necrosis may also occur following previous surgery and with pelvic abscess or infection. Tissue necrosis results in fibrosis and induration, eventuating in an epithelial or mucosal lining of the fistula tract (Kursh, 1988) [476].

In 1980 Goodwin reported 32 patients with fistulae as a direct result of gynaecological intervention (Goodwin
Tancer (1992) [475] noted a similar group of 151 patients and found that 91% (137) were postsurgical with 125 caused by gynaecological surgery. The most common procedure accounting for fistula was hysterectomy in 73% (110) of cases (99 of which were performed transabdominally). Factors thought to contribute to the risk of fistula formation due to hysterectomy include: prior caesarean section, intrinsic uterine disease (endometriosis) and prior ablative treatment for carcinomas (pelvic radiation therapy). Similar risk factors were identified by Blandy et al. (1991) [478]. The incidence of fistula after hysterectomy is generally accepted to be 0.1 - 0.2%. (Harris, 1995) [479] Recent meta-analysis of the gynaecological literature suggests that the rate of iatrogenic ureteral injury during hysterectomy approaches a crude occurrence rate of 6.2 per 1000 cases, while bladder injury occurs at 10.4 per 1000 cases. (Gilmour, 1999) [480] Additional surgical aetiologies include: general surgical interventions in the pelvis (i.e. low anterior resection), anterior compartment repairs, or stress incontinence interventions. (Armenakas, Pareek, & Fracchia 2004) [481]. In a large series of 207 VVF, 83% were due to abdominal hysterectomy, 8% vaginal hysterectomy, 4% radiation and the remainder miscellaneous causes (Elieber et al. 2003) [482]. Intraoperative cystoscopy appears to lessen the risk of fistula formation by up to 90% for ureteral and 85% for bladder lesions. (Gilmour, Dwyer, & Carey 1999) [480].

Other causes of fistulae include: malignancy (Kottmeier, 1964) [483], radiation (Cushing, 1968, Stockbine 1970, and Villasanta, 1972) [484-486] gastrointestinal surgery (low anterior resection) (Cross, 1993) [487], inflammatory bowel disease and urinary tuberculosis (Ba-Thike et al, 1992) [488]. Symmonds' experience at the Mayo clinic revealed only 5% of 800 vesicovaginal fistulae to be due to obstetric causes (Symmonds, 1984) [473]. Rarely, foreign bodies such as pessaries, diaphragms, and intrauterine devices also may lead to fistula formation (Goldstein et al., 1990) [489]. Iatrogenic CO2 laser therapy for cervical disease has also resulted in bladder fistulae (Colombel, 1995) [490]. Autoimmune diseases such as Behcet's have also been implicated as causative for vesicovaginal fistulae, due to extensive vasculitis related bladder wall necrosis. (Monteiro, 1995) [491]. Cervical, vaginal and endometrial carcinoma account for 3-5% of VVF in the developed world, and are the most common malignancies associated with this phenomenon.

3. EVALUATION

The best preventative strategy for fistulas is early identification at the time of surgery with immediate repair of the bladder / ureteral injury. Physical examination is the most important diagnostic component in the evaluation of a woman with a suspected genitourinary fistula. Vaginal examination should try to identify the fistula tract and the degree of vaginal access.

Aiding physical examination, dyes may be instilled into the bladder and coloured vaginal drainage assessed. This tool is particularly helpful for obscure fistulas (Drutz & Mainprize 1988) [492].

Cystoscopy (Figure 14) is a crucial adjunct to demonstrate the location and size of the fistula as well as proximity to one or both ureteral orifices. Cystoscopy also assesses the bladder mucosa for oedema and persistent necrosis which may complicate planned surgical repair.

Figure 14: Post-hysterectomy cystoscopic appearance of a VVF

Patients may present while in the hospital with prolonged ileus, excessive pain, haematuria or flank pain (if a simultaneous ureteral injury also is present) (Kursh, 1998) [476]. If the fistula tract is large enough a significant amount, if not all, urine drains through the vagina, producing continuous or total incontinence. In other cases, fistula drainage may be minimal and intermittent and may be initially mistaken for stress incontinence occurring postoperatively. Patients with urethrovaginal fistulae arising from urethral catheter trauma may not develop symptoms until catheter removal has occurred. Incontinence arising from a urethrovaginal fistula may be intermittent unless the fistula extends across the bladder neck, in these cases severe and total incontinence is usually encountered. Fistulae may develop up to twenty years post radiation (Graham 1965; Raz 1992) [493,94]. Additionally, persistent clear vaginal discharge after hysterectomy may arise from leakage of peritoneal fluid from a vaginal cuff through a peritoneal sinus tract (posthysterectomy pseudo incontinence) (Ball, 1995) [494]. Ginsberg et al, 1998 [495], reported five patients with this finding, all of whom were cured by vaginal cuff revision.
Intravenous pyelography should be performed in women with any urinary fistula primarily to detect ureteric injury but also for congenital ureteric anomalies. Symmonds (1984) reported a 10% risk of a simultaneous ureteral component with vesicovaginal fistulae. The cystogram phase of the IVP may also suggest the presence of a fistula if early pooling of urine in the vagina occurs or wisps of urinary extravasation are noted. Retrograde pyelography may be employed for diagnosing the site of a ureterovaginal fistula or the possibility of a combined uretero- and vesicovaginal fistula, although no direct studies have evaluated this diagnostic technique against other imaging modalities.

Voiding cystourethrogram (VCUG) may also help determine fistula presence and location. Also, the VCUG may demonstrate other lower urinary tract abnormalities that may impact upon surgical reconstruction (vesicoureteral reflux, cystocele, urethral diverticulum). Occasionally contrast examination of the vagina (vaginography) may help demonstrate an irregular fistulous tract. Zimmern et al. (1994) [496] described the procedure for injecting contrast material through the vagina with a large balloon occluding the vaginal introitus. Level 3 evidence supports the use of this study.

Hilton (1998) [497] argues that urodynamics are necessary in the woman with a lower urinary tract fistula. He noted the following urodynamic abnormalities while evaluating 30 women with fistulae: 47% urodynamic stress incontinence, 44% detrusor overactivity, and 17% with poor bladder compliance. Urodynamics, however, are often difficult to perform due to continuous loss of instilled fluid through the fistula tract and therefore in many cases may not be additive to the overall evaluation of the patient. No evidence exists as to the role of urodynamics in predicting post-operative stress incontinence after fistula repair.

Summary

The evaluation of urinary fistulae is based on evidence of loss of urine on physical evaluation, cystoscopic inspection of the bladder, and assessment of lower ureteral integrity (either IVP of retrograde pyelography).

Mandatory evaluation includes clinical examination with or without the use of dyes (Level 3) Intravenous urogram (Level 3,4), Cystoscopy (Level 3)

Optional testing: Voiding cystourethrography (Level 3,4), Urodynamics (Level 4)

4. TREATMENT

a) Conservative and minimally Invasive treatment

Regardless of the timing of presentation, a trial of conservative therapy may be implemented which uses continuous urethral catheter drainage. Level 4.5 evidence suggests that a variety of conservative techniques may be curative and possibly should be attempted first in patients with single fistula tracts which are less than 1 cm in size, and which are not associated with complicating factors such as prior radiation. Tancer et al (1992) [438] reported 3 of 151 patients with spontaneous closure of fistula using this strategy. Spontaneous closure occurred with 3 fistula tracts identified early in the postoperative period in 45 women managed in this fashion. Often, however, the patient has already undergone a trial of catheter drainage at the time of initial evaluation and therefore further catheter drainage may be helpful. No definitive evidence suggests the optimal time for catheter drainage. (Level 4)

Another possible conservative therapy utilizes electrocoagulation or fulguration of the lining of the fistulous tract (O’Connor 1980, Alonso 1985, Molina 1989, Stovsky, 1994) [498-501]. In Stovsky’s experience 11 of 17 (73%) of patients with small (less than 3mm) fistulae treated with electrofulguration and 2 weeks of catheter drainage resolved. McKay (1997) [502] recently described successful cystoscopically placed suture closure of a vesicovaginal fistula, with no secondary incision.

Recently, the use of tissue adhesives has been described as a sealant for fistula tracts. Evans et al. (2003) [503] reported the use of fibrin sealant for five patients who had complex vesicovaginal fistulae. All five were successfully managed without complication. (Level 4)

Summary

Level 4/5 evidence suggests that conservative management techniques may be utilized in selected patients with small fistulae. More research is needed to better identify the patients who would best be managed in this manner.

b) Surgical Therapy

1. TIMING OF INTERVENTION

Previously, many authors have advocated a waiting period of at least 3 to 6 months before intervening with surgical therapy (O’Connor 1951, Wein 1980, Blandy 1991) [504,505,478]. No specific evidence exists as to the need for this delay in intervention. More recently surgeons have advocated an individualized approach without an observational period. Several authors have reported excellent results with early interventions (Persky, 1979, Goodwin 1980, Wang 1990, Raz 1992, Blaivas 1995, Raz 2000) [506,477,507,94,508,509]. There is Level 3 evidence that fistulae identified within the first 24 to 48 hours postoperatively can be safely repaired immediately. Those identified days to weeks after surgery require careful planning and selection. Wang and Hadley
successfully managed 15 of 16 (94%) high lying (vaginal apical) fistulae through a transvaginal approach, with all 7 patients who were less than three months from initial surgery cured of fistula. (Wang 1990) [507].

Summary
The timing for surgical intervention may depend on presenting factors such as tissue integrity. Intervention immediately following early diagnosis is successful in some series. Additionally, surgical approach (abdominal versus vaginal may also impact this decision). More research is necessary to identify optimal timing of fistula repair.

Evidence for timing of Surgery Level 4,5

2. Preoperative Preparation
No specific evidence supports any preoperative preparation as being crucial for surgical success. Individualization of operative decision will be impacted by the unique needs of each woman undergoing intervention. Local preparation such as vaginal douches with antiseptic agents the evening before and the morning of surgery have been used in the past but no evidence supports this technique. A recent RCT evaluating the use of antibiotic prophylaxis for fistula surgery showed no benefit to use of perioperative antibiotics (Tomlinson AJ & Thornton JG 1998) [510]. Oestrogen replacement therapy has also used in those patients with poor quality of vaginal tissues (Raz 1992) [94]. (Level 4/5)

Summary
No specific preoperative preparation has been shown to alter outcome. Antibiotic prophylaxis does not influence post-operative infective morbidity or outcome. (Level 1 / 2)

3. Surgical Approaches
Surgical approaches used for vesicovaginal fistulae include: combined abdominal vaginal, vaginal, or abdominal approaches. The approach chosen is dependent upon several factors, including location of fistula, quality of the tissues, and surgical experience and training. Vaginal surgery is more rapid and results in less morbidity and more rapid recovery; however, the vaginal route is difficult in patients with a significant degree of fibrosis, pelvic immobility, or with large fistula tracts with possible injury in close proximity to the ureteral orifices. (Carr & Webster 1997) [329] (Dupont & Raz 1996) [511] The abdominal approach may be more appropriate for the poorly visualized tract, the narrow or immobile vagina, and those with close proximity to a ureteral orifice. Laparoscopic repair also provides an alternative approach.

Other considerations for surgical repair include; type of suture, method of urinary drainage, and the use of tissue interposition graft.

There is only level 4 and 5 evidence to support any of the surgical techniques.

5. Vaginal Approach
The vaginal approach utilizes an anterior vaginal wall flap for coverage. Subsequently a tension free closure is performed utilizing a long acting (polyglycolic acid or polydioxanone) suture and non-overlapping multiple closure lines. Interposition tissue may be mobilized from labia, peritoneum, or vagina.

There is only level 4,5 evidence to support these techniques.

A suprapubic catheter should be placed (Zeidman 1988) [512]. Urinary drainage may also be supplemented with a urethral catheter. If the fistula communication occurs in proximity to the ureteral orifices, ureteric catheterization with cystoscopic assistance is generally performed prior to fistula closure. Optimal visualization is dependent on tissue mobility. The use of lateral relaxing incisions may help operative visualization and approach to the fistulous tract (Zimmern 1994) [602]. If the fistula repair is tenuous or there is concern regarding apposition of suture lines a Martius interpositional graft may be utilized. If this is not obtainable, alternative graft sources include a peritoneal flap (Raz 1993) [513] or an interposition graft utilizing gracilis muscle tissue. The peritoneum can be freed from the posterior aspect of the bladder and easily advanced to cover the layers of the closure as well (Raz 1993) [513]. (Level 4)

Level 4,5 evidence suggests that the Martius labial interposition graft provides a satisfactory graft material (Raz 1992, Blaivas 1995, Blaivas 2000, Hoskins, 1984) [94,508,514,515]. Several authors have used this graft as an adjunct to repair associated with complicated incontinence with excellent results. (Ghoniem 1995, Carr 1997) [517,329] Martius flap interposition has been used for both urethrovaginal and vesicovaginal fistulas and seemed to convey an advantage (0 recurrences in 13 women) over repairs which did not use flap interposition (4 recurrences in 21 women) (Rangnekar, Imdad, Kaul, & Pathak 2000) [518].

The vast majority of vesicovaginal fistulae can be closed in one operation using the previously described approach. Raz reported a success rate of 92% (64/69) for vesicovaginal fistulae, 2/3 of which had failed 1 to 3 prior repairs using this technique (Raz 1992) [94]. Many of these repairs used a peritoneal graft interposition.

Other variants for vaginal the approach include the Latzko which essentially produces a partial colpocleisis with risks of vaginal shortening and overlapping suture lines. (Enzelsberger & Gitsch 1991) [519] Additionally, vaginal cuff excision has been advocated as another ablative method for closing fistula tracts. (Iselin, Aslan,
6. **Abdominal Approach**

All bladder fistulae (except those extending into the urethra) may be approached utilizing the abdominal approach, and this is the preferred approach in those patients requiring bladder augmentation or ureteral re-implantation. The earliest experience was reported by O’Conor (1951, 1973) for abdominal transvesical repair of vesicovaginal fistulae. This technique may require placement of ureteral catheters to localize the ureteral orifices. An abdominal incision is then performed (midline or Pfannenstiel), followed by bisection of the bladder to the level of fistula. The bladder and vagina are mobilized and separated from each other by dissecting along the vesicovaginal septum. A complete excision of the fistula tract is completed. If the tract is extensively indurated, a posterior bladder flap may be mobilized to repair the defect. (Gil-Vernet, 1989) [522]. Recently, Nesrallah et al reported a 100% success rate using the O’Conor transabdominal supravaginal technique in 29 patients. (Nesrallah 1999) [523]. Other authors have reported similar results.

Separate closure of the vagina and bladder are performed utilizing absorbable sutures (polydioxanone or polyglycolic) and may be performed intra- or extraperitoneally. The intraperitoneal technique allows for easy harvest of the omentum.

Level 4 evidence supports the use of omentum as an interpositional graft. Wein (1980b) [524] utilizing an omentum graft based on the right gastroepiploic artery noted adequate length and tension free apposition of this tissue between the vaginal and vesical components of the fistula repair. Other authors have found the omentum to be reproducibly present for interpositional uses. (Turner-Warwick, 1976) [525] (Kiricuta, 1972) [526] The omentum is secured between the bladder and vagina with 3-0 polyglycolic acid sutures.

Bladder augmentation can also be performed with the intraperitoneal approach into the already bivalved bladder. Large or small bowel may be utilized. This closure is often reinforced with an omentum pedicle graft. Reported success rates with this approach are approximately 85% - 90% and have been reported by numerous authors. (Marshall 1979, Wein 1980a, Gil-Vernet 1989, Udeh 1985, Demirel 1993, Kristensen 1994, Blaivas 1995, Raz 2000) [527,505,522,528-530,508].

7. **Laparoscopic Approach**

Laparoscopy provides an alternative approach for fistula repair. Level 3,4 evidence suggests that this approach may be successful for some patients. Nehzat et al (1994) [531] reported a successful repair of a laparoscopically caused fistula is a single patient. In a larger series Ou et al (2004) [543] evaluated retrospectively the value of laparoscopic repair as compared to vaginal or abdominal repair in 16 patients. Only two patients actually underwent laparoscopic repair, and both repairs were successful, however one patient had a prolonged hospitalization. (Level 5 Evidence)

8. **Complicated Vesicovaginal Fistulae**

Complicated vesicovaginal fistulae can be defined as those fistulae of large size (3 to 5 centimetres or greater in diameter), fistulae occurring after prior attempt at closure, fistulae associated with prior radiation therapy, fistulae associated with malignancy, fistulae occurring in compromised operative fields due to poor healing or host characteristics, and fistulae that involve the trigone, bladder neck and/or urethra.

Prior radiation therapy may increase the risk of vesicovaginal fistula despite the use of the tissue interposition (Obrink 1978, Raz 1992) [542,94]. Overall results range around 50% successful closure, but Bissada achieved 80% successful closure in his group of 10 post-radiation patients. (Bissada, 1992 Level 5 Evidence) [541]

**Summary**

No specific intra-operative intervention has been shown to influence outcome.

Urethrovaginal fistulae may be very small pinpoint fistulae demonstrated by vaginal voiding or may present as complete urethral and bladder neck loss with total urinary incontinence. This circumstance most commonly results from prior gynaecological surgery, with anterior repair and urethral diverticulectomy comprising the most common inciting procedures (Blaivas 1989, Raz 2000) [555,520] (Level 4 Evidence)
Previously, birth trauma was a cause of majority of urethral defects; however, in developed nations this is now a rare cause of urethrovaginal fistulae. Prolonged obstructive labour, however, remains a major cause of urethral injury in developing nations (Elkins 1994) [544].

Level 4 Evidence suggests that techniques used for urethrovaginal fistula closure are very similar to those utilized for transvaginal vesicovaginal fistula repair (Webster 1984) [545]. A significant difference however is that the urethrovaginal fistula should not be completely excised but rather circumscribed and oversewn. Complete urethral loss is a more daunting surgical challenge and a multiplicity of techniques has been described for this (Blaivas 1989, Blaivas 1996, Hendren 1980 and 1998, Patil 1980) [555,546-548,540]. These techniques usually employ some type of flap utilizing either vaginal, bladder, or alternative tissue in an inlay versus tabularised reconstruction (Blaivas 1989) [555]. Simultaneous stress incontinence procedures should be performed to obviate the risk of postoperative incontinence (Blaivas 1990) [549] (Level 3,4 Evidence)

i) Preoperative Evaluation

The physical examination is important to identify the extent and amount of urethral loss and associated vaginal pathologies such as prolapse and functional problems such as stress incontinence.

ii) Operative Technique

Small to intermediate size fistulae may be managed with a tension-free layered closure. Distal fistulae may be managed with extended meatotomy (Spence 1970) [468]. (Level 5) Complete reconstruction is necessary for large fistulae with extensive loss including those that involve the bladder neck. The optimal continence procedure required in such cases has not been critically studied.

Interpositional tissue should be considered whenever the closure lines or vaginal tissues are of poorer quality (Webster 1984, Leach 1991) [545,550] (Level 4,5 Evidence)

Summary

Although the risk of non-obstetric fistulae after gynaecological surgery approaches 0.1% in developed countries, evidence supporting optimal surgical preparation, approach and technique, and post surgical management is predominantly based on case series (Level 4).

Conservative or minimally invasive management (including catheter drainage, cystoscopic fulguration of fistula tract, and use of occlusive agents) has been reported the overall results for vesicovaginal fistulae with these methods are highly variable. Expert opinion suggests that an attempt at conservative management should be considered during the early management of a newly diagnosed vesicovaginal fistula. (Level 4 / 5)

Although vaginal, abdominal, and laparoscopic techniques have been described no clear advantage exists between these techniques. Very little evidence supports laparoscopic management. Surgeon preference, fistula location, and complicating factors (such as prior pelvic radiation, altered wound healing – i.e. chronic steroid use, proximity to ureteral orifices, and time of diagnosis) may all impact on method of repair. Timing of repair (Level 4) appears not to influence long term success and surgical repair may be performed at time of identification if factors such as wound healing are considered optimal by the operative surgeon.

Evidence supporting surgical adjuncts such as use and type of interpositional tissues and effect on outcome of repair is limited (Level 4).

Rigorous scientific assessment of the outcome of surgery for urinary incontinence is important because it enables comparison to be drawn between procedures. Patients can then make informed decisions in light of the risks and benefits demonstrated. Health care providers can identify cost effective treatments and surgeons can bench mark their practice.

Commonly used outcome measures are urodynamics, pad tests, bladder diaries, symptom questionnaires, symptom-bother questionnaires, quality of life (QoL) instruments, and measures of satisfaction. All of these tools are discussed in more detail by other chapters. The aim of this section is to highlight issues specific to the assessment of surgical outcome.

Any outcome measure must be reliable, valid, and responsive to change. It is also important that the results are interpretable within clinical practice.

Reliability concerns the extent to which an experiment, test or any measurement yields the same results on repeated trials.

Any measurement will have a degree of error associated with it. If this is large the test is not reliable and it is unlikely to be a useful outcome measure.

1. OBJECTIVE TESTS

a) Urodynamics

Several studies have demonstrated that urodynamics have poor test re-test reliability. Homma et al (Homma et al. 2000) [606] demonstrated that on repeating urodynamics after 2-4 weeks the results tend towards
normality. The was a 10-13% increase in bladder volumes (p<0.01), a 10% decrease in the number of subjects with detrusor overactivity and 18% reduction in the amplitude of detrusor contractions.

The test-retest reliability of urodynamics to detect detrusor overactivity was investigated in children by Griffiths et al. Urodynamics were repeated on three occasions, 10% changed from stable to unstable and 14% from unstable to stable (Griffiths et al. 1982) [551].

Cardozo et al. found 15% of women who complained of stress incontinence had no demonstrable loss on videourodynamic but were wet on Urilos pad tests (Cardozo et al. 1980) [552]. Urodynamics appeared not to be sensitive enough to detect this loss.

In 1997, Jensen et al. reviewed 26 studies that compared the urodynamic diagnosis to patients’ symptoms. They found that urodynamic evaluation failed to demonstrate incontinence in up to 25% (mean 9%) of patients who complained of urinary leakage (Jensen et al. 1997) [553].

Studies comparing static to ambulatory urodynamics have shown 25-60% of patients, with symptoms of overactive bladder, have negative stationary tests for detrusor overactivity which can then be identified on ambulatory testing (van Waalwijk van Doorn et al. 1987; Griffiths et al. 1989; Webb et al. 1991) [564, 580,557. However there is no test re-test data for ambulatory studies.

Hilton demonstrated that post operative urodynamics failed to demonstrate leakage in almost 40% of women who on questionnaire responses still had some leakage.

Post-operatively urodynamics have become the gold standard in the ‘objective’ assessment of surgical outcome (Jarvis 1994) [20]. However, there is little evidence of reliability to support this position.

**b) Cough stress test**

This can be a useful test to assess the resolution of stress incontinence following surgery(Yalcin et al. 2004) [558]. It however cannot be used to assess improvement. Before and after surgery the test should be standardised for bladder volume, number and force of coughs, and the position of the subject. There is no agreed standard for these factors and this limits the use of cough test data in meta-analysis of incontinence surgery.

**c) Pad tests**

Pad tests have been used to objectively define cure using a cut-off point at which the test is positive. There is considerable variation in the duration of pad tests are used. Short pad test 1-hour have been demonstrated to be unreliable measures and therefore not suitable outcome measures (Simons et al. 2001) [559]. There is evidence that the 72 hour pad test is most reliable duration for pad testing (Karantaxis et al. 2005) [560].

The number of pads used per 24 hours has been shown not to accurately reflect the amount of urine lost. (Dylewski et al. 2007) [561].

However all of these evaluations have been made in pre treatment samples and therefore may not be valid post-operatively when leakage episodes may be less frequent and severe.

**d) Bladder Diaries**

Bladder diaries, 3- 7 days, have been shown to be reliable measures of incontinence prior to surgery (Wyman et al. 1988) [562] however, their reliability may also be a function of the duration of the test and the frequency of incontinence episodes. Hence following surgery a patient with infrequent but bothersome incontinence episodes may appear cured on a 3 day diary- having no incontinence episodes. There has been no research to establish the clinical significance of improvements in bladder diaries, whether change in incontinence episodes should be reported as a percentage change from baseline or in reduction in the number of episodes.

**2. SYMPTOM QUESTIONNAIRES**

There a several symptom questionnaires available. Committee x has evaluated the psychometric properties of the available symptom questionnaires in detail, using an A,B,C grading system.

The content of a questionnaire is a psychometric property which is important, yet frequently overlooked. In selecting a symptom questionnaire for a surgical study it is important to consider if the instrument covers the recognised complications. For example the Severity of Symptoms Index SSI is a psychometrically valid instrument but it only addresses stress incontinence symptoms (Black et al. 1996) [237]. It does not measure common complications such as voiding difficulty or overactive bladder. Few questionnaires have comprehensive assessment of the impact incontinence on sexual function.

If an instrument is being used to assess a new innovation then one should select an instrument with the capacity to report in free text other symptoms not covered by the questionnaire.

Other factors which should be consider are the incidence of recurrent UTI, any pad use, drugs for OAB, re-operation , clean intermittent self catheterisation rates, and the speed of recovery. These can be used to compare procedures and are useful to counsel patients before surgery.

Another property to consider is does the questionnaire measure the presence of symptoms and the bothersomeness as separate items? Some instru-
ments separate symptoms and bother e.g. BFLUTS however others combine these factors one question e.g. KHQ.

Bother is a complex factor which is probably affected by personality, previous experience, other comorbidities and other factors. It is probably therefore more useful to use separate questions of symptoms and bother.

Symptoms are easily comparable between studies for meta analysis however they cannot be summated into a meaningful primary end point.

New innovations can be associated with new complications. It is important that these are assessed. Although it is difficult to compare the significance of different complications.

3. QUALITY OF LIFE (QoL) INSTRUMENTS

Committee x has provide a comprehensive review of the large number of QoL instruments available and their psychometric properties, reliability, validity, responsiveness.

To be a useful outcome measure in research & clinical practice the output of these instruments must have clinical meaning. Many studies report statistic changes in score but these have no clinical meaning. Further research is required to establish clinical meaning.

The most commonly use method to establish this is Minimally Clinically Important Change (MCID), although even this has limitations. There are several method to calculate MCID and it is probably disease and population dependant (Wyrwich et al. 2005) [563]. To date three QoL instruments have reported MCID but none are for a surgical interventions (Kelleher et al. 2004; Yalcin et al. 2006; Hendriks et al. 2008) [564-566]. MCID is not specific to an instrument and therefore for should currently be calculated for each study.

QoL instruments frequently are divided into domains for example physical, social, emotional & personal. An individual may attribute different importance to each of these domains therefore they should not be combined into a global score unless there is psychometric evidence that this is valid. Instead a global assessment scale should be used.

4. GLOBAL ASSESSMENT SCALES

This is term applied to a health-related index that provides a broad overview of a complex phenomenon. Selection of a response involves a patient implicitly evaluating feelings, perceptions, opinions, expectations, goal achievement, satisfaction, beliefs, and previous health state and then coming to a single judgement.

Global assessments usually consist of a single question. There are two common formats; state evaluation (How are you today?) and transition evaluations (How are you compared to before treatment?). These scales are very simple to use and are clinically intuitively understandable however they lack detail to identify reason for success or failure.

They are often used as anchor questions to determine MCID of QoL instruments.

The fact that a global impression index results in a single score means they can used as primary endpoints.

5. SATISFACTION

Almost 30 years ago, Norton hypothesised that a reduction in the number of leaks by 50% may not mean patients feel 50% better (Norton 1982) [567]. It may be that the fact of being incontinent, regardless of the amount or frequency, is what determines restrictions. This implies that nothing short of total dryness will be accepted by the patient as success. It is this concept which is addressed when assessing satisfaction.

Satisfaction is also a function of patients’ goals and expectations. Robinson et al found that 43% patients wanted “a good improvement so that symptoms no longer interfere with their life” however 17 % expected a complete cure of all symptoms in keeping with the National Institute of Health (NIH) definition of cure. The NIH definition of cure of stress incontinence is the resolution of the symptom of incontinence, the resolution of the sign of stress incontinence (a negative stress test with a full bladder) and the absence of new symptoms or side effects (Weber et al. 2001) [568]. It may be that pre-operative counselling can alter patients’ expectations and thereby ultimately alter the outcome of surgery – if it is assessed through satisfaction.

6. HEALTH-ECONOMIC OUTCOMES

Several incontinence operations appear to have similar efficacy. The trend is to develop less invasive operations for incontinence. Health-economic factors may ultimately be the only significantly different factor between procedures. Generic instruments such as ED-5D from which QALYs can be estimated may not be sensitive enough to detect change however there are currently no condition specific tools available. A preference-based measure of health developed from the King’s Health Questionnaire has been published however this is for use in OAB conditions not stress incontinence.(Brazier et al. 2008) [569]

CONCLUSION

Currently used objective outcome measures may not be sensitive enough to detect surgical failure. The only ‘subjective’ outcome measure which does not involve complex judgemental factors is the assessment of symptoms. These should be administered using a validated symptom questionnaire, by an independent party to avoid bias associated with patient surgeon.
relationship. Symptoms are easily comparable between studies for meta analysis however because they consist of multiple answers they are not suitable as primary outcome measure. The lack clinical meaning of results from QoL instruments restricts their usefulness and requires further research. In view of this a validated global impression scale may be a better primary outcome measure. Until further research establishes a universal outcome tool it is advisable to use multiple outcomes. This is in keeping with the recommendation of several societies and regulatory organisations; the AUA ([Lose et al. 1998] [261], the NIH ([Weber et al. 2001] [568] the IUGA, ([Ghoniem et al. 2008] [570] and ICS ([Mattiasson et al. 1998] [571]).

**Recommendations**

1. Most outcome measures used have been developed in non-surgical areas. Further research is required ensure they are clinically useful surgical outcome measures.
   a. When a QoL instrument is to be used ensure the study includes a calculation of MCID.
   b. A validated global impression index may be a useful primary outcome measure for surgical trials.
2. Until further research establishes a universal outcome tool it is advisable to use multiple outcomes.
   a. Symptoms and separate bother questionnaire
   b. Clinical important outcomes (pad use, re-operation rates, anticholinergics, CISC, recurrent UTI)
   c. Complications
   d. QoL tool with MCID
   e. Global Impression Index
   f. Health- economic outcome

**XI. ARTIFICIAL URINARY SPHINCTER IN WOMEN**

The artificial urinary sphincter has been utilized for the treatment of sphincter dysfunction in women in special circumstances (failed prior procedures) or rarely as a primary intervention. The majority of experience with the artificial urinary sphincter in women has been in neurogenic patients, with comparatively little data for women with non-neurogenic stress incontinence. The procedure may be performed either by a transvaginal [572] or transabdominal approach [573,574] (**Figure 15**).

Appell in 1988 reported results of artificial sphincter implantation in 34 women who experienced complete incontinence, with only three of the 34 requiring revision after transvaginal placement [575]. Subsequently, Hadley in 1991 reported 13 of 14 patients (93%) who attained reasonable urinary control (defined as no or one pad per day for stress incontinence).

Various authors have proposed either the trans-abdominal or the transvaginal approach as being superior due to operative technique-related issues, including operative dissection for cuff placement though no robust evidence is available to support their views. The trans-vaginal approach is considered to be superior for cuff dissection and placement. The transabdominal approach is considered to provide better exposure, especially for bladder neck placement, assuring placement between the urethra and the vaginal wall [573,576,577]. Laparoscopic placement has been described as a method to decrease morbidity associated with the abdominal approach [578].

Overall success rates range between 76% and 89%, with lower success rates and higher revision rates being noted in those patients with neurogenic voiding dysfunction as the primary indication for placement. The most extensive experience with artificial sphincter implantation is that of Costa (2001) who reported 207 patients with a mean of four-year follow-up. An overall success rate of 89% was reported in the non-neurogenic population with an overall vaginal extrusion rate of 6%.

A recent Cochrane Review failed to find sufficient evidence to support use of the artificial urinary sphincter and recommended large scale clinical trials to determine the possible role of these devices in the management of incontinence in women [579].

**Recommendation**

Only Level 3 / 4 evidence is available to support use of the artificial sphincter. This would support a Level B recommendation for use.

INTRODUCTION

Surgery for pelvic organ prolapse (POP) is common with increasing high-quality evidence to guide surgical practice. Yet many important basic questions remain, including the optimal timing for POP surgery, the optimal pre-operative evaluation of urinary tract function and the post-operative outcome assessment. Olsen [1] and Fialkow [2] have separately documented high rates of surgery for POP and/or urinary incontinence (UI) in US women. In Fiakow’s study, 169 women who underwent a primary prolapse surgery (+ concomitant UI procedure) were identified (Table 1).

In addition, there remains uncertainty about the longevity of prolapse repairs, with some experts stating that recurrences may be inevitable in at least a subgroup of women. Olsen’s recurrence rate estimate was based on 384 women in the Kasier Permanente Northwest population who underwent at least one POP/UI procedure. In that study, only 13 sacrocolpopexies were performed, reflecting the surgical practice in 1995. Until women at higher risk for recurrence are reliably identified prior to surgery, re-operation rates of up to 30% may persist.

Despite the need for additional studies to guide many aspects of POP surgical care, this chapter can be used to facilitate evidence-based management of POP. This committee has deliberated, graded evidence and provided recommended areas of high priority for current surgical care as well as further POP research. Readers of this chapter are also encouraged to periodically review continuously updated evidence from reviews including the Cochrane and NICE reports [3, 4]. This chapter also includes scientific contributions with lower levels of evidence than these reviews so that we can highlight the areas for future research.

I. OUTCOME ASSESSMENT

One of the most glaring limitations in recommending evidence-based POP surgery is the lack of an optimal method for determining outcome. While anatomic correction is usually reported, there is good evidence that POP and POP repairs have significant impact on urinary, sexual, and ano-rectal function; these aspects should be taken into account when assessing the outcome of POP surgeries. Therefore, recognizing that pelvic organ prolapse is a multidimensional disorder, outcomes of treatments should be evaluated in multiple domains. Group consensus statements

agree with this philosophy, although there is no evidence-based recommendation for optimal outcome assessment at this time [5]. In addition, it is imperative that future research address the patient’s global perspective as an outcome in order to understand the contributions of various anatomical and functional sub-outcomes on the overall patient experience.

1. OUTCOME ASSESSMENT: ANATOMY

There is no consensus on several critical areas of outcomes. There are significant difficulties in creating dichotomous anatomical outcome criteria for success and failure, especially in the absence of symptoms. This difficulty is exacerbated in the situation where support loss is evident in an unoperated portion of the vagina and there is no consensus regarding coding of “de novo” POP. Finally, it is likely incorrect to strive for “perfect” support of the vagina (Stage 0) as this is inconsistent with the demographic profile of asymptomatic vaginally parous women [6].

In addition, the five-level staging system of the current POP-Q (Stages 0-IV) may be insufficient to discriminate among clinically important groups of women with POP, placing virtually all such women into Stage II or III. While the staging may facilitate comparisons, it may not describe sufficient detail as the individual POP-Q measurements provide. While most surgeons believe that prolapse beyond the hymen following POP surgery is not an optimal anatomic outcome, the required level of support above the hymen is not known and the relationship with symptoms remains poorly understood.

2. OUTCOME ASSESSMENT: SYMPTOMS

It is well recognized that symptoms and anatomy do not necessarily correlate in women with pelvic organ prolapse. Burrows et al reported that while women with more advanced prolapse are less likely to experience stress urinary incontinence, bothersome sexual or ano-rectal symptoms do not correlate with prolapse severity [7]. The symptom of feeling or seeing a bulge is reliably associated with the anatomic finding of prolapse [8]. However, other symptoms may impact the perception or bother of the anatomic finding. FitzGerald et al reported that women planning sacrocolpopexy with Stage II POP and prior pelvic surgery reported more symptoms and quality of life impact than those with more advance prolapse [9]. Symptoms of urinary incontinence, fecal incontinence, sexual dysfunction, voiding dysfunction and defecatory dysfunction are common in women with prolapse, but are not well correlated with anatomic findings [10]. Nonetheless, most patients expect resolution of pelvic symptoms following surgery.

a) Urinary Symptoms

Urinary Incontinence: There is a risk of de novo stress incontinence following POP repair by any route. This risk is approximately 44% following sacrocolpopexy in stress continent women [11] and can be reduced by concomitant Burch colposuspension. It is not known if other continence procedures are protective in this surgical setting. Estimates for de novo stress incontinence following vaginal repair range between 15 to 80% [12]. An ongoing trial (Clinicaltrials.gov NCT 00460434) is assessing the utility of concomitant TVT at the time of vaginal prolapse repair in stress continent women. The risk of urge incontinence is also present, although there is growing evidence that prolapse repair improves this risk [13, 14]. Improvement of urge incontinence may be a welcome side effect of the surgery, but it is not an indication for surgery per se.

Voiding dysfunction: Voiding function is expected to improve after surgical correction of prolapse. Fitzgerald and co-workers found significant improvement in bladder emptying in patients after surgery for advanced POP [15]. Before surgery, the average post-void residual in 35 patients was 226 mL, and this was reduced to less than 100 mL in 89% of the women after surgery for POP.

b) Sexual function

The effect of POP on sexual function is variable, but repair of POP may improve sexual function. In the Colpopexy and Urinary Reduction Efforts (CARE) trial, more women were sexually active one year after abdominal sacrocolpopexy (171, 76.3%) compared to before surgery (148, 66.1%), and significantly fewer women reported sexual interference from pelvic and vaginal symptoms [16]. Pauls and colleagues [17] reported no change in sexual function and sexual frequency using the Female Sexual Function Index (FISI) and other standardized questionnaires in prospectively surveyed women undergoing POP surgery with and without continence procedures. In those women, the most bothersome barrier to sexual activity before repair was vaginal bulging; postoperatively, it was vaginal pain. De novo dyspareunia is a risk of many transvaginal prolapse repairs.

c) Ano-Rectal Symptoms

Ano-rectal symptoms are common in women with POP [18]. Fifteen to 20% of women with POP or SUI also report fecal incontinence [19]. Meschia evaluated 881 women with UI or POP, of whom 178 also had anal incontinence. Two-thirds reported constipation, with other common complaints of incomplete evacuation, and splinting in the vaginal or perineal body to effect evacuation [20].

Although such symptoms are common, they do not correlate well with prolapse stage. Bradley et al [18] described the prevalence of pre-operative bowel symptoms and Colorectal-Anal Distress Inventory symptom scores in 322 women planning sacrocolpopexy. Correlations between symptoms and
prolapse were negative and weak, indicating that bowel symptoms do not increase with increasing prolapse stage [18].

Although there is no level 1 evidence regarding the impact of POP surgery on these symptoms, ano-rectal symptoms were assessed in the CARE trial. Surgeons were allowed to include posterior colporrhaphy (in addition to sacrolcopexy) at their discretion. The sacrocolpopexy with posterior colporrhaphy group (n= 87) had more baseline obstructive colorectal symptoms (higher Colo-Rectal-And Distress Inventory(CRADI) and CRADI-obstructive scores: P =.04 and .01, respectively) than the sacrocolpopexy alone group (n =211). However CRADI total, obstructive, and pain/irritation scores significantly improved in both groups (all P =.01) [21].

3. OUTCOME EVALUATION: QUALITY OF LIFE

It is recommended that investigators describe the impact of POP surgical treatment on quality of life. Maher et al reported significant improvements in condition-specific and generic QOL after SSLF, similar to that after abdominal sacrocolpopexy [22]. The CARE trial also reported significant improvements in quality of life following sacrocolpopexy at three months and two years [11, 14]. In that trial, Nygaard et al reported pre-surgical physical activity levels [23]. Most participants were physically active preoperatively, but reported that prolapse substantially interfered with exercise or recreation (27%), household work or yard work (19%) and work outside the home (8%). The interference was not associated with the stage of prolapse.

In the first study of its kind, Jelovsek et al assessed body image using a modified body image scale [10]. These investigators reported that women seeking treatment for advanced pelvic organ prolapse had measurable decreases in body image and overall quality of life. The idea that distortion of body image is a factor that impacts quality of life is novel and a fruitful area for further research.

II. SELECTION OF SURGICAL ROUTE FOR RECONSTRUCTIVE POP PROCEDURES

The individual woman’s surgical history and goals, as well as her individual risks for surgical complications, prolapse recurrence and de novo symptoms impact surgical planning. In addition, the route and method of access for reconstruction may include laparoscopic and robotic techniques. In the U.S., 80-90% of prolapse surgeries are completed vaginally [24].

1. COMPARISON OF OPEN ABDOMINAL TO VAGINAL

Level one evidence supports a higher anatomic efficacy with abdominal route of surgery. There are three randomized controlled trials designed with the specific aim to compare vaginal and abdominal routes for the surgical correction of POP [22, 25-27] as well as a Cochrane review [27] and the major outcomes are summarized in Table 14. Although these studies had relatively small numbers for comparison (approximately 40 women in each comparison group), the effect sizes were large.

In the first trial designed to compare route of POP repair, Benson et al reported that the abdominal route had better anatomic results 1 to 5.5 years (mean 2.5 years) after surgery compared with the vaginal route, OR for optimal cure (no symptoms of POP, no anatomic defect beyond the hymeneal ring) 3.44, 95%CI 1.24-9.69). The Benson study was stopped when the planned interim analysis revealed the superiority of the abdominal approach. Of the 101 women randomized, ten decided against surgery after randomization, 3 refused their abdominal route randomization assignment, and 8 were not available for long term evaluation, leaving a sample size of 80 women. A significant proportion of participants who were randomized to the abdominal group also had vaginal procedures performed (30% anterior colporrhaphy and 50% posterior colporrhaphy.) Needle urethropexy, a widely used procedure at the time of the trial that has since been abandoned, was used as the primary incontinence procedure in the vaginal repairs. Since that time, the combination of needle urethropexy and sacrospinous ligament suspension has been abandoned because it predisposes to upper vaginal wall prolapse [28]. Given that this was the first such trial, the optimal vaginal approach was not known.

Experts have expressed concern that the specific primary prolapse procedures performed may have been responsible for differences in outcome rather than the surgical route: these include (vaginal route) bilateral sacrospinous suspension, vaginal paravaginal repair, Pereyra needle urethropexy; and (abdominal route) sacrocolpopexy, retropubic paravaginal repair, and Burch colposuspension. In addition, the results for women with concomitant hysterectomy were not reported separately. The abdominal route was associated with higher costs, longer operating times, and increased complications, although the numbers did not reach statistical significance due to small numbers. Of note is that post-operative dyspareunia was seen only in the vaginal group (15/26, 58%).

Lo and Wang (1998) randomized 138 women with Stage III-IV uterine prolapse or vaginal vault prolapse; 20 were excluded after randomization for inability to follow-up. Of the remaining 118, 52 underwent sacrocolpopexy with mersilene mesh and 66 underwent sacrospinous ligament fixation with polypropylene suture. The definition of cure was POP no greater than Stage II (no greater than 1 cm beyond the hymeneal ring), and at a median of 2.1 years after
the index surgery, 49/52 (94%) of women undergoing SC were cured, while 53/66 (80%) of women undergoing SSLF met the definition of cure. Complications were higher in the vaginal group with increased blood loss and longer hospital stays, with some serious complications of rectovaginal fistula and ureteric injury. While there are several methodologic problems with this RCT, there was a higher rate of dyspareunia due to vaginal narrowing in the SSLF group (7/66, 39%, 4 of whom were sexually inactive due to the complication) compared to the SC group (1/52, 9%).

Maher and colleagues (2004) performed an RCT randomizing 95 women to sacrocolpopexy (n=47) and sacrospinous ligament fixation (n=48) with follow up at two years (6-60 months). This study differs from that of Benson in that all subjects had already undergone hysterectomy, no patients in the vaginal group had either a needle urethropexy or vaginal paravaginal repair, and the minimum allowed duration of follow-up was six months (mean 22-24 months) rather than Benson’s 12 months (mean 30 months.) Although this group reported comparable subjective and objective outcomes between the two surgical groups, a subanalysis showed anatomic superiority of the abdominal group (OR18, 95% CI .05, .55) with a significantly higher rate of combined recurrent anterior and apical prolapse. However, the abdominal route had longer operating times, longer hospitalization, more complications, and higher medical costs compared with the vaginal route.

The Cochrane review on the surgical management of prolapse by Maher et al summarizes these studies and concludes that these trials provide level 1 evidence that the overall outcome (including quality of life) is similar between abdominal and vaginal approaches, but that sacrospinous-based vaginal procedures have a higher anterior and apical anatomical recurrence rate and higher rates of dyspareunia than sacrocolpopexy-based abdominal repairs. This is somewhat offset by the higher short term morbidity of open abdominal sacrocolpopexy [22].

2. SAFETY ISSUES RELATED TO THE CHOICE OF SURGICAL ROUTE

In these trials, serious perioperative injuries are more common with abdominal than vaginal surgery. While it is known that the number of complications increases as the number of procedures increases, the number of procedures is less related to the route of surgery and more to the severity and number of pelvic floor defects requiring surgical correction. Safety associated with mesh will be considered separately later in the chapter.

Boyles [24] found that pre-existing comorbidities did not increase the risk of complications in a review of discharge diagnoses after surgery for POP, but this finding seems counter-intuitive and points out the limitation of this kind of review: it is unknown how the route of surgery nor preventative measures in individual cases affects these findings, and a prospective comparison is needed. Boyles examined mortality risk in some detail. Although the mortality rate was low (.53 per 1000 women), women who died were significantly older than those who survived (69.1 versus 52.1). Details on the route of surgery were often incomplete. In summary, what little is known about safety agrees with the commonly held opinion that vaginal surgery for POP is safer than abdominal surgery, and this may be an important consideration when deciding on the route of surgery for individual patients.

3. LAPAROSCOPIC AND ROBOTIC SURGERY

There are multiple reports of the feasibility of various abdominal prolapse repairs being performed using laparoscopic (with or without robotic assistance) surgical techniques, most reporting good short- and intermediate-term results. As of March 2008, no randomized controlled trials have been reported comparing laparoscopic to conventional abdominal POP procedures. There is no reason to believe that the same procedure performed in precisely the same manner using the same materials would have any different outcome using the laparoscopic abdominal technique compared to the open abdominal technique. However, there is likely to be different adverse events depending on the technique of access. In addition, procedures are sometimes modified to allow them to be performed more easily with laparoscopy, and so it is essential to establish independently the effectiveness and safety of the modified procedures in a well-designed RCT. Similarly the learning curves and number of procedures together with the frequency of performing these technically challenging operations have yet to be established for prolapse surgery by all routes and techniques.

III. EFFICACY OF SPECIFIC PROCEDURES

There are a variety of procedures suitable for surgical correction of prolapse. Table 2 briefly summarized the main concepts of the broad surgical categories.

1. RECONSTRUCTIVE PROCEDURES

a) Apical support procedures

The apex is the keystone of pelvic organ support. Support of the apex must be assessed regardless of the presence or absence of the uterus. Without good suspension of the uterus or post-hysterectomy vaginal cuff, the anterior and posterior walls are exposed to intra-abdominal forces that drive these tissues toward the introitus. Because of the significant contribution of the apex to anterior vaginal support, the best surgical
correction of the anterior and posterior walls may fail unless the apex is adequately supported [30, 31].

While recognition of apical defects is one of the biggest problems in the evaluation of pelvic support defects, surgical correction of the apex has several good options with relatively high success rates.

1. SACROCLOPOPExY

Sacrocolpopexy has proven to be a durable technique for apical support with an acceptable risk/benefit ratio (Tables 3 and 4). While level 1 evidence supports the usefulness of this procedure in POP, investigators are just beginning to test the hypothesis that will refine this technique, optimize concomitant procedures and urinary tract function. Because concomitant hysterectomy increases the risk of mesh erosion [32], alternative techniques including sacrohysteropexy or supracervical hysterectomy are being used based on clinical judgment.

Sacrocolpopexy requires an intervening material, typically a synthetic mesh. Level 1 evidence supports the superiority of polypropylene mesh to fascia lata for objective anatomic support following sacrocolpopexy [97]. There is no evidence for the equivalence or superiority of any material other than permanent synthetic mesh for this procedure. Expert opinion strongly warns against simple suturing of the apical skin as this is insufficient fixation and likely to result in recurrent prolapse.

Mesh erosion is a known complication of sacrocolpopexy regardless of performance of concomitant hysterectomy. A recent review [33] noted the rates of erosion to be 2-11% from institution to institution. Visco and colleagues [98] reported on 155 women and found an erosion rate of 3.2% with abdominal sacrocolpopexy, 4.5% when combined with colpoperineopexy, 20% when a combined abdominal/vaginal approach was used (sutures passed vaginally to abdominally) and 40% when mesh was introduced vaginally. Cundiff et al presented suture/mesh complications from the CARE trial [32] The predominant graft used was synthetic mesh; Mersilene (42%) or Polypropylene (48%). Twenty subjects (6%) experienced mesh/suture erosion. Unadjusted risk factors for mesh/suture erosion were expanded polytrfluoroethylene (ePTFE) mesh (ePTFE 4/21 (19%) versus non-ePFTE 16/301 (5%): OR 4.2), concurrent hysterectomy (OR 4.9) and current smoking (OR 5.2). Of those with mesh erosion, most affected women (13/17) underwent at least one surgery for partial or total mesh removal. Two were completely resolved, 6 had persistent problems and 5 were lost to follow-up. No resolution was documented in the 4 women who elected observation. These investigators concluded that expanded PTFE mesh should not be used for sacrocolpopexy and documented that concurrent hysterectomy and smoking are modifiable risks for mesh/suture erosion. These data is corroborated by the majority of other evidence from Level 3 reports [84, 99, 100], although there is conflicting level 2 data from [91]. While uterine preservation (or supracervical hysterectomy) is an alternative, the utility and safety of these techniques are not known. In a level 2 RCT, Roovers et al reported poor outcomes for sacral hysteropexy as compared to vaginal repair [90].

Allograft fascia lata has been described variably as an alternative to mesh: the biologic graft avoids the risk of mesh erosion, but resulted in unexpected failures in which no mesh could be seen during reoperation [101-104].

Similarly, Flynn et al [105] reported on 24 colpopexies using allograft fascia lata in a retrospective design, and found unacceptable rates of anatomic improvement at one year follow-up.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>FOR APICAL SUPPORT (UTERINE OR VAULT PROLAPSE)</strong></td>
<td></td>
</tr>
<tr>
<td>Sacrocolpopexy</td>
<td>Fixation of vagina through suspension material (preferably anterior and posterior vaginal arms of synthetic mesh to bridge to the anterior longitudinal ligament of sacrum.</td>
</tr>
<tr>
<td>Sacrocolpoperineopexy</td>
<td>Same technique as above, except that the posterior arm of mesh extends to the perineal body.</td>
</tr>
<tr>
<td>Iliococcygeus fascia fixation</td>
<td>An extraperitoneal vaginal procedure that attaches the vaginal apex to the fascial coverings of the iliococcygeus muscles bilaterally, often with a suture-passing device.</td>
</tr>
<tr>
<td>Levator myorrhaphy with apical plication</td>
<td>Wide midline plication of the levator with fixation of the vaginal cuff.</td>
</tr>
<tr>
<td>Mayo culdoplasty</td>
<td>A modification of the McCall’s culdoplasty attaches the apex to plicated uterosacral ligaments.</td>
</tr>
<tr>
<td>Sacrospinous ligament suspension procedures</td>
<td>This procedure suspends the vaginal apex to the sacrospinous ligament either unilaterally or bilaterally, typically using an extraperitoneal approach. The enterocele, anterior and posterior walls are repaired as needed.</td>
</tr>
<tr>
<td></td>
<td>Traditional version: attaches one edge of the apex to the ligament using permanent suture.</td>
</tr>
<tr>
<td></td>
<td>Michigan modification [29] avoids a suture bridge and draws the entire vaginal apex into direct contact with the coccygeus muscle and underlying ligament, using delayed absorbable sutures across the entire vaginal cuff.</td>
</tr>
<tr>
<td>Uterosacral ligament suspension</td>
<td>This intraperitoneal vaginal procedure traditionally uses permanent suture to suspend the vaginal apex to the remnants of the uterosacral ligaments at the level of the ischial spines and cephalad, with incorporation of the (often reconstructed) fibromuscular walls of the anterior and posterior vagina.</td>
</tr>
<tr>

NS = not stated  
SUI = stress urinary incontinence  
RPU = retropubic urethropexy  
RCT = randomized clinical trial  
*Some patients also included in Addison’s series  
**Only abstract reviewed (paper not in English)  
***Question 5 on the Pelvic Floor Distress Inventory – “Do you usually have a bulge or something falling out that you can see or feel in the vaginal area?”
Gastrointestinal problems may occur following open sacrocolpopexy. One in 20 women in CARE trial experienced significant gastrointestinal morbidity after sacrocolpopexy. Of 322 women in the study, 19 had symptoms of possible ileus or small bowel obstruction; of these, 4 had reoperation for small bowel obstruction, 11 were readmitted for medical management, and 4 had a prolonged initial hospitalization for gastrointestinal symptoms [106].

Abdominal sacrocolpopexy has greater morbidity, higher cost and less dypareunia than vaginal sacrospinous ligament suspension [22, 25]. These disadvantages have prompted surgeons to seek alternatives that maintain the advantages and reduce procedure-associated morbidity.

Laparoscopic sacrocolpopexy is performed in some centres, with and without robotic assistance. Only case series are available for evaluation. Von Theobald et al reported a series of 100 patients with 8 year followup [107]. Higgs reported on 140 consecutive women undergoing laparoscopic sacrocolpopexy with mesh [108]. At a median follow up of 66 months, 66 women were examined and a further 37 had questionnaire data available only. Subjects lost to follow-up were not included in the analysis, and could be failures or successes. Symptomatic improvement was good with 79% subjects reporting prolapse symptoms as “cured” or “improved”, but 39/103 (38%) had persistent symptoms of POP. Anatomic prolapse was seen on exam in 21/66 women examined.

2. Transvaginal Apical Suspension Techniques

Support of the vaginal cuff following hysterectomy is recommended by most authorities, and may be achieved by sacrospinous ligament suspension or reattachment of the uterosacral ligaments to the vaginal cuff, McCall culdoplasty, and Mayo culdoplasty. A single study compared these three methods of transvaginal apical suspension at the time of hysterectomy to determine th efficacy of prevention of posterior enterocele as a proxy for apical support [109].

- Iliococcygeus fascia fixation

There are no randomized trials that support the use of this procedure. Several case series have provided some information. Shull reported that apical support was optimal in 39/42 (83%) of patients, but eight others had apical or other defects [110]. Meeks and colleagues reported a 96% objective cure in 110 women followed up to 13 years [111]. In a retrospective case-control study, Maher and colleagues reported similar subjective (91% v 94%) and objective (53% v 67%) cure rates with iliococcygeus fixation (n=50) compared to sacrospionous fixation (n=78) [112].

- Levator myorrhaphy with apical plication

Francis and Jeffcoate [113] described their retrospective series using levator myorrhaphy with vaginal vault suspension to the plication. A large sponge pack in the rectum is used to avoid overplication and bowel dysfunction. Five of 35 women responding to the questionnaire had transient ureteral complications, one requiring re-operation. Seventeen women were quite satisfied, while six were dissatisfied.

- Mayo culdoplasty

A large retrospective series from the Mayo clinic described an 82% satisfaction rate on subjective follow-up with few complications [114]. It may achieve its suspension in a mechanism similar to the uterosacral ligament suspension, but no direct comparisons have been reported. A retrospective case series of 411 women undergoing Mayo culdoplasty in two other institutions found that a more dorsal “deep” placement of sutures through the uterosacral ligaments reduced the incidence of ureteral obstruction compared to other published series [115].

- Sacrospinous ligament suspension (SSLS)

The sacrospinous ligament suspension was first described in 1958 [116]. The traditional procedure as described by Nichols has been associated with high rates of anterior wall recurrences in some studies [117].

Table 5 contains outcomes from studies that have included SSLS. Uncontrolled retrospective case series and clinical trials in which SSLS was used in one arm suggest that anterior recurrence is more common (6% to 28.5%) than apical recurrence (2.4% to 19%). Reoperation rates after SSLF range from 1.3% to 37%, with all but two series reporting rates less than 7%.

Case series provide the majority of evidence regarding the SSLS complications which include buttock pain and sacral/pudendal neurovascular injury. Sze et al reviewed 22 studies that included 1229 SSLS procedures and reported that 3 patients (0.2%) had life-threatening hemorrhage from sacral or pudendal vascular injury with a 2% transfusion rate [118], Buttock pain occurred in 3% of patients, with resolution within 6 weeks for most affected women.

- Uterosacral ligament suspension

First described by Miller [126] in 1927 and popularized by Shull [127], this procedure maintains the vaginal axis in the midline and allows adjustment of the vaginal length. A weakness of the procedure is the risk of ureteral injury; therefore intraoperative cystoscopy after the sutures are tied down is an essential part of this procedure. The current evidence supporting the use of ULS is limited to seven uncontrolled retrospective case-series (Table 6). In these studies, ULS is associated with low overall recurrence (4% - 18%), anterior vaginal prolapse recurrence of 3.5% - 11%, and reoperation of less than 7%. These promising results are balanced by ureteral injury with this procedure.

b) Anterior vaginal wall prolapse

1. ANTERIOR COLPORRHAPHY

Since the first description in 1913 by Kelly [134], the success rates of anterior colporrhaphy in the management of cystoceles ranges from 80-100% in retrospective series [135-138] (Table 7). Experts agree that there is a great deal of variation in the clinical performance of anterior colporrhaphy. In two separate randomized control trials, Weber et al [139] and Sand et al [140] reported less favorable outcomes with the anterior colporrhaphy, 42% and 57% respectively. Although colposuspension is not used as a treatment for anterior vaginal support defects, Colombo et al reported long-term follow-up randomized trial results suggesting that the anterior colporrhaphy (97% success rate) was superior to the colposuspension (66%) in the management of the cystocele in women with cystocele and stress urinary incontinence [141].

2. PARAVAGINAL REPAIR

In 1976, Richardson [149] popularized the paravaginal repair originally described by White [142] as early as 1912. Several case series have reported that the range of success rate for the abdominal paravaginal repair is 75-97% [149-153] (Table 8). While this technique can be duplicated laparoscopically, no efficacy information is available.

Since Shull’s [143] initial report on the safety and efficacy of the vaginal paravaginal repair in 1994, several case series have reported success rates between 67 –100% [142-147]. The high success rates have been tempered by complications such as those reported by Mallipeddi [146] in her case series of 45 patients including: 1 bilateral ureteric obstruction, one retropubic haematoma requiring surgery, two vaginal abscesses; two transfusions. In a series of 100 women Young [147] reported 21 major complications and a 18% transfusion rate.

3. OPTIMAL ROUTE OF SURGERY

Surgical correction of pelvic organ prolapse can be divided into two main categories: reconstructive procedures to correct anterior and posterior wall defects and resuspend the vaginal apex or obliterate procedures to close off the vagina. Reconstructive surgery may use the vaginal route or the abdominal route. In planning surgery, the individual patient’s risk for surgery, risk of recurrence, previous treatments, and surgical goals are all considered in deciding on obliterator versus reconstructive procedures, and in deciding whether the vaginal or the abdominal approach will be used for reconstructive repairs. The goal of this section is to examine the evidence for selecting the surgical route in prolapse repairs.

- Selection of Paravaginal Defect Repair Route (vaginal vs abdominal):

No randomized control studies have evaluated the abdominal or vaginal paravaginal repair in isolation. As discussed in the apical section of this chapter, Benson et al [25] and Maher et al [22] have reported RCT’s on upper vaginal prolapse comparing abdominal sacral colpopexy and vaginal sacrospinous colpopexy. Abdominal paravaginal repair was performed in the abdominal group if required and an anterior colporrhaphy without or without vaginal paravaginal laterally. Both authors reported the abdominal group to have a statistically lower rate of postoperative anterior vaginal prolapse than the vaginal group.

Raz et al [154] popularized the needle suspension type procedure for cystoceles and success rates in case series vary from 90-98% [154, 155, 156]. The addition of polyglactin mesh to the repair appears to

APR Abdominal paravaginal repair
AC Anterior colporrhaphy
Definition varies between authors
have little impact on the success [160]. Dmochowski et al [158] reported a lower success rate using a stricter outcome definition of success.

Goldberg et al [161] reported results from a case control study of women with cystocele and stress urinary incontinence. He suggests that the addition of the pubovaginal sling to the anterior colporrhaphy significantly reduced the recurrence rate of cystocele from 42% in the control group to 19% in the anterior colporrhaphy and sling group (P<0.05).

The surgical management of anterior vaginal prolapse remains controversial. In reconstructive gynaecology surgery Level 1 [22, 25] evidence suggest the combined use of abdominal sacral colpopexy with or without retropubic colposuspension or paravaginal repair is superior to the vaginal approach including sacrospinous colpopexy and anterior colporrhaphy with or without vaginal paravaginal repair in the management of anterior vaginal prolapse (Grade B recommendation).

Level 2 evidence suggests that in women with stress urinary incontinence and anterior vaginal support defects, the addition of a sling at the time of anterior colporrhaphy enhances anatomical outcome as compared to anterior colporrhaphy alone or in combination with other continent surgery [140, 161]. This evidence arises from one institution and one sample of women is reported twice.

c) Posterior vaginal wall prolapse

In standard posterior colporrhaphy, the posterior vaginal wall is incised in the midline and rectovaginal fascia identified. The fascia is then approximated in the midline either with continuous or interrupted absorbable suture. In the traditional technique described by Jeffcote [113], this was supplemented with levator ani muscle approximation in the midline.

With the site specific defect repair, following posterior vaginotomy, the defects in the rectovaginal fascia are identified with a rectal finger bringing the rectal wall forward. The connective tissues are pulled across over the defects and sutured with absorbable sutures to close the defect.

1. Midline Plication (traditional posterior colporrhaphy)

In five studies, where traditional posterior colporrhaphy was evaluated, the success rate ranged from 76% to 97% (Table 8), while postoperative dyspareunia rates range from 11 to 27% (Table 8) with denovo dyspareunia rates of 4% to 16% [137, 162-164]. This has been attributed to levator ani plication forming a rigid band across the vagina. Midline fascial plication of rectovaginal fascia without levator plication is believed to reduce this high rate of dyspareunia.

2. Site specific defect repair

Richardson identified discrete defects in rectovaginal fascia and directed repair at the specific sites of defect to produce a more anatomical repair [169]. Both prospective and retrospective case series on the site specific defect repair, have reported success rates in the range of 67-92% with good functional outcomes (Table 9) [167, 170-172]. Table 9 contains a summary of reports using site specific defect repair for posterior vaginal support defects. One uncontrolled comparison of posterior colporrhaphy with site-specific defect repair [173] reported that the recurrence risk was higher in the site specific group at the end of 1 year follow-up (33% vs. 14%) and the postoperative Bp point was (-2.2 SSDR vs. - 2.7 PCR) P=0.001. The functional outcomes of difficult evacuation, fecal incontinence and post-operative dyspareunia were similar in both groups.

Posterior vaginal wall prolapse repair has traditionally used the vaginal approach, although several studies

*includes levatorplasty

**without levatorplasty
address the transanal / transperineal approaches. The threshold for surgical intervention in the posterior wall has been poorly studied and the relationship between symptoms and anatomy is particularly poorly understood. There is insufficient evidence to recommend a surgical threshold based on anatomical support loss. Symptoms that have been associated with posterior wall prolapse include difficult defecation and splinting. Constipation is recognized as a colonic motility disorder that is not treated by posterior vaginal surgery.

The transvaginal approach appears to be superior to the transanal approach for repair of posterior wall prolapse. Two prospective randomized controlled trials compared the transvaginal and transanal techniques. Nieminen et al reported one-year outcomes for 30 women with symptomatic rectocele who were randomly assigned to vaginal vs. transanal surgery [175]. Despite the small sample size of this group, they reported superiority of the transvaginal route with significant differences in recurrence rate (7% vs. 40%, p=0.04) and symptom improvement (93% vs. 73%, p=0.08) in the transvaginal and transanal groups respectively. No differences were reported in post-operative splinting or sexual function, perhaps due to the small sample size. Improved posterior support was reported with the transvaginal point (POP-Q Ap point -2.8 vs. -1.36). Kahn et al reported the superiority of the 2 year anatomic outcomes transvaginal route in 57 women randomly allocated to transvaginal (N=24) vs. transanal repair (N=33) with 13 % vs. 30%, (p=0.01) respectively [164].

Puigdollers et al reported results from a prospective cohort of women with rectocele and constipation who underwent surgery via endorectal or transperineal route, according to preference of the surgeon). At the end of one year the subjective improvement in constipation was reported in 43% (p < 0.001) and the need to splint decreased in 52%.(p=0.001) [176].

A single non-randomized study reports outcomes for a cohort of women with symptomatic rectocele who were treated laparoscopically (N=40) vs. transanally (n=40). Level 2B evidence from this study supports the superiority of the transanal approach for symptomatic relief (55% vs. 28%, p < 0.02), but lower post-operative dyspareunia rates (22% vs. 36%) with laparoscopic approach [177].

Paraiso et al compared three techniques of vaginal repair – posterior colorrhaphy (PCR), site specific repair (SSDR) and graft augmentation with site specific repair by prospective RCT [174]. Women randomly assigned to the posterior colorrhaphy (n= 37) and the site-specific repair group (n= 37) were reviewed at 17 months. The anatomical success rates were 86% and 78% respectively in the PCR vs. SSDR group. The functional outcomes of difficult evacuation and vaginal digitations were similar in both groups, and there was improvement in the PISQ –12 scores in all the treatment groups. The dyspareunia rates were 20% in the PCR compared to 14% in the SSDR. The anatomical and functional outcomes between SSDR and PCR were similar in this study. These studies do not provide evidence to support use of augmenting materials for posterior prolapse repair.

3. Modifications to traditional repairs

In the case series by Van Dam J H et al combined transvaginal and transanal repair was done in 89 women and evaluated at a follow-up of 52 months. The anatohical success rate was 71% with no persistent or recurrent rectocele on defecography at 6 months. However, denovo dyspareunia was reported in 41% of women and there was deterioration of fecal incontinence in 7 patients [178].

The abdominal route has been employed in the correction of posterior vaginal wall prolapse when a co-existing apical defect required surgery. The technique is a modification of sacrocolpopexy with extension of the posterior mesh to the rectovaginal septum or upto the perineal body. The procedure has been performed completely abdominally or as a combined abdominal and vaginal approach. Table 10 summarizes a series of studies using extended posterior fixation of sacrocolpopexy mesh.

2. OBLITERATIVE PROCEDURES: LeFort colpocleisis, Colpectomy and colpocleisis

These procedures are offered to women with Stage II-IV POP seeking a relatively non-invasive surgical procedure with cure rates as high as 100% [181] and who no longer wish to preserve coital function per vaginam (Table 11). With partial colpocleisis (for vaginal vault prolapse) or LeFort colpocleisis (for uterine prolapse), rectangles of vaginal epithelium are excised from the dorsal and ventral surfaces of the prolapsed vagina. The vagina is inverted and closed with the two raw surfaces in direct contact and reinforced with sutured skin edges. A small amount of skin is usually preserved on each side of the vagina, speeding the excision and allowing drainage of any secretions. The enterocele need not be addressed because there is no longer room in the vagina to permit descent, and the uterus can be left in situ unless there is separate pathology. In total colpectomy, all vaginal skin is removed, often including a high levator myorrhaphy.

In the U.S., the number of colpocleises has declined from a high of 17,200 procedures in 1992 to a low of 900 procedures in 1997 [24], while the number of total colpectomies decreased from a high of 3229 in 1989 to a low of 32 procedures in 1995. Nevertheless, obliterative procedures have an important role to play in the management of POP: in many women, the loss of coital function is offset by the positive impact on their daily activities. These procedures are performed on an outpatient basis with an immediate return to normal activities, and success rates have been described as high as 100%. High rates of patient satisfaction have been reported [182, 183] with low rates of regret for loss of sexual function. Barber et al reported results from a multicenter study followed by a prospective cohort design with a concurrent control group (184). Despite permanent alterations in sexual function and potential alterations in self-image, improvements in quality of life for the thirty women aged 65 or older who selected obliterative prolapse surgery were similar to the concurrent cohort of forth women who selected reconstructive surgery.

The Pelvic Floor Disorders Network recently completed a large series of women undergoing colpocleisis with one year follow-up [185]. All pelvic symptom scores and related bother significantly improved at 3 and 12 months, and 125 (95%) patients said they were either ‘very satisfied’ or ‘satisfied’ with the outcome of their surgery. These investigators concluded that colpocleisis was associated with high patient satisfaction and was effective in resolving prolapse and pelvic symptoms.

IV. CONCOMITANT SURGERY

1. EFFECT OF COMBINATION PROCEDURES

With apical suspensions: The success of anterior wall support procedures seems to interact with concomitant vaginal apical suspension procedures. Paraiso et al [121] reported a 37% cystocele rate after 243 women had undergone sacrospinous colpopexy and suggested the rate of cystocele may decrease with the iliococcygeous fixation as there was less posterior displacement of the vault. Subsequently, Maher et al [112] reported high rates of cystocele after both sacrospinous and iliococcygeous fixation.

With bladder neck suspension, Kohli et al [186] found the concomitant use of transvaginal bladder neck suspension used in conjunction with the anterior colporrhaphy was also problematic. Women undergoing anterior colporrhaphy alone had a 7% recurrence rate as compared to a 33% recurrence rate after combined anterior colporrhaphy.

2. Hysterectomy - The Role of Hysterectomy in Surgical Treatment of Prolapse

Hysterectomy at the time of POP repairs is the standard practice in most parts of the world despite the fact that descent of the uterus may be a consequence, not a cause of POP. Surprisingly, given its widespread use, concomitant hysterectomy is not an evidence-based practice. Increasingly, women may wish to avoid hysterectomy at the time of POP repairs because of factors such as desire for further childbearing, the belief that the uterus is important for sexual satisfaction, and the success of recent conservative procedures for uterine bleeding and fibroids. While there are no prospective comparative trials, a few smaller studies suggest that there may be no disadvantage in outcome with conservation of the uterus, and operating time is shorter. Well-designed RCT studies comparing the repair of POP with and without hysterectomy should be prioritized.

Several studies report results of preservation of the uterus with sacrohysterectomy. Banu 1997 [187] reported 100% success in a case series of 19 women with following sacrohysterectomy using mersilene mesh at 3-5 year follow-up. Lerón 2001 [188] reported 92% success with the same procedure using teflon mesh in 13 subjects at a mean 15.6 months. Maher 2001 used a laparoscopic-assisted high McCall procedure for hysterectomy in 43 patients, with a reported 79% success rate at a mean 12 months follow-up [189]. Jeon, et al [190] reported outcomes after a median follow-up of 36 months in their retrospective comparison of 168 patients in 3 groups: sacrocolpopexy with synthetic mesh and hysterectomy (N=63); abdominosacral uteropexy with mesh (N=35), and abdominal uterosacrococinal colpopexy and hysterectomy (N=70). Recurrence in the latter group was 6.2 times higher than in the sacrocolpopexy/hysterectomy group, however due to the design and group size, specific hypothesis testing was not possible.

Dietz [191] and co-workers observed 133 Dutch women undergoing a sacrospinous hysteropexy, and examined 60 of these women with mean follow-up of 22.5 months. Eight-four percent of women were highly satisfied about the outcome of the procedure, and the rate of reoperation for uterine descent was 2.3%. The recurrence of anterior wall defects in this study was 35%.

Three studies describe uterine preservation at the time of vaginal reconstruction. Uterine preservation or removal did not appear to affect the risk of POP recurrence, although these studies are significantly underpowered.

Maher et al [189] reported a retrospective comparison of 34 sacrospinous hysteropexies and 36 vaginal hysterectomies with sacrospinous fixation. Uterine conservation was associated with significantly less blood loss (198 vs 402 ml) and decreased operating time (59 vs. 91 minutes). At a 36 month mean follow-up in the hysterectomy group and a slightly shorter follow-up of 26 months in the hysteropexy group, the investigators did not detect differences in subjective success (86% vs. 78%, p=0.70), objective success 72% vs. 74%, p=1.00) or patient-determined satisfaction (86% vs. 85%, p=0.10).

Hefni [192] et al reported a nonrandomized prospective controlled study of 109 women who underwent sacrospinous cervicocolpopexy with uterine conservation [61 (56%)] and sacrospinous colpopexy + vaginal hysterectomy [48 (44%)]. Uterine conservation was associated with significantly less blood loss, decreased operating time and complication rate. At approximately 34 months, anatomic success was similar for the upper vaginal support (93.5% vs. 95%), anterior wall (11.4% vs. 10.4%, p=0.9) and re-operation (5% vs. 4.2%) for the uterine conserving vs. hysterectomy groups respectively.

Van Brummen [193] performed a retrospective comparison of the same two procedures (n=30 with hyst, 44 with hysteropexy) and recurrence of prolapse defined as ≥ grade 2 was similar in hysterectomy (2/30, 6.7%) and women with uterine preservation (5/44, 11.4%).

Neuman et al [194] reported their prospective non-randomised series in an abstract comparing 44 patients undergoing Posterior Intravaginal Sling (PIVS) with (N=44) and without (N=35) hysterectomy according to the patient’s preference. The women who selected uterine conservation were younger (51 vs. 63 yrs). With mean follow-up of 30 months, the
investigators did not detect a significant difference in anatomical results (98.7), patient satisfaction (89.9%), or perioperative morbidity.

**Risks of concomitant hysterectomy**

There is growing evidence that concomitant hysterectomy increases the risk of suture or mesh erosion at the time of sacrocolpopexy. Cundiff et al, [32] in a prospectively planned analysis of the randomized CARE trial, reported that hysterectomy increases the risk of suture/mesh erosion. There are no comparative studies of complete vs. supracervical hysterectomy at the time of sacrocolpopexy to address the appropriate clinical treatment, given this finding.

Several case series have addressed specific risks that concomitant hysterectomy may confer at the time of prolapse repair, especially with regard to concomitant synthetic mesh use. Federow [195] did not detect significant differences in short-term post-op febrile morbidity, haemoglobin change or duration of hospital stay in a series of 235 sacrocolpopexy patients, 36.6% of whom had concomitant total abdominal hysterectomy. Belot et al reported that an inverted T-colpopotomy and concomitant hysterectomy increased the risk of mesh erosions fourfold [198]. Gauruden-Burmeister reported on 120 women, 12 months following armed monofilament polypropylene mesh with a mesh erosion rate of 3% which was not affected by performance of inverted T-colpopotomy in over 50% (197). Collinet et al (198) reported that concomitant hysterectomy at the time of mesh-augmented vaginal reconstructive surgery increases the risk of mesh erosion [OR = 5.17 (p = 0.003] in his retrospective series of 277 patients.

One non-randomized comparative study of 124 women reported by Brizzolara et al suggests that concomitant hysterectomy (n=60) is not a risk factor for mesh erosion [91].

Concomitant culdoplasty. There is insufficient evidence to comment on the utility of concomitant culdoplasty at the time of prolapse repair by any method.

**3. CONTINENCE TREATMENT**

**(Treatment and Prophylaxis)**

Although many women with anterior vaginal wall prolapse also experience stress urinary incontinence, women with advanced prolapse may not have incontinence symptoms. There is no standardized nomenclature to describe clinical or urodynamic findings for stress continent women who exhibit urine loss during prolapse reduction testing. In published papers, the terms "occult", "potential", "masked", "latent", "hidden" and "iatrogenic" are used interchangeably to describe SUI, which occurs following POP surgery in symptom-free patients before surgery. Conventionally, occult stress incontinence is diagnosed when leaking occurs with Valsalva maneuvers after reduction of the prolapse in the absence of detrusor contractions. Using these criteria, incidence of occult stress incontinence has been shown to range between 36% and 80% [12].

Many case series have documented the risk of de novo SUI following POP repair with the incidence of de novo postoperative stress incontinence in patients with a negative preoperative reduction cough stress test has been showed to be 1.9% [199] in a recent retrospective chart review study. Concomitantly, a 67.9% prevalence of occult SUI has been reported in a population of 78 women with POP[200].

The pre-operative lack of symptoms in some women who experience de novo SUI following POP surgery is due to anatomic obstruction of the kinked urethra [201], and may have voiding difficulties due to similar urethral mechanics [202]. Techniques for prolapse reduction to optimally predict the risk of post-operative SUI has not been evidence-based. Visco et al (203) reported that certain techniques have poor predictive values for predicting de novo SUI following sacrocolpopexy.

Level 1 evidence exists from the CARE study which randomized 322 stress-continent women with Stage II-IV POP to a Burch colposuspension or no continence procedure at the time of concomitant open abdominal sacrocolpopexy [11]. The trial ended when the first planned interim analysis demonstrated the significant reduction of de novo SUI three months after surgery in women who were assigned to the Burch colposuspension compared to the group without a continence procedure. This benefit was not offset by any untoward intra-operative or post-operative side effects such as worsening urge incontinence or voiding dysfunction. These benefits were maintained at one year [13] and two years [14].

In the trial reported by Costantini, et al, [204] 66 patients with a negative stress test before and after prolapse reduction and no preoperative history of SUI symptoms were randomized to colposuspension or no colposuspension with a mean follow-up of 39.5 months. The pre- and post-operative definitions are not consistently defined or standardized. Although this paper does not support the routine use of colposuspension at the time of sacrocolpopexy in patients with negative preoperative stress test, the study was significantly underpowered and concluded the concomitant colposuspension increases the rate of post-operative stress incontinence.

The contradictory results between these two studies may be due to different inclusion criteria or differences in sacrocolpopexy technique. Participants in the CARE study were randomized without regard to results of urodynamic testing with prolapse reduction, in order to determine the pre-operative utility of such testing.
Recent prospective randomized trial has shown that women who are continent with prolapse reduction prophylactic TVT® (or other prophylaxis) among bother, was used as an endpoint. Thus, the use of included and any de novo incontinence, regardless of who were incontinent with prolapse reduction were [205]. Although this was a positive trial, only women addressed the surgical stress incontinence prophylaxis from their single small randomized clinical trial that ligament plication [141]. Meschia et al reported results incontinence to cystopexy with or without pubourethral anatomic changes that improve anterior support and decrease posterior vaginal wall support (Table III-IV prolapse but without stress incontinence to either a needle suspension or endopelvic fascial placation without detecting a difference in urinary continence [28]. Similarly Colombo et al. did not find differences in continence outcomes following randomization of 102 women with stage 2-4 prolapse without stress incontinence to cystopexy with or without pubourethral ligament plication [141]. Meschia et al reported results from their single small randomized clinical trial that addressed the surgical stress incontinence prophylaxis with TVT® at the time of vaginal prolapse surgery [205]. Although this was a positive trial, only women who were incontinent with prolapse reduction were included and any de novo incontinence, regardless of bother, was used as an endpoint. Thus, the use of prophylactic TVT® (or other prophylaxis) among women who are continent with prolapse reduction remains an unanswered but important clinical question.

A recent prospective randomized trial has shown that anterior mesh repairs are more likely to lead to postoperative SUI than colporrhaphy alone (23% to 10% respectively) [206] (Tables 12, 13). The Effect of Concomitant Continence Surgery on Prolapse Outcome:

a) Concomitant Sling

Goldberg et al reported that a suburethral sling is protective in the anterior wall [161]. In a randomized trial designed to evaluate the efficacy of cadaveric fascia patch for augmentation of anterior colporrhaphy, Gandhi et al reported that concomitant sling placement reduces anterior wall recurrence [221].

b) Concomitant Colposuspension

In a secondary analysis of a randomized controlled trial of the utility of Burch colposuspension for prevention of post-operative stress incontinence, Brubaker et al reported that Burch colposuspension at the time of open sacrocolpopexy results in anatomic changes that improve anterior support and decrease posterior vaginal wall support (Table 4) [14].

4. CONCOMITANT PERIOPERATIVE PELVIC PHYSICAL THERAPY

Jarvis et al reported the only study to date that has evaluated perioperative pelvic muscle training in women undergoing prolapse surgery [222]. Three months after surgery, subjects in the intervention group had significantly greater reduction in urinary symptoms, including reduction in daytime urinary frequency, and greater improvement in quality of life compared to the control group. Subjects were not followed beyond 3 months postoperatively, however, and only urinary symptoms were assessed. The role of perioperative pelvic muscle training for reducing the recurrence of prolapse or its symptoms in the long-term is unknown.

a) Risk factors for POP and their relationship to the choice of surgical route

Experts believe that it is important to understand the specific risk factors for an individual patient in planning her surgical correction POP results from a continuum of predisposing, inciting, promoting, and decompensating factors [223]. There are limited data regarding risk factors for POP recurrence after surgery, but expert opinion supports the concept that there are certain women who are at high risk for primary and/or recurrent POP. Some established risk factors for primary POP include vaginal delivery, age, obesity, and family history. Most experts recommend that, whenever feasible, POP repair be delayed until after childbearing is complete. As older women may have increased surgical risks compared to younger women [224] some surgeons may advocate the vaginal approach avoiding an incision. Obesity may be viewed as a separate risk for abdominal surgery, with the vaginal approach avoiding the risk associated with an abdominal wall incision [225].

There is no evidence to guide clinical decision making for the woman who develops POP without evident risk factors, such as the young woman or the nulliparous woman. In fact, one study of nulliparous nuns and their multiparous sisters reveals similar rates of POP in siblings after menopause, regardless of parity [226]. Younger women needing repair of POP often choose the most durable procedure allowing coital function.

Expert opinion is supported by level 2 evidence that there are certain women who are at high risk for primary and/or recurrent POP. Dietz-Itza and co-workers [191] found that women with increased body weight (>65 kg) and women under 60 years of age had increase in both anatomical and functional recurrence of prolapse. Women with more severe prolapse are more likely to recur than those with milder support abnormalities.

Other factors are not considered to be risk factors for POP but influence surgery itself. Obviously

concomitant clinical consideration, such as a pelvic mass or extensive abdominal mesh from prior hernia repair alters the risk/benefit for certain surgical routes. There is insufficient evidence to guide the route of prolapse surgery for women with known intra-abdominal adhesions. Some surgeons may seek to avoid adhesions using an extraperitoneal approach from the vagina, while others may prefer to manage the adhesions through an incision. A shortened vagina with dyspareunia may dictate procedures that have the potential to improve vaginal depth. In an retrospective cohort study, Hilger found that almost 50% of elderly women who underwent successful abdominal repair of POP did not resume sexual activities, despite the fact that the abdominal repair was selected to preserve coital function [95].

In summary, individual risks factors should be weighed against the perceived risk of recurrence in any one individual woman in order to select the most favorable risk/benefit ratio for their specific support defects.

V. THE ROLE OF AUGMENTING MATERIALS IN POP SURGERY

The use of material is inherent in the performance of abdominal sacrocolpopexy. However, there is increasing interest in the potential role of augmenting materials to enhance POP surgery outcomes with other POP procedures, including vaginal surgery. The Cochrane review of surgically managed POP in 2007 concluded that there were insufficient data about mesh and biological graft augmentation of vaginal repairs, and stressed the need for adequately powered randomized controlled clinical trials [27]. Despite recent results from three recent RCTs [227] addressing the anterior wall and demonstrating the utility of mesh augmentation for that indication, the committee considered the current levels of uncertainty about clinical care scenarios, especially in primary prolapse repairs completed with mesh. Although a prolapse persistence or recurrence is an undesirable outcome, a secondary prolapse procedure has a good likelihood of success, especially when sacrocolpopexy is used. The clinical scenarios for subsequent procedures following failed mesh procedures are highly anecdotal. There is insufficient information about risks and efficacy of secondary procedures following primary mesh repairs.

1. AUGMENTATION FOR ANTERIOR WALL SURGERY

- Synthetic material

In line with our surgical colleagues there has been a move towards the use of prosthesis to augment the native tissue repair in reconstructive gynaecology. Given the relatively high failure rate of the anterior vaginal compartment at prolapse surgery it is likely that anterior vaginal wall repair would benefit most from the use of prosthesis.

The majority of Level 1 and 2 evidence [140, 228] suggest that the use of absorbable synthetic mesh overlay offers a superior anatomical outcome for anterior wall prolapse as compared to anterior colporrhaphy alone, although the evidence is divided based on relatively few women [139].

Synthetic mesh was used by Julian et al who described his prospective case control study in women who had undergone at least 2 previous vaginal repair [228]. These women had an overlay of Marlex mesh to the anterior colporrhaphy reduced the recurrence rate of cystocele from 33% to 0%, but the mesh erosion rate was 25%. Flood et al in a retrospective review of 142 women with Marlex mesh augmentation of anterior colporrhaphy demonstrated a 100 % success rate for cystoceles at 3.2 years and a mesh erosion rate of 2% [229].

Weber et al [139] in a randomized control trial compared the anterior colporrhaphy [33], ultra-wide anterior colporrhaphy [24] or anterior colporrhaphy with absorbable polyglactin (Vicryl) 910 mesh [26] in the management of cystoceles. The study size was too small to detect small differences (or no differences) in efficacy or adverse events. However, at a mean follow-up of nearly 2 years the groups had similar proportions of women experiencing satisfactory or optimal anatomic results, 30%, 48% and 42% respectively.

Sand et al [140] in a larger RCT randomly allocated cystoceles to anterior colporrhaphy alone (n=70) and to anterior colporrhaphy plus polyglactin mesh overlay (n=73). At I year the success rate in the mesh group was 75% and significantly greater than the 57% success rate in the anterior repair group alone (P=0.02). Concurrent paravaginal defect were present in 11 women and concomitant paravaginal repair was significantly associated with a lower recurrence of cystocele overall (P=0.02). In a separate study multivariate logistic regression demonstrated concurrent pubovaginal slings for stress urinary incontinence, to be associated with significantly fewer recurrent cystoceles (odds ratio, 0.32; p=0.005) [221].

A variety of polypropylene mesh overlays have been evaluated in case series for the management of anterior wall prolapse. The anatomical success rate varies from 76 to 100% [230-235]. Salvatore et al reported worrying functional outcomes after a prolene mesh overlay including a mesh erosion rate of 13%, overactive bladder increasing from 28 to 56% and dyspareunia increasing from 18 to 38% postoperatively [236]. Visco et al suggested that the mesh erosion or infection rate was increased four-fold when mesh was
Two randomised control trials have been published comparing overlaying polypropylene mesh and traditional anterior colporrhaphy. Hiltunen et al compared 104 women undergoing anterior compartment prolapse repair with 6x11cm low weight monofilament polypropylene (Parietene light, Sofradim Co, Trevoux, France) with 97 undergoing traditional anterior colporrhaphy [206]. At 12 months the objective success (stage 0 or 1 Aa and Ba) rate was 93 in the mesh group and 61% in no mesh group (P<.001). Symptomatic anterior compartment prolapse was significantly lower at 4% in the mesh group as compared to 15% in the no mesh group (p<0.05). Mesh erosions were seen in 17.3%. Sivaslioglu et al reported on 43 undergoing low weight polypropylene mesh as compared to 42 undergoing site-specific vicryl repair and at 12 months found the objective success rate (leading edge of cystocoele was <71 cm in relation to hymen (stage 1) was significantly higher at 91% in the mesh group and 72% in the non-mesh group [239]. The mesh erosion rate was 6.9% and de novo dyspareunia was reported in 4.6% in the mesh group and none in the non-mesh group. Quality of life assessment demonstrated no difference in outcomes between the groups and no patient in either group underwent further surgery for anterior compartment prolapse. Since 2004, a variety of kit transobturator armed polypropylene meshes have been available. A recent RCT compared anterior polypropylene mesh (n=38) with anterior colporrhaphy. At 1 year the objective success rate (defined as less than POP-q stage II anterior vaginal prolapse) was higher in the mesh group (89% vs. 55%). Functional outcomes including quality of life, sexual activity and dyspareunia were similar in both groups with a 5% mesh erosion and 2% unilateral leg pain that settled by 8 weeks after the surgery in the mesh group [240].

Fatton et al reported on 106 women three months following vaginal mesh polypropylene mesh (anterior, posterior or total) with a 95% success rate and 4.7% mesh erosion rate in short term followup [241]. Concomitant hysterectomy was not performed and the authors felt surgeon experience was important in minimizing mesh erosion, a view that was supported by Dwyer and Orielly who reported a decreasing rate of mesh complications with increasing surgeon experience [242].

Gauruden–Burmester reported on mesh contracture rate by performing postoperative introital ultrasound measurements and revealed the vaginal polypropylene anterior mesh contracted from 7.5cm to 3.5cm (54%) and 11.5cm to 6.4cm (46%). While the mesh contracture was significant the authors found the mesh contraction was not associated with postoperative vaginal length measurements [197]. Majority Level 1 evidence suggests that polypropylene mesh overlay has a superior anatomical outcome as compared to traditional anterior colporrhaphy. These findings need to be tempered with Level 2 and 3 evidence suggesting that significant functional complications are associated with the employment of non-absorbable meshes at the time vaginal reconstructive surgery [98, 228, 236].

The consequences of these complications are not insignificant and may result in multiple subsequent surgical procedures and residual symptoms. There is a lack of evidence on the optimal management of such mesh-provoked complications. A single RCT demonstrated an armed polypropylene mesh kit had a superior anatomical outcome at one year compared to anterior colporrhaphy. This study is significantly underpowered to adequately assess functional outcomes [240]. There remains a significant paucity of data available on efficacy of the commercially available kit armed polypropylene meshes for anterior compartment prolapse. A single well designed RCT and level 2 evidence suggest the porcine dermis graft overlay to be more effective than Anterior colporrhaphy alone. A significant body of Level 2 and 3 evidence has not been able to reproduce these results. A single RCT and level 3 evidence suggest little benefit is be derived from cadaveric fascia lata or dermis as a graft material.

2. BIOLOGIC GRAFTS

Alternatively to synthetic prosthetic grafts autologous material may have a lower risk of host rejection or infection. Cosson [243] described an autologous 6-8cm long and 4 cm wide vaginal patch suspended from the tendinous archs of the pelvic fascia and tucked under the anterior repair. The success rate (~grade 1 POP) was 93% at a mean follow-up of 16 months. Allografts from postmortem tissue banks have been used for many years in orthopedic surgery and decrease the risk associated with harvesting autologous rectus sheath or fascia lata. Cadaveric fascia lata with or without pubovaginal sling has been utilised to correct anterior compartment prolapse with a success rate varying from 81-100% with acceptable
complication rates [244-247]. Gandhi et al have reported preliminary results of a randomized control trial comparing anterior colporrhaphy alone and augmented with fascia lata graft for cystoceles [221]. At 1 year they were not able to demonstrate that the addition of the fascia lata graft improved outcomes with the success rate after anterior colporrhaphy alone being 71% as compared to 82% in those augmented with the fascia lata graft (P=0.07). No complications were reported. Cadaveric dermis has been employed as a graft material in the anterior compartment with success rates varying from 42-84% at 2 years [248-250]. Concerns regarding prion transmission causing infectious diseases [251] or residual antigenicity [252] that may cause host graft reactions have encouraged the use of porcine or bovine xenografts.

Leboeuf et al retrospectively reviewed 24 women with native tissue four corner defect repair (FDR) and 19 FDR [253]. At 15 months the success rate was 100% in the FDR group and reduced to 84% if Pelvicol overlay was utilized. Wheeler et al reported on 36 women who all underwent high uterosacral vault suspension with anterior repair augmented with porcine dermis and at 17 months found a 50% recurrence rate [254]. The authors highlighted that despite the high objective failure rate greater that 90% of the women were satisfied or somewhat satisfied with the repair and 83% would undergo the surgery again. Handel et al retrospectively compared anterior colporrhaphy (n=18), porcine dermis (n=56) and polypropylene graft (n=24) in those with cystocele [255]. The success rate at 13 months was 94%, 64% and 96% respectively with a 21% rate of vaginal extrusion of the porcine dermis graft. Alternatively to these relatively disappointing results, a number of groups have reported satisfactory objective results utilizing the porcine dermis. Goemelsky et al found in 70 women after 2 years, an 87% success rate with no complications [256]. Simmsman et al also after 2-year review of 89 women reported a 78% success rate with a 17% rate of graft erosions [257]. Meschia et al in a multicentre randomised clinical trial compared the anterior colporrhaphy (n=103) and anterior colporrhaphy-augmented with 4x7cm piece of porcine dermis [258]. The success rate at 1 year was 93% in the anterior colporrhaphy with porcine graft overlay group as compared to 81% in anterior colporrhaphy alone group (P<0.001) with a 1% rate of graft erosion.

Tables 15, 16 and 17 summarize studies using augmenting materials for various transvaginal procedures. Biological grafts do not appear to enhance to results of traditional posterior colporrhaphy. Pariso, et al reported the results of a randomized trial in which 3 groups of women were allocated to posterior colporrhaphy, site-specific defect repair or biograft augmentation with xenograft and followed over 17 months [174]. Women with graft augmentation had the highest anatomic failure rate (46%) compared to PCR and SSDR group (14% and 22% respectively). The functional outcomes in all the 3 groups were similar. Similarly, in the prospective cohort study by Altman, et al, augmentation with the porcine collagen in 23 patients resulted in a recurrence rate of 41% at 38 months [271] without major materials-related complications.

Several case series demonstrate that the surgical therapeutic ratio of augmentation with synthetic material is not favourable. Case series report that synthetic grafts are associated with high anatomical success rates at the cost of complications and sequelae. De Tayrac and colleagues reported an anatomical cure rate of 92% at two-years following a combined sacrospinous suspension with polypropylene mesh posterior repair. In this case series of 26 women, one patient developed denovo dyspareunia and 3 developed vaginal erosion [237]. In the French multicenter case series reported by de Tayrac et al, investigators evaluated 76 women who underwent posterior repair using low-weight polypropylene mesh coated with absorbable hydrophilic film [238]. At a median follow-up of 10 months, they reported a 2.6% recurrence rate, 12% denovo dyspareunia rate and 6.3% vaginal mesh erosion rate.

A retrospective case series of 50 women with mesh placement in the posterior compartment (with or without anterior placement) was reported by Dwyer et al. [242]. Despite no recurrences, at a mean follow-up of 29 months, he reported 6 mesh erosions (12%), 1 denovo dyspareunia and one rectovaginal fistula. Similarly, Lim et al reported a 30% rate of vaginal erosion, 27% denovo dyspareunia rate as well as a 22% recurrence rate 35 months after posterior repair augmented with composite polyglactin 910-polypropylene mesh [268]. Milani et al augmented the midline fascial plication for rectoceles repair with polypropylene mesh in 31 women. After the median follow-up of 17 months the anatomical success rate was 94% but the rate of dyspareunia in this group increased from 6% to 69% (p= <0.05) and the mesh erosion rate was 6.5% with one pelvic abscess [269].

Gauruder-Burmester et al evaluated 48 subjects with posterior wall defects in their study with a polypropylene mesh kit. At the end of one year follow-up reported good outcomes with an anatomical success at posterior vaginal wall as 100%, cure of dyspareunia postoperatively and no mesh erosions in the posterior compartment [197]. In the case series by Fatton et al, evaluating a polypropylene mesh kit,

</table>
58 women with rectocele underwent posterior mesh repair. At the short-term follow-up at 3 months, there were two cases of Stage 2 prolapse of the posterior vaginal wall and there were five patients with mesh exposure [241].

Altman, et al, reported a 91% posterior anatomical cure rate in their interim analysis at 2 months following polypropylene mesh repair. The same authors evaluating the perioperative morbidity with this technique at the 6-month follow-up reported four cases of rectal perforation and one wound infection [264].

A variety of kits have been proposed for repair of prolapse that includes apical support loss. Routine use of these kits should be regarded cautiously based on the complications reported in the series in Table 17.

VI. RECTAL PROLAPSE

External rectal prolapse is a circumferential, full-thickness protrusion of the rectum through the anus. This section is limited to a discussion of surgically treatment for external rectal prolapse and does not discuss internal rectal prolapse or various forms of intrasuccesception. More than 90% of patients with rectal prolapse are women [281] and the incidence peaks in women older than 70 years old [282] Pelvic organ prolapse and rectal prolapse may occur concurrently. In a recent study, 48% of patients treated for rectal prolapse developed genital prolapse at some point of time [283]. Patients with rectal prolapse have debilitating symptoms and they usually therefore require surgical intervention. There are some 100 different surgical methods described for surgical correction of rectal prolapse, but there are no randomized, well powered, studies to base clinical decision making on. Available randomized studies have major methodological limitations.

Surgical treatment of complete rectal prolapse includes traditionally been divided into perineal and transabdominal approaches. Perineal procedures include complete (the “Altemeier procedure”), or partial resection (the “Delorme procedure”) of the prolapse. Transabdominal procedures can be performed either with open or laparoscopic techniques and include different types of suspension and sometimes concomitant bowel resection. Mobilization of the rectum down is an integral part of correction of the prolapse. The extent of mobilization varies and there are some data suggesting that the lateral ligaments should be preserved. A recently introduced surgical technique, laparoscopic ventral rectopexy, avoids posterior rectal mobilization and has been found to have low rate of postoperative constipation in initial studies. These results need to be confirmed in larger trials, with longer follow-up, at other institutions.

Concomitant sigmoid resection is frequently used in patients with preoperative constipation symptoms and there are some data that this addition may slightly decrease the risk for postoperative constipation.

There are few randomized studies evaluating surgical treatment for rectal prolapse. In 2000, Bachoo et al. performed a review for the Cochrane collaboration evaluating all randomized or quasi-randomized trials of surgery for rectal prolapse [284]. Ten trials were included with a total of 324 participants and the studies had varying aims. The small sample size of included trials, together with methodological weaknesses, limited the review and the authors suggested larger and better designed trials to define the optimal treatment for rectal prolapse.

The Association of Coloproctology of Great Britain and Ireland initiated a randomized multicenter trial, the PROSPER (Prolapse Surgery: Perineal or Rectopexy) trial, in 2000 which is currently recruiting.

1. PERINEAL PROCEDURES

Perineal procedures offer less surgical trauma, but are associated with higher recurrence rates and therefore usually reserved to old or frail patients. The two most common perineal procedures for rectal prolapse are the Delorme procedure and the Altemeir procedure. In several studies the recurrence rate is stated to be approximately 20% for both these procedures. However, recurrence rates tend to increase with the follow-up time in the studies and it is conceivable that the recurrence rate is significantly higher in fit patients. There are no prospective randomized studies comparing the recurrence rates between these procedures. The Delorme procedure has been the more popular in Western Europe, while the Altemeir procedure has been the dominating perineal procedure in North America.

Agachan et al. compared the outcome after the Delorme procedure and the Altemeir procedure with or without concomitant levatorplasty [285]. The recurrence rate was highest after the Delorme procedure (38%) and lowest after the Altemeir procedure including a concomitant levatorplasty (5%).

a) The Delorme procedure

The Delorme procedure was first described in 1900 by the French military surgeon Edmond Delorme [286]. The procedure includes stripping of the mucosa of the prolapsed rectum and suture plication of the remnant rectal wall. There are several studies on the outcome after the Delorme procedure and results vary between studies [287-291]. The vast majority of studies are retrospective and there are no prospective randomized studies published comparing the results with other surgical techniques. In a recent retrospective study, Marchal et al. [288] reported a complication rate of 15%
and a recurrence rate of 23% in 60 patients undergoing the Delorme procedure. The authors compared the Delorme group of patients with a group of patients undergoing the Orr-Loygue rectopexy and found that the Delorme procedure had a higher recurrence rate. After the Delorme procedure, patients with preoperative constipation had this symptom improved or completely resolved in 54% and worsened in 12% postoperatively. 42% of patients with preoperative incontinence were continent or had continence improvement postoperatively.

b) The Altemeier procedure

Perineal rectosigmoidectomy for rectal prolapse was tried in a few patients in the late 19th century, but it was not until 1952 the procedure was popularized by Altemeier [292]. The prolapsed bowel is transected 2-4 cm proximal to the dentate line and the level should not include the internal or external anal sphincters. The inner tube of the rectum is then mobilized until there is some resistance to achieve more mobilization. The vessels to the rectal mesentery are ligated or transected using the ultrascision equipment. The inner tube of the rectum is transected and sutured to the outer tube with an anastomosis. Some surgeons add a levatorplasty, to decrease the size of the levator hiatus, before suturing the anastomosis. Some surgeons use a stapled technique to achieve the anastomosis.

There are several studies on the outcome after the Delorme procedure and results vary between studies [282, 293-296]. The vast majority of studies are retrospective. There is one randomized study comparing perineal rectosigmoidectomy with pelvic floor repair with abdominal resection rectopexy and pelvic floor repair [297]. The study included ten patients in each group and only one patient had a recurrence. There were no significant differences in functional outcomes.

In a recent retrospective study, Kim et al. reported a complication rate of 14% and a recurrence rate of 16% in 60 patients undergoing the Delorme procedure [294]. Functional improvement was not significantly different, and most patients were satisfied with treatment and outcome.

2. TRANSABDOMINAL PROCEDURES

Transabdominal procedures can be performed either with open or laparoscopic techniques and they include different types of suspension and sometimes concomitant bowel resection. Laparoscopic rectopexy is reported to offer the same or better outcome as after open rectopexy [298-305]. There are two small (21 and 40 patients respectively) randomized studies, with 21 and 40 patients respectively in the literature comparing laparoscopic mesh rectopexy with open mesh rectopexy [299, 306]. Recurrence rates were quite small after both types of procedures and there were no significant differences in functional outcome.

Transabdominal procedures result in general in low recurrence rates [307-309] and the discussion regarding outcomes is therefore focused on functional outcome. As discussed above, some patients may develop worsened constipation postoperatively and not all patients regain normal continence. The mobilization of the rectum at transabdominal procedures can be of varying degrees. The effect of lateral ligament division was assessed in one small randomized study involving 26 patients [310]. The study demonstrated a trend for higher recurrence rate after preservation of the lateral ligaments, while this preservation seemed to decrease the risk for postoperative constipation. A recently introduced technique (laparoscopic ventral rectopexy) provides rectal prolapse repair without any significant rectal mobilization [311]. In the first initial reports, the authors have reported excellent postoperative outcome [311, 312]; however there is no high-quality evidence to recommend this procedure.

a) Rectopexy

The dominating transabdominal technique for the treatment of rectal prolapse in recent decades has been rectopexy. The surgical procedure, open or laparoscopic, begins with mobilization of the rectum. The extent of dissection varies in different series, but most surgeons tend to mobilize the rectum down to the coccyx posteriorly, preserve the lateral ligaments laterally. The extent of anterior dissection varies, from none to mobilization of 2-4 centimeters of the rectovaginal septum.

The choice of fixation method varies in different reports [172, 294, 309, 313, 314]. The fixation can be achieved with different mesh materials fixated usually posteriorly, but sometimes laterally or anteriorly. Suture rectopexy is frequently used and the mesorectum is then fixated to the sacrum with a few sutures. There are few studies comparing different fixation methods or materials in the same report. Novell et al compared the use of Ivalon sponge with suture rectopexy in one randomized trial involving 83 patients [315]. The recurrence rates were the same (one in each group) and functional outcome was not significantly different. Two other randomized trials compared the outcome after different types of mesh. Galili et al. [316] compared polyglycolic acid mesh with polypropylene mesh and Winde et al [317] compared polyglycolic acid mesh with polyglactin mesh. Sample sizes were limited (37 and 49 patients respectively) and no significant differences in recurrence rates or functional outcome were detected. As there has not been possible to detect any difference in outcomes between different fixations methods, some authors argue that suture rectopexy may be preferable as this method does not carry an associated risk for mesh complications [309]. The combination of rectopexy and concomitant sigmoid resection (the “Frykman-Goldberg operation”) is frequently used to decrease the risk for postoperative complications.
constipation problems. Several studies have evaluated postoperative constipation symptoms after resection rectopexy [318, 319]. Benoist et al. compared results after laparoscopic suture rectopexy with (n = 18) or without sigmoid resection (n = 16) [298]. Postoperative constipation was observed in 2 patients (11%) after resection rectopexy and in 10 (62%) after suture rectopexy (P < 0.01). Two small randomized studies have evaluated the effect of concomitant sigmoid resection on constipation after rectopexy. McKee et al. prospectively randomized 18 patients to rectopexy alone or rectopexy combined with concomitant sigmoid resection [320]. Three months postoperatively, 7 patients after rectopexy alone and 2 patients after concomitant sigmoid resection complained of severe constipation. Luukkonen et al. prospectively randomized 15 patients to rectopexy and sigmoid resection or rectopexy without resection [321]. The authors found a lower risk for postoperative constipation in the patients who underwent concomitant sigmoid resection.

Orr-Loygue rectopexy includes mobilization of the rectum and fixing the rectum with two strips of synthetic mesh from the anterolateral sides of the distal rectum to the sacral promontory [322]. In a recent prospective study, Douard et al. evaluated 31 consecutive patients operated with this technique [323]. They reported no recurrences after a mean follow-up of 28 months. Patients with incontinence decreased from 81% preoperatively to 55% postoperatively and continence improved in 96% of patients. Evacuation difficulties increased significantly after surgery, from 23% to 61% of patients. In another recent study, Marchal et al. [288] reported similar results, with a recurrence rate of 4% in 49 patients with a mean follow-up time of 88 months (Marchal, 2005). In patients with preoperative constipation, this symptom was improved or completely resolved in 33% and worsened in 58% postoperatively. In patients with preoperative incontinence, 73% were continent or had continence improvement postoperatively.

b) Laparoscopic ventral rectopexy

Laparoscopic ventral rectopexy provides rectal prolapse repair without any significant posterior rectal mobilization, which therefore decreases the risk for autonomic nerve damage [311]. The rectovaginal septum is opened and dissected. A Marlex mesh is thereafter sutured to the anterior aspect of the distal rectum and fixed proximally to the sacral promontory. No posterior mobilization of the rectum is performed.

The authors have reported recurrence rate of less than 5% after a mean follow-up of 61 months and constipation resolved in 16 of 19 patients with preoperative constipation [311].

VII. RECOMMENDATIONS

The committee makes the following graded recommendations:

- **GRADE A** (usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway.

  Sacrocolpopexy is a highly recommended apical prolapse procedure.

  Synthetic material is superior to biological material for sacrocolpopexy.

  The use of polypropylene mesh for trans-vaginal anterior wall repair improves 1 year anatomic outcomes; this advantage should be weighed against the risk of mesh-related complications and uncertainty regarding long-term functional outcomes.

  Transvaginal route is preferable to transanal route for posterior vaginal prolapse repair.

- **GRADE B** (usually depends on consistent level 2 and/or 3 studies, or “majority evidence from RCTs”)

  A single RCT provides level 1 evidence that concomitant Burch colposuspension is recommended in women without symptoms of stress incontinence at the time of open sacrocolpopexy. There is conflicting Level 2 evidence.

  Concomitant total hysterectomy at the time of mesh-augmented repairs increases mesh erosion; therefore, alternative surgical plans with reduced risks should be considered.

  When hysterectomy is indicated, concomitant anterior repair without augmenting materials is reasonable.

  There is no evidence to support the use of synthetic mesh for trans-vaginal repair (or augmentation of repair) in the posterior wall.

  Levator ani plication during posterior colporrhaphy should rarely be used in sexually active women because of the increased risk of dyspareunia.

  A single RCT provides level 1 evidence that porcine dermis without fascial repair is inferior to posterior vaginal fascial plication or site specific defect repair. This is consistent with a Level 2 cohort study.

- **GRADE C** (usually depends on level 4 studies or “majority evidence” from level 2/3 studies or Dephi processed expert opinion.

  Suspension of the apex by an appropriate method should be considered at the time of each vaginal prolapse repair.
There is no evidence for the superiority of any specific technique for transvaginal apical suspension using native tissue.

Traditional fascial plication of the posterior vaginal wall has a lower anatomic failure rate than site-specific fascial defect repair.

A single level 1 study provides evidence that the use of porcine dermis as an overlay for anterior vaginal repair is superior to traditional vaginal fascial plication, although there is conflicting Level 2 and 3 data.

Trans-vaginal placement of mesh after intraoperative procotomy is discouraged.

Trialists should report sufficient detail regarding anatomic and symptomatic outcomes so that subsequent outcome definitions can be tested in a wide variety of datasets. Primary and recurrent cases should be reported separately. Outcomes of treatments should be evaluated in multiple domains.

Laparoscopic sacrocolpopexy is used as an alternative to open sacrocolpopexy, although no comparative studies report outcomes.

Anatomic support defects without accompanying, relevant symptoms are rarely an indication for prolapse surgery.

Evidence-based surgical alternatives should be offered to all women planning prolapse surgery.

The safety and feasibility of reoperation in the event of recurrent prolapse should be considered when performing the primary repair.

GRADE D = “no recommendation possible” to be used where the evidence is inadequate or conflicting and where expert opinion is delivered without a formal analytical process, such as by Delphi.

There is insufficient information to provide evidence-based recommendations for the route of primary prolapse repair. There is level I evidence that sacrocolpopexy is more effective and durable in correcting anatomical defects, while the native tissue vaginal route is faster and less expensive to perform with a quicker return to activities of daily living. In addition, the vaginal route has fewer serious perioperative complications.

There is insufficient information to provide evidence-based recommendations for the optimal vaginal repair approach, including technique and materials.

There is insufficient information to provide an evidence-based recommendation for trans-vaginal mesh placement following intraoperative cystotomy.

The committee recommends that the following areas be prioritized for future research:

- It is essential to standardized mal method for determining outcome for POP surgery. The lack of consensus significantly impacts the ability to conduct, compare and contrast clinical research in this area.
  - Patient-reported and functional status before and after prolapse surgery.
  - Anatomic resolution (in operated and unoperated compartments) and relationship with symptoms.

- Well-designed RCT studies are needed to:
  - determine the role of hysterectomy (total or subtotal) during repair of POP with in situ uterus,
  - determine the optimal procedure for repair of post-hysterectomy POP,
  - compare native tissue vs. mesh-based apical repair techniques,
  - compare various trans-vaginal techniques for apical support,
  - compare the role of peri-operative physical therapy,
  - compare native tissue vs. mesh-based apical repair techniques,
  - determine the optimal management of stress continent women at the time of prolapse repair, by any technique, and
  - determine the optimal technique for repair of recurrence after primary mesh repair in any compartment.

- Well-designed comparative studies are needed to study
  - the utility of self-prepared mesh vs. kit-prepared mesh for apical and/or anterior prolapse repairs,
  - the safety and efficacy of prolapse-repair meshes that include arms that traverse non-vaginal spaces,
  - management of mesh complications especially mesh contracture and complications associated with armed meshes, and
  - management of recurrent anterior compartment prolapse following unsuccessful permanent mesh.

- Registeries are strongly recommended with the introduction of new devices to ensure safety and inform clinical trial planning.
There is sufficient evidence to support recommendations for some, but not all, decisions regarding the route of POP surgery. Textbooks of pelvic surgery often describe both abdominal and vaginal routes for POP procedures without commenting on the basis for selection of the route of surgery. When mentioned, most authorities state that pelvic surgeons should be proficient at procedures using both routes, and should tailor the procedure to the patient and her specific defects, decrying the “one procedure fits all” concept. However, some procedures for POP require special skills or experience, and not all surgeons will feel comfortable with all procedures. Relative indications cited for abdominal surgery include other reasons that mandate an abdominal approach, such as pelvic masses, the likelihood of dense pelvic adhesions, or the need for other extrapelvic abdominal procedures. Additional factors must include risk factors for failure, medical condition of the patient, risk of abdominal surgery in obesity or the frail elderly, and prior failed procedures for POP.

The emergence of mesh-based procedures poses a dilemma as there is significant uncertainty about the safety and efficacy of secondary prolapse procedures for prolapse recurrence following a primary mesh procedure. There are surgical concerns regarding the status of normal dissection planes, especially following a uterine-conserving mesh-based procedure. Given the high success rates of sacrocolpopexy in women with recurrent prolapse, the risk/benefit ratio of routine mesh placement for primary prolapse procedures needs further evaluation. Appropriate counseling of patient must include the known serious risks of mesh placement and the uncertainty of long-term functional outcomes.

I. INTRODUCTION

At present there is no accepted international consensus on terminology for faecal and anal incontinence. A working definition of anal Incontinence (AI) was adopted at the last consultation [1] as:

“Anal incontinence is the involuntary loss of flatus, liquid or solid stool that is a social or hygienic problem”.

It is proposed by this committee that the consultation adopt this definition, with the additional definition of “faecal incontinence” (FI) as:

“Faecal incontinence is the involuntary loss of liquid or solid stool that is a social or hygienic problem”.

The committee did not recommend that it is essential to choose one or other term to use exclusively, but rather recommends that either AI or FI can be used depending on context, as long as the definition is made clear. As the majority of intervention studies have focused on FI rather than AI as an outcome measure, FI is covered in this chapter, except where AI is specified.

This chapter covers conservative management of FI in adults. There is a specific section on issues of particular relevance to frail older adults (section 9). Covered elsewhere in the volume are surgical management of FI (Committee 17), and people with neurological disease or injury (Committee 10). Risk factors and prevention are covered for all groups. Some techniques developed and evaluated in these specific groups may have applications to an adult population, but most have not yet been evaluated. There is at present a very limited evidence base of high quality trials in FI and it remains challenging to provide strong evidence for most interventions. However, expert consensus in this committee and the world literature is unanimous in recommending conservative interventions, singly or in combination, for the majority of patients with FI as first-line management.

It was noted that outcome measures for FI and AI remain in the development stage and there is no consensus on the best measure to use in treatment trials (see Committee 5); this impacts evaluation of study findings because different criteria for successful outcome have been employed.

Conservative management is defined as any non-operative intervention designed to improve FI incontinence or prevent deterioration. No studies were found exploring how to select patients for operative versus conservative or drug management, and only one study [2] compared these approaches in comparable patient groups, and one study investigated the adjunctive benefits of conservative with surgical management [3], so patient selection remains empirical. The committee recommends a trial of conservative and drug management in the vast majority of patients before considering surgical options because these conservative options are comparatively inexpensive and involve no significant morbidity (see Figure 1). Exceptions would be patients with acute traumatic anal sphincter rupture or an endosonographically confirmed major defect in the external anal sphincter in the presence of gross FI: these patients would be referred for surgical evaluation as first line treatment.

II. PREVALENCE OF FI AND RISK FACTORS

1. SEARCH

For the previous ICI report [4], the literature review covered the period 1966 to 2003, and 11 population based studies were identified. Since then new population-based studies have been published (Table 1), and additional population based surveys have been identified that were missed in our earlier review. We have updated Table 1 to include all studies published through February, 2008, which met the
Active screening in high risk groups

Patient presents with AI

Basic assessment (history, examination, medication and diet review)

- Take out of pathway:
  - Alarm signals: referral for investigation
  - Impaction: treat then evaluate
  - Surgical evaluation needed: e.g. rectal prolapse, recent sphincter injury, recto-vaginal fistula, chloacal deformity

- Address reversible risk factor
  - e.g. Medication; toilet access; loose stools

  - Patient and / or carer education
    - Bowel habit and training
    - Manage constipation
    - Diet (e.g. soluble fibre for loose stool)
    - Medication (e.g. loperamide for loose stool)
    - PFMT / anal sphincter exercises
    - Adequate containment (e.g. pads or plugs) and practical management advice (Committee 20)

If initial management fails to achieve adequate symptom relief consider:
- Diagnostic testing; Biofeedback; Irrigation

Surgical evaluation or symptom management if adequate relief not obtained from conservative management, depending on symptom severity and patient preference

following criteria: [1] Sample is representative of the general population (not a convenience sample or sample recruited from a medical clinic or other setting in which there is a probable selection bias) [2]. At least 500 subjects provided data.

In 2006, Pretlove and colleagues [5] published a systematic review and meta-analysis of 29 studies of AI published prior to September 2004. However, many of the studies included in their analysis were drawn from medical or surgical clinics or were convenience samples. In 2007, the Center for Disease Control commissioned the University of Minnesota to prepare a systematic review of the prevalence and risk factors associated with FI for the State of the Science Conference on the Prevention of Fecal and Urinary Incontinence [6]. Their inclusion criteria differed from ours. The studies identified in both of these publications were reviewed for this report.

2. REVIEW OF EVIDENCE

Prevalence estimates for faecal or anal incontinence vary widely, from 2.2% to 25%. This variability is related to the following differences among studies: a.) Case definition – some studies focus on AI and include subjects with accidental loss of flatus as well as solid stool [7,8], while other studies report the prevalence of FI, defined as the loss of solid or liquid stool or mucus. A few studies have also defined a category of soiling of underwear only and suggest that this occurs frequently [9;10]. In this review, the case definitions used by authors are listed in the literature tables. In the text, FI refers to the loss of solid or liquid stool or mucus, and when studies are referenced that used other definitions such as AI or soiling, these are specified. b.) Age range – FI is strongly associated with aging (Table 1), and studies that limit their subject selection to older individuals yield higher prevalence estimates [11]. Few studies have adjusted their estimates to the demographics of the population. c.) Inclusion of subjects from skilled nursing facilities – Most studies of community prevalence exclude the institutionalized population where prevalence is known to be higher than in the community [12;13], while other studies include a representative mixture of community dwelling and institutionalized subjects [14].

The National Health and Nutrition Examination Survey (NHANES) in the United States (US) provides the a.) best estimate of FI prevalence to date because it surveyed both sexes, all major races represented in the US, and the full range of adult ages, and the authors extrapolated an age-adjusted prevalence estimate for the US; and b.) it provided separate estimates for different types (e.g., solid, liquid, mucus, and flatus) and frequencies of stool loss [15;16]. However, institutionalized individuals and those too ill to travel to examination sites were excluded.

Prevalence estimates. The age-adjusted prevalence of FI (defined as accidental loss of solid, liquid, or mucus incontinence in the month preceding the interview) in the non-institutionalized population of the United States is 8.9% of women and 7.7% of men [16]. When the data are broken down by type of incontinence, liquid incontinence is 2-3 times more common than solid stool incontinence, and incontinence for flatus is 2-3 times more common than the combination of liquid and solid [7;17-19]. In the NHANES study, liquid stool incontinence was reported by 6.2%, solid stool incontinence by 1.6%, and incontinence for mucus by 3.1%; 26% of subjects with any FI reported two or more types of FI consistency. Accidental loss of flatus, which was not included in the definition of FI in the NHANES study, was reported to have occurred at least once in the past month by 46% of men and 51% of women surveyed by NHANES. Table 1 gives prevalence estimates for several countries, but differences in survey methodology make it difficult to interpret observed differences between countries. There are no published data on the incidence (i.e., rate of new onset) of FI or AI in non-institutionalized populations.

Under-reporting of FI. In population based surveys, when people with FI or AI are asked whether they have discussed this problem with their health care providers, only a third have done so: the reported proportion are 36% in the United States [8], 32.6% in France [20], 40.8% in Sweden [21], 27% in Australia [19], and a third in The Netherlands [22]. This is found even in acute care hospitals [23] and nursing homes [24]. In a 1986 study of UK nursing home residents, only 4% of patients with long-standing FI had been referred to their general practitioner for further assessment of this problem [25]. A 1982 study of US nursing home patients found that only 15% of those with incontinence had a physician mention of it in the nursing home records [26]. A possible reason for the failure to recognize and report FI in acute care hospitals and nursing homes is the belief of many health care providers that FI is a normal part of aging: a UK nursing home survey found that the trained staff cited advanced age as the main cause of incontinence [27].

a) Patient characteristics associated with increased risk of FI

1. Age

Most surveys that include young as well as older adults find age to be strongly associated with FI (Table 1). This age-related increase in prevalence of FI is likely attributable to age-related declines in general health, muscle strength, mobility, and cognitive functioning, and the increased prevalence of other diseases that may contribute to FI (see below).

2. Admission to an acute care hospital

Admission to an acute care hospital is frequently
associated with a new onset or exacerbation of FI. A British survey of 627 hospitalised patients aged 65 and over (FI defined as at least one episode weekly) found a prevalence of 14% [28], and this is significantly higher than the community prevalence of FI. An Australian survey of 247 consecutive admissions to an acute care hospital (all ages) found that 22% self-reported FI [29]. Bliss et al. [30] reported that FI was present in 33% of hospitalized patients.

Risk factors for the development of FI subsequent to hospital admission include the following: having loose/liquid stool consistency (RR=11.1; 95% CI=2.2-56.7), greater severity of illness (5.7, 2.6-12.3) and older age (1.1, 1.02-1.1) as independent risk factors in a multivariate analysis [30]. A UK descriptive study found contributing factors to FI in acute hospital inpatients aged 65+ to be faecal loading (57%), functional disability (83%), loose stools (67%), and cognitive impairment (43%) [31]. When compared with 3 other settings (home, care homes and rehabilitation wards), acute hospital inpatients with FI were significantly more likely to have faecal loading, functional disability, and loose stools. Patients with loose stools and less comorbidity were more likely to have resolution of FI after 3 months follow-up.

3. RESIDENCE IN A SKILLED NURSING FACILITY (Table 2)

FI in nursing homes is often discussed separately from FI in community dwelling individuals because a.) risk factors differ and may include a significant iatrogenic contribution, and b.) treatment/management strategies differ. In nursing homes the prevalence of FI ranges from 43% [12] to 54% [32], which is approximately 5 times the rate seen in community dwelling individuals. The incidence (onset rate) of FI in nursing homes was reported to be 20% [32] in France and 27% [33] in the U.S. An estimated 97% of nursing home residents with FI also have UI [13], which is significantly higher than is reported for community dwelling individuals of comparable age; this suggests a different spectrum of aetiologies.

There is a wide variation in the reported prevalence of FI among nursing homes in the UK, ranging from 17% to 95% between individual nursing homes [25;28;34]. As the case-mix within British nursing homes is likely to be comparable, the variations may well be more reflective of different standards of care, rather than of different patient characteristics. A recent nation-wide UK audit of FI in older people found that patients admitted to care homes with pre-existing FI tended to simply be placed on a containment management plan rather than being assessed for causes and possible treatment, and this was despite having good access to continence specialist care [35].

The strongest univariate associations with FI in long-term care studies are physical dependency and impaired mobility, particularly where help is needed to transfer from bed to chair [28;34]. However, faecal loading is also believed to be a significant and treatable cause of FI in this population: A UK study found faecal loading in 70% of residents with FI [31], which suggests that treatable overflow FI is being overlooked in this setting.

4. SEX

Among 15 population-based studies that surveyed both men and women (Table 1), six surveys [8;9;17;36-38] found a significantly higher prevalence in women, eight [10;19;39-43] found no difference, and one study that was limited to people 75 years of age and older found a higher rate in men [11]. Thus, sex is a weak predictor of who will develop FI. However, young women are vulnerable to a unique set of risk factors associated with childbirth (see below). In older people men and women are found to have equal prevalence and men may predominate in advanced old age.

5. RACE

In population based studies, race has not been found to be significantly associated with FI or AI [23;42;44]. However, there is evidence that obstetrical tears are more common in Hispanic, Filipino, and Chinese women compared to Caucasian women [45;46]. In addition to sphincter lacerations, there appears to be a higher incidence of post-partum FI in Asian women compared to Caucasians (OR=3.2) [47] and a lower incidence of post-partum FI in African Americans compared to Caucasian Americans [48;49]. These results may be confounded by a tendency to different parity rates in different groups and possibly by differing birthing practices.

6. OBESITY

Having a body mass index (BMI) >30, which defines obesity, was associated with an increased risk of FI for women in two studies [18;48]. However, other surveys failed to find a significant association [50;51].

7. POOR GENERAL HEALTH

In population-based surveys, poor general health is an independent predictor of FI [8;19;24;42]. FI is associated with increased mortality both in community dwelling older subjects [40] and in nursing home patients [32].

8. PHYSICAL LIMITATIONS

Three population-based surveys assessed physical limitations and found them to be risk factors for FI [8;37;40]. In nursing home patients, mobility impairment is consistently found to be a predictor of FI [12;32;33;52;53].

9. PHYSICAL EXERCISE

Endurance running is associated with diarrhoea and FI in over 10% of individuals [54]. Regular exercise did not predict prevalent FI or incident FI at a five and

</table>
In community-based surveys, FI is strongly associated with urinary incontinence [18;38] and overactive bladder [7] in both men and women. Among nursing home patients, the association between urinary incontinence and FI is even stronger [12;13;32]. Pelvic organ prolapse is also significantly associated with FI [7;18].

Urinary incontinence and pelvic organ prolapse are unlikely to be causally related to FI but may serve as marker variables to identify patients who are at risk for the development of FI.

Some patient characteristics found to be associated with FI or AI in epidemiological surveys suggest pathophysiological mechanisms that may cause incontinence, and the modification of these risk factors might reduce the risk of developing FI or AI; examples are diarrhoea, obesity, mobility impairment, and endurance running. For other variables found to be associated with FI or AI, no plausible pathophysiological mechanisms that may cause incontinence are identified. For the last group of variables, e.g., age, poor general health, and the development of FI, it may be useful to identify patients at risk for screening and early treatment.

</table>
have been reported to cause diarrhoea include lactose (in lactase deficient individuals); fructose, sorbitol, aspartame, and other artificial sweeteners that are poorly absorbed; and fat substitutes such as olestra. Some natural foods such as prunes and figs may also cause diarrhoea. The research literature has not established that these foods, food additives, and drugs cause FI, but it has established a link to diarrhoea.

2. Urgency to defecate

Bharucha and colleagues [14] reported that the symptom of urgency (having to rush to the toilet) is a strong risk factor for FI which is independent of diarrhoea and constipation. This is supported by an independent survey in Australia [19] and a survey of elderly health maintenance organization patients in the U.S [24].

3. Constipation

Constipation was found to be a significant positive risk factor for FI in one nursing home survey [12], but in another study, hard stools appeared to be protective [53]. A UK survey of nursing home residents with FI found that faecal loading was present in 70% of individuals [31]. Constipation is considered to be the most common aetiology for FI in children (often referred to in the paediatric literature as encopresis when there is no recognized structural anomaly to explain the incontinence) [62;63]. The mechanism that is presumed to explain constipation-related FI is overflow: a mass of hard stool in the rectum or sigmoid blunts sensitivity for perceiving the movement of new stool into the area and also reflexly dilates the internal anal sphincter allowing liquid stool to seep out [62].

4. Irritable bowel syndrome

Three population based [48;64;65] and several studies of clinic samples have shown an excess incidence of FI in patients with IBS with estimates of odds ratios ranging from 2 to 8. When research criteria are used to diagnose IBS in population based samples [64;65], the proportion of IBS patients with FI is 12.0% to 22.7%. However, Varma et al [48] estimated that 44.6% of patients with a self-reported diagnosis of IBS had FI.

5. Inflammatory bowel disease

FI is more common in patients with inflammatory bowel disease, although the precise prevalence has not been the focus of study and is not known. Estimates range from 22% [66] to 41% [48]. Two mechanisms are recognized for this association: both ulcerative colitis and Crohn’s disease are associated with diarrhoea, which is a risk factor for FI. Crohn’s disease is also associated with the development of anal fistulae that may drain liquid stool to the skin surface and abscesses that may create anatomical defects in the anal sphincters.

6. Haemorrhoids

A significant number of patients with prolapsing haemorrhoids (Grade 3 and 4) experience faecal soiling, although this has not been the specific focus of any study. Johansson and colleagues [67] reported that 21% of 507 patients treated for haemorrhoids listed hygiene or soiling as an indication for seeking treatment. Following treatment with the Milligan-Morgan procedure, 24% of patients who had not listed soiling or hygiene as an indication for surgery developed new onset FI. Bliss and colleagues [24], in a survey of 1,352 subjects older than 65 years who were attending health maintenance organization clinics, found that self-reports of haemorrhoids predicted the frequency and severity of FI.

7. Imperforate anus

High anal atresia is associated with FI 85% of the time and low anal atresia about 57% of the time [68]. The surgical correction of high anal atresia involves identifying the striated external anal sphincter and pulling the healthy portion of the bowel down through this sphincter to create an anus; contributing causes of incontinence are absence of an internal anal sphincter (passive barrier to soiling), weak contraction of the external anal sphincter, and decreased compliance of the neorectum [69-72]. The outcome of surgical repair is improving with improved surgical techniques and the use of the Malone antegrade colonic enema technique, but 10-30% of these patients remain totally incontinent for faeces [73].

c) Obstetric and other injuries to the pelvic floor

Obstetric injuries are the most thoroughly investigated category of risk factors for FI or AI. Table 3 shows studies that were enriched by recruitment from obstetrical hospitals or urogynaecology clinics and that included at least 500 subjects. The table shows that studies which assessed the impact of obstetrical injury soon after childbirth found strong associations to FI while studies that assessed the impact of obstetrical injury retrospectively in middle aged and older women found weaker associations or no associations [18;74-76].

1. Parity

Most surveys investigating parity find it to be a risk factor for FI. The first vaginal delivery carries the greatest risk of new onset FI [77], and each subsequent delivery adds to that risk [7;17;74;75]. A French study [78] found a higher prevalence of AI in women who delivered at home compared to those who delivered in the hospital.

2. Sphincter laceration

A prospective cohort study demonstrated that primiparous women with a 3rd or 4th degree sphincter

laceration recognized at delivery have a substantially increased risk of FI even though sphincteroplasty is routinely performed when a sphincter laceration is detected [79]. Other studies [18;19;74;80-82] support this association, although two studies [14;80] did not.

3. INSTRUMENTED DELIVERY

Forceps delivery was found to be a risk factor for sphincter laceration [83] and FI [47;78;81;82], although two studies did not find this association [14;80]. The evidence that vacuum extraction is a risk factor for FI is more equivocal; two studies reported a significant association [81;84], and one study showed that vacuum extraction increases the risk of sphincter tear [83]. However, other studies failed to find an association of FI with vacuum extraction [18;47]. The evidence for a protective effect of caesarean section is inconclusive.

4. EPISIOTOMY

Midline episiotomy, which was formerly advocated for the prevention of uncontrolled sphincter lacerations and associated FI, has been found to increase the risk of sphincter laceration [77;83]. The risk of AI was reported to be increased in two studies [80;85] and unchanged in a third study [47]. No studies have found episiotomy to be associated with a reduced risk of sphincter laceration or FI/AI.

5. LARGE BABY, PROLONGED SECOND STAGE OF LABOUR

Two studies [77;83] showed a significant association between sphincter laceration and foetal weight greater than 4000 grams. Other studies showed an association between AI and foetal weight greater than 4000 grams [80;81] or foetal head diameter greater than 93 mm [78]. However, a fourth study did not confirm this association [82]. A prolonged second stage of labour was associated with a greater risk of AI in one study [81] but not in a second study [80].

6. MATERNAL CHARACTERISTICS

Age of the mother at the time of vaginal delivery was positively correlated with the risk of FI or AI in 5 studies [47;75;78;79;81], but was reported to be protective in one study [82]. Maternal depression and stress were also reported to be associated with an increased risk of AI [76]. A French study also found AI to be more common in women who had a history of anal or UI surgery and in those who completed high school [76].

d) Sequelae of surgical procedures

1. COLECTOMY AND ILEOANAL ANASTOMOSIS

Because ulcerative colitis and familial polyposis both convey a high risk of colon cancer, the colon is often removed prophylactically. While a number of variations in surgical technique have been described, the commonest procedure is to create a neorectum from loops of ileum sewn together to create a pouch and to connect this to the anal canal. A temporary ileostomy
is usually performed to give the pouch time to heal. Post-operatively, 25-35% of these patients have daytime FI [86-89] and 32-52% have nocturnal FI [86;86;87]. Fazio and colleagues [89] reported that the preoperative frequency of FI was as great in their series of patients as was post-operative FI. The mechanisms that lead to FI in this population include frequent bowel movements (8 or more per day), high pouch pressures that exceed anal canal pressures, and high amplitude contractions of the pouch [90]. Such pouch contractions are recorded in continent as well as incontinent patients with an ileal pouch because the pouch is constructed from innervated bowel; however, the contractions produce higher pouch pressures in the incontinent patients.

When it is possible to preserve the rectum, the ileum can be sutured directly to the rectum, substantially reducing the risk of FI [91]. When bowel resection is performed for the treatment of colon or rectal cancer, some or the entire colon may be preserved, and the remaining colon may be sutured directly to the anal canal or it may be used to create a pouch that is connected to the anal canal. This is associated with a lower incidence of FI (estimated at 18%) according to some authors [92;93], but others [94] reported a rate of 49% FI following colo-anal anastomosis.

One randomised controlled study has investigated the use of daily irrigation of a colonic J-pouch prior to ileostomy closure. Irrigation was not found to improve post-closure nocturnal continence or defaecation frequency [95].

2. INTERNAL ANAL SPHINCTEROTOMY

Patients with chronic anal fissure or haemorrhoids may be offered internal anal sphincterotomy (silt in the internal anal sphincter for 50-60% of its length to reduce anal canal pressures). In a large series of 585 patients with a chronic anal fissure treated in this fashion at the Mayo Clinic, 45% developed FI at some point in their recovery. However, this tended to improve with time from surgery, and at follow-up an average of 72 months after surgery, 11% reported FI [96].

3. RADICAL PROSTATECTOMY FOR PROSTATE CANCER

Published prevalence rates of FI following radical prostatectomy alone range from 9% [97] to 15% [98]. In the largest survey, Bishoff and colleagues [99] reported that prostatectomy by the retropubic approach was associated with FI in 17% of cases whereas prostatectomy by the perineal approach was associated with FI in 32% of cases; the loss of moderate to large amounts of stool was reported by 4% and 10% respectively. Rates of FI are higher when prostate cancer is treated by radiation therapy [47]. These differences may be confounded by differences in severity of disease before treatment, extent of resection, and dose of radiotherapy.

4. HAEMORRHOIDECTOMY

A large series of 507 patients who received the Milligan-Morgan surgical treatment for haemorrhoids were followed up by postal questionnaire 2-11 years after surgery (average of 6 years). A total of 33% (139/507) reported AI including 72 who were incontinent of gas only, 56 who were incontinent to liquid faeces, and 11 who were incontinent to solid faeces [67]. Other reports of surgical treatment for haemorrhoids list a lower incidence of FI [100], but only cases with loss of liquid or solid stool are usually reported. In a community based survey of people over age 65, Bliss [24] found self-reported haemorrhoid surgery was significantly associated with FI.

e) Sequelae of radiotherapy for cancer

The prevalence of FI following external beam radiation therapy for prostate cancer ranges from 14% [97] to 21% [67]. One group estimated the prevalence at up to 46% for a mixed group most of whom had been treated with both surgery and radiotherapy [101]. Radiotherapy for cervical cancer is associated with FI in 25% of cases compared to 8% for cervical cancer patients treated exclusively by surgery [102]. The mechanism through which radiotherapy contributes to FI is believed to be a decrease in rectal compliance [103], leading to increases in symptoms of urgency and loose stools [67;102].

f) Neurological Diseases that predispose to FI

1. COGNITIVE IMPAIRMENT

Dementia is a significant predictor of FI both in the community [40] and in nursing homes [12;32;53]. In some community studies, dementia was not found to be a significant predictor after controlling for other risk factors [40;40;55], possibly because patients with severe dementia associated with FI are frequently admitted to nursing homes [104].

In people with a developmental disorder, the prevalence of FI in those with mild learning disability is little different from that of the general population; however, rates for those with moderate and severe learning disability are higher than population norms and are similar to each other. The prevalence of FI is substantially higher in those with a profound learning disability [105]. Nevertheless, around half of those with a profound learning disability will acquire bowel control by adulthood.

2. SPINAL CORD INJURY

Traumatic spinal cord lesions result in substantial or complete denervation of pelvic floor muscles and loss of voluntary control over the external anal sphincter. However, many of these patients avoid FI because they are constipated due to delayed whole gut transit and/or hyper-reflexia of the external anal sphincter. Occasional FI is reported by 33-66% [106-108] but
frequent FI (more than monthly) is limited to 11% [109] to 14% [108;110]. Approximately 70% require mechanical or manual assistance to initiate defecation [110]. In patients with congenital spinal cord lesions (spina bifida), anorectal dysfunction may be more common; 53% in one study [111] and 34% in another survey [112] report that they soil regularly. As with traumatic spinal cord lesions, the majority of patients with spina bifida are constipated, which reduces the frequency of FI that would otherwise occur in these patients because they have partial or complete disruption of the efferent innervation to the pelvic floor muscles [113].

3. Stroke

Two large studies have assessed the incidence of FI following stroke. In the Copenhagen Stroke Study of 935 consecutive admissions for stroke [114], 34% were fully incontinent and 6% were partially incontinent on admission to the hospital; 6 months later, 5% were fully incontinent and 4% were partially incontinent. In a study of 1069 patients taken from the South London Stroke Register [115], 29.7% were faecally incontinent 7-10 days after stroke, 10.8% were still incontinent at 3 months, 10.9% at one year, and 15.0% at 3 years. These data suggest that FI is transient for the majority of patients affected, but the prevalence of FI remains elevated compared to population norms at one year and shows little further improvement. A study of 186 stroke patients in Spain showed a similar pattern: 56% had FI at admission, and 22% remained incontinent 6 months later. Risk factors for FI included age, severity of stroke, diabetes, and comorbidity of other diseases [114].

4. Traumatic brain injury

An excellent study [116] of the prevalence of FI following traumatic brain injury was carried out in 1,013 patients consecutively enrolled in any of 17 acute rehabilitation facilities. Prevalence rates were 68% at admission, 12.4% at discharge, and 5.2% at one year follow-up. The risk of incontinence at each time point was significantly related to all measures of the severity of brain injury including Glasgow Coma Scores and length of stay. In addition, at discharge from the rehabilitation facility, FI was significantly associated with pelvic fracture, urinary tract infection, and patient age (older patients were more likely to be incontinent); at one-year follow-up, FI was significantly associated with urinary tract infection and patient age. Patients with FI were more likely to be discharged to an institution rather than to return to their homes.

5. Diabetes mellitus

Bytzer and colleagues [117] carried out a large population-based postal survey in 8,657 adults including 423 with self-reported diabetes mellitus (DM). The response rate was 60%. When patients with DM were contrasted to the remainder of the sample the frequency of FI occurring at least “sometimes” was 12.8% vs. 3.8% (p<0.001) and the prevalence of FI occurring “often” was 2.6% vs. 0.8%. The odds ratio (after adjusting for confounders) was 2.74 (CI, 1.40-5.37). The prevalence of FI was shown to be related to self-reported degree of glycemic control. These results were confirmed by two other studies that recruited patients from a diabetes register [118] or a diabetes clinic [60]. The risk of FI among patients with DM is known to be related to weakness of anal canal resting and squeeze pressures and impaired sensation in the rectum [119;120], and these physiological defects are related to duration of DM and the presence of microcirculatory abnormalities and autonomic and peripheral neuropathies [120].

6. Multiple sclerosis

FI is reported by 29-51% [121-123] of multiple sclerosis patients living in the community, and it is frequent in 5% [121] to 25% [123]. Among 14,000 nursing home residents with multiple sclerosis, FI was present in 58% and occurred more than twice a week in 7.5% [124]. Incontinence in this group is associated with weak strength of contraction of pelvic floor muscles, a low threshold for elicitation of the internal anal sphincter inhibitory reflex, and impaired sensation for rectal filling [125;126]. Approximately half of patients with multiple sclerosis are also constipated, but constipation seems to occur about equally often in multiple sclerosis patients with and without FI [123].

3. SUMMARY OF EVIDENCE ON RISK FACTORS FOR FI AND POTENTIAL FOR PREVENTION

1. There is a high prevalence of FI in community-dwelling populations

2. High risk groups fall into four main categories and include:

1. Patient characteristics
   • Increasing age
   • Nursing Home residence
   • Gender: equivocal evidence
     - Younger: 6 studies women>men; 8 studies no difference
     - Older men>women (one study)
   • Race: no difference except obstetric injuries
   • Obesity, poor general health and physical limitations, urinary incontinence & pelvic organ prolapse, endurance running are all associated with FI
   • Neurological disease or injury (learning disability, dementia, spinal cord injury, multiple sclerosis, spina bifida, stroke, head injury, diabetes mellitus)

2. Patients with gastrointestinal symptoms and disorders
   • Diarrhoea or loose stools (community & NH)
- Drugs (antibiotics, SSRIs, laxatives, digoxin, orlistat), dietary supplements (lactose, fructose, artificial sugars, olestra) foods (prunes, figs)

• Urgency (independent of stool consistency)
• Constipation ("overflow")
• Irritable bowel syndrome (IBS) (OR 2-8)
• Inflammatory bowel disease (IBD) (diarrhoea + perianal)
• Haemorrhoids (before and after surgery)
• Congenital anomaly (imperforate anus)

3. Obstetric factors (note the disparity population vs. selected clinic studies)
• Parity for AI (1st vaginal delivery, subsequent deliveries: clinic populations)
• Sphincter laceration for AI & FI (7 studies found increased risk, 2 not)
• Instrumental delivery (forceps 5 studies found increased AI risk, 2 not; vacuum equivocal)
• Episiotomy: midline ? risk; mediolateral not protective
• CS: inconclusive, tending to not protective
• Large baby, prolonged 2nd stage: equivocal

4. Sequelae of surgical procedures
• Colectomy & ileo-rectal anastomosis or pouch: diarrhoea + pressures: 18-49% FI
• Sphincterotomy: 11% FI in long term
• Haemorrhoidectomy: 33% AI
• Radical prostatectomy: 9-32% (retropubic vs. perineal)
• Pelvic radiotherapy 14-46% (diarrhoea + compliance)

4. RECOMMENDATIONS FOR PRACTICE ON PREVENTION

1. Primary prevention:
• Public health measures to prevent diarrhoeal diseases (Grade B/C)
• Treat reversible causes of diarrhoea (C)
• Obstetric: no convincing evidence of role for preventive caesarean section; avoid midline episiotomy; restrictive episiotomy protocols (A)
• Discourage the use of internal anal sphincter division for treatment of anal fissure and haemorrhoids (A)

2. Secondary prevention (Table 4):
• Active case finding/screening in high risk groups (C)
• Proactive bowel management in high risk groups (eg neurological) (C)
• Optimise stool consistency in people with loose stools (all ages); hard stools (children and older pops) (B)
• Treat obesity? (D)
• Consider medication alternatives in patients with FI & medication-induced diarrhoea (C)
• Alert patients to risk of FI following colorectal surgery (C)

5. RECOMMENDATIONS FOR RESEARCH ON PREVENTION

- Longitudinal studies to map natural history, especially in women with obstetric risk factors
- Prevention studies in childbearing women and other high risk groups
- Colorectal surgery and radiotherapy techniques
- Bowel management strategies in high risk groups (e.g. neurological)
- Understanding mechanisms of FI in men
- Frail Elderly: community prevention/ screening/ early treatment to prevent NH admission
- Measures to prevent/reduce FI in nursing homes (functional FI, staffing etc)

III. EDUCATION & “LIFESTYLE” INTERVENTIONS

1. BACKGROUND

Most patients do not know how the bowel works and what might improve bowel function. Many also have attitudes to defaecation that are influenced by stigma and taboos prevalent in their particular family and wider cultural group within a society [127].

Expert opinion supports the use of general health education, patient teaching about bowel function and advice on lifestyle modification [128;129], but the evidence base is small. Unlike urinary incontinence, few “lifestyle” associations have been identified with FI and little is known about whether interventions designed to reduce potential risk factors might improve FI. Diet and fluid intake are covered in Section 4.

2. SEARCH

The following keywords were searched: “anal, anorectal, bowel, faecal, fecal, rectal, stool” and “continent$ or incontinent$,” or “diarrhea, diarrhoea” and the relevant lifestyle or intervention term: exercise; irrigat$ and rectal or rectum or anal or transanal; smoking, tobacco smoke pollution, tobacco use disorder, and tobacco$ or cigarette$ with use$ or abuse$ or smok$; toileting and toilet$; psycholog$ or effect$ with carer, caregiver, spouse, family, families or parent$ and nursing or care. The following databases were searched: CINAHL 1982- March, 2008 MEDLINE 1955- March, 2008. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and FI was also reviewed [6]. All seemingly relevant abstracts were reviewed then salient articles were retrieved and reviewed, and the reference lists searched for further studies.

3. REVIEW OF EVIDENCE ON THE EFFECT OF EDUCATION AND LIFESTYLE CHANGES ON FI

a) Weight reduction

Obesity is a well-documented risk factor for FI (Section 2 above). The only data available about the association of weight loss and FI reduction is in morbidly obese individuals undergoing weight reduction surgery and findings conflict. One preliminary report of surgical intervention [130], is published only in abstract form so far and is included because of limited studies available. In that study, bariatric surgery was not beneficial: 159 massively obese patients underwent either gastric bypass surgery or gastric banding and were asked approximately 2 years later to report retrospectively on their continence status before and after surgery. A higher than expected proportion of them reported FI prior to surgery (23% solid, 47% liquid FI), but FI was worse rather than better in more than half of these patients following surgery despite an average 48kg weight loss. It is possible that diarrhoea, a common consequence of bariatric surgery and which exacerbates FI, might account for this worsening of FI, but this was not noted in the preliminary report. In contrast, a second study [49] reported a significant decrease in the prevalence of FI of solid or liquid stool from 19.4% preoperatively to 8.6% at 12 months (p= .018; 95% CI = 2.1–19.4%) in women who underwent bariatric surgery for morbid obesity (mean (sd) body mass index (BMI) = 48.9 (7.2) kg/m²). In a single group cohort study (i.e., no control group), 93 women (aged 20–55 years) received a laparoscopic Roux-en-Y gastric bypass and reported data about FI by answering two questions before and after surgery. Any association between weight loss and FI reduction was not reported.

b) Physical exercise and work

One study in a nursing home population found that a structured daily exercise programme, combined with increased fluid intake and regular toileting opportunities, significantly improved FI and increased the percentage appropriate toilet use compared with controls [131;132]. However, lack of exercise is not an established risk factor for FI or AI (see Section 2 above).

c) Smoking

Nicotine is thought to slow upper gut motility and increase total transit time [133], but it seems that it can speed recto-sigmoid transit [134], and this stimulation of distal colonic motility may exacerbate a tendency to faecal urgency. This fits with many anecdotal reports that smoking a cigarette facilitates initiation of defaecation. Smoking is a known risk factor for urinary incontinence and genital prolapse (OR 2.9) [135],
presumably via chronic coughing. No association has been found between antenatal smoking and postnatal FI [136]. In a survey of 271 pairs of identical twin sisters, smoking was not significantly related to FI or flatus incontinence [137]. In a study of community-living elderly men and women, smoking was not predictive of prevalent or incident FI [55]. Smoking cessation is anecdotally reported to be useful for reducing urgency of defaecation, but no formal studies were identified.

c) Medication side-effects

Medication used specifically to treat FI is covered in section 6 below. A vast number of drugs have direct or indirect effects on the gastrointestinal system, tending to cause constipation, diarrhoea, or either in different people. A careful drug history (including all over the counter or “herbal” preparations) should be taken in each person with FI. It is beyond the scope of this chapter to review drug effects in detail, and prescribers should be aware of the possible unintended side-effect of FI. No studies were identified that evaluated the benefits of patient or provider education regarding the gastrointestinal side-effects of medications.

One single case report was found reporting that a combination of olestra in the diet and orlistat given to treat obesity led to symptoms of FI, which resolved when the olestra was stopped [138]. Patients reporting soiling while on treatment with orlistat for obesity have been found to have pre-existing impaired anorectal function, thus predisposing them to symptom development [139].

d) Toilet facilities

In individuals who have physical or mental impairments, an adverse physical or social environment may impair the ability to maintain continence. This is particularly relevant to those in institutional settings; use of physical or chemical restraints in institutions also limit or delay access to toilet facilities (see Committee 13). Adverse environmental factors include: (a) toilet facilities that are inaccessible or that lack privacy so that the person avoids using the toilet; (b) care providers who are insensitive to the individual’s needs and bowel habit; (c) clothes which are difficult to manipulate in a hurry; and a variety of other factors which vary with abilities of the individual. The toilet itself may be too high, leaving the feet dangling and thus making abdominal straining difficult. The toilet may be too low, making sitting and rising difficult for those with immobile hips. A social environment in which care-givers are overworked and harassed may lead the patient to repeatedly ignore the call to stool, in the hope of finding a quieter time later. Commode use is reviewed in Chapter 20.

There are many adaptations that can be made to a toilet to facilitate access and stability in use [140]. Effective bowel evacuation is helped by sitting well-supported, with feet slightly raised to enable appropriate use of abdominal effort if needed, and leaning forward slightly [141]. Horizontal grab rails assist pushing up from a seated position, while vertical ones can enable pulling up. A raised seat or foot blocks can adjust the height as needed. For lateral transfer from a wheelchair, both seats need to be at the same height. Where it proves impossible for a person to use the toilet, alternative commodes or chemical toilets are available with appropriate features for the individual’s needs. No studies were found examining the effect of modifying the physical or social environment in treating FI.

e) Patient and care-giver education and attitudes

The strongest data on education and lifestyle comes from a single RCT. Patients were randomised to nurse-led education and advice alone, or education with the addition of exercises and/or, biofeedback. The education and advice group showed reduced frequency of FI and was as effective as biofeedback or exercises [142]. Other support for the benefits of patient education comes from a study reported in abstract form [143] which showed that education and standard medical care, when provided systematically to a group of FI patients who had failed prior attempts at medical management, led to a successful outcome in 38%. Success in this trial was defined as a patient’s report that they had experienced adequate relief of bowel symptoms.

An RCT of a combination nurse-led intervention for bowel problems in 146 stroke patients found that a single educational visit with a detailed information booklet improved bowel dysfunction up to 6 months later, and changed diet and fluid behaviour up to one year later compared to controls who received routine care. The intervention group were more likely to have sought professional help from their family practitioner for bowel problems, demonstrating a heightened awareness of the possibility of treatment [144]. However, there was no difference in the rates of FI between the intervention and control groups.

For people with dementia or other severe intellectual impairments, expert opinion holds that the attitude and management methods adopted by care providers is as important as bowel function in maintaining continence [144]. No controlled studies on this subject were found. However, one quasi-experimental study examined care-givers’ knowledge and compliance before and after an educational intervention [145]. Forty home care-givers of people with dementia, over half of whom had some degree of FI, completed a study-specific questionnaire before and after receiving a videotape and information booklet entitled “a practical approach to maintaining bowel control in people with dementia”. Ninety percent of the care-givers accessed the information and there was an improvement in post-intervention knowledge scores measured on a
55-point scale, with the mean score increasing from 23 pre-test to 32 post-test (p=<0.001). However, it is not known if this improved knowledge translates into improved care or reduced FI.

f) Complementary therapies

No hypnosis treatment study was found which included FI as an outcome variable. Psychotherapy does not appear to enhance the effectiveness of behavioural interventions for FI in children [146], but no studies were found in adults. Likewise, there have been no studies of the use of acupuncture, reflexology, homeopathy or any other complimentary approach reported in the literature.

4. SUMMARY OF EVIDENCE ON EDUCATION AND LIFESTYLE INTERVENTIONS IN FI

There is at present limited evidence for any lifestyle intervention for FI.

- Obesity: FI may improve after bariatric surgery (Level 3)
- Smoking: not predictive; no studies
- Medication side effects may cause FI related to diarrhoea

5. RECOMMENDATIONS FOR PRACTICE ON EDUCATION AND LIFESTYLE

- Medication side effects: consider alternatives if causing diarrhoea (C)
- Toilet access for people with disabilities (C)
- Education
  - of patient (B/C)
  - of carer (C)
- Complementary therapies: no evidence (D)

There is insufficient evidence to recommend or discourage most lifestyle modifications either for the prevention or treatment of FI. Based on the consensus of experts (Level 3 evidence) the committee recommends patient education about the causes of FI and a systematic effort to remove barriers to effective toileting as an intervention that is likely to be beneficial. This may be provided at relatively low cost and involves no significant risk to the patient.

6. RECOMMENDATIONS FOR RESEARCH ON EDUCATION AND LIFESTYLE

- Based on encouraging preliminary reports that patient education, combined with conservative medical management, can reduce the frequency of FI, we recommend further research. An RCT may not be possible due to the challenge of identifying a suitable control for expectancy and attention, but a study which demonstrates a sustained benefit from a limited educational intervention (provided to patients or caregivers), would provide useful guidance for clinical management.

- Further investigation of the benefits for FI of weight reduction, especially in moderately obese patients without bariatric surgery.
- Exercise programmes, when incorporated into a multi-component intervention, have produced promising preliminary results and should be tested further. Such trials should differentiate between constipation-associated FI and diarrhoea-associated FI as exercise may be more beneficial to the former group.
- Evaluation of the incremental or additive value of different lifestyle interventions in the patient pathway.
- Research on the contribution of complementary therapies.

IV. DIET AND FLUID INTAKE

1. BACKGROUND: RATIONALE FOR DIETARY INTERVENTIONS

The basis for investigating diet modification as a strategy for managing FI comes from anecdotal reports of this practice by patients to clinicians and recent qualitative and survey research reports. Community-living adults and elderly individuals, especially women, report that they manipulate their diet and eating patterns as a strategy for managing their FI [30; 147; 148]. Dietary manipulation is employed by the approximately 20% of patients with irritable bowel syndrome (IBS) who also have FI [129; 149] and by the approximately 19% to 40% of patients with inflammatory bowel disease who have FI [56; 66; 129; 150-152].

Empirical observations of a suspected relationship between diet and changes in bowel pattern are not limited to FI but have been reported by individuals with constipation, those with IBS with constipation (IBS-C) and some healthy individuals, and together with physiological principles of gastrointestinal (GI) function, supported an investigation of the evidence and discussion of possible mechanisms.

2. LITERATURE SEARCH

The following databases were searched for studies to include in this review of dietary interventions for FI management: CINAHL (1982 to March, 2008) and Medline (1966 to March 2008). The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and FI was also reviewed [6] (Table 5).

The following key words were linked with anal, anorectal, bowel, faecal, fecal, rectal, stool and “continent$ or incontinent$, “ or “diarrhea, diarrhoea,

| Bliss et al. [175] | - Randomised, parallel-group, placebo-controlled, single-blind trial.  
- The participants, statisticians, laboratory technician, and participants' clinicians were blinded.  
- 39 adults (79% female) completed the study.  
- Subjects had faecal incontinence of loose or liquid stool at least weekly.  
- A block scheme resulted in equal numbers (n=13) in each group.  
- Groups' characteristics were comparable in the baseline period. | - One of the following soluble fibre supplements mixed into fruit juice: 25 g of psyllium source per day, 25 g of gum arabic source per day, or placebo (0.25 g of pectin source per day).  
- Based on the percent of fibre in each of the sources, the total amount of dietary fibre administered was: 7.1 g of psyllium per day, 21.5 g of gum arabic per day, or 0.2 g of the pectin placebo.  
- The supplements were taken for 31 days in addition to usual diet intake, determined by a prospective diet record for 8 days in each period.  
- Participants prospectively reported faecal incontinence on a daily stool diary for 8 days in each period.  
- The proportion of incontinent stools during the baseline and fibre supplementation periods was the primary measure.  
- Secondary clinical measures included stool consistency and frequency, stool wet and dry weights, and percentage water content of stool. The adverse event of flatulence was monitored daily by self-report of the participants on the stool diary.  
- Secondary measures of the effects of the fibres on the stools included the water-holding capacity of stool solids, total fibre content of stool, stool pH, and faecal short chain fatty acids. | - The rate of faecal incontinence for the groups ingesting psyllium or gum arabic were significantly lower than those taking the placebo.  
- The rate of stool with loose and unformed or liquid consistency for the groups ingesting psyllium or gum arabic were significantly lower than those taking the placebo.  
- There was no significant difference in baseline diet intake among groups.  
- The water-holding capacity of stool solids was highest for the group ingesting psyllium.  
- Faeces did not differ between the baseline and fibre supplementation periods or among fibre groups.  
- There were no differences among the groups in stool frequency, wet or dry weight of stool, weight of stool solids, total fibre content of stool, stool pH, or short chain fatty acids. | - The inclusion and exclusion criteria were reported.  
- Sample size was based on a power analysis.  
- The timing of supplement consumption and allocation concealment were not provided.  
- How power was calculated was not explained.  
- Small group sizes reduced generalizability of findings. | - Details of the procedures for random assignment and allocation concealment were not provided.  
- Supplements were pre-mixed and ready-to-take. Adherence to taking the supplements was determined by self-report.  
- 95% of subjects completed the study and reasons for attrition were reported.  
- Measures of stool characteristics were made using standard objective laboratory procedures. |

| Levati et al.  | A double-blind, randomized, cross-over design | - Treatment A: self-titrated dose of loperamide (starting at 2 mg twice per day, 1 rounded teaspoon of a food thickener containing maize starch, methylcellulose, and linseed gum twice per day, and a diet advice sheet about a low-fibre residue diet.  
- Treatment B: same self-titrated dose of loperamide, one rounded teaspoon of psyllium hydrocolloid fiber in water twice per day, and a diet advice sheet about a high and low-fiber residue diet.  
- Participants self-reported anal incontinence outcomes for the last 4 weeks of the 6 weeks of each fiber treatment using the patient weighted FISI. FISI score during each treatment period was the primary measure of anal incontinence.  
- Secondary clinical measures included a fecal incontinence specific quality of life scale and the SF-36, a measure of general health status. | - 67% of treatment A fiber and 73% of treatment B fiber were taken as determined by weighing the container containing the fiber source at the end of each fiber phase.  
- The mean difference in the FISI score between treatments was -0.8 (95% confidence interval = -4.9 to 3.3) and was not statistically significant.  
- There were no adverse events. It was noted that some subjects reported having a dry mouth and thought the supplements had low palatability. | - There were two power calculations based on a five-point difference in the Fecal Incontinence Severity Index, which was considered by the investigators to be clinically significant. One for a test of paired data and one for tests of unpaired data in the event of high attrition at the crossover point.  
- Subjects were randomly assigned to treatments using a computer-generated list in blocks of 10.  
- Independent pharmacists dispensed the treatments.  
- The interval for data collection during both treatments was the same.  
- 75% of subjects completed the study protocol and reasons for attrition were reported. | - Given the cross-over design, period and sequence effects were not reported prior to combining all subjects on Treatments A or B for analysis.  
- Baseline FISI scores do not appear to be included in the main analysis.  
- There was no theoretical or physiological rationale for use of dietary fiber for leakage of mucus or solid stools.  
- The total amount of fiber in each supplement source was not reported.  
- Participants mixed their own supplements.  
- The definition of an adverse event or the method of reporting them was not provided.  
- Although two different diet advice sheets about high and low residue diets were provided, no record of usual diet intake was analysed.  
- There was no record of the doses of the anti-motility medication that were taken or use of suppositories that were provided for constipation.  
- There was no record of control of concomitant treatments for fecal incontinence during baseline or treatment periods.  
- The FISI was designed and tested using recall of anal incontinence characteristics. How the FISI was used (e.g., daily or by recall) in each treatment phase was not reported. |
signs and symptoms digestive or digestive disease: alcohol, alcoholism, alcoholic beverages, ethanol, drinking; beverages, fluid, fluid intake; liquid, water; coffee, caffeine, cola; diet, dietary therapy, diet, eat, intake, consume, fat, lipid, fibre/fiber, lactose, dairy; prebiotic, probiotic, symbiotic; oligofructose, oligosaccharide, fructans, fructo, fos or fructooligosaccharide; sorbitol or glycol, meglumine; spice, spicy, hot; yogurt, bifidobacteria, Lactobacillus acidophilus, acidophil. All seemingly relevant abstracts were reviewed; then salient articles were retrieved and reviewed, and the reference lists of these articles searched for further studies.

a) Criteria for considering studies for this review

1. Types of studies

Only studies in the English language were reviewed. Systematic reviews and meta-analyses of randomised controlled trials and full-length manuscripts reporting individual studies published in a peer-reviewed journal were considered. Individual studies or reports were required to have one of the following designs as defined in the ICDR review guidelines: randomised, controlled trial; prospective, non-randomised cohort; case-control; or recommendations from an expert consensus panel or Delphi process.

2. Types of study participants

Studies that involved people who were 18 years or older, had FI, and received a dietary intervention were included. People who were tube-fed or had an intestinal ostomy were ineligible.

3. Types of dietary interventions

A dietary intervention was defined as any type of food, supplement, dietary product, or fluid that is purposefully consumed or restricted, limited or avoided to manage FI. Studies were excluded if it was not possible to distinguish any direct effect of the dietary intervention from other interventions introduced simultaneously. For example, a study was excluded if it combined pelvic floor muscle training and a dietary intervention and compared it to another intervention such as drug therapy making it impossible to determine the effect of the dietary intervention alone.

4. Types of outcome measures

FI was required to be a primary outcome measure of the studies. Studies which focused primarily on the outcomes of stool consistency or form, stool amount, volume or bulk, defecation frequency, diarrhoea, or constipation without including any measure of FI were excluded.

b) Method of review

The reviewer examined the list of citations and abstracts yielded from the electronic search strategy. Potentially relevant papers were retrieved in full text. The reviewer was not blind to the journal titles, authors’ names or their institutional affiliations. The quality of the studies was evaluated using the checklist accompanying the CONSORT statement available at http://www.consort-statement.org. The levels of evidence for therapeutic interventions developed by the 3rd ICI 2004 were adopted.

3. Review of evidence on diet and fluids in FI

a) Diet modification

Studies of diet modification primarily used qualitative research methods or surveys and provide background and rationale for examining the effects of diet. A survey about FI and self-care practices administered to community-living elderly people showed that many of the respondents changed their diet and skipped meals as a management strategy for FI. Changing diet was a significantly more common practice among women (35.4%) compared to men (12.5%) [147]. A qualitative interview of women with FI revealed that one avoided eating anything on days they were going to be away from home or restricted the amount eaten while out in public [148]. Many also restricted foods that they thought worsened FI (for example, fried or spicy foods or caffeinated beverages and chocolate), or foods that increased flatulence (for example, cabbage, onions); a few purposely ate certain foods as a therapy to decrease FI (for example, yogurt).

Using a trial and error approach, women with FI often modified their diet based on recommendations for other gastrointestinal problems (e.g., lactose intolerance and IBS) that were available in the professional or lay literature [148]. The effectiveness of these diet modifications was unmeasured and variable. Concerns of diet manipulation are nutritional deficiencies and subsequent poor health. However, Bliss et al. [153] found few significant differences in the nutritional composition of usual diets of persons with FI compared to the usual diets of age and gender matched controls with normal bowel function. The group with FI had a greater intake of carbohydrates, manganese, and vitamin B1.

b) Fluid intake

FI is associated with constipation in nursing homes (see section 2). Approximately 30% of elderly residents in long-term care institutions have faecal impaction, and general clinical recommendations for FI management in these cases are for an adequate intake of fluid to prevent hard stool consistency and constipation. However, there are no empirical data to support the recommendation of increased fluids either for constipation or for FI, and there is no evidence that the diets of patients with FI or constipation are deficient in fluids.

c) Dietary fibre, prebiotics, probiotics, and synbiotics

A prebiotic is a general term describing a food ingredient that is not digested in the human small intestine and thus stimulates the growth and/or activity of...
of one or more types of bacteria in the colon that have the potential to improve the health of the host. Because of its ability to stimulate growth of bacteria in the colon, dietary fibre can be considered a prebiotic. Fructo-oligosaccharides and galacto-oligosaccharides are popular prebiotics. A probiotic is a food supplement containing live non-pathogenic and non-toxic microbes that have the potential to affect the balance of colonic microbes or improve the host’s health. Bifidobacteria and lactobacilli are the most commonly used probiotics, and yogurt which has active microbial cultures can be considered a probiotic. A synbiotic refers to a product that combines a prebiotic and probiotic. Probiotics have been investigated for their potential to improve the health of the host. Because the presence of lactose creates an osmotic shift of intestinal water into the small intestine and speeds transit. In the large intestine, fermentation of lactose by colonic bacteria may result in flatulence, distension, diarrhea, and cramps. However, the majority of adults who have lactase deficiency can tolerate a small amount of lactose in foods [160]. Yogurt is usually well tolerated by lactose maldigesting individuals because the lactose is partially digested by the beta-galactosidase of the bacteria used to ferment the yogurt. However, yogurt has not been found to aid the digestion or tolerance for additional lactose simultaneously consumed with it [161].

Due to its prevalence in approximately two-thirds of the world’s population, hypolactasia is currently regarded as a normal physiological pattern rather than a disease [162]. The prevalence ranges from highs of nearly 100% in some Asian countries and 70% in Italy to lows of 2% in Scandinavia and 15% in U.S. Whites [163]. Malabsorption of fructose and sorbitol results in osmotic diarrhea and adverse symptoms, similar to lactose. A diet reduced in fructose and sorbitol content is suggested for some patients with irritable bowel syndrome to reduce adverse GI symptoms [164].

Caffeine, of which coffee is a popular source, induces a desire to defecate [165-169]. Caffeine has also been observed to stimulate defaecation urgency in some patients with FI [158]. However, regular consumption of coffee was not associated with prevalent or incident FI in elderly men and women [55], and no studies were found on caffeine restriction to improve FI.

Chronic consumption of alcohol has been associated with accelerated gastric emptying and small bowel transit in animal studies whereas a single large dose has an inhibitory effect on these parameters [170-172].

Excessive alcohol consumption leads to injury of the duodenal and upper jejunal mucosa and inhibition of sodium and water absorption. There is an increased prevalence of bacterial overgrowth in the small intestine of alcoholics, which may contribute to loose stools, diarrhea, incontinence, and other GI symptoms [173]. No studies were found in which alcohol restriction was reported to reduce FI.

e) Review of RCT evidence on diet and fluid intake

Two studies were found that met the inclusion criteria for review [174;175]. The methods, strengths and limitations of the studies are presented in Table 5. In the Bliss study, subjects were community-living adults living in the United States with incontinence of loose or liquid stools . The intervention was supplementation with one of two soluble dietary fibres compared to placebo. This study provided level 1 evidence suggesting that dietary fibre can reduce the rate of FI in patients with loose stool [175].

In the second study, subjects were outpatients of a colorectal service in Australia who were incontinent of mucus, liquid, or solid stools. Two combination treatments consisting of an antimotility medication, a diet advice sheet and a fibre supplement or placebo were compared.
This study was not limited to patients with FI of loose or liquid stools (i.e., other types of FI were included), and the study showed no additional benefit of a dietary fibre supplement over use of the antimotility medication, loperamide, for reducing incontinence of flatus, mucus or solid or liquid stool [174]. Differences in the findings of these studies (Table 5) may be explained in part by differences in the interventions, level of control of threats to internal validity, and lack of some analysis data.

4. SUMMARY OF EVIDENCE

Patients consider diet a factor affecting the severity of their FI and they use diet modification as a self-care strategy (level 3 evidence). Dietary fibre supplementation appears to be a safe and tolerable intervention. However, findings from two randomised trials about its effectiveness differ.

5. RECOMMENDATIONS FOR PRACTICE ON DIET AND FLUIDS

- Soluble dietary fibre is recommended for the management of FI associated with loose stool. This recommendation is made despite inconsistent results between two RCTs because the methodology for the positive study was significantly better than that of the other study. (Evidence level 1. Recommendation Grade B).
- Dietary fibre is not recommended as an adjuvant to antimotility medication for managing AI when stools are not loose or liquid. (Evidence level 2 Grade B).
- Patients should be asked about dietary restrictions and meal skipping.

6. RECOMMENDATIONS FOR RESEARCH ON DIET AND FLUIDS

Further studies on the effect of dietary fibre and other diet modifications on FI are encouraged to build a greater body of evidence. Because dietary fibres differ in their chemical composition and properties, future studies are recommended to determine the optimal type and amount of fibre to use for FI. Whether a dietary intervention can augment other behavioural interventions, such as pelvic floor muscle exercises or bowel training, needs further study.
- Role of fibre and fluid in constipation/impaction related FI
- Effect of diet and eating pattern as a management strategy for FI
- Role of caffeine restriction in the treatment of FI and AI

There are several recommendations for methodological rigour in future studies. Theory-based, adequately powered, controlled trials are sought. Studies should control for variability in an individual’s baseline severity of incontinence and any adjuvant therapies. Monitoring adherence to the dietary intervention is recommended. A common set of outcome measures that includes tolerance to diet interventions is recommended. Reporting outcomes of FI in addition to those of AI (which incorporates flatus incontinence) is recommended.

V. BOWEL MANAGEMENT AND RETRAINING PROGRAMMES

1. BACKGROUND

Constipation is a well-established risk factor for FI in children and older people but has not been found to be a consistent risk factor for FI in young and middle aged adults. Frail older people are covered in section 9. The use of rectal medications and enemas is covered in section 6. This section is limited to studies in younger adults.

2. SEARCH

The following keywords were searched: “anal, anorectal, bowel, faecal, fecal, rectal, stool” and “continent$ or incontinent$, “ or “diarrhea, diarrhoea” and the relevant lifestyle or intervention term: bowel$ and train$ or retrain$; digital$ and stimulat$); crede or massage; enema; and suppositor$. The following databases were searched: CINAHL 1982- March, 2008 MEDLINE 1955- March, 2008. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and FI was also reviewed [6]. All seemingly relevant abstracts were reviewed, after which salient articles were retrieved and reviewed, and the reference lists searched for further studies.

3. REVIEW OF EVIDENCE ON BOWEL MANAGEMENT AND RETRAINING PROGRAMMES

a) Bowel habit

Expert opinion supports the importance of attempting to establish a regular, predictable pattern of bowel evacuation by patient teaching and adherence to a routine [128;176]. Because peristaltic contractions of the colon that are associated with defaecation increase in frequency following awakening from sleep and following meals [177;178], the period after breakfast is the best time for scheduled defaecation. However, no studies have evaluated the effectiveness of this in young and middle aged adults.

b) Resisting urgency

The sensation of a strong urge to defaecate is frequently associated with diarrhoea, and it is a recognized risk factor for FI in adults [179]. In contrast to urinary incontinence, particularly the overactive bladder syndrome (Committee 14) for which a body of knowledge has developed on the efficacy of bladder...
training techniques (i.e., voiding at specific intervals rather than in response to urge and deferment techniques), the possibility of bowel retraining for resisting urgency to defeate is relatively unexplored. Some biofeedback protocols focus on altering rectal sensory thresholds (see below).

One RCT compared patients who received education, including urgency resistance techniques [158] and dietary advice, to a group of patients who received the same training plus anal sphincter exercises with or without home or clinic biofeedback. There were no significant difference in outcomes [142]. However, this study did not assess the effectiveness of the behavioural training compared to an appropriate control group.

c) Evacuation training

A common factor in the genesis of pelvic floor problems may be chronic straining with perineal descent from constipation; this may lead to pelvic floor damage (direct or neurological) [180;181] and may be associated with pelvic organ prolapse or urinary or FI. In one small study women who reported straining were more likely to develop urogyneacologic symptoms such as prolapse and stress urinary incontinence [182]. However, straining has not been shown to be a risk factor for FI. No studies were identified examining the effect of treating constipation or decreasing straining on preventing or treating FI in non-institutionalised adults.

Clinically, many patients with FI are taught evacuation techniques or are encouraged to use laxatives, enemas or suppositories in an attempt to ensure that the rectum remains empty most of the time, thus giving less chance of FI. This is known to improve continence in children and elderly patients (Section 9), but there is no evidence that it improves FI in young and middle-aged adults.

Committee 10 has reviewed the evidence for digital rectal stimulation and manual evacuation. The use of these techniques to assist complete evacuation in non-neurological populations has not been evaluated.

One RCT of a combination treatment package for FI included training on evacuation techniques and noted that patients reported improved ease of evacuation after treatment [142]. No separate data on FI were presented. No studies were found utilising specific evacuation training to treat FI in younger adults.

d) Behaviour modification

Toilet training with rewards, either alone or in combination with laxatives has been found helpful in children with FI [183]. It is not known if a similar approach might be applicable to adults with learning difficulties or frail older people in institutional settings, although a behavioural approach to such problems has been recommended based on expert opinion [184]. Adults with learning difficulties may respond to formal behaviour modification techniques, but only small case series are currently available as evidence [185]. Similarly there are no controlled studies of training in adults with non-retentive FI [186].

e) Rectal irrigation

Irrigation of the lower bowel has been used for many years to manage both FI and constipation. Surgical construction of a portal for antegrade irrigation is covered in Chapter 17. Various equipment has been used for retrograde irrigation, including a stoma irrigation cone held in place manually against the anus [187], a mechanical pump [188] and more recently purpose-designed anal irrigation equipment [189;190]. Use in FI secondary to spina bifida has been widespread [189].

One single RCT was found in the literature. Rectal irrigation with tap water was found in an RCT to improve bowel management, constipation and FI in patients with problematic bowel management following spinal cord injury [190]. This warrants further evaluation in other populations as uncontrolled case series report possible efficacy in FI without neurological injury [188;191]. Benefit may be maintained with continued use in up to 50% in the long term [192].

f) Combination therapies

It is recognised that in many people, the symptom of FI is the result of a complex combination of disordered anatomy and physiology, stool consistency and gut motility, emotional and psychological status and restricted access to toilet facilities, amongst other factors (see Committee 5). Hence in clinical practice most patients receive a combined approach addressing diet, medications, lifestyle, muscle function and bowel habit simultaneously, depending on the result of initial assessment [193;194]. However, with the exception of one study [142] the few well-conducted studies on the conservative management of FI in adults have usually focused on evaluating a single intervention such as biofeedback, often not specifying what other advice (that might confound the results) was given to patients.

Norton et al compared a combination of conservative measures, including patient teaching, advice on diet, medication titration, and bowel retraining, with the same measures combined with anal sphincter exercises and/or biofeedback [142]. No statistically significant differences were detected between the four groups on any of the outcome measures (including diary, symptom questionnaire, manometry, anxiety, depression and quality of life). Over 50% of those randomised (171 patients) reported improved continence. Of those completing the protocol, 74% felt that they remained improved at one year following the end of treatment. The authors of this study suggest that the most effective element may have been
education and therapist-patient interaction rather than specific interventions.

In children a combination of behavioural training techniques and laxative therapy is as effective alone as it is when combined with biofeedback (183). Anecdotally, laxatives may enhance the effect of behaviour modification alone.

4. SUMMARY OF EVIDENCE

There is very limited evidence in this area. In particular there are:

- No studies in adults with learning disabilities
- No studies in frail elders or Nursing Home patients
- No studies in neurological patients
- One study in adults (combination intervention: [142]): retraining alone is possibly as effective as biofeedback
- One RCT of rectal irrigation in SCI has found benefit for FI, constipation, time spent & QoL [190] (Level of evidence 2)

5. RECOMMENDATIONS FOR PRACTICE ON BOWEL TRAINING

- Attempt to establish a bowel routine (C)
- Urgency resistance training possibly useful for urgency (D: need for research)
- No evidence on behaviour modification methods (D: need for research)
- Digital stimulation and manual evacuation useful in neurological patients (C)
- Rectal irrigation is useful in SCI (B) and has potential in other patients with FI (D)

6. RECOMMENDATIONS FOR RESEARCH

Research is needed in all areas.
Combination studies with urinary incontinence are recommended.

6. DRUG TREATMENT OF FI

1. GOALS

The goals of this section are to identify the drugs and other medical interventions that have been used to treat FI and to evaluate the evidence regarding their efficacy. The medical management of FI has focused exclusively on three mechanisms:

1. Reduction of diarrhoea. Diarrhoea is consistently found to be a strong risk factor for FI (see Section 2 above).
2. Increasing resting anal canal pressure. Low resting anal canal pressure is a risk factor for passive FI, and is commonly seen following some types of anorectal surgery (e.g. sphincterotomy, ileal pouch procedures, abdominoperineal pull-through for imperforate anus).
3. Treatment or prevention of constipation. Constipation is frequently found to be a risk factor for FI, especially in children and the elderly (see Section 2 above).

2. SEARCH METHODS

1. The Medline database and the Cochrane reviews [183;195] were searched for studies in any language and any year through March 2008 which matched the following search terms:
2. “Faecal incontinence” OR “anal incontinence” AND “drug” OR “medical management” OR “medical treatment.”
3. “Faecal incontinence” OR “anal incontinence” AND “loperamide” OR “diphenoxylate.”
4. “Faecal incontinence” OR “anal incontinence” AND “laxative” OR “polyethylene.”
5. “Faecal incontinence” OR “anal incontinence” AND “phenylephrine gel.”

Additional articles were identified by examining systematic reviews [195-197].

3. REVIEW OF EVIDENCE ON MEDICATION AND FI

a) Treatment of diarrhoea-associated FI with antidiarrhoeal drugs.

1. LOPERAMIDE AND DIPhenoxylate

The most extensively tested drug treatment for diarrhoea-associated FI is loperamide. We identified 6 studies in adult subjects [174;198-202] and 3 studies in children [203-205]. These studies all have methodological weaknesses including small sample sizes and use of crossover designs or they are case series. These studies generally support the efficacy of loperamide for decreasing diarrhoea-associated FI. Three of these studies are briefly summarized below:

Palmer and colleagues [198] compared loperamide (average of 4.6 mg per day) to codeine (average of 103 mg per day) and diphenoxylate (average of 12.5 mg per day) in 30 patients with diarrhoea, of whom 19 had FI prior to treatment. However, FI was not the primary outcome measure. Loperamide was superior to diphenoxylate and similar to codeine with respect to decreased stool frequency, improved stool consistency, and reduced side-effects. Although not statistically significant, there was a trend for less FI while taking loperamide compared to diphenoxylate.

Haeford and colleagues tested diphenoxylate against placebo in 15 patients with diarrhoea-associated FI and reported a tendency for decreased FI.
Mechanism of action in this patient population.

benefit for diarrhoea [209] and a worsening of FI [210] pelvic cancer [208]. However, subsequent large sucralfate might reduce diarrhoea secondary to stomach lining. An early study suggested that aluminium hydroxide used primarily for the treatment benefit for treating FI. Sucralfate is a formulation of and other tricyclic antidepressants are of possible complexes.” This study suggests that amitriptyline pressure and decreased numbers of “rectal motor authors attributed the benefits to increased anal resting became continent and 3 reported improvement. The authors were selected for study because they had previously been found to soil while taking orlistat. In this study, loperamide decreased soiling and FI and increased resting anal canal pressure. Lauti’s group [206] compared loperamide plus fibre supplementation to loperamide with a low fibre diet and placebo fibre supplement in the first adequately powered study. This was a double-blind crossover study with order of treatments counterbalanced. Results showed a significant improvement in continence relative to baseline in both groups, but the addition of fibre to loperamide did not increase benefit. This suggests that loperamide may be more effective than fibre supplementation alone for the treatment of diarrhoea-associated FI. An earlier study by Bliss and colleagues [175], which is reviewed in Section 4, showed that fibre supplementation with either psyllium or gum agar improved diarrhoea-associated FI more than placebo.

2. OTHER ANTIDIARRHOEAL DRUGS

Santoro and colleagues [207] carried out an uncontrolled study of the tricyclic antidepressant, amitriptyline, given 20 mg at bedtime, in 18 patients with FI; diarrhoea was not required. Thirteen of 18 became continent and 3 reported improvement. The authors attributed the benefits to increased anal resting pressure and decreased numbers of “rectal motor complexes.” This study suggests that amitriptyline and other tricyclic antidepressants are of possible benefit for treating FI. Sucralfate is a formulation of aluminium hydroxide used primarily for the treatment of duodenal ulcers; it has the property of coating the stomach lining. An early study suggested that sucralfate might reduce diarrhoea secondary to radiation proctitis in patients receiving radiotherapy for pelvic cancer [208]. However, subsequent large randomized controlled trials have shown no significant benefit for diarrhoea [209] and a worsening of FI [210] in this patient population.

Mechanism of action Three possible mechanisms of action have been identified in the these studies of the drug treatment of diarrhoea-related FI: Loperamide, diphenoxylate, and amitriptyline appear to work in part by decreasing bowel movement frequency through an effect on motility and absorption. Fibre supplements (reviewed in Section 4 above), on the other hand, work by binding more water into the stools. Resting anal canal pressures were reported to be increased in response to loperamide [199;200] and amitriptyline [207].

b) Increasing anal canal pressure in patients with passive FI

A subgroup of patients with FI have passive incontinence, defined as FI that is not preceded by a sensation of urgency to defecate and that occurs without awareness. This is believed to be related to decreased resting pressure in the anal canal due to an impaired internal anal sphincter and/or to decreased sensation for rectal distension. A specific aetiology for passive FI is the patient with a colectomy (usually for ulcerative colitis) with a surgically constructed ileal reservoir connected to the anal canal [87].

1. PHENYLEPHRINE GEL

Phenylephrine gel, an alpha-1 adrenergic agonist, has been investigated for the treatment of passive FI in several studies [211;211-215]. In an initial study of 36 patients with intact sphincters, no significant benefit was seen [214]. Two subsequent studies [211;215] suggested a benefit of phenylephrine gel, but a recent randomized controlled trial in 35 patients with passive incontinence secondary to low anterior resection failed to show a benefit [213]. Thus, the clinical utility of phenylephrine gel (if any) may be limited to patients with passive incontinence associated with ileal pouches.

L-erythро methoxamine gel, an alpha-1 adrenoceptor agonist similar to phenylephrine, has also been shown in two proof-of-concept studies to increase internal anal sphincter resting pressure [216;217], although no clinical trial data are available as yet.

2. VALPROATE SODIUM

The gamma-amino butyric acid transaminase inhibitor, valproate sodium, also increases anal canal resting pressure. It was compared to placebo in a double-blind, randomised crossover study [218] in 17 patients with diarrhoea-related FI secondary to colectomy and ileoanal anastamosis. The drug decreased FI episodes and stool frequency relative to baseline and increased anal canal pressure, whereas placebo did not have these effects. In a second randomized controlled trial by the same investigators [219], 12 patients with ileal pouches were treated with valproate sodium or placebo. There was a significant improvement in anal canal pressures, pouch capacity, and continence. Therefore, valproate sodium is of possible benefit in this population.

c) Drug treatment of constipation-associated FI

Constipation-associated FI, sometimes referred to as “overflow incontinence”, occurs more frequently at the two ends of the lifespan. The prevalence of FI in children is estimated to be 0.8% [220] to 3% [221] and in 35% [63] to 96% of cases, FI in children is associated with constipation. FI occurs in 46% [222] to 47% [12] of nursing home residents and is more common in those with constipation [223]. However, the proportion of faecally incontinent nursing home residents whose FI is attributable to constipation is not known. Constipation-associated FI is also common in patients with spinal cord injury, occurring in an estimated 33% [106].
Constipation-associated FI in nursing homes is often treated with the prescription of daily or frequent laxatives. However, we found only two RCTs which tested the effectiveness of laxatives for treating FI associated with constipation in adults. Ryan [224] randomised 87 new admissions to a single nursing home to receive either 15 ml daily of sorbitol for up to 15 days or routine care without the use of a laxative. Patients were enrolled whether or not they had constipation or FI. The outcome measures recorded by nurses were amount of nursing time required for the care of FI and amount of soiled linen. Patients treated with sorbitol were found to have significantly less soiled linen, and they tended to require less nursing time. Limitations of the study included (a) analysing the aggregate amount of soiled linen used by each group rather than the proportion of the subjects in each group who had FI; (b) failure to control for expectancy by providing a placebo treatment to members of the control group; and (c) failure to include all randomised subjects in the data analysis, i.e. failure to use an intention to treat analysis.

A second study [225] compared daily enemas to no treatment in 206 nursing home residents who had FI and documented constipation. This was an open label RCT. Results showed no difference between groups either for frequency of FI or for amount of soiled linen. However, post hoc subgroup analysis showed that patients with complete rectal emptying by digital examination exhibited a significantly greater improvement than the group that continued to have a faecal impaction. Strengths of this study were the large sample size, randomisation, strict inclusion criteria, and assessment of whether the enema regimen in fact eliminated faecal impaction. A weakness was that the post hoc analysis of the physical examination data suggest that the trial is not interpretable since the daily enema regimen did not eliminate faecal impaction in most patients.

A double-blind RCT testing the effectiveness of the prokinetic (motility stimulant) drug cisapride in paediatric FI found no evidence for efficacy [226] and adverse events led the US Food and Drug Administration to restrict access to this drug. An alternative prokinetic drug, tegaserod, has been approved for the treatment of chronic constipation in adults, but has not been tested for its effectiveness in patients with constipation-associated FI.

Several trials [227,228], including one high quality RCT [229] have compared laxatives alone to the combination of laxatives plus biofeedback in children with constipation-associated FI. For this indication, biofeedback is designed to teach the patient to relax the pelvic floor muscles during attempts to defecate in order to overcome a tendency to paradoxically contract these muscles and to obstruct defecation. The RCT by van der Plas and colleagues [229] showed that combined treatment was associated with a higher success rate at the end of training (39% vs. 19%), but by follow-up 12 months later, there were no differences between groups.

Other studies support these findings by showing either no difference between the laxative only group and a biofeedback group [227] or faster acquisition of continence in the biofeedback group but no long-term difference in success rate [228].

These trials suggest that laxatives alone are as effective as biofeedback for constipation-associated FI in children in the long term, but they were not designed to show that laxatives are superior to placebo or to no treatment.

4. SUMMARY OF EVIDENCE ON MEDICATION AND FI

- Loperamide is useful for diarrhoea-associated FI. There is some evidence that the loperamide may be superior to diphenoxylate (level 2 evidence).
- There is a possibility that medication may improve FI associated with faecal impaction in a nursing home population if impaction is resolved.

5. DRUG TREATMENT OF FI: RECOMMENDATIONS FOR CLINICAL PRACTICE

- Treat FI with diarrhoea with anti-diarrhoeal medication (C): titrate the dose to individual response (C).
- We are unable to recommend sphincter modifying drugs (D).
- Use oral or rectal laxatives/evacuants to treat constipation-associated FI (C): no evidence on the most effective agent. Need to confirm impaction is resolved (C).
- For constipation-associated FI, there is level 2 evidence suggesting that daily or more frequent oral laxative regimens may be effective for the treatment of constipation-associated FI in nursing home residents [224] and children [230], but there are conflicting data [225,231].

6. DRUG TREATMENT OF FI: RECOMMENDATIONS FOR RESEARCH

- Additional, well-designed studies are needed to validate the common clinical practice of using laxatives to treat constipation-associated FI.
- There is a need for further research on preparations, doses and combination therapies for all types of FI and all patient subgroups.
VII. BIOFEEDBACK AND/OR ANAL SPHINCTER / PELVIC FLOOR MUSCLE TRAINING

1. BACKGROUND

Biofeedback can be defined as the use of an instrument that delivers a concurrent measurement of selected biological responses to enable the individual to alter his/her physiological response in directions associated with improved function [232].

The earliest reported application of biofeedback to treat FI used a simple pressure device in the anal canal to reinforce external anal sphincter (EAS) contraction [233], a procedure somewhat analogous to the vaginal perineometer that was used by Kegel to treat stress urinary incontinence [234]. However, the seminal biofeedback procedure [235] for FI, which was followed in a series of studies, used a 3-balloon manometry probe to reinforce changes in 3 distinct physiological variables rather than just EAS contraction. The responses that were reinforced with this protocol included: (a) the perception of sensory cues associated with rectal distension and potential loss of stool; (b) a short-latency EAS contraction; and (c) inhibition of activity that would increase rectal pressure (i.e. contraction of the abdomen rectus and diaphragm). The overall goal of this protocol was to strengthen the presumed EAS reflex contraction that normally counteracts the internal anal sphincter inhibitory response to rectal distension. However, reinforcement for EAS contraction was contingent upon maintaining stable rectal pressure, because increases in rectal pressure during stool urgency can overcome relative sphincter closure pressure, and thus would be counterproductive to retention. Subsequently, the EAS response to rectal distension was determined to be a learned, rather than an involuntary response. As a result, the theoretical basis for the use of operant conditioning (biofeedback) in the treatment of bowel disorders was established [236].

There is no standardisation in the biofeedback literature for FI. Studies use different instrumentation, training procedures, adjunctive strategies, samples, outcome measures, and follow-up periods. Therefore, straightforward comparison of study outcomes and statistical analysis of multiple outcomes is difficult. Most biofeedback protocols can be placed into one of three general categories on the basis of the procedures used for training and include:

1) Strength training, defined as the reinforcement of anal sphincter and/or pelvic floor muscle (PFM) contraction to improve EAS strength, speed or endurance without attention to sensation.

2) Sensory training, defined as the reinforcement of heightened sensitivity to stepwise reductions in rectal distension volumes without emphasis on improvements in sphincter strength.

3) Coordination training, enhancing deliberate voluntary anal contraction in response to rectal filling and thus countering the effect of the recto-anal inhibitory reflex in lowering anal pressure, usually combined with the reinforcement of rectal sensitivity, a rapid EAS response in the absence of rectal pressure changes and also sustained EAS contraction to improve sphincter strength.

These approaches can be combined. Variations of these procedures include the reinforcement of tolerance to progressively larger volumes of rectal distension and control of urgency. Instrumentation used to measure and reinforce the changes in biological activity include pneumatic and perfusion manometry, surface electromyography (EMG) and transanal ultrasound. Some workers have suggested the use of a multivariable EMG protocol that mirrors the manometric protocol by substituting surface abdominal EMG electrodes for the rectal pressure balloon to measure extraneous abdominal muscle wall contraction that is associated with increases in rectal pressure. An EMG probe is placed within the anal canal or vagina to measure external anal sphincter or pelvic floor muscle activity.

Historically, the use of pelvic floor muscle training (PFMT) without biofeedback has seldom been used as a primary treatment for FI, unlike its application for UI where PFMT has been recommended as an intervention prior to the use of biofeedback. For FI, most exercise protocols have used PFMT secondarily to augment the biofeedback protocol.

2. LITERATURE SEARCH

A search of Medline, Cinhall and Embase (1970-April 2008) was conducted using the search terms “biofeedback”, “exercise therapy”, “pelvic floor” and “fecal incontinence”, limited to randomised controlled trails (RCTs) in adults. The search was supplemented by a crosscheck of citations in the identified papers and other systematic reviews.

A Cochrane review [237] of randomised or quasi-randomised studies found 11 eligible studies that used biofeedback and/or PFMT to treat FI. Our current review found three additional studies [238-240]. A total of 14 studies were therefore identified by this search. One study was published in a very brief German abstract only, with no extractable data [239], and a further two were in abstract form only [240:241] and so were excluded, leaving 11 studies for the review (Table 6). In addition, a large number of uncontrolled studies were identified. These are only quoted where they serve to augment the evidence.

Key: NSD = no statistically significant difference  
ITT = intention to treat analysis
from RCTs, for example on possible mechanisms of efficacy or sustainability of effect. All RCTs that included at least one arm where patients were given instrumented biofeedback or instructions/coaching in PFMT to treat FI in adults were eligible for inclusion.

3. REVIEW OF THE EVIDENCE

The 11 studies included a total of 592 patients. The median sample size was 40 (range 8-171). Only one study mentions an intention to treat analysis [142], three trials did not mention number of drop-outs. Of those that do mention drop-outs, a total of 18% of recruited subjects failed to complete.

The majority (90%) of patients in the 11 RCTs were female. Ages ranged from 8-92 (studies primarily of children were excluded). Aetiology and symptom severity was highly heterogeneous. However, some studies did select subjects according to specific problems such as obstetric injury [238;242;243] or older people [244] or following sphincter repair (3). All studies were from a single hospital centre. All but one [238] were from English-speaking countries. Methodological quality was variable, and in many cases unclear.

Two studies attempted a component analysis to determine whether rectal sensory training or EAS strength training was more effective in reducing FI. They concluded that the primary mechanism responsible for symptomatic improvement was increased rectal sensitivity [245;246]. However, both studies were small, underpowered, and involved a complex cross-over design which makes analysis difficult due to carry over effects [247]. Also limitations in the applied strength training procedures preclude valid comparisons of strength vs. sensory training methods in these studies.

Other studies have investigated the additional benefits of aspects of therapy. In a between-group design, one study [248] compared out-patient intra-rectal EMG strength training to EMG plus sensory training using an intra-rectal balloon, EMG plus home biofeedback training, and EMG, sensory training plus home biofeedback. No added benefit was found when the more comprehensive protocols were used, but small group sizes make this study inconclusive.

One study using a between-group design of 4 different treatments, compared management and advice that included the use of diet advice, urge resistance training and anti-diarrhoeals to the same protocol plus: EAS exercise; EAS exercise and clinic biofeedback; or EAS exercise, biofeedback and the use of a home trainer [142]. There were no statistically significant differences between the four groups.

In addition to diet and bowel management, another adjunctive treatment that has been used with biofeed-

back is electrical stimulation [243;249]. The first of these studies found some benefit from the electrical stimulation (however the biofeedback methods and therapist were also different between groups). The second study found no difference with or without electrical stimulation.

Some studies have added home biofeedback equipment [142;248]. There was no evidence of additional benefit over clinic biofeedback.

Most studies report that patients are instructed in home exercises but many do not specify the precise instructions given to the patients. Some studies state that subjects were simply instructed to contract the EAS with any feeling of rectal distension at home, while others provided structured sphincter exercise programmes. Some have taught exercise with biofeedback or digitally, while others have not mentioned the method of teaching. There was no measure of compliance with exercises. A relationship between long-term improvement and continued exercise has not been established. In one uncontrolled study, [250] only 26% of the subjects reported that they continued to perform PFM exercise at 12 month follow-up even though all subjects who improved initially (71%) maintained the gains at follow-up. No controlled study has examined intensity of follow-up, although one case series suggests that telephone follow up can be as effective as face-to-face clinic visits [251].

One study [248] compared 4 different biofeedback protocols but did not have a non-biofeedback control group. Before patients were randomised to the different biofeedback protocols, they underwent medical and bowel management but the time period of initial intervention was unspecified. Although there was an overall 74% reduction in stool incontinence after biofeedback, no difference in effect was found between the different protocols. However, interpretation of effects was hampered by small group size.

Another study compared manometric biofeedback, anorectal ultrasound biofeedback and sphincter exercise taught with digital examination alone [252]. All groups showed modest improvements in bowel control with 70% of the subjects reporting at least some clinical improvement. Improvements in bowel control were associated with modest changes in anorectal measures. However, neither manometric or ultrasound biofeedback provided added benefit to digitally taught sphincter exercise on any of the nine outcomes measures.

Another RCT [142] used four groups to compare the effects of a behavioural treatment from a specialized nurse that included advice on bowel management, diet, urgent control and the use of anti-diarrhoeal medication, to the same behavioural management but with the addition of: sphincter exercises; exercises plus clinically administered biofeedback; or exercises, clinical biofeedback and home biofeedback. Each
group received a median of five (range 1-9), 45-90 minute treatment sessions. No difference was found between groups on ratings of bowel control or physiological measures. These findings suggest that biofeedback did not provide any additional benefit to behavioural and medical management. When outcomes were collapsed across all subjects, modest reductions in symptoms of 54% and 53% were reported to occur in the advice and biofeedback groups, respectively. Although manometric indices of sphincter function improved across all groups, an unexpected and unexplained numerical decrease in squeeze pressure was reported in one of the biofeedback groups, and minimal change was reported in the other biofeedback group. However, the outcome analysis was appropriately conducted on an intention to treat basis. In this study a 20% drop out rate was reported, which is consistent with other studies that have also reported drop out rate. But unlike Norton, most studies have reported outcomes only on subjects completing treatment rather than on an intention to treat basis. As result of the more stringent analysis, the Norton outcomes appear to be lower than many of the other reports.

While there was little difference between groups in the RCTs, it should be noted that on a before-after analysis, all studies showed at least some improvement in patient symptoms or other parameters. This is consistent with the majority of case series. There are over 70 uncontrolled studies of BFB and/or PFMT for FI. All but one [253] report benefit to patient symptoms and a variety of other outcome measures. Most studies report an overall response rate that combines improvement and cure rates. Reported improvement ranges from 0% [253] to 100% [254], with the majority being in the range of 50-80% [255;256].

**a) Long-term follow-up**

There are few long term follow up studies. One RCT found little fall-off in efficacy at one year [142]. One uncontrolled study found that a majority of patients maintained, and in some cases exceeded, improvements reported immediately after treatment [247]. The long-term positive outcome in this study was attributed to the 83% home exercise compliance during the active treatment phase. An uncontrolled study reports that 63% of patients were continent at one year [257] and another study reported that most responders are still improved at 5 years [258].

**b) Mechanism of treatment benefits**

Many studies have reported changes in physiological variables such as resting and squeeze pressures and changes in rectal sensory threshold volumes as an outcome of biofeedback training. A few studies also have reported changes in the duration of EAS contraction [142] with researchers concluding that the ability to sustain an EAS contraction is more important than maximum squeeze pressure. Two uncontrolled studies found that it was the subjects who learned to extend the duration their sphincter contraction who developed continence [259;260] after biofeedback training. This notion was supported by a study that compared the EAS fatigue rates of healthy controls to patients with constipation, seepage and stool incontinence and found that the EAS fatigue rate in incontinent patients was significantly greater compared to healthy controls and those with seepage [261].

Several studies report that improved rectal sensation is most consistently linked to improvements in continence as a result of biofeedback training [245;246;262]. Conversely, changes in sphincter strength are not consistently found to be associated with reductions in incontinence [245;263-267] and in two studies, squeeze pressure was found to increase even in those patients that did not improve in bowel control [250;268]. These inconsistencies have lead to questions regarding the mechanism(s) presumed to be responsible for symptom reduction as a result of biofeedback training [269]. They may also call into question the use of such proxy measures of patient improvement, as symptoms are only loosely related to physiology test findings.

**c) Identifying people likely to benefit from biofeedback**

There are no established criteria that might predict which patients would most likely benefit from biofeedback or exercise therapy. One case series found that in addition to a rectal sensory threshold of 50ml or less, a lower EAS and IAS response threshold and an urgency threshold less than 100ml were associated with better outcomes after biofeedback [250]. Another study noted that positive outcomes were associated with those patients 55 years and older and having normal defecation patterns, while poorer outcomes were associated with those younger than 55 and having abnormal evacuation patterns [270]. One study noted that the need for more than 3 biofeedback sessions and a poor early response to biofeedback predicted poor long-term improvement at follow-up [258].

Several reports noted that improvements were not associated with the presence or absence of anal sphincter defects found with ultrasound [142;261;271;272], but one study found that less robust improvements were obtained in those having passive incontinence rather than urgency incontinence [271]. In the one study that found that no functional improvement was obtained with biofeedback, all subjects had severe pudendal nerve neuropathy and absent sensation for call to stool [253]. Another study found that patients with spinal cord lesions were least likely to respond to treatment [273]. On the other
hand, one study did find that subjects with pudendal neuropathy could improve bowel control with biofeedback but were less likely to show improvement in EAS strength [266]. However, the effects of bowel management strategies were not controlled. Currently, there is little evidence that shows a relationship between pre-treatment anorectal function as measured by manometry and biofeedback outcomes, with the exception of rectal sensitivity which, if found to be greater than 100ml before treatment, is associated with a poor response to biofeedback [273]. As a result, some studies have excluded patients who have a rectal sensory threshold greater than 100 ml.

Unsurprisingly, one case series has found that those who completed treatment were most likely to benefit [274]. The latter study also found that patients who were older, female and had more severe incontinence were most helped, but this may be compounded by the greater likelihood of these patients completing treatment. One further study found that older and less obese patients were most likely to benefit [142].

d) Comparison of PFMT and BFB

Given that PFMT without BFB has been accepted as a valid treatment for UI, similar protocols may potentially improve FI as well. Two studies that have directly examined the effects of pelvic floor muscle training on FI report similar outcomes [142;252]. When PFMT was used in addition to a comprehensive behavioural management programme, no added benefit was obtained [142]. Both studies found PFMT alone to be as effective as BFB combined with PFMT.

In a RCT which recruited women with urinary incontinence three months postnatally, the intervention group reported less FI at 12 months follow-up [275], although the effect does not appear to last at six years [276]. However, in this study, the effect of PFMT was not studied separately from education and patients were not recruited with FI as their primary problem. Given the limited data available, there is an obvious need to investigate the effectiveness of PFMT alone on FI because there are no known risks associated with its application and its cost is low relative to biofeedback.

4. SUMMARY OF THE EVIDENCE: BIOFEEDBACK AND EXERCISES FOR FI

In general, the outcomes reported from uncontrolled biofeedback studies for FI have been favourable. However, most studies have been small and have a multitude of methodological flaws that include inadequate descriptions of subject characteristics and procedures, the use of heterogeneous samples, and limited follow-up data. Only a handful of the studies have made efforts to control for non-specific effects. In contrast to the mostly favourable outcomes reported in uncontrolled studies, randomised controlled trials have generally found no additional benefit when biofeedback was added to either a comprehensive behavioural and medical management programme [142] or to digitally taught sphincter exercises. There are limitations in all studies to date.

We still lack precise knowledge of the mechanisms responsible for improvement when biofeedback or exercise is used to treat FI, and we do not yet understand the extent to which any specific biofeedback protocol alters parameters of anorectal function. The exception is rectal sensitivity, which is the single physiological parameter that has been reported to most consistently improve with biofeedback. However, not all subjects who show improvements in rectal sensitivity also develop continence. Thus, good rectal sensitivity can be considered a necessary but not sufficient requirement for reliable continence. In contrast to rectal sensation, EAS strength has not been shown to consistently improve with biofeedback even when protocols have been directed to improve EAS function. Hence lies an essential empirical question for the field that must be answered before we can determine whether biofeedback is a useful tool in the treatment of stool incontinence.

For, if changes in sphincter function are not observed when the stated goal of a biofeedback procedure is to improve sphincter strength, the validity of the protocol can be questioned and accordingly, conclusions based on the outcomes must be limited. Protocols then should be appropriately altered to achieve the stated goal of changing EAS function. As in the field of psychophysiology from which biofeedback has evolved, a test of biofeedback effectiveness for any disorder cannot be accepted as an adequate evaluation of the treatment without evidence that the targeted physiology has been changed to a valid criterion of function [277].

Accordingly, any biofeedback protocol for FI should first be shown to have altered some target aspect of anorectal or bowel physiology, before it is be tested as a treatment. Additionally, measurement of these functions has yet to be standardised and validated. Without validation of the biofeedback procedure itself, the analysis of group effects tends to be primarily a test of non-specific effects.

In summary, the primary problems in the biofeedback and pelvic floor muscle literature are:

1. Biofeedback studies for FI have employed a variety of methodologies that range from rectal sensitivity training to sphincter strength training but without standardisation of methodology or outcome evaluation tools.

2. Although uncontrolled studies using biofeedback for FI have reported mostly favourable outcomes, results from larger RCTs have mostly not demonstrated a benefit of biofeedback over
comprehensively administered behavioural and medical management or sphincter exercises alone.

• Only one study has found significant differences between groups [242]

• Rectal sensation may be more important than sphincter strength [245;250]

• Changes in sphincter strength are not necessarily linked to symptoms

• There are few established predictors of outcome of biofeedback or exercises (rectal sensation, IBS, age, weight, sphincter disruption; each have weak or contradictory evidence as predictors)

• PFMT may be as effective as BFB [142;252]; advice alone may be as effective as PFMT [142]

• More than 50% of patients in all groups improve

5. RECOMMENDATIONS FOR PRACTICE

Because recent RCTs have raised questions as to whether biofeedback provides a specific benefit relative to education and good clinical management despite a large body of uncontrolled studies supporting its efficacy, the consensus of the committee is that it is possibly effective but currently unproven. This reinforces the case for using maximal education, lifestyle and dietary interventions before PFMT or BFB, as recommended by recent national guidelines in the UK [278].

• PFM exercises are recommended as an early intervention in the treatment of FI as part of a conservative management bundle of interventions, based upon low cost and morbidity and some, although limited, evidence suggesting efficacy (C).

• The use of biofeedback as a treatment for FI is recommended after other behavioural and medical management has been tried if inadequate symptom relief obtained, given the numerous positive outcomes from uncontrolled trials, limitations in the current RCTs and low morbidity associated with its application. (C).

6. RECOMMENDATIONS FOR RESEARCH

There is a need to conduct further RCTs to determine whether specific biofeedback and pelvic floor muscle exercise protocols can alter the hypothesised target physiological parameters of ano-rectal function (muscle strength and/or sensation) with concomitant changes in bowel control.

• Clear description of modalities and evaluation of different elements of BFB

• Adherence monitoring

• Standardisation of outcome measures

• Long term follow up

• Robust patient-focused outcome measures

• Understanding of physiological effect and relationship to symptom change

• Work on clinically meaningful improvement and distinguishing cure from improvement rates

• The exploration of possible synergies between urinary and faecal incontinence interventions and evaluations should be considered in study designs

VIII. EXTERNAL ELECTRICAL STIMULATION FOR FI

1. BACKGROUND: THE PHYSIOLOGICAL BASIS FOR ELECTRICAL STIMULATION

Sacral nerve stimulation through surgically implanted electrodes and stimulators have been found to be effective for reducing the severity of FI in randomized controlled trials [279;280]. These studies, which are reviewed in detail by Committee 17, provide an impetus for identifying electrical stimulation protocols for the treatment of FI that are less invasive than other surgical approaches such as sphincteroplasty and injection of bulking agents. This section reviews the use of external (surface) electrical stimulation.

Anal electrical stimulation was first described for treatment of FI over 40 years ago, firstly as an implanted stimulator [281] and later as needle EMG stimulation [282]. As technology developed, more comfortable surface electrodes became available either as skin or intra-anal plug devices with a battery box. ES may be provided by a mains-powered machine or by a portable battery-powered stimulator. The advantage of a small device is that it is easier for the patient to use on a daily basis. Development of vaginal and anal electrodes make it possible for the patient to sit, stand or move during a training programme. There is at present no experimental evidence upon which to select optimum electrical stimulation parameters for different symptoms and clinical conditions.

An electric current of sufficient amplitude will excite nerve and muscle tissue in its field. In addition, the current will alter cell membrane potentials and therefore exert an influence on all living cells. The full extent of this influence is not known but studies have shown an increase in axonal budding following denervation and an increase in vascularisation and muscle bulk when the stimulating electrodes are placed in an area of striated muscles [283]. Also normalisation of the reflex activity of the bladder by using electrical stimulation (ES) has been reported [284]. In an animal model (dog) anal stimulation significantly increased anal sphincter pressure and rectal compliance without changing recto-anal inhibitory reflexes. Vaginal
stimulation also reduces rectal tone and increases anal pressure. Pressure increases are dose-dependent.

Maintenance of continence requires volitional cortical control which is dependent upon the sensory feedback from the ano-rectum [285] and the ability to sense rectal distension and impending defecation and to relax or contract the striated muscles of the pelvic floor [286]. Reduced rectal sensitivity is common in patients with constipation and/or FI [287]. The motor control of the pelvic floor muscles is a learned voluntary response albeit often at a subconscious level [236;288].

Functional electrical stimulation activates both sensory and motor axons. The sensory axons send signals to the brain and it is thought may cause plastic changes in the representational area of a body part. The result of this is enlargement of the representation and improvement of awareness of the stimulated body part. This leads to better control of movements. In theory ES may therefore reinforce weak functional signals that come from the pelvic floor musculature during the treatment [289], although this remains to be demonstrated experimentally.

Stimulation parameters such as stimulation frequency, pulse width, on:off ratios, and current intensity are very important as it is possible to cause fatigue and other problems by using incorrect parameters, too long a treatment time or too high an intensity.

2. SEARCH

The following databases were searched for controlled trials up to April 2008 using the terms “faecal/fecal incontinence” and “electrical stimulation”: Scopus, Medline, Embase, Cinahl. The reference lists of relevant studies and the Cochrane review [290] were also considered.

3. RESULTS

Six controlled studies of ES in FI were found (Table 7).

The first controlled study in forty women with obstetric-related FI [249] randomised patients to anal biofeedback and pelvic floor exercises with adjunctive electrical stimulation, or vaginal biofeedback and pelvic floor exercises without electrical stimulation (carried out by a different therapist). Both groups improved symptomatically, with no difference in symptoms between the groups. The stimulation group also improved manometric pressures. However, electrical stimulation was not the only variable in the study, and there was no follow up beyond the 12-week study period. Another attempted controlled study in patients who had FI following repair of obstetric third degree tear, abandoned stimulation because it caused discomfort [291].

Mahony et al studied a group of 60 women with FI secondary to obstetric trauma and compared 12 weeks of anal EMG biofeedback to anal electrical stimulation [243]. They found no difference between the groups in outcome at the end of the treatment period. Healy [292] found no difference in outcome between home electrical stimulation and clinic stimulation with or without biofeedback. Naimy likewise found no difference between patients given electrical stimulation plus home exercises and those given clinic biofeedback plus home exercises [238]. Norton reported no difference between stimulation at 35Hz and 1Hz, suggesting any effect may be sensory rather than motor [293]. Osterberg (2) compared stimulation with surgical levatorplasty and found few differences in outcome at 2 years. In all studies a significant proportion of patients reported improvement compared to pre-treatment, whatever treatment was given.

4. SUMMARY OF EVIDENCE ON ELECTRICAL STIMULATION FOR FI

A Cochrane review of trials of electrical stimulation for FI has concluded that “At present, there are insufficient data to allow reliable conclusions to be drawn on the effects of electrical stimulation in the management of FI. There is a suggestion that electrical stimulation may have a therapeutic effect, but this is not certain. Larger, more generalisable trials are needed “ [294].

Because there is a lack of consistency in electrical stimulation protocols and also a failure to use physiological principles when employing electrical stimulation, direct comparisons between studies are impossible. There are many parameter and clinical applications that have not yet been investigated. We know little about which patients are likely to benefit from ES. Sensory awareness of the body schema and the possibility of improving this cortically by using ES may be important in motor re-learning for those patients with severe sensory lost, but this has not been investigated.

5. RECOMMENDATIONS FOR PRACTICE ON ELECTRICAL STIMULATION FOR FI

Based on currently available evidence it is not possible to recommended electrical stimulation for FI.

6. RECOMMENDATIONS FOR RESEARCH ON ELECTRICAL STIMULATION FOR FI

- Randomised controlled trials with adequate sample sizes are necessary to investigate all aspects of the effectiveness of ES in FI.

- The effect of electrical stimulation in changing consciousness of the pelvic floor is one of the interesting future areas for research.

- When planning future research basic knowledge of electrical stimulation parameters and their likely physiological effects is essential.

IX. Faecal Incontinence in Frail Older People

1. BACKGROUND

FI in older people is a distressing and social isolating symptom and is associated with increased risk of morbidity [8;37], mortality [32;295], and dependency [8;295]. Frailty, defined by having multiple comorbid chronic illnesses and/or limitations to physical activity (see Section 2), is an independent risk factor for FI. Many older individuals with FI will not volunteer the problem to their general practitioner or nurse, and regrettably, health care providers do not routinely enquire about the symptom. This ‘hidden problem’ can therefore lead to a downward spiral of psychological distress, dependency, and poor health. The condition can especially take its toll on informal care providers of home-dwelling patients [296], with FI being a leading reason for requesting nursing home placement [297;298].

Even when older people are noted by health care professionals to have FI, the condition is often managed passively, especially in the long-term care setting where it is most prevalent. Current surveys show that the level of awareness regarding appropriate assessment and treatment options is limited among primary care physicians [299]. The importance of identifying treatable causes of FI in frail older people rather than just managing passively (e.g. pads provision without assessment) is strongly emphasised in national and international guidance [1;278;297], but audits show that adherence to such guidance is generally poor, with non-integrated services, and sub-optimal delivery by professionals of even basic assessment and care [35;300].

This section covers specific issues for frail older people with FI. As this group frequently has co-existing urinary incontinence, it should be read in conjunction with Chapter 11. Healthy older people should be managed using the interventions covered previously in this chapter.

2. SEARCH

The PUBMED database was searched up to March 2008 using the following keywords:

1. ‘anal, bowel, faecal, fecal’ and ‘incontinence’
2. constipation
3. ‘urinary’ and ‘incontinence’
4. laxatives, enemas, suppositories
5. other relevant phrases such as ‘comprehensive geriatric assessment’ ‘stroke’

Additional articles were identified by examining reference lists, and the Cochrane other recent systematic reviews.

3. SUMMARY OF EVIDENCE ON PREVALENCE AND RISK FACTORS FOR FI IN FRAIL OLDER PEOPLE

The prevalence and risk factors for FI are detailed in Section 2. Summarized below are key points that are specific to the frail elderly population. The level of evidence is given in brackets.

- FI affects 1 in 5 older people (aged 65+) living in the community, and half of those resident in care homes (Level of evidence 1)
- The prevalence of FI increases with age alone, particularly in the 8th decade and beyond (1)
- The prevalence of FI is higher in the acute hospital and nursing home setting than in the community (1), thus the group most affected is frail older people.
- The prevalence of FI in frail older men is equal to or greater than in women (2). This predominance of older men over women with FI is most striking among nursing home residents (2).
- The prevalence of FI varies dramatically between institutions in nursing home studies (2)
- FI usually coexists with urinary incontinence in frail older people (1)
- Aside from age, the following are primary risk factors for FI in older people (2):
  - Loose stool
  - Impaired mobility
  - Dementia
  - Neurological disease
  - Chronic medical conditions
  - Depression
- Loose stool is a primary cause of transient FI in older people (2)
- Faecal loading and constipation are clinically linked to FI, but there is little epidemiological work assessing this association (3)
- Physicians and nurses in primary care, acute hospital, and long-term health care settings do not have a high awareness of FI in older people (2)
- Within nursing homes, there is a low rate of referral by nursing staff of residents to primary care physicians or continence nurse specialists for further assessment of FI (2), and there is a tendency toward passive management (e.g. use of pads only without further evaluation) (2). Faecal loading is often present in older care home residents with FI (2)
- Older people may be reluctant to volunteer the symptoms of FI to their health care provider for social or cultural reasons, or due to a popular misperception that the condition is part of the ageing process and therefore ‘nothing can be done about it’ (2)
- FI is associated with reduced quality of life, and poor health perception (2)
4. RECOMMENDATIONS - IDENTIFYING FAECAL INCONTINENCE IN FRAIL OLDER PEOPLE

- Bowel continence status should be established by direct questioning and/or direct observation in:
  - all nursing and residential home residents
  - hospital inpatients aged 65 and over
  - people aged 80 and beyond living at home
  - older adults with impaired mobility
  - older adults with impaired cognition
  - older adults with neurological disease
  - older adults with chronic disease

- Primary care staff, hospital ward staff, and long-term care staff should routinely enquire about FI in frail older patients

- Enquiry about FI should be systematic and include stool consistency, severity of FI and impact on activities of daily living and quality of life

- Health care providers should be sensitive to cultural and social barriers discouraging patients from talking about the condition

- Frail older patients with restricted ability to access primary care such as nursing home residents, and those with mobility, chronic illness, or cognitive impairments, should be screened for FI through systematic case-finding methods

- Systematic outreach programmes which make it easier for frail older people and those who care for them to volunteer the problem to their primary care provider should be implemented

- There are significant geographic variations in provision of specialist expertise in bowel care (both medical and nursing) nationally and globally, which may affect case-finding in older people

- Further examination of underlying reasons for the variations in prevalence of FI between nursing homes (standards of care, patient case-mix, reporting) is needed

- Urinary and FI often coexist; continence care workers (e.g. nurse specialists) should be trained in identification and management of faecal as well as urinary incontinence in older people

- Key requirements to improving detection in the practice setting should be implemented:
  - (a) education of health care workers to embed both a sense of value in identifying FI, plus confidence that the condition can be treated
  - (b) protocols should be in place clarifying all details of screening enquiry (who will ask, how to ask, when to ask, and who to ask)
  - (c) patients and carers should have access to educational materials at the point of enquiry

5. THE AGEING LOWER BOWEL AND PATHOPHYSIOLOGY IN OLDER ADULTS WITH FAECAL INCONTINENCE

Chapter 4 covers the pathophysiology of FI. This section considers factors specific to frail older people.

a) Quality of data

The findings from physiological studies of the lower bowel in older adults tend to be variable due to a) a variety of different techniques used in measuring anorectal function, b) unclear definition of the normative range of manometric measures for older people, c) poor matching between cases and controls of clinical factors which may affect gut function (e.g. level of mobility), or inaccurate clinical information and d) usually small subject numbers. Studies reviewed are cohort case-control to evaluate age-effect [301-304], young-old healthy subject comparisons [305;306], and age- and sex-matched case-control studies of continent versus incontinent patients [154;307;308].

b) Anorectal function in healthy older adults

Studies of age effect in healthy volunteers have shown a linear reduction with ageing in squeeze pressures (external anal sphincter tone) in women after the age of 70, and in men from the 9th decade onwards [301;302]. Age beyond 70 years was associated with reduction in basal pressures (internal anal sphincter tone) in both genders, but to a greater degree in women [301;302;306]. The internal sphincter thickness and diameter is significantly increased in older versus younger nulliparous women with, however, reduced functionality in this smooth muscle [309].

Rectal motility appears to be unaffected by healthy ageing [305], but an age-related increase in anorectal sensitivity thresholds, and reduced rectal compliance has been observed, starting at an earlier age in women than men [303].

c) Anorectal function in older adults with faecal incontinence

One study demonstrated prolonged pudendal nerve terminal motor latency (>2.2ms) in 34% of women aged over 50 with FI, though no relationship was observed between pudendal neuropathy and basal or squeeze pressures [310]. Advancing age was however related to declining basal pressures. Another study similarly found an age-related increase in pudendal neuropathy in incontinent women, again unrelated to squeeze pressures [311]. Single fibre EMG in incontinent patients aged over 70 years showed increase in polyphasic potentials in the external anal sphincter muscles compared with continent subjects, indicating some local reinnervation of these muscles following neurogenic damage [308]. A study comparing anorectal function in young (mean age 42) and old (mean age 72) women with FI (patients with constipation and/or pelvic floor dysfunction excluded) showed that older women were more likely to have
bilateral pudendal neuropathy, but less likely to have a sphincter deficit of >90 degrees and thin perineal body [304], although the validity of this test is questionable (Committee 7). Anorectal physiology was similar aside from a trend toward lower resting tone in older women.

An examination of anorectal function in elderly medically frail incontinent patients and continent age- and sex-matched controls showed that individuals with FI had reduced internal anal sphincter pressures, and a lower threshold for expulsion of a rectal balloon (307). Patients with FI and dementia were more likely to exhibit multiple rectal contractions in response to rectal distension, though the role of these ‘uninhibited’ contractions in causing incontinence was unclear [307;312].

A similar matched case-control study showed that elderly patients with rectal impaction and soiling had impaired rectal sensation (needing a larger volume before feeling the presence of a rectal balloon and the desire to void), lower rectal pressures during rectal distension, and impaired anal and perianal sensation (‘rectal dyschezia’) [154]. Basal and squeeze pressures were however unimpaired in these patients, and the rectoanal inhibitory response was well-preserved. The authors concluded that overflow FI is primarily due to locally secreted mucus from around an irritative rectal faecal mass leaking out, despite well-preserved anal sphincter integrity.

**SUMMARY OF EVIDENCE ON FAECAL INCONTINENCE AND THE AGEING GUT**

- Anorectal function in healthy older persons is characterised by a tendency towards an age-related reduction in internal anal sphincter tone (Level of evidence 2), and a more definite decline in external anal sphincter tone, especially in older women (2)
- An age-related decline in anorectal sensitivity in women has been observed (2), but rectal motility is well-preserved (2)
- Ageing alone however, appears to have little impact on anorectal function until later old age – from the 7th decade upwards in women and even later in men (2)
- Age-related internal anal sphincter dysfunction (reduced anal resting tone) is an important factor in FI in later old age (3)
- Pudendal neuropathy is an age-related phenomenon in women with FI (2), and a likely predisposing factor for FI (2) although the validity of this test is questioned.
- Stool impaction predisposing to overflow is related to rectal dyschezia in frail older adults, a condition characterised by reduced tone, increased compliance and impaired sensation (3)
- Overflow FI is due primarily to mucus secretion from around a rectal faecal bolus, rather than to impaired sphincter function (3)

**RECOMMENDATIONS - PATHOPHYSIOLOGY OF FI IN OLDER PEOPLE**

- Overall, the physiological data suggests that FI should not be considered an inevitable consequence of ageing
- Older adults with FI should be evaluated for age-related reduction in internal and external sphincter function
- Older patients with FI require a digital examination to identify rectal stool impaction causing overflow
- Patients who are unaware of the presence of a large faecal bolus in the rectum may have rectal dyschezia, and should be considered at risk of recurrent impaction with overflow

**6. CLINICAL CAUSES OF FI IN OLDER PEOPLE**

The evidence for this review is poor and the following section is based largely on case series and expert opinion rather than robust empirical data. The causes of FI in older people are often multifactorial. The aim of this section is to categorise the causes of FI in the frail older adult in a clinically meaningful way emphasising the identification of potentially reversible factors. Comprehensive geriatric assessment (assessing medical, functional and psychosocial factors in addition to the bowel) is key to identifying all contributing causes for FI in frail older people.

**6.1 OVERFLOW INCONTINENCE SECONDARY TO CONSTIPATION AND STOOL IMPACTION**

Constipation is the most important cause of FI in frail older people, as it is treatable, preventable, and frequently overlooked. In a UK hospital, faecal impaction was a primary diagnosis in 27% of acutely hospitalised geriatric patients admitted over the course of a year [154]. A more recent survey found that faecal loading was present in 57% of older acute hospital inpatients with FI (31). Care home studies show that 52-70% of care home residents have faecal loading underlying FI [25;31]. In a Finnish study, the prevalence of constipation (defined as self-reported difficult evacuation or infrequent bowel movements) was 57% in women and 64% in men living in residential homes, and 79% and 81% respectively in the nursing home setting [223]. The high prevalence of constipation in nursing homes is all the more striking in that 50-74% of long-term care residents use one or more daily laxative [34;223;313-315].

A prospective study in the US looked at baseline characteristics predictive of new-onset constipation in elderly nursing home patients using the Minimum Data Set instrument [316]. Constipation was defined as having two or fewer bowel movements per week or straining on more than 25% of occasions. Seven percent (n=1,291) developed constipation over a 3-month period. Independent predictors were white
OLDER PEOPLE AND RISK FACTORS FOR CONSTIPATION IN SUM

PREVALENCE

are summarised below.

constipation (and their supporting level of evidence)

epidemiological data regarding risk factors for constipation (and their supporting level of evidence) are summarised below.

SUMMARY OF EVIDENCE ON PREVALENCE AND RISK FACTORS FOR CONSTIPATION IN OLDER PEOPLE

- The prevalence of both self-reported and symptomatic constipation are high in frail older people (Level of evidence 2)
- Women predominate over men in prevalence rates of self-reported constipation and related symptoms among older people, though this gender difference is less marked beyond the age of 80 (2)
- Nursing home residents have a higher prevalence than community-dwelling individuals of all constipation-related symptoms, including infrequent bowel movements, straining, and hard stool (2)
- Faecal loading is often present in older patients with FI in the acute hospital (3) or care home setting (2)
- Advancing age increases the risk for heavy laxative use and symptom-based constipation among nursing home patients (3)
- The prevalence of constipation in nursing homes is high despite heavy laxative usage (2) implying that a) laxative prescribing may be ineffective, and b) non-pharmacological approaches to treatment are under-utilised in this setting.
- Frail older people are at greater risk of faecal impaction and overflow FI and other complications of constipation (2)
- There are numerous potentially modifiable risk factors for symptomatic constipation in frail older people (2). These include:
  - Polypharmacy (2) [223;316-318]
  - Anticholinergic drugs (2) [319] [314]
  - Opiates (2)
  - Iron supplements (3) [320]
  - Calcium channel antagonists (3) [321]
  - Nonsteroidal anti-inflammatory drugs (2) [322;323]
  - Immobility (2) [223;319;324]
  - Institutionalisation (3) [223]
  - Parkinson’s disease (2) [316;319;325]
  - Diabetes mellitus (2) [326;327]
  - Dehydration (2) [316] [328]
  - Diet deficient in fibre (3) [318] [329]
  - Dementia (2) [154;307;316]
  - Depression (3) [318;330]

6.2 OTHER CLINICAL CAUSES

a) Functional incontinence

Functional incontinence occurs in individuals who are unable to access the toilet in time due to impairments in mobility, dexterity, vision, intellect / awareness. These patients may even have normal lower gut function. Epidemiological studies in older people (see above) have repeatedly shown that poor mobility is a strong risk factor for FI after adjustment for other variables [8;32;40;53;296]. It is also a primary risk factor for constipation in older people [223;319;324]. While these studies particularly examined immobility as a risk factor, it is likely that problems of impaired sensation and dexterity are also contributory.

b) Dementia-related incontinence

Some patients with advanced dementia lack cortical control of the defecation process, and so tend to void formed stool once or twice daily following mass peristaltic movements. One study identified dementia as the primary cause of FI in 46% of nursing home residents [25], and the condition has been identified as an independent risk factor in epidemiological studies [32;40;53]. These individuals are very commonly incontinent of urine also [40].

c) Comorbidity-related incontinence

The following diseases may cause FI, and are more common in older people:

1. STROKE

FI affects 30-56% of individuals acutely after stroke, 11% at 3 months, and 11-22% at 12 months [114;115]. Major FI is four and a half times more prevalent in stroke survivors than the non-stroke population [331]. FI may develop months after acute stroke and can be transient, consistent with constipation with overflow as one possible cause [115;332]. Epidemiological data suggest that FI is associated more with disability-related factors (particularly functional difficulties in using the toilet, and anticholinergic medications) than stroke-related factors (e.g. severity and lesion location) [115;331;333].

2. DIABETES MELLITUS

Prospective data show that diabetes is a risk factor for the development of FI, especially in men [55]. FI may occur in people with diabetic neuropathy affecting the gut through the dual mechanisms of a) bacterial overgrowth resulting from severe prolongation of gut transit causing the characteristic nocturnal diarrhoea [326] and b) multifactorial anorectal dysfunction. Case-control studies show that diabetic patients with FI have reduced basal and squeeze pressures, spontaneous relaxation of the internal anal sphincter, reduced rectal compliance, and abnormal rectal sensation [327;334]. Diabetic anorectal dysfunction predisposing to FI can be further exacerbated by acute hyperglycaemia [335].
3. SACRAL CORD DYSFUNCTION

The neuropathophysiology of rectal dyschezia [154] is compatible with diminished parasympathetic outflow from the sacral cord. Rectal dyschezia is characterised by impaired rectal sensation (needing a larger volume before feeling the presence of a rectal balloon and the urge to void), lower rectal pressures during rectal distension, and impaired anal and perianal sensation, and is clinically associated with recurrent rectal impactions and continuous faecal soiling [154]. Common conditions in older persons that could impair sacral cord function are ischaemia and spinal stenosis.

4. ANORECTAL INCONTINENCE

Studies of older people with FI suggest that age-related internal anal sphincter dysfunction is an important contributing factor [310;312], as it lowers the threshold for balloon (stimulated stool) expulsion [312]. A study of women with anorectal FI compared underlying causes in young (mean age 42) and old (mean age 72) patients - the younger women were more likely to have an anal sphincter defect only, while the aetiology was more multifactorial in the older group, including a significantly higher occurrence of haemorrhoidectomy, diabetes, rectal and vaginal prolapse and pudendal neuropathy [304]. Later-life FI is linked to childbearing via structural damage to the external anal sphincter, and pelvic musculature [336]. Uterovaginal prolapse and rectocele have been shown to be a predominant independent risk factor for FI in women attending urogynaecology clinics [337;338]. Rectal prolapse is also a condition associated with FI which occurs more commonly in older adults [302].

5. LOOSE STOOLS

Loose stool increases the risk of incontinence in normally continent older adults by overwhelming a functional but age-compromised sphincter mechanism. Frail older individuals are particularly susceptible to bowel leakage in the context of loose stools [25;32]. Forty-four percent of cases of FI in a prospective nursing home study were related primarily to acute diarrhoea [32].

POSSIBLY REVERSIBLE CAUSES OF LOOSE STOOLS IN FRAIL OLDER ADULTS ARE:

i) Excessive use of laxatives

One-third of community-dwelling people aged 65 and over regularly take laxatives, far exceeding the prevalence of constipation in this population [339]. In the nursing home, laxative use (in particular ‘Codanthermer’ a Docusate-stimulant combination agent) has been linked to FI [34].

ii) Drug side-effects e.g.

Proton-pump inhibitors, selective serotonin re-uptake inhibitors, magnesium-containing antacids, choline-sterase inhibitors.

iii) Lactose intolerance

An age- and ethnicity-related phenomenon - Goulding et al. found a lactose malabsorption rate of 15% in healthy women aged 40-59 years as compared with 50% in those aged 60-79 [340].

iv) Antibiotic-related diarrhoea

Among hospitalised patients, age, female gender and nursing home residency significantly increases the risk for Clostridium difficile-associated diarrhoea associated with antibiotic use [341]. The diarrhoea also takes longer to resolve following treatment of C.Difficile in frailer older patients [341]. In a case-control study of hospitalised patients, Tal et al found FI to be a risk factor for recurrent C. Difficile (53% of patients studied), in addition to prolonged fever during initial infective episode, and H2-antagonist treatment [342].

v) Cancer

Loose stools should also be considered a possible indicator of colorectal cancer, and all patients with this symptom should be screened clinically for neoplastic and systemic illness. A study comparing underlying aetiologies in younger and older (age >70) men with FI found colon cancer to be significantly more common in the older group [343]. Where a change in bowel in habit is identified, colonoscopy or other imaging should be considered to rule out a colorectal cancer.

SUMMARY OF EVIDENCE ON CAUSES OF FI IN FRAIL OLDER PEOPLE

- Overflow incontinence secondary to stool impaction is a primary cause of FI in frail older people (Level of evidence 2).
- There are multiple potentially modifiable causes of constipation in older people (2), which are likely also to be risk factors for overflow FI.
- Frail older people (particularly those with neurological disability) may be incontinent because they are unable to use the toilet for physical functional reasons (2).
- Dementia is an important cause of FI in frail older people (2).
- FI is a common complication following stroke (2), but factors other than stroke status itself are contributory causes for incontinence in stroke survivors (2).
- Older people with diabetes (particularly if associated with autonomic neuropathy) are at risk of FI secondary of anal sphincter dysfunction (2)
- Loose stools predispose older people to soiling (1), and have numerous potentially reversible causes. Loose stools may however be indicative of underlying colonic disease such as colorectal cancer or colitis (2).
RECOMMENDATIONS - IDENTIFYING REVERSIBLE CAUSES OF FI IN OLDER PEOPLE

- The following potentially modifiable risk factors for FI should be carefully identified in all cases:
  1. Constipation causing impaction and overflow
  2. Loose stool
  3. Impaired mobility
  4. Difficulty with using the toilet (acute or chronic)
  5. Delirium (as a reversible cause of cognitive impairment)
  6. Anal sphincter weakness
  7. Impaired vision and/or manual dexterity
  8. Medications
    - All older people with FI should be assessed for reversible causes, regardless of their institutionalisation status
    - All frail older people with overflow FI should be assessed for potentially modifiable causes of constipation
    - The symptom of loose stools should be elicited in all older people with any degree of FI, and underlying causes rigorously sought
    - Evaluate nursing home administrative factors such as poor resident:staff ratios as a reversible cause of FI
    - Colorectal carcinoma may present with the symptom of loose stools, and this diagnosis should be considered where a change in bowel habit, or other indicators (rectal bleeding, abdominal pain, weight loss, anaemia) are present.

7. ASSESSMENT AND DIAGNOSIS OF FI IN OLDER ADULTS

The algorithm (Figure 2) summarises the clinical evaluation and management of FI in this population. The emphasis is on a structured comprehensive clinical approach, which can be undertaken by doctor or nurse specialist. In most cases the clinical approach will provide sufficient diagnostic information on which to base a feasible management plan without resorting to more specialised tests and assessments. The clinical usefulness of anorectal function tests and defecography in assessing FI in older people is limited by a) lack of normative data from healthy elderly, b) few standardised test protocols, and c) poor association between detected abnormalities and symptoms [344-346].

There is however much room for improvement in this clinical area; current surveys indicate a lack of thoroughness by doctors and nurses in assessing FI in older people in all settings (community, acute hospital, and nursing home), with failure to obtain an accurate symptom history or to perform rectal examinations [35;347]. A national UK audit of older patients with FI in primary care, acute hospital, and care home settings showed that only 50% of individuals within each setting had a history taken, and only 22-33% had a documented basic examination (history and rectal) [35]. Cause(s) for FI was documented in 27-49%, the 27% being in the acute hospital sector.

a) Results of search

Self-report of bowel symptoms relating to FI have been shown to be reliable and reproducible in older cohorts, including those in long-term care [348-350]. A study of women aged 65 years and older who were hospitalised with fractured neck of femur showed that proxy responses (proxy nominated by patient) for questions concerning FI has also been shown to concord well with index responses given by the patients [351].

Documentation of the type of incontinence is diagnostically very important [297]. There is a strong association between loose stool and FI in older people. Urgency is more associated with diarrhoeal disease (e.g. infective). Constant passive leakage of loose stool or stool-stained mucus is characteristic of overflow around an impaction, while patients with anal sphincter dysfunction tend to leak small amounts of stool. A symptoms study in adults with FI showed that where external anal sphincter weakness predominates the patient often reported urgency prior to leaking (urge FI), while those with internal sphincter dysfunction tended to have passive leakage of stool (passive FI) [352]. Patients with dementia-related incontinence often pass complete bowel movements, especially after meals in response to the gastrocolic reflex.

Assessment of FI must include an assessment for constipation. Based on international consensus, constipation is defined according to self-report of a combination of at least two of the following symptoms: usually 2 or less bowel movements per week over at least 3 months, hard stool, straining on more than 25% of evacuations and, feeling of incomplete evacuation [322;353].

It is important to identify the constipation subtype of rectal outlet delay in older people, as it affects 21% of community-dwellers aged 65 and over [322], and may lead to rectal impaction and FI. It is defined as: feeling of anal blockage during evacuation and prolonged defaecation (more than 10 minutes) and/or need for manual evacuation. Constipated older people tend to suffer primarily from difficulties with rectal evacuation and symptoms of straining and hard stool rather than from reduction in stool frequency [354].

Objectively however, the clinical definition of constipation relies on evidence of excessive stool
Figure 2: Multifactorial assessment and intervention protocol

1. Physical function history
   - Functional toileting problems?
   - Weak pelvic floor and/or sphincters?
   - Rectal stool impaction?
   - Rectal outlet delay?
   - Constipation?

2. Digital rectal examination
   - Glycerine suppositories daily and as required
     If ineffective, Bisacodyl suppositories daily and as required
     Written instruction on suppository insertion
     Advise footstool use during evacuation
     Phosphate enemas for severe impaction

3. Bowel symptom history
   - Faecal incontinence?
   - Impaction rectally or on abdominal xray?
     - Yes
     - No
       - Senna 2-3 tablets at night + lactulose 15 mls daily with instruction on dose titration according to ease of evacuation
       - Fybogel 1-3 daily with fluids instead of lactulose if diverticular disease or if weak anal sphincters
       - Polyethylene glycol 1 sachet for 3 days for colonic impaction without obstruction, then continue as above

4. Education (targeted verbal information with provision of booklet)
   - What is normal bowel function?
   - How stroke affects bowels?
   - Symptoms and tests
   - Diet (with food lists)
     - Fibre, fruit, vegetables
   - Caffeine avoidance
   - Fluids
   - Exercise
   - Regular toilet habits
   - Abdominal massage
   - Skin care
   - Pads
   - Odour control
   - When should I see my doctor
   - Helpful addresses
   - Alert patient and GP to drugs causing possible bowel-related side-effects

Explore problems with toilet access
In hospital: Ensure privacy
Use toilet (or sani-chair) rather than commode
Avoid bedpans
In community: Recommend community
OT/Physio assessment

Anal sphincter and pelvic muscle strengthening exercises

Loperamide 2mg up to 3 times daily according to symptoms
Anal sphincter strengthening exercises
Holding on exercises (bowel retraining)
Retention in the rectum and/or colon. Such objective assessment is particularly important in frail older people who may:

- be unable to report bowel-related symptoms due to communication or cognitive difficulties
- have regular bowel movements despite having rectal or colonic stool impaction
- have impaired rectal sensation and rectal dyschezia and so be unaware of symptoms associated with a large faecal bolus in the rectum [154].
- have non-specific signs or symptoms (such as delirium, leucocytosis, anorexia, functional decline) in association with severe faecal impaction

Digital examination can reasonably assess anal sphincter tone in the clinical setting. Easy finger insertion with gaping of the anus on finger removal indicates poor internal sphincter tone, while reduced squeeze pressure around the finger when asking the patient to ‘squeeze and pull up’ suggests external sphincter weakness. Digital assessment of squeeze and basal tone has been shown to be as sensitive and specific as manometry in discriminating sphincter function between continent and incontinent patients aged over 50 [355].

A digital rectal examination is essential for identifying stool impaction, although an empty rectum does not exclude the diagnosis of constipation [324]. Incontinent patients without evidence of rectal stool impaction should ideally undergo a plain abdominal radiograph in order to a) establish or rule out the diagnosis of overflow, b) measure the extent and severity of faecal loading, c) evaluate the degree of bowel obstruction secondary to impaction, and d) rule out acute complications of impaction such as sigmoid volvulus and stercoral perforation [356;357].

Certain symptoms associated with FI (abdominal pain, rectal bleeding, recent change in bowel habit, weight loss, anaemia) should prompt further consideration of underlying neoplasm [358]. Colorectal cancer is associated with both constipation and use of laxatives, though this risk association is likely to be confounded by the influence of underlying habits [359]. Chronic constipation alone is generally not considered an appropriate indication for lower endoscopy [360]. However, as the prevalence of colorectal cancer increases with age, the index of suspicion should be higher in older adults [361]. It should be noted that bowel preparation for lower endoscopy or barium enema may itself cause FI. Furthermore, a prospective study of 649 patients showed that dementia and stroke were independent predictors of inadequate colonic preparation [362].

Evaluation of toilet access should be multidisciplinary, and include a broad functional assessment (e.g. Barthel Index), mobility test (e.g. ‘up and go’ test), visual acuity test (count fingers), upper limb dexterity assessment (undoing buttons), and cognitive measure (e.g. Abbreviated Mental Test Score). An even more practical assessment is to watch someone transfer and manage clothing.

Appropriateness of the commode design for the individual concerned should be considered (e.g. trunk support, adaptability, mobility, foot support etc.) [35;363] (see Chapter 20). For community patients, the health care provider should be aware of the physical layout of the patient’s home, and in particular bathroom details (location, distance from main living area, width of doorway for accommodating walking aids, presence of grab rails or raised toilet seat). Low lighting levels, high degree of clutter and hard to manage clothing may also be relevant.

FI is a primary independent risk factor for pressure sores in frail older people [296;364], so evaluation of skin integrity (with pressure ulcer risk assessment) is important. Pelvic examination is also relevant in view of the association between urogenital prolapse (particularly rectocele) and FI in older women [337;338;365].

Bowel-specific quality of life scores have not specifically validated in the frail older population.

A UK RCT evaluated a multi-component assessment and treatment intervention for constipation and/or FI in frail older stroke patients, using an approach summarised in Figure 1 [144]. The assessment was undertaken in patients’ homes, outpatient clinics and hospital wards by a non-specialist nurse who had received simple training in bowel care. The structured assessment showed that the majority of patients had more than one bowel problem. Forty-eight (66%) had constipation, 41 (56%) rectal outlet delay and 16 (22%) rectal impaction. Twenty-two (30%) reported FI, of whom 12 had constipation with overflow. Thirty (41%) had reduced internal sphincter tone, 40 (55%) weak external sphincter tone, and 27 (37%) excessive pelvic floor descent. Thirty-four (47%) had difficulties with toilet access.

**SUMMARY OF EVIDENCE ON ASSESSMENT OF FI IN FRAIL OLDER PEOPLE**

- Evidence shows that current assessment of FI in frail older adults in routine healthcare settings is suboptimal (Level of evidence 2)
- Structured assessment of frail older people with bowel problems are likely to demonstrate multi-factorial causes for FI and constipation (2)
- Structured nurse-led assessment is a feasible approach in various healthcare settings (2)
- Documentation of the type of incontinence and related bowel symptoms by self-report, proxy report or observation is feasible (2) and diagnostically important (2)
• Constipation can be characterised clinically according to standardised symptom-based definitions in patients able to give a history (2)

• Rectal examination can reveal faecal impaction in patients with overflow (2)

• Digital assessment of sphincter tone can effectively estimate anal sphincter function in assessment of adults with FI (3)

• Anorectal function tests and defecography show poor association between abnormal findings and symptoms in older people with FI (3)

• FI-related quality of life measures have not been specifically validated in frail older persons

**RECOMMENDATIONS ON ASSESSMENT OF FI IN FRAIL OLDER PEOPLE (ALL GRADE C)**

- The emphasis in older people is on a structured clinical approach to identify multiple causes of FI, including cognitive and functional assessments. A standardised assessment of FI in frail older people is required to ensure proper identification of underlying causes. These assessments can feasibly be undertaken by nurses or doctors both in institutions, and in patients persons

- Physicians should prioritise assessment of FI of frail older people (especially in nursing homes). Nurses may be more aware of the problem, but should be specifically trained to look for underlying causes. A feasible practice-based approach is targeted training of non-specialist nurses providing routine care

- Hospital wards, primary care practices, and long-term care institutions internationally should have appropriate multidisciplinary protocols of case-finding and risk assessment

- Carers should be trained to routinely perform rectal examinations to evaluate stool retention

- A careful bowel symptom history (FI and constipation) and assessment of bowel pattern should form part of the assessment

- Digital assessment of sphincter tone should be performed in all older people with FI

- Ano-rectal physiology tests are not generally required in the frail elderly as they do not tend to alter the clinical examination conclusions or the management plan

- In the initial assessment of an older patient with FI, those without evidence of rectal stool impaction should undergo a plain abdominal radiograph to rule out higher impaction and other problems

- FI can be the presenting symptom of colorectal cancer and may require investigation by colonoscopy or barium enema. Bowel preparation should be carefully planned in frail older people to avoid causing acute diarrhoea, and/or inadequate clear-out

- Pelvic examination should form part of the assessment for FI, in particular to identify prolapse and rectocoele

- The impact of FI on patient and carer quality of life and usual activities should be qualitatively assessed, as well as patient attitude to their condition

- Evaluation of ability to access and use the toilet should be multidisciplinary

8. TREATMENT OF FI IN OLDER ADULTS

a) Quality of data

There are very few published trials of treatment of FI in older people, and no trials on prevention of FI. The studies reviewed had small numbers [25;144;244], problematic methodology (e.g. not applying intent-to-treat analysis, unclear reporting of drop-outs) [25;32;225], and were all non-blinded. Randomised controlled trials examining effective laxative treatment for constipation in older adults generally lack power, and are therefore unlikely to detect effects of treatment [366]. Issues of surgery, biofeedback, containment (pads and anal plugs) and skin care are covered elsewhere in the chapter.

b) Treatment of faecal impaction and overflow FI in older people

(See also section VI.3.c). One trial evaluated a therapeutic intervention in 52 nursing home residents with FI, based on treatment recommendations to general practitioners [25]. Patients with rectal impaction and continuous faecal soiling were classed as having overflow and recommended treatment with enemas until no further response followed by lactulose - complete resolution of incontinence was achieved in 94% of those in whom full treatment compliance could be obtained. Compliance with the recommended treatment was obtained in 67% of patients.

A French nursing home study of 206 frail elderly nursing home residents found that treatment of constipation was only effective in improving overflow FI (incontinence at least once weekly associated with impaired rectal emptying) when long-lasting and complete rectal emptying (monitored by weekly rectal examinations) was achieved using daily lactulose plus daily suppositories, plus weekly tap-water enemas. The number of FI episodes was reduced by 35% and staff workload (based on soiled laundry counts) fell by 42% in those with effective bowel clearance. However,
complete rectal emptying was only achieved in 40% of people receiving this regimen.

Over half of nursing home residents take laxatives at least once daily, prompting speculation that non-pharmacological approaches to optimise management of constipation may be under-utilised in this setting [34].

A 1997 a systematic review of laxative treatment in elderly persons found that the few published randomized controlled trials were potentially flawed due to small numbers and other methodologic concerns [366]. In the 10 years since that review, there has been little rigorous research specific to the older population. The following conclusions are drawn from the recent meta-analytical reviews [323;366] of efficacy of laxatives in treating chronic constipation in adults (it should be noted that none of these studies had relief of constipation-related FI as an outcome measure):

- Availability of published evidence is poor for many commonly used agents including senna, magnesium hydroxide, bisacodyl and stool softeners
- In trials conducted in older people, significant improvements in bowel movement frequency were observed with a stimulant laxative (cascara) (Level of evidence 3) and with lactulose (2), while psyllium (2) and lactulose (2) were individually reported to improve stool consistency and related symptoms in placebo-controlled trials
- Level (1) evidence supports the use of polyethylene glycol (PEG) in adults
- Level (2) evidence supports the use of lactulose and psyllium in adults
- None of the currently available trials include quality of life outcomes
- In trials conducted in older adults (>55 years) there is little evidence of differences in effectiveness between categories of laxatives
- A stepped approach to laxative treatment in older people is justified, starting with cheaper laxatives before proceeding to more expensive alternatives
- Note that none of these studies had relief of constipation-related FI as an outcome measure.

Polyethylene glycol (PEG) is a potent hyper-osmolar laxative. An RCT evaluating its use in treatment of faecal impaction (in combination with daily enemas) in elderly nursing home residents, showed greater efficacy than lactulose, without the dehydration or haemodynamic side-effects. Another RCT of adults (aged 17-88) with fecal loading on Xray or rectal examination, and bowels not open for 3-5 days showed that 1L (or 8 sachets) a day of PEG plus electrolytes (Movicol®) for 3 days resolved impaction in 89% of patients, with few adverse effects. The current evidence base suggests that the role of PEG in older people is for acute disimpaction (ensuring that easy toilet access is guaranteed), and for regular use as a laxative only in high risk people whose constipation has proved resistant to milder and cheaper alternatives (e.g. senna).

Enemas and suppositories have a role in both acute disimpaction, and in preventing recurrent impactions in susceptible patients [25;225]. They induce evacuation as a response to colonic distension. Frail elderly patients with recurrent episodes of overflow FI despite regular laxative and suppository use can benefit from weekly enemas. Regular use of phosphate enemas should be avoided in patients with renal impairment as dangerous hyperphosphatemia may occur [367]. Tap water enemas are the safest type for regular use, although they take more nursing administration time than phosphate enemas, and are not available in certain countries. Soapsuds enemas should never be administered to older patients. Arachis oil retention enemas are particularly useful in loosening colonic impactions. In patients who have a firm and large rectal impaction, manual evacuation should be performed before inserting enemas or suppositories, using local anesthetic gel if needed to reduce discomfort.

The value of treating constipation in preventing FI in frail older people has not yet been reported.

c) Treatment of dementia-related FI

Prompted toileting programmes significantly increased the number of continent bowel movements in an uncontrolled study of elderly nursing home residents in the US with dementia-related incontinence over a period of a few weeks, but no impact was seen on frequency of FI [368]. A further nursing home RCT showed that prompted toileting in frail residents significantly reduced the frequency of FI and increased the rate of appropriate toilet use in the intervention group, but did not overall impact the primary outcome measure of pressure ulcers [132].

A bowel programme in 25 nursing home residents with dementia-related FI consisting of daily codeine phosphate and twice weekly enemas achieved continence in 75% of those fully treated [25].

d) Treatment of anorectal FI in older adults

Biofeedback treatment for FI in older people resulted in a 75% reduction in incontinent episodes short-term in one small study of a highly selected group of patients with no cognitive impairment, good motivation and intact anorectal sensation [244]. Pelvic floor retraining is effective treatment in older women with urinary incontinence [369], and there is no evidence to suggest that frail older people without significant cognitive problems are any less able to adhere to such programmes.
There is no data on the use of Loperamide in frail older people. Expert opinion suggests that it should be used only with extreme caution and monitoring for impaction in this patient group.

e) Treatment of loose stools in frail older people

For prevention of C. Difficile in frail older hospital inpatients (and consequent loose stool with FI in those with weak sphincters), strict antibiotic policies and hand washing by all staff before and after contact with patients have been shown to reduce the risk of infectious disease. Preliminary trials suggest that use of probiotic yogurt drinks started simultaneously with antibiotic prescribing and continued for 2 weeks after course completion can reduce antibiotic-related diarrhoea and C.Difficile incidence.

f) Multi-component treatment of FI in frail older people

While a multidimensional approach to FI treatment would clearly be indicated in view of the multifactorial causation in older people, there are few published studies of multicomponent interventions. A UK RCT in frail older stroke survivors with constipation and/or FI evaluated a one-off assessment leading to targeted patient/carer education with a booklet, and treatment recommendations to the routine health care provider [144]. At one year follow-up the intervention group (as compared with controls receiving usual care) were more likely to be altering their diet and fluid intake to control their bowels, and at 6 months had significantly more 'normal' defecations. This type of evaluation does not define any specific action that had a particular beneficial effect, but does test a multicomponent approach that non-specialist doctors and nurses could feasibly apply in various settings (see Figure 1).

A US study specifically looked at self-care practices among 242 home-dwelling older people with FI [147]. Most commonly used practices were dietary change, wearing pads, and limiting activity.

A UK study asked frail older patients with FI about privacy during defecation [370]. Adequate privacy was reported by only 23% of nursing home residents, and 50% of hospital inpatients. Lack of privacy, particularly in dependent older people in institutions, is a major care issue.

SUMMARY OF EVIDENCE ON THE TREATMENT OF FI IN FRAIL OLDER PEOPLE

- Current evidence shows that stimulant laxatives, osmolar laxatives (PEG and lactulose), suppositories and enemas can be effective in treating faecal impaction in older people at risk of overflow (Level of evidence 2).
- Complete rectal clearance is required to reduce overflow FI (2), but may be hard to achieve in frail older patients (2). Weekly digital rectal examination is helpful in monitoring the effectiveness of a bowel clearance programme (2).

- Structured approaches to bowel care (including prompted toileting) can reduce the frequency of FI in the nursing home setting (2)
- Older people with FI may benefit from biofeedback and sphincter strengthening exercises if they are able to comply (3)
- Loperamide can reduce frequency of FI, particularly when associated with loose stool (once infection and other causes have been excluded) but should be used with caution (2)
- Changes in antibiotic prescribing and use of probiotics in antibiotic users can reduce the risk of C.Difficile and antibiotic related diarrhoea in older people (2)
- Multicomponent structured nurse-led assessment and intervention can improve bowel symptoms and alter bowel-related habits in older stroke patients (2)
- Self-care practices are prevalent in older people with FI, especially in those with more severe FI (3)
- Dependent older people with FI in care homes and hospital often lack privacy during defecation (3)

RECOMMENDATIONS - TREATMENT OF FI IN FRAIL OLDER PEOPLE (ALL GRADE C)

- Patients identified as having constipation with overflow should have effective bowel clearance (using a combination of laxatives and enemas), and then maintenance therapy with stimulant or osmotic laxatives
- Regular digital rectal examinations should be performed to assess the effectiveness of a bowel clearance programme in frail older people with overflow
- Suppositories are useful in treating rectal outlet delay and preventing recurrent rectal impaction with regular use
- Loperamide is a useful treatment in anorectal FI, in the absence of constipation, but should be used with caution
- Causes of loose stool must be identified and treated. In the case of C. Difficile, appropriate preventive measures should be taken, particularly in frail older people who are at risk of recurrent infection
- All frail older people with FI should have a structured multidisciplinary assessment and treatment of their bowel problem. Figure 1 summarises a structured approach that can be used in multiple health care settings.
**8. AREAS FOR FURTHER RESEARCH ON FI IN FRAIL OLDER PEOPLE**

- Patient and carer education (using verbal and written materials) should be undertaken to promote self-efficacy and other coping mechanisms, and where appropriate self-management (e.g. reducing risk of constipation and impaction through dietary and lifestyle measures, advice on how to take loperamide). Advice on skin care, odour control, and continence aids is also important.
- Privacy and dignity of care during defecation should be afforded to all older people in institutionalised settings. Particular attention should be paid to this in patients with FI, as privacy may be relatively overlooked in their care.
- Greater emphasis needs to be placed on systematic and effective management of FI in older people backed up by sound communications between all health care providers, especially in the nursing home and acute hospital setting.
- Education of health care providers with regards to heightening awareness of the problem plus methods of identification, assessment and management of FI in older people should be broad-ranging and include geriatricians, general practitioners, hospital physicians, hospital, community, general practice and long-term care nurses, and related disciplines (physiotherapists, occupational therapists, dieticians, pharmacists).
- Cyclical national audit with provider accountability, of current practice in managing FI in older people is needed to lay the ground-work for standardized care, and provide a culture of continuous quality improvement. Such audit tools should be developed using standardized consensus methodologies (35). Incentives to providers could be benchmarking their practice against national averages, opportunities to share successful practice change strategies, and professional validation linked to good practice.

**• Trials of laxative and nonpharmacological treatment and prevention of faecal impaction and overflow are needed to optimise standards of prescribing and care.**

**• Multicomponent interventions to treat FI in frail older people should be evaluated in applied research projects to assess effective ways of delivering this type of intervention within routine health care settings.**

**• Multidisciplinary study assessing the feasibility and efficacy of a step-wise approach to the management of dementia-related FI in nursing home residents (prompted toileting in those with mild to moderate dementia, scheduled toileting plus suppositories next step, and a bowel programme of controlled evacuation in those with persistent incontinence) would provide useful evidence.**

- The challenges of undertaking RCT’s in frail older people are summarised in the chapter on urinary incontinence in frail elderly (Committee 11). In particular, it is important to balance feasibility and practicality versus high strength intervention, i.e. a team of specialist continence nurses in nursing homes are likely to have an impact, but at what cost, and what carry-over will there be when they are gone? Other methodologies (e.g. pre-post with multivariate case-mix adjustment) should also be considered.

**• Evaluation of case-finding methods for FI in different settings including the fundamentals of staff education, screening protocols, patient’s educational information would be very informative.**

**• Testing the feasibility of providing an integrative approach to assessment of FI in the frail older person, including a range of health and social care providers and different health care settings (acute, intermediate or sub-acute, long-term care, and community) would be relevant to national implementation of bowel care improvement programmes.**

**• Examination of the variability of FI rates between nursing homes within single nation states, (taking into consideration case-mix) will highlight problems areas both organizationally and clinically. Nursing home administrative factors such as resident:nurse staff ratios should be evaluated as a contributing factor to FI.**

**• Further epidemiological studies are required to document causes of FI in frail older people in different health care settings. Such studies should include evaluation of unmet need for patients and carers.**

**• Evaluation of aetiologies, and in particular the pathophysiological basis for high prevalence of FI in older men. Evaluation of potentially preventable causes of loose stools in institutionalized older people, and impact of their treatment on FI.**

**• Nurse-led initiatives are needed to develop care pathways for assessing of bowel problems in frail older people with a view to establishing integrated service delivery.**

**• Examine the research question, ‘Do educational interventions by health care providers to informal carers of home-dwelling older people with FI reduce carer burden and improve quality of life for patient and carer?’**
X. CONCLUSIONS, RECOMMENDATIONS AND ALGORITHM

1. PREVENTION

a) Primary prevention:
   • Public health measures to prevent diarrhoeal diseases (Grade of recommendation B/C)
   • Treat reversible causes of diarrhoea (C)
   • Obstetric: no convincing evidence of role for preventive caesarean section; avoid midline episiotomy; restrictive rather than liberal episiotomy protocols (A)
   • Discourage the use of internal anal sphincter division for treatment of anal fissure and haemorrhoids (A)

b) Secondary prevention:
   • Active case finding/screening in high risk groups (C)
   • Proactive bowel management in high risk groups (e.g. neurological) (C)
   • Optimise stool consistency in people with loose stools (all ages); hard stools (children and older populations) (B)
   • Treat obesity? (D)
   • Consider medication alternatives in patients with FI & medication-induced diarrhoea (C)
   • Alert patients to risk of FI following colorectal surgery (C)

c) Recommendations for research on prevention
   • Longitudinal studies to map natural history, especially in women with obstetric risk factors
   • Prevention studies in childbearing women and other high risk groups
   • Colorectal surgery and radiotherapy techniques
   • Bowel management strategies in high risk groups (e.g. neurological)
   • Understanding mechanisms of FI in men
   • Frail: community prevention/screening/early treatment to prevent NH admission
   • Measures to prevent/reduce FI in nursing homes (functional FI, staffing etc)

2. EDUCATION AND LIFESTYLE
   • Medication side effects: consider alternatives if causing diarrhoea (C)
   • Toilet access for people with disabilities (C)
   • Education
     - of patient (B/C)
     - of carer (C)
   • Complementary therapies: no evidence (D)

There is insufficient evidence to recommend or discourage most lifestyle modifications either for the prevention or treatment of FI. Based on the consensus of experts (Level 3 evidence) the committee recommends patient education about the causes of FI and a systematic effort to remove barriers to effective toileting, are both interventions that are likely to be beneficial. They may be provided at relatively low cost and they involve no significant risk to the patient.

Recommendations for research on education and lifestyle

• Based on encouraging preliminary reports that patient education, combined with conservative medical management, can reduce the frequency of FI, we recommend further research. An RCT may not be possible due to the challenge of identifying a suitable control for expectancy and attention. A study which demonstrates a sustained benefit from a limited educational intervention (provided to patients or caregivers), would provide useful guidance for clinical management.

• Further investigation of the benefits for FI of weight reduction, especially in moderately obese patients without bariatric surgery.

• Exercise programmes, when incorporated into a multi-component intervention, have produced promising preliminary results and should be tested further. Such trials should differentiate between constipation-associated FI and diarrhoea-associated FI as exercise may be more beneficial to the former group.

• Evaluation of the incremental or additive value of different lifestyle interventions in the patient pathway.

Research on the contribution of complementary therapies.

3. DIET AND FLUIDS
   • Soluble dietary fibre is recommended for the management of FI associated with loose stool. This recommendation is made despite inconsistent results between two RCTs because the methodology for the positive study was significantly better than that of the other study. (Evidence level 1. Recommendation Grade B).

   • Dietary fibre is not recommended as an adjuvant to antimotility medication for managing AI when stools are not loose or liquid. (Evidence level 2 Grade B).

   • Patients should be asked about dietary restrictions and meal skipping.
Recommendations for research on diet and fluids

Further studies on the effect of dietary fibre and other diet modifications on FI are encouraged to build a greater body of evidence. Because dietary fibres differ in their chemical composition and properties, future studies are recommended to determine the optimal type and amount of fibre to use for FI. Whether a dietary intervention can augment other behavioural interventions, such as pelvic floor muscle exercises or bowel training, needs further study.

- Role of fibre and fluid in constipation/impaction related FI
- Effect of diet and eating pattern as a management strategy for FI
- Role of caffeine restriction in the treatment of FI and AI

There are several recommendations for methodological rigour in future studies. Theory-based, adequately powered, controlled trials are sought. Studies should control for variability in an individual’s baseline severity of incontinence and any adjuvant therapies. Monitoring adherence to the dietary intervention is recommended. A common set of outcome measures that includes tolerance to diet interventions is recommended. Reporting outcomes of FI in addition to those of AI (which incorporates flatus incontinence) is recommended.

4. BOWEL TRAINING

- Attempt to establish a bowel routine (C)
- Urgency resistance training possibly useful for urgency (D: need for research)
- No evidence on behaviour modification methods (D: need for research)
- Digital stimulation and manual evacuation useful in neurological patients (C)
- Rectal irrigation is useful in SCI (B) and has potential in other patients with FI (D)

Recommendations for research on bowel training

Research is needed in all areas.

Combination studies with urinary incontinence are recommended.

5. DRUG TREATMENT OF FI

- Treat FI with diarrhoea with anti-diarrhoeal medication (C); titrate the dose to individual response (C)
- We are unable to recommend sphincter function modifying drugs (D)
- Use oral or rectal laxatives/evacuants to treat constipation-associated FI (C): no evidence on the most effective agent. Need to confirm impaction is resolved (C)
- For constipation-associated FI, there is level 2 evidence suggesting that daily or more frequent oral laxative regimens may be effective for the treatment of constipation-associated FI in nursing home residents and children, but there are conflicting data.

Drug treatment of FI: recommendations for research

- Additional, well-designed studies are needed to validate the common clinical practice of using laxatives to treat constipation-associated FI.
- There is a need for further research on preparations, doses and combination therapies for all types of FI and all patient subgroups.

6. BIOFEEDBACK AND/OR ANAL SPHINCTER / PELVIC FLOOR MUSCLE TRAINING

Because recent RCTs have raised questions as to whether biofeedback provides a specific benefit relative to education and good clinical management despite a large body of uncontrolled studies supporting its efficacy, the consensus of the committee is that it is possibly effective but currently unproven. This reinforces the case for using maximal education, lifestyle and dietary interventions before PFMT or BFB, as recommended by recent national guidelines in the UK.

- PFM exercises are recommended as an early intervention in the treatment of FI as part of a conservative management bundle of interventions, based upon low cost and morbidity and weak evidence suggesting efficacy (C).
- The use of biofeedback as a treatment for FI is recommended after other behavioural and medical management has been tried if inadequate symptom relief is obtained, given the numerous positive outcomes from uncontrolled trials, limitations in the current RCTs and low morbidity associated with its application (C).

Recommendations for research

There is a need to conduct further RCTs to determine whether specific biofeedback and pelvic floor muscle exercise protocols can alter physiological parameters of ano-rectal function with concomitant changes in bowel control.

- Clear description of modalities and evaluation of different elements of BFB
- Adherence monitoring
- Standardisation of outcome measures
- Long term follow up
- Robust patient-focused outcome measures
7. ELECTRICAL STIMULATION FOR FI

Based on currently available evidence it is not possible to recommended electrical stimulation for FI.

Recommendations for research on electrical stimulation for FI

• Randomised controlled trials with adequate sample sizes are necessary to investigate all aspects of the effectiveness of ES in FI.
• The effect of electrical stimulation in changing consciousness of the pelvic floor is one of the interesting future areas for research.
• When planning future research basic knowledge of electrical stimulation parameters and their likely physiological effects is essential.

8. FI IN FRAIL OLDER PEOPLE

Bowel continence status should be established by direct questioning and/or direct observation in:
• all nursing and residential home residents
• hospital inpatients aged 65 and over
• people aged 80 and beyond living at home
• older adults with impaired mobility
• older adults with impaired cognition
• older adults with neurological disease
• older adults with chronic disease

Appropriate investigation and active treatment is needed in all older adults with FI (see Chapter for details).

Therapy for faecal incontinence is readily divided into non-surgical and surgical therapy. Selection of specific therapy is based upon a number of considerations, including the severity of incontinence and structural integrity of the anal sphincter.

Conservative therapy is most applicable to relatively mild cases of incontinence. Biofeedback retraining can be attempted for incontinence of any cause or severity, as the therapy is painless and risk-free. These treatments are discussed in detail elsewhere in this monograph.

The most widely accepted surgical therapy for faecal incontinence is overlapping sphincteroplasty. Typical of other well-established therapies, the evidence base supporting this approach is paradoxically less robust than that supporting more recent treatment options. Sphincteroplasty is useful only in cases in which there is an anatomic sphincter defect, and it has been reported to provide satisfactory results in many case series. However, several recent studies have now shown that results of sphincteroplasty deteriorate with time [1, 2].

A number of operations were developed in the early to mid 20th century to provide a treatment option for patients whose native sphincter was either intact but weak or not repairable. Muscle transposition procedures using either gluteus maximus or gracilis were devised to create a functional biological neosphincter, but the approach did not gain widespread popularity. The Parks postanal repair was devised in 1975 to treat patients with incontinence due to pelvic neuropathy [3].

Dissatisfaction with available operations for faecal incontinence led to development of a variety of novel procedures during the last 20 years. The stimulated (dynamic) graciloplasty and the artificial anal sphincter were devised as salvage procedures for patients who had failed or were not candidates for standard therapy. A more recent approach is the use of sacral nerve stimulation, which was adopted for this purpose from its previously better-defined role in urinary voiding dysfunction. Moreover, there has also been a trend towards development of minimally invasive approaches to faecal incontinence, such as the use of injectable biomaterials.

Several important caveats apply to interpretation of the results of surgery for faecal incontinence reported in the literature. First, the vast majority of reports are uncontrolled case series. Randomized controlled studies are rare, and those reported include only small numbers of patients [4]. Second, numerous quantitative measures have been used to report outcomes, but only recently have any of these been validated, such as the Faecal Incontinence Quality of Life (FIQL) instrument. Third, criteria for “successful” outcomes have been variable and often arbitrary. Fourth, the quality of data reported is variable, though it has generally improved with the passage of time. Chart review has been supplanted by patient questionnaires and interviews by independent data auditors; daily continence diaries, the most stringent form of data collection, have become increasingly commonplace (though not routine). Despite the fact that studies using lax data collection are certain to report better results than those using methodology that is more stringent, of necessity, composite reviews of surgical results include studies using various methods of data collection. Finally, results are not always reported on an intention to treat basis, particularly in the implantable device literature.

SEARCH METHODS
PubMed search was conducted to identify studies published on the use of surgery for faecal incontinence in children and adults. Keywords used were faecal incontinence and surgery. Full text copies of studies deemed to be potentially relevant were obtained. Priority was given to systematic reviews, randomized controlled trials, and controlled clinical trials; if those were unavailable or inadequate, comparative observational studies, case series, case reports and narrative reviews were also included. Reviewers were not blinded to the names of studies’ authors, institutions or publications. In view of the nature of the guideline, priority was given to the reports with large number of
A meta-analysis of 717 vaginal deliveries found an incidence of anal sphincter injury is higher [6, 7]. 

It can be prospectively looked for with endoanal ultrasound, second and subsequent deliveries [5]. When following primiparous delivery and 0.5-1% following anal sphincter injury (grade 3 or 4 tear) is low, 3-5% in Western obstetric practice, the incidence of overt other pathology particularly surgery for anal fistula. 

Mechanisms are more commonly involved in primary repair of injury that is the result of blunt or penetrating trauma. Occasionally, the anal sphincter mechanism is damaged during anorectal surgery for other pathology particularly surgery for anal fistula. 

In Western obstetric practice, the incidence of overt anal sphincter injury (grade 3 or 4 tear) is low, 3-5% following primiparous delivery and 0.5-1% following second and subsequent deliveries [5]. When prospectively looked for with endoanal ultrasound, the incidence of anal sphincter injury is higher [6, 7]. 

A meta-analysis of 717 vaginal deliveries found an incidence of new anal sphincter defects of 27% in primiparous and 9% in multiparous women using 2D endo-anal ultrasound [8]. 3D ultrasonography suggests that the incidence is somewhat less, perhaps 11%, following primiparous delivery [9]. The risk factors for sphincter injury include instrumental vaginal delivery, prolonged second stage of labor, fetal macrosomia, and a persistent occipito-position of the fetal head [7, 10-12]. Midline episiotomy is associated with higher incidence of anal sphincter injury and the angle of mediolateral episiotomy may also influence perineal outcome [13]. A policy of restrictive use of episiotomy may reduce the incidence of anal sphincter injury [14]. 

Obstetric injury of the perineum is classified as a first degree tear if confined to vaginal epithelium and skin, second degree if the perineal muscles are torn, third degree if the anal sphincter muscles (external: EAS; internal: IAS) are torn, (3a: less than 50% EAS torn; 3b: more than 50% EAS torn; 3c: IAS torn), or fourth degree if both EAS and IAS and rectal or anal mucosa are torn [15]. Primary repair of an obstetrical tear is correctly termed anal sphincter repair and is usually performed by the obstetrician immediately after delivery most commonly in the delivery room under local or epidural anesthetic. By tradition, the technique of repair has been a direct oppositional repair of the severed external anal sphincter. The internal anal sphincter, if divided, is difficult to identify separately and when separately repaired it is usually en block with the anal canal mucosa in a complete or 4th degree tear. There have been four randomized clinical trials [16-19] and one meta-analysis [20] that have investigated different techniques of immediate primary repair of the external anal sphincter following obstetric injury. 

There was a trend towards better outcome with an overlap repair; however, the meta-analysis concluded that it would be inappropriate to favor one type of repair over another [20]. [LEVEL OF EVIDENCE: 1] With regard to management of the internal anal sphincter, Mahoney et al [21] have shown persistence of an IAS defect to be adversely associated with continence outcome in a series of 500 consecutive women assessed following repair of a 3rd or 4th degree tear. 

It has been suggested that primary anal sphincter repair might be best performed by a colorectal surgeon rather than an obstetrician [22]. Nordenstam et al [23] concluded, in a single institution study of 156 women, that technique and expertise impact on the outcome of primary repair and that if needed, the repair could be safely delayed until such expertise was available. Soerensen et al [24] have found no adverse outcome with delayed primary repair. [LEVEL OF EVIDENCE: 2] 

There have been two randomized trials of post-operative management of the bowel after primary anal sphincter repair. These have shown benefit in use of a laxative rather than a constipating regimen but no advantage to the addition of a stool bulking agent [25, 26]. [LEVEL OF EVIDENCE: 1] 

Alteration in faecal continence occurs in approximately 13-17% of women following primiparous vaginal delivery [6, 27, 28]. The prevalence is greater if urgency of defecation is included as a symptom [7]. Incontinence to flatus has been reported in up to 27% of 7,879 women surveyed 12 weeks after delivery [29]. [LEVEL OF EVIDENCE: 2] The prevalence is significantly higher in women who have undergone anal sphincter repair. Fenner et al [30] found that women who had sustained third and fourth degree tears were more likely to have bowel incontinence than women without anal sphincter injury 6 months following delivery. This was more pronounced in women with a history of 4th degree tear. Mahoney et al [21] studied 500 consecutive women after repair of a recognized 3rd or 4th degree tear and found some alteration in continence in 50% at 3 months post partum. The median Cleveland Clinic Continence score [31] in this cohort was 2 (range 0-19) and 4.4% of defecation is included as a symptom [7]. 

Non-English language papers were noted but excluded from the review unless they contained an English-language abstract providing sufficient information.

A. SURGERY FOR ADULT FAECAL INCONTINENCE

I. SPHINCTER REPAIR

Anal sphincter repair is the term used to describe primary repair of the anal sphincter mechanism following direct trauma. The most common indication is following childbirth and repair in this situation is usually performed by the attending obstetrician. Colorectal surgeons are more commonly involved in primary repair of injury that is the result of blunt or penetrating trauma. Occasionally, the anal sphincter mechanism is damaged during anorectal surgery for other pathology particularly surgery for anal fistula. 

In Western obstetric practice, the incidence of overt anal sphincter injury (grade 3 or 4 tear) is low, 3-5% following primiparous delivery and 0.5-1% following second and subsequent deliveries [5]. When prospectively looked for with endoanal ultrasound, the incidence of anal sphincter injury is higher [6, 7]. 

A meta-analysis of 717 vaginal deliveries found an incidence of new anal sphincter defects of 27% in primiparous and 9% in multiparous women using 2D endo-anal ultrasound [8]. 3D ultrasonography suggests that the incidence is somewhat less, perhaps 11%, following primiparous delivery [9]. The risk factors for sphincter injury include instrumental vaginal delivery, prolonged second stage of labor, fetal macrosomia, and a persistent occipito-position of the fetal head [7, 10-12]. Midline episiotomy is associated with higher incidence of anal sphincter injury and the angle of mediolateral episiotomy may also influence perineal outcome [13]. A policy of restrictive use of episiotomy may reduce the incidence of anal sphincter injury [14]. 

Obstetric injury of the perineum is classified as a first degree tear if confined to vaginal epithelium and skin, second degree if the perineal muscles are torn, third degree if the anal sphincter muscles (external: EAS; internal: IAS) are torn, (3a: less than 50% EAS torn; 3b: more than 50% EAS torn; 3c: IAS torn), or fourth degree if both EAS and IAS and rectal or anal mucosa are torn [15]. Primary repair of an obstetrical tear is correctly termed anal sphincter repair and is usually performed by the obstetrician immediately after delivery most commonly in the delivery room under local or epidural anesthetic. By tradition, the technique of repair has been a direct oppositional repair of the severed external anal sphincter. The internal anal sphincter, if divided, is difficult to identify separately and when separately repaired it is usually en block with the anal canal mucosa in a complete or 4th degree tear. 

There have been four randomized clinical trials [16-19] and one meta-analysis [20] that have investigated different techniques of immediate primary repair of the external anal sphincter following obstetric injury. There was a trend towards better outcome with an overlap repair; however, the meta-analysis concluded that it would be inappropriate to favor one type of repair over another [20]. [LEVEL OF EVIDENCE: 1] With regard to management of the internal anal sphincter, Mahoney et al [21] have shown persistence of an IAS defect to be adversely associated with continence outcome in a series of 500 consecutive women assessed following repair of a 3rd or 4th degree tear. 

It has been suggested that primary anal sphincter repair might be best performed by a colorectal surgeon rather than an obstetrician [22]. Nordenstam et al [23] concluded, in a single institution study of 156 women, that technique and expertise impact on the outcome of primary repair and that if needed, the repair could be safely delayed until such expertise was available. Soerensen et al [24] have found no adverse outcome with delayed primary repair. [LEVEL OF EVIDENCE: 2] 

There have been two randomized trials of post-operative management of the bowel after primary anal sphincter repair. These have shown benefit in use of a laxative rather than a constipating regimen but no advantage to the addition of a stool bulking agent [25, 26]. [LEVEL OF EVIDENCE: 1] 

Alteration in faecal continence occurs in approximately 13 - 17% of women following primiparous vaginal delivery [6, 27, 28]. The prevalence is greater if urgency of defecation is included as a symptom [7]. Incontinence to flatus has been reported in up to 27% of 7,879 women surveyed 12 weeks after delivery [29]. [LEVEL OF EVIDENCE: 2] The prevalence is significantly higher in women who have undergone anal sphincter repair. Fenner et al [30] found that women who had sustained third and fourth degree tears were more likely to have bowel incontinence than women without anal sphincter injury 6 months following delivery. This was more pronounced in women with a history of 4th degree tear. Mahoney et al [21] studied 500 consecutive women after repair of a recognized 3rd or 4th degree tear and found some alteration in continence in 50% at 3 months post partum. The median Cleveland Clinic Continence score [31] in this cohort was 2 (range 0-19) and 4.4%
had a score >9, a score deemed to be socially disruptive [32]. [LEVEL OF EVIDENCE: 2]

Management of subsequent labor following a previous anal sphincter tear must take account of obstetric risk factors, symptoms of incontinence and patient preferences. Harkin et al [12] found an approximately 5 fold increase in the incidence of recurrent sphincter tear compared to the incidence of first sphincter injury during second labor. Fynes et al [33] found that women with altered continence after first vaginal delivery were at risk of deterioration if delivered vaginally on their second pregnancy. Caesarian delivery before the onset of the second stage of labor was found to be protective [33]; however, in a systematic review, Nelson et al [34] found that pregnancy rather than delivery was a more important indicator of post partum continence. [LEVEL OF EVIDENCE: 3]

A number of studies have looked at long term outcomes after repair of a 3rd or 4th degree tears and all have shown an increasing prevalence of continence disorders with age. These findings parallel those of the general population of parous women who have not had a recognized tear [35-37]. Eogan et al [38] found in a study of women 10, 20 and 30 years following delivery that onset of menopause was the most significant determinant of symptoms, whereas Mous et al [39] found the incidence of incontinence increased with age irrespective of menopausal status. Fornell et al [40] found that subjective and objective anal function after an sphincter injury deteriorates with time and subsequent deliveries. A persistent defect in the internal anal sphincter was found to be an important determinant, an observation supported by Mahony et al [21]. [LEVEL OF EVIDENCE: 3]

II. SPHINCTEROPLASTY

The term anal sphincteroplasty is used to describe secondary or delayed reconstruction of the anal sphincter musculature, injury to which has either not been recognized at the time of injury or the outcome of primary repair has been unsatisfactory. Anterior sphincteroplasty is the most common type of reconstruction performed because of the association with obstetric injury. In this situation, the anal sphincter muscles and perineal body have separated, leaving a large defect in the anterior quadrants with horseshoe type configuration to the anal sphincter mechanism. Occasionally, the defect is such that the anal and vaginal mucosa have healed to form a cloacal defect. Anal sphincter defects related to previous anal fistula surgery or direct trauma are usually less complex and are not associated with a deficient perineum. The results of sphincteroplasty are shown in Table 1 [1, 2, 41-56].

# metanalysis  * Median follow-up  + 130/190 available for 10 year follow-up  $ defined as “successful”
The decision to perform anal sphincteroplasty is a function of symptoms and the anatomical extent of the sphincter defect [56]. In assessing symptoms, one of several continence scores should be used [31, 57, 58]. The two most commonly applied are the Cleveland Clinic Continence Score [31] and the St Mark's Continence Score [59]. In addition, a quality of life instrument should be applied [32]. Endoanal ultrasound is helpful in defining the extent of anal sphincter injury. 3D endoanal ultrasonography may provide further information [9]. Pelvic floor assessment using fMRI [60] or multiple contrast defecating proctography [61] is valuable in the assessment of a more global pelvic floor injury. [LEVEL OF EVIDENCE: 4]

Other causes of disordered continence should be excluded, e.g., inflammatory bowel disease, colorectal cancer and neurological lesions. Patients with background IBS are more likely to be symptomatic than those more predictable bowel habit and equivalent anal sphincter defects [62]. Pelvic floor electrophysiological assessment, while not essential, should be comprehensive and not confined to measurement of pudendal nerve terminal motor latency [63].

For symptomatic patients with a less than one quadrant anal sphincter defect, a trial of dietary modification, stool regulating drugs and physiotherapy is appropriate. There are limited data regarding the role of biofeedback with or without electrical augmentation [64, 65]; however, a recent Cochrane review concluded there were insufficient data to allow definitive assessment [66].

For patients with a more than one quadrant anal sphincter defect, anal sphincteroplasty is appropriate [4, 15, 56]. Preoperative counseling should identify post operative wound healing as the most common difficulty. The majority of patients can expect significant improvement in continence after the procedure, with a mean of 66% reporting excellent or good results in the short term [56]. [LEVEL OF EVIDENCE: 3]

Concomitant repair of a cloacal defect or vaginal fistula should be undertaken [67, 68]. There is no evidence that a defunctioning colostomy improves outcome.

Anal sphincteroplasty can be performed in the lithotomy or in the prone jack-knife position. Full bowel preparation is often performed but not mandatory, although most surgeons at a minimum would give a cleansing enema pre-operatively. The conventional incision is an inverted ‘V’ that may be closed as an inverted ‘Y’ as described by Parks [69]. If anterior levatorplasty and particularly if rectocele repair is contemplated, then a posterior fourchette incision with the patient in lithotomy may have advantages [50]. The external anal sphincter is usually repaired using an overlapping technique without separate identification and repair of the internal anal sphincter [15]. There has been one small randomized trial of direct versus overlapping sphincteroplasty which showed similar outcomes [70].

Initial success of sphincteroplasty is related to whether the anal sphincter defect is corrected [42, 71]. Early failure is usually associated with a persisting defect, identifiable using endoanal ultrasound [72]. This may be amenable to a further attempt at repair [71, 73, 74]. There is, however, increasing evidence that continence outcomes deteriorate with long-term follow-up [15, 56]. In the largest study reported to date, Bravo Gutierrez et al [51] found that only 6% of patients retained full continence 10 years following anal sphincteroplasty. The effect of age at time of operation on long-term function is controversial [75, 76]; however, long-term atrophy of the sphincters may be relevant [15]. [LEVEL OF EVIDENCE: 2]

Pre-operative physiologic testing may be helpful in the overall management of patients with faecal incontinence. However, the value of anal manometry and pelvic floor electrophysiological assessment as prognostic indicators for outcome following sphincteroplasty is controversial. There are no established parameters that reliably predict outcome following sphincteroplasty [77, 78].

III. POSTANAL REPAIR

Postanal repair was first reported by Sir Alan Parks in 1975 [3]. This procedure was designed to increase the length of the anal canal, restore the anorectal angle and re-create the flap valve mechanism, which at the time was thought essential for maintaining faecal continence. Success rates ranged from 15% to 83%, depending on the definition of the success, the length of follow-up, and possibly the cause of incontinence. The published studies regarding postanal repair include two systematic reviews of randomized controlled trials (level 1) [4, 79], two randomized controlled trials (level 1 [80] and 2 [81]), two non-randomized cohort studies (level 2) [82, 83], 8 case series of good quality (level 3) [84-91] and 10 case series of poor quality (level 4) [3, 92-100]. The results of postanal repair are shown in Table 2 [3, 80-100].

Subsequent observational studies with a median follow-up of more than 5 years revealed that continence deteriorated with time. Despite 60% to 80% of patients reporting persisting improvement, only one-third were actually continent to liquid or solid stool [86, 89, 100]. Even in the most recent study reporting the “long-term” outcome of postanal repair [91], only 23% were continent to liquid or solid stool, while 68% improved symptomatically with a median follow-up of 3 years. Possible explanations for deterioration of continence following initial improvement included unrecognized denervation and/or muscular injury of the sphincter and pelvic floor musculature,

</table>
and the presence of occult anal sphincter disruption, particularly in the studies reported before endoanal ultrasonography or magnetic resonance imaging were available. Moreover, physiological and radiological evaluations before and after postanal repair have not demonstrated consistent changes in anal canal length, resting pressure, voluntary contraction pressure, anorectal sensitivity and movement of the anorectal angle [81-84, 101]. These reports of increasingly poor outcomes have diminished the popularity of this procedure significantly. [LEVEL OF EVIDENCE: 3]

Deen et al [80] in a randomized controlled trial comparing three procedures in 36 women with neuropathic faecal incontinence, found that complete continence was achieved in 42% of patients after postanal repair, 33% after anterior levatorplasty, and 67% after total pelvic floor repair. In contrast, van Tets et al [81] conducted a randomized controlled trial comparing postanal repair and total pelvic floor repair in 20 women with neurogenic faecal incontinence. Complete continence to solid or liquid stool was achieved in 27% of patients after postanal repair and in 22% after total pelvic floor repair.

IV. NON-STIMULATED MUSCLE TRANSPOSITION

A variety of muscle transposition procedures have been devised for the treatment of faecal incontinence. Early efforts focused upon the use of transposed skeletal muscle to supplement the function of a weak or disrupted anal sphincter. Early in the 20th century, a number of surgeons utilized gluteus maximus muscle, transposed in a variety of configurations, to create a neosphincter [102, 103]. In 1952, Pickrell et al [104] described the use of transposed gracilis muscle to create a neosphincter for incontinent children.

Published series of gracilis transposition are uncontrolled and demonstrate variable success rates [105-114]. [LEVEL OF EVIDENCE: 3] One study reviewed the functional results of graciloplasty longitudinally in 22 patients followed for a median 63 months [115]. 18 patients (81%) were improved at 6 months, though only one regained normal continence. Results deteriorated in 5 patients during subsequent follow up. Bilateral gracilis transposition has been used successfully in several small series [106, 116].

Success rates following gluteus transposition have likewise been variable [117-121]. [LEVEL OF EVIDENCE: 3] A prospective randomized trial in women with post-obstetric neuropathic incontinence showed similar significant degrees of improvement following both gluteus maximus transposition and total pelvic floor repair [122]. A recent retrospective review of 25 gluteoplasty patients reported restoration of continence in 18 patients (72%) and partial restoration in an additional 4 patients (16%). Donor-site and peri-rectal complications occurred in 16 patients (64%) [123].

V. STIMULATED MUSCLE TRANSPOSITION

The transposition of the gracilis muscle to reconstruct the anal sphincter was first performed in children in 1952 [104]. The blood supply is primarily from a single proximal artery that allows excellent mobility for transposition [124]. Successful electrical stimulation of a previously transposed gracilis muscle was first reported in 1988 [125], and case series from 2 independent centers were simultaneously reported in 1991 [126, 127]. Baeten et al [126] showed improved continence in 8 of 10 patients; Williams et al [127] in 12 of 20.

Even after successful muscle transposition, functional outcomes are limited by two physiological factors. First, patients are unable to consciously maintain tonic contraction of their neosphincters over long periods of time. Furthermore, even if patient volition were not a problem, gracilis muscle is poorly suited to tonic contraction. While the external anal sphincter comprises predominantly slow-twitch, fatigue-resistant type I fibers, the gracilis muscle comprises predominantly type II, fast-twitch fibers that are rapidly fatigable [128]. Graded electrical stimulation transforms type II into type I muscle fibers [129], and use of an implantable electrical pulse generator has been shown to convert transposed gracilis to a muscle with predominantly type I fibers [126-128]. The gracilis muscle is well suited to electrical stimulation due to the relatively constant proximal location of the neurovascular bundle, which is easily identified at surgery [130].

The results of stimulated graciloplasty are shown in Table 3 [131-141]. [LEVEL OF EVIDENCE: 2] In 1995, Baeten reported his results in 52 patients, with 38 (72%) becoming continent after surgery [131]. In a subsequent paper by this group published in 2003, 200 patients followed for a median of 261 weeks were reported [139]. The overall success rate was 72%. Patients with incontinence due to trauma had the best results (82% success), while patients with incontinence due to congenital anorectal malformation had the worst results (52% success). 138 complications were reported, including disturbed evacuation in 32 patients (16%), infection in 24 (12%), pain in 16 (8%) and pulse generator displacement in 12 (6%). Ten patients (5%) had anorectal perforations, 7 of whom eventually obtained a successful outcome. Rosen et al [142] reported restoration of continence in 9 of 10 patients treated by dynamic graciloplasty using a “split-sling” wrap configuration. Sleznezef et al [143] treated 16
patients and 13 had improved continence. However, 8 patients suffered morbidity, resulting in 33 subsequent admissions and 23 reoperations.

Three multicenter prospective trials of dynamic muscle plasty have been performed to date [134-136]. In each of these studies, patients served as their own controls. No randomized prospective trials have been performed.

Madoff et al studied 139 patients from 12 centers, 128 of whom had gracilis wraps and 11 gluteus wraps. [134] Of those patients, 104 were treated for faecal incontinence, and 35 underwent total anorectal reconstruction following abdominoperineal resection for cancer. Success rates for graciloplasty were 71% for patients with acquired incontinence and 50% for those with incontinence due to a congenital abnormality. There were a total of 138 complications for the entire group. Wound complications (41 major and 35 minor) were both the most prevalent and the most consequential. Other complications included pain in 28 patients (22%), hardware problems in 14 (11%) and tendon detachment in 4 (3%). Centers with significant prior experience with the procedure had substantially fewer major wound complications (17.4 vs. 33.1%) and significantly higher success rates (80% vs. 47%).

Mander et al [135] reported the results of dynamic graciloplasty in 64 patients with refractory faecal incontinence treated at 7 centers. Of those patients, 104 were treated for faecal incontinence, and 35 underwent total anorectal reconstruction following abdominoperineal resection for cancer. Success rates for graciloplasty were 71% for patients with acquired incontinence and 50% for those with incontinence due to a congenital abnormality. There were a total of 138 complications for the entire group. Wound complications (41 major and 35 minor) were both the most prevalent and the most consequential. Other complications included pain in 28 patients (22%), hardware problems in 14 (11%) and tendon detachment in 4 (3%). Centers with significant prior experience with the procedure had substantially fewer major wound complications (17.4 vs. 33.1%) and significantly higher success rates (80% vs. 47%).

Baeten et al [136] reported the results of dynamic graciloplasty in 123 patients treated at 20 centers as part of the Dynamic Graciloplasty Therapy Study Group (DGTSG). The aims of this study were to assess both the safety and efficacy of this treatment; 189 adverse events occurred in 91 patients, including one death due to pulmonary embolism. There were 18 major and 31 minor infectious complications. There were 42 instances of therapy-associated pain, occurring variably in the donor leg, at the anal canal, or at the device site. There were 11 lead dislodgements but no problems with lead breakage or pulse generator malfunction. A follow-up study showed full or partial recovery from these complications in 87% of patients. [137] This study, in contrast to others, was based upon data from daily continence diaries. A successful result (defined as a 50% or greater decrease in incontinent events in patients without pre-existing stomas) was achieved in 63% of patients after one year. Another follow-up of this patient cohort demonstrated stable success rates at 18 months (55%) and 24 months (56%) [138]. Statistically significant improvements in the physical and social function scales of the SF-36 were also recorded at 12 months.

A multicenter retrospective trial from Belgium using dynamic graciloplasty treated 60 patients with 27 failures [140]. Continence was achieved in 78% of the group. However, more than half (26 patients) required the use of antegrade continence enemas or other measures to maintain continence. Seven patients had a permanent stoma constructed. Seventy-five complications occurred with 61 total reoperations. Loss of muscle stimulation occurred in 22 patients; 10 were due to issues specific to the stimulator and leads, 4 were due to technical failure of the muscle wrap. Functional outcome was directly associated with a

* variable definitions; does not necessarily denote perfect continence. Issues of divergence in technique arose from these studies, each of which has seen increasing consensus in the literature despite a lack of randomized trial data. Thus, intramuscular (vs. epineural) electrodes are now universally employed, and diverting stomas and ‘vascular delay’ prior to muscle transposition are no longer utilized.
maintenance of stimulation and initiation of stimulation within 50 days of surgery.

Very few studies have examined the long term results with dynamic muscle wraps. Thornton et al [144] reported on the 5-year follow up of 38 patients who had undergone dynamic graciloplasty. Of the 33 patients available for follow-up by telephone interview, obstructive defecation was a problem for 11% of the cohort and 16% had been converted to a permanent colostomy. Of those with a functioning graciloplasty (22 patients) who reported a faecal incontinence score of less than 12 (range 0-24), 50% reported problems with obstructive defecation and 64% felt their bowel habits had negatively impacted their quality of life. Long-term complications were primarily related to stimulator issues; ten patients required 15 operations to replace stimulator components. However, 72% of patients reported pain, swelling or paresthesias of the donor leg and 27% reported sexual dysfunction.

Tillin et al [141] performed a prospective case-comparison study of 49 patients who had a dynamic graciloplasty and 87 patients who either refused the surgery or were not offered the surgery. The primary outcomes evaluated were symptoms, quality of life, anxiety, and depression. Of the treated group, the procedure failed completely in 15 patients. At two year follow-up, two-thirds of patients were either never or rarely incontinent to liquid or solid stool. Up to 50% of patients with a satisfactory outcome reported disordered evacuation and 8 other patients were deemed failures due to this problem. In comparison to the 87 patients who did not undergo treatment, there were significantly more patients in the dynamic graciloplasty group who reported a greater than 20% improvement in their incontinence scores. However, the treated group also had a significantly worse pain as assessed on a validated pain scale.

Chapman et al [145] performed a systematic review of dynamic graciloplasty for faecal incontinence on behalf of the Australian Safety and Efficacy Register of New Interventional Procedures- Surgical (ASERNIP-S). The authors reviewed 37 original articles published between 1991 and October 2000. All of the papers were judged to be of low-evidence quality, as all but one paper were case series, and the sole comparative study utilized historical controls. Mortality excluding cancer deaths was 1% (95% confidence interval 1-3%) and morbidity 1.12 (95% CI 0.14 - 2.08) events per patient. Success was variably defined between studies, but was reported as ranging from 42-58%. The ASERNIP-S Review Group determined that “the safety of the procedure cannot be determined at the present time due to an incomplete and/or poor-quality evidence base” and that “efficacy is established.” Tan et al [146] examined three treatments for faecal incontinence including dynamic graciloplasty, artificial bowel sphincter and end stoma. They concluded that the most cost effective intervention was an end stoma, the artificial bowel sphincter was most cost-effective after 10 years and that dynamic graciloplasty should only be considered as an alternative in highly specialized centers.

VI. ARTIFICIAL ANAL SPHINCTER

Artificial sphincters have been used for the treatment of urinary incontinence since 1973 [147]. A success rate of 79% with a mean follow-up of 7.2 years has been reported. The device (AMS Sphincter 800® Urinary Control System, American Medical Systems, Minnesota, USA) and its subsequent modifications is a totally implantable system consisting of 3 parts: an inflatable occlusive cuff that is implanted around the native sphincter, a pressure-regulating balloon that is implanted in the prevesical space, and a control pump that is implanted in the labia majora or the scrotum. In 1987, Christiansen & Lorentzen [148] applied this device to a patient with faecal incontinence. The patient had an excellent result with no complications at a follow-up of three months.

Early promising results [149] prompted the modifications of the AMS Sphincter 800®, which eventually culminated in the development of Neosphincter® (American Medical Systems, Minneapolis, USA) that was specifically designed for faecal incontinence and became available in May 1996.

The published studies evaluating the safety and effectiveness of the newest sphincter system (Acticon Neosphincter®) include one randomized controlled trial (level 1) [150], one non-randomized cohort case control study (level 2) [151], 9 non-randomized cohort studies (level 2) [152-160], three systematic reviews of various types of studies with some heterogeneity (level 3) [161-163], one retrospective case control study (level 3) [164], 3 case series of good quality (level 3) [165-167], 4 case series of low quality (level 4) [168-171], and 3 case reports (level 4) [172-174]. The results of these studies except for case reports are shown in Table 4 [150-160, 164-171]. Two studies by Romano et al [175, 176] and two case reports [177, 178] were excluded from the analysis because artificial anal sphincters in those studies were not implanted for faecal incontinence, but as a part of total anorectal reconstruction in patients who had abdominoperineal resection for rectal cancer. [LEVEL OF EVIDENCE: 2]

No mortality was reported, but overall complication rate varied between 11 and 87%. Surgical site infections (9 to 58%) and erosion of the adjacent skin (6 to 32%) were common. Up to 46% of patients underwent revisional surgery, and the proportion of patients with a functioning device at the time of evaluation after follow-up of between 6 and 34 months ranged between

CCF-FI: Cleveland Clinic Florida Faecal Incontinence (0: full continence - 20: worst incontinence); AAS: artificial anal sphincter; DG: dynamic graciloplasty; SC: supportive care; GN: gracilis neosphincter; ns: not stated; *Success* is defined as “continence to solid and liquid stool without significant obstructed defecation, otherwise defined in each study.”
24 and 100%, with up to 67% patients having their devices explanted. Most of the patients (78 to 100%) with a functioning device were continent to solid stool, 56 to 95% were continent to solid and liquid stool, and 22 to 67% were completely continent. The success rate in patients with a functioning device was 44 to 100%, and the intention-to-treat success rate was 41 to 83%. Studies of smaller number of patients or shorter follow-up period tend to report better outcomes.

Wong et al [156] has reported the largest, multicenter prospective trial to date. Of 115 patients, 75 patients (65%) retained a functioning device after a median follow-up of 12 months. Overall complication rate was 87%. Forty-six percent of patients underwent revisional surgery and device explantation was required in 37%. Thirty patients (40%) experienced obstructed defecation with 21 reporting to have been impacted. A successful outcome was achieved in 85% of the 61 patients with a functioning device, while the intention-to-treat success rate was 54%.

With a longer follow-up period of presumably 5 years, Altomare et al [171] reported a poorer and “disappointing long-term” results. In their initial report of 28 patients in 2001 [166], 21 patients (75%) retained a functioning device with a median follow-up of 19 months. The success rate in patients with a functioning device was 76%, and the intention-to-treat success rate was 50%. In their follow-up study of the 21 patients who retained the device in their initial report, a further 4 patients had the device removed, because of mechanical failure (2), late infection (1) or untreatable obstructed defecation (1). Out of the 17 patients who continued to have an implanted device, 14 were available for long-term evaluation. Out of the 14 patients, 5 had a revision operation, and 8 no longer activated the device because of obstructed defecation (7) or anal pain (1). Obstructed defecation occurred in 7 patients, who were unable to defecate without an enema. Although 8 patients were reasonably continent to stool, 5 of them were significantly constipated. Over all, out of the initial 25 patients for whom longer follow-up was available, only 6 patients (24%) retained a functioning device, and a good functional result was achieved only in 3 (50%) out of the 6 patients, while the intention-to-treat success rate was only 12%.

O’Brien et al [150] conducted a prospective randomized controlled trial, comparing the artificial anal sphincter (AAS) and a program of supportive care (SC). Out of the 7 patients who underwent the implantation surgery, 6 (86%) retained a functioning device after a 6 month follow-up with complication rate being 43%. The Cleveland Clinic Faecal Incontinence (CCF-FI) score (0: full continence – 20: worst incontinence) significantly decreased from a preoperative mean of 19.0 +1.2 to a postoperative mean of 4.8±4.0 in the AAS group, while it did not change in the 7 patients of SC group with an initial mean of 17.1+2.3 and a final mean of 14.3+4.6 at 6 months. Ortiz et al [151] performed a non-randomized cohort case control study, comparing the AAS and the dynamic graciloplasty (DG). Out of the 8 patients who underwent AAS implantation, 5 (63%) continued to have a functioning device after a median follow-up of 44 months with 75% complication rate. Out of the 8 patients who underwent DG, 4 (50%) retained the stimulator after a median follow-up of 39 months with 63% complication rate. The median CCF-FI score significantly decreased from 16 to 8 in the AAS group, while it did not change from 18 to 18 in the DG group.

A retrospective case control study was reported by da Silva et al [164], comparing the AAS and the gracilis neosphincter (GN) procedure in patients with imperforate anus. All of the 11 patients who underwent the AAS retained a functioning device after a mean follow-up of 12 months with complication rate being 45%. In the 5 patients who underwent the GN, the complication rate was 60% after a mean follow-up of 38.8 months. The mean CCF-FI score significantly decreased in both groups (AAS: before 18 vs. after 7.5; GN: 17.4 vs. 9.4).

There is another artificial sphincter developed and reported by Hajivassiliou et al [179]. Different from the artificial anal sphincter (AAS), Acticon®, this prosthetic bowel sphincter (PBS) is implanted around the rectum at the supralevator plane through an abdominal approach. Finlay et al [180] implanted the PBS in twelve patients with severe faecal incontinence. At a median follow-up of 59 (range 30–72) months, nine of the 12 patients had a functioning device. There were no device-related infective complications after the initial operation, but one patient developed pseudomembranous colitis and had the device removed. The PBS was effective in restoring continence in ten of 11 patients. Median (range) Cleveland Clinic continence scores improved from 16 (7–20) before to 3 (0–7) after surgery. In two patients, the device was eventually removed owing to infection after revisional surgery that was performed due to the displacement of the sphincter component.

The PBS has two potential advantages over the AAS: it may cause less infective complications due to its sterile transabdominal implantation, and it can be applied to a severely incontinent patient with major perineal tissue loss. On the other hand, possible disadvantages include the need for a transabdominal implantation and the possibility of a severe pelvic or intraabdominal infection should an erosion occur.

At present the AAS is more widely used, and its safety and efficacy have been examined by many institutions. The PBS may have some place as an artificial sphincter because of its apparent advantages over the AAS, but its safety and efficacy need to be investigated extensively before widespread implantation is undertaken.
Sacral nerve stimulation (SNS) was first applied for the treatment of faecal incontinence in 1994 by Matzel et al [181] in patients with functional deficits of the anal sphincter but no morphologic defect. The concept of recruiting residual function of an inadequate anorectal continence organ by electrostimulation of its peripheral nerve supply, i.e. the sacral spinal nerves, was adopted from the field of urology in the early 1990's [182], where it has been used since 1981 [183]. The rationale for applying sacral nerve stimulation (SNS) to faecal incontinence was based on both clinical observations and anatomic considerations (from the former, the beneficial effect on bowel habits and anorectal continence function and increased anorectal angulation and anal canal closure pressure seen in urologic patients; from the latter, the demonstration by dissection of a dual peripheral nerve supply of the striated pelvic floor muscles that govern these functions [182] with the sacral spinal nerves being the most distal common location of this dual nerve supply. It was hypothesized that stimulating the sacral spinal nerves could both enhance physiologic function and improve the symptoms of faecal incontinence.

1. TECHNIQUE

SNS has become a minimally invasive technique with low morbidity. The surgical technique can be divided into two stages:

As no other predictors of SNS outcome exist at present, patients are uniformly selected for operative implantation of a permanent neurostimulation device on the basis of clinical improvement during test stimulation. This first stage, termed percutaneous nerve evaluation (PNE), is used to confirm a satisfactory nerve response and then evaluate the clinical effect of stimulation prior to the implantation of a permanent device. Therapeutic trial stimulation is performed for a one to three-week period, a time period sufficient to prove its therapeutic effect - commonly considered if the frequency of episodes of faecal incontinence documented by bowel-habit diary is alleviated by at least 50% and if the improvement is reversible after discontinuation. Two technical options are used for subchronic percutaneous nerve evaluation (PNE): a temporary, percutaneously placed, test stimulation lead (or multiple leads) that will be removed at the end of this phase; or operative placement of a quadripolar lead, the so-called “foramen electrode” close to a target nerve. This electrode can stay in place and be used for permanent stimulation, if the test stimulation is effective. Today most commonly this foramen electrode is placed by a minimally invasive technique that uses a foramen electrode with a modified anchoring device, the so-called “tined lead” placed through a trochar. For screening, both types of leads are connected to an external pulse, the latter with a percutaneous extension cable.

The second stage is implantation of a permanent electrode and neurostimulator if screening is successful. Those with a temporary lead require simultaneous implantation of the pulse generator and the quadripolar lead, most commonly as a tined lead procedure. Those with a foramen electrode already in place for screening will undergo removal of the percutaneous extension before placement of the pulse generator (so-called “two-stage implant” [184]). Bilateral placement of foramen electrodes remains the exception, based either on improved outcome of bilateral stimulation during the screening phase [185] or on conceptual considerations [186]. The pulse generator is placed subcutaneously in the abdominal wall or gluteal area. The pulse generator is activated and stimulation parameters are set early after surgery by telemetry. The pulse generator can be deactivated by the patients with a small, handheld device commonly referred to as a “patient programmer.”

2. PATIENT SELECTION AND INDICATIONS

Today, a variety of causes leading to faecal incontinence can be treated with SNS. During the initial SNS experience, only patients presenting with deficient function but no morphologic defect of the striated anal sphincter and levator ani were eligible for treatment. [182, 187, 188]. However, because of the high predictive value of the test-stimulation, investigators took a more pragmatic, trial and error approach to subsequent patient selection. Patients are now selected for SNS based upon PNE results rather than conceptual considerations of the potential mechanism of action. Test stimulation is indicated, not by an underlying physiologic condition, but by the existence of an anal sphincter with reduced or absent voluntary squeeze function and existing reflex activity, indicating an intact nerve-muscle connection (confirmed by intact anocutaneous reflex activity or by muscular response to pudendal stimulation with the St. Mark’s electrode) [187].

At present, the test stimulation is the only reliable modality to select patients who will likely benefit from permanent therapeutic stimulation. Two studies focused on potential predictors of success of SNS: In a study by Gourcerol et al [189], age was the only variable related with success of temporary stimulation. In patients with a permanent implant, neurologic disorders, delay of the left bulbocavernous reflex and a prolonged or absent bulbocavernous reflex were more frequent in patients with successful outcome. In another cohort analysis, the need for repeated temporary procedures was associated with failure during the screening in univariate and multivariate analysis [190]. A low threshold to obtain motor response during temporary lead placement.
was revealed to be associated with improved outcome only in univariate, but not in multivariate, analysis. Evidence of anal sphincter injury was related to a greater risk of failure during temporary testing, but not with permanent implant.

Contraindications to SNS include pathologic conditions of the sacrum preventing adequate electrode placement (such as spina bifida), skin disease at the area of implantation, anal sphincter damage requiring a sphincter substitute (e.g. artificial bowel sphincter, dynamic graciloplasty), trauma sequelae with micturition disorders or low bladder capacity, pregnancy, bleeding complications, psychological instability, low mental capacity, and the presence of a cardiac pacemaker or implantable defibrillator.

3. MECHANISM OF ACTION

The mechanism of action of SNS remains uncertain. Clinical outcome of SNS has been seen to correlate with results of anorectal physiology studies, but the effect of chronic stimulation varies greatly among published reports [187, 188]. Data are in part contradictory and inconclusive and sometimes not reproducible. The effect appears to be somatomotoric [191-198], somatosensoric [191], based on changes in the autonomic nervous system [191, 193, 199], and not limited to the continence organ per se, but also affecting the central nervous system [200]. Qualitative changes in anal and rectal motility, reduction of spontaneous rectal motility complexes [201, 202], and spontaneous anal sphincter relaxation [201] have been recorded during SNS. An effect on the mucosal neurochemistry during SNS has also been shown with elevation of Substance P and TRPV1 levels [203].

The relevance of each of these effects has not been proven in specific pathophysiological conditions. The mechanism of action is most likely multifactorial and different depending on the underlying condition. [LEVEL OF EVIDENCE: 4]

4. OUTCOME

The results of permanent SNS following the initial and pragmatic, trial-and-error, patient selection process are shown in Table 5 [186, 191-194, 204-220]. Most studies have represented patients with very heterogeneous pathophysiologic conditions. Most commonly, clinical outcome is reported as an improvement in incontinent episodes or days with incontinence during the period of observation, changes in Cleveland Clinic Incontinence score and in quality of life. The studies vary with regard to design and number of patients, but there is general agreement regarding the two-step stimulation for selection for permanent implant.

Matzel et al [208] published a multicenter prospective trial of SNS in 37 patients, 34 of whom underwent a permanent neurostimulator implant. Not only were the frequency of incontinence episodes and the CCIS score improved significantly, but also the ability to postpone defecation. These effects were attained immediately.

In most studies, quantitative measures are used to describe the clinical benefit, such as days with incontinent episodes/period of observation, absolute numbers of incontinent episodes/period of observation, ability to postpone defecation (in minutes), and percentage of improvement. Even though published reports differ with regard to patient population, a general pattern of outcome can be observed: when compared with baseline status, the clinical outcome is significantly improved. [LEVEL OF EVIDENCE: 2]

Melenhorst et al [194] published the largest single center study, with 100 patients undergoing permanent SNS. Late failure occurred in 21 patients as defined by a relapse of symptoms to less than 50% improvement over baseline, implementation of another therapy for faecal incontinence, or patient dissatisfaction. The mean time for definitive failure was 13.6 months (range 3–42.4). There was no evidence of technical failure as lead migration or lead breakage. Leroi et al [210] reported a double-blind, cross-over multicenter study in 34 patients with faecal incontinence treated with SNS. Three months after implantation, patients were randomized in a double-blind manner to on- or off-stimulation for a 2-month period, with reversal of the activation mode after 1 month. Of these, 24 of 27 randomized patients completed the 2-month trial. A significant decrease in median frequency of faecal incontinence episodes was noted during the on-stimulation period compared with the off-stimulation period. No significant change was observed between on and off stimulation for frequency of urgency episodes, delay in postponing defecation, or median number of bowel movements per week (10.2 and 11.1 for on and off, respectively).

There was a trend towards greater improvement in the Cleveland Clinic Incontinence Score during on stimulation compared with off stimulation (8.5 vs 10.5; ns). A total of 24 patients (89%) considered that they had improved during the on period compared with 17 (63%) during the off period.

A report by Rosen et al [191] highlights the effect of SNS in a cohort of patients, 75% of whom suffered from faecal incontinence of neurologic origin. Frequency of incontinence episodes/week was reduced from 6 to 2 at 15 months follow-up.

Recently, some small case series and individual case reports have demonstrated the therapeutic effect of SNS in groups of patients presenting with distinct conditions and well defined anorectal physiology findings, e.g. muscular dystrophy [221], a history of rectal resection for cancer [216], neurologic dysfunction including spinal disc prolapse [217], status after rectal prolapse repair [218], after rectal resection and neoadjuvant chemoradiation [187], and with internal and external sphincter disruption due to Crohn’s disease [219]. [LEVEL OF EVIDENCE: 4]

* median, otherwise all data presented at mean
† A: after sphincter repair, †† B: with sphincter gap 17-33% of circumference, without repair.
An increasing body of evidence indicates that SNS may also be a treatment option for patients with sphincter defects, un repaired or after attempted anatomic reconstruction. The presence of an internal anal sphincter defect on anal sonography is reportedly unrelated to the success of permanent SNS [190]. Three of five patients with ultrasound evidence of sphincter disruption measuring 25%–33% of the circumference benefited from chronic SNS [222]. In 20 patients with unrepaired obstetric trauma, SNS resulted in significant improvement of the Cleveland Clinic score (CCS; from 16 to 3) in 19, and of the numbers of incontinent episodes per week (from 10–1) with a minimum follow-up of 4 years [223]. In patients with an unrepaired external or internal anal sphincter or both, the frequency of incontinent episodes per week decreased from 1.3 to 0.3 and the CCS improved (from 15 to 3.5) with a follow-up of 12–97 months [224]. Melenhorst et al. showed that the primary use of SNS in patients with a sphincter gap 17–33% of the circumference appeared to result in an outcome similar to its use after failed sphincter repair [215].

SNS in 6 of 8 patients presenting with faecal incontinence related to obstetric full thickness anal sphincter lesions ranging from >30-150 degree resulted at a median follow-up of 26.5 months in improved frequency of incontinent episodes per week from 5.5 to 1.5 clinical function [220], improved ability to postpone bowel emptying and improved ASCRS quality of life scores. A further cohort study [225] reports on the effect of permanent SNS in 53 patients presenting with either an intact external anal sphincter (N=32 [37.5% after sphincter repair]) or an external anal sphincter lesion (N=21 [81% after prior sphincter repair]) of ≤90° (N=11) or 90–120° (N=10). Improvement of symptoms and quality of life was achieved in all groups. Outcome after 12 months was statistically not significantly different between those patients with an intact sphincter complex and those without. Chan & Tjandra [226] reviewed 53 consecutive patients who underwent SNS for faecal incontinence. There was no significant difference in outcomes between those with and without an external sphincter defect. [LEVEL OF EVIDENCE: 3]

In a randomized controlled trial Tjandra et al [225] compared the effect of sacral neurostimulation for severe faecal incontinence with supervised optimal medical therapy that comprised pelvic floor exercises, bulking agents, and dietary manipulation. Permanent SNS in 53 patients was significantly better than conservative treatment in 60 patients: Cleveland Clinic Continence Score 1.2 vs. 14.1; incontinent episodes/week: 3.1 vs 9.4, days with incontinence/week: 1 vs. 9.4, lifestyle: 3.31 vs. 2.31, coping/behavior: 2.68 vs. 1.86, depression/self-perception: 3.25 vs. 2.64, embarrassment: 2.76 vs. 1.78. [LEVEL OF EVIDENCE: 2]

5. QUALITY OF LIFE

As with indications, outcome assessment has also evolved and aspects of quality of life were added to the evaluation of outcome (Cleveland Clinic Continence Scoring System, SF36 and FIQL Score.) The therapeutic impact of SNS is most evident when a disease-specific quality-of-life instruments ASCRS FIQL scale is applied.

In the multicenter clinical trial by Matzel et al [208], ASCRS FIQL was significantly increased in all 4 scales, SF-36 scores improved in 7 of 8 scales, the greatest being social functioning and mental health; but only social functioning reached statistical significance. A similar result was published by Leroi et al [210] using the French version of the ASCRS QOL (FIQL): at the final follow-up visit improvements in lifestyle, coping and behavior, depression and self-perception and embarrassment were significantly improved. Hetzer et al [213] demonstrated a significant improvement of the median Gastrointestinal Quality of Life Index score with permanent from a baseline score of 96 (range 47–128) to 107 (range: 36–128) at 6 months post-implantation. [LEVEL OF EVIDENCE: 2]

6. COST BENEFIT / ROLE IN THE TREATMENT ALGORITHM

Permanent SNS is expensive. Hetzer et al [227] conducted a comparative cost analysis of SNS with conservative treatment, anterior sphincteroplasty, dynamic graciloplasty and creation of a stoma in 34 consecutive patients. The 5-year cumulative costs for SNS is €19333, compared with €35965 for stoma with annual costs of €5339, and €34953 for dynamic graciloplasty with annual costs of €1659. The equivalent cost for conservative treatment was €3895. The overall median real cost for an anterior sphincteroplasty was €5327. [LEVEL OF EVIDENCE: 4]

7. SAFETY

SNS is a safe procedure. The rate of complications is relatively low [187, 188]. In only approximately 5% of the patients has discontinuation of treatment with device removal been necessary because of loss of effect, deterioration of symptoms, pain lead dislocation, or infection. When infection has necessitated removal, re-implantation at a later date has been successful [204]. [LEVEL OF EVIDENCE: 3]

VIII. POSTERIOR TIBIAL NERVE STIMULATION

For peripheral stimulation the tibial nerve is temporarily stimulated with surface or needle electrodes at the level of the malleolus. Scattered preliminary data from short term studies with temporary posterior tibial nerve
stimulation [228] indicate a therapeutic effect in idiopathic faecal incontinence [229] and incontinence due to partial spinal trauma [230] on frequency of incontinence episodes, incontinence scores and QoL. Larger patient studies are awaited. [LEVEL OF EVIDENCE: 4]

IX. INJECTABLE BIOMATERIALS

Injection of bulk-enhancing agents into the anal canal to treat faecal incontinence was a natural consideration after its successful use in urinary incontinence. The use of injectable agents to increase urethral resistance at the level of the bladder neck has had variable success; however the benefit of performing an outpatient procedure without anesthesia has resulted in its continued use [231]. The ideal agent for injection should be biocompatible, non-allergenic, non-immunogenic, easy to inject and not migrate within the tissues. No agent currently has all these properties. Agents that have a diameter of 80 µm are felt to be less prone to migration; however larger agents require a larger bore needle to inject, which put them at a higher risk for leakage from the injection site. The results of injectable biomaterials are shown in Table 6 [232-242].

The history of using injectable agents for faecal incontinence began in 1993 when Shafik [232] treated 11 patients (7 of whom had internal sphincterotomy and 4 idiopathic incontinence) with injections of polytetrafluoroethylene paste into the anal submucosa. After an 18-24 month follow-up, 64% reported complete cure and 36% had partial improvement. Shafik [233] subsequently treated 14 patients with autologous fat injections. All patients became continent after repeat injections. There were no complications using either agent. However, subsequent reports of autologous fat injection have resulted in serious complications including death, stroke and pulmonary embolism and thus at the present time is not used for faecal incontinence [243].

Other agents used for injection thus far include micro balloons, glutaraldehyde cross-linked synthetic bovine dermal collagen (Contigen), PTQ implants (Bioplastique), Pyrolytic carbon-coated zirconium oxide beads (DuraspHERE), dextranomer- hyaluronic acid co-polymer (Zuidex), cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (BulkaKam). A small series of six patients injected with self-detaching cross-linked silicone micro balloons with a biocompatible filler material demonstrated fairly good results with Browning-Parks incontinence scores for the group decreasing from 16 to 5 (range 0-20) [234]. However, sterilization issues have prevented the ongoing use of this product.

The first reported injections of glutaraldehyde cross-
linked collagen for faecal incontinence included 17 patients [235]. Following injection, with a mean follow-up of 8 months, 11 patients showed marked symptomatic improvement. A much larger series was recently reported by Stojkovic et al [236]. Patients were injected with 1.7 ml of collagen transanally into the submucosa in three separate areas just proximal to the anal canal. Of the 73 patients, 63% reported an improvement in their incontinence. The 49 patients with idiopathic incontinence (no sphincter defect and no pudendal neuropathy) had a significant decrease in their Cleveland Clinic Florida Incontinence Score (CCFIS). The disadvantages of using synthetic collagen are its potential to be allergenic and degradation over time. Furthermore, its success in urinary incontinence has been limited [231].

Injectable silicone biomaterial, also previously known as macroplastique and bioplastique, has been used extensively for urinary incontinence. It consists of polydimethylsiloxane particles suspended in a bioexcretable carrier hydrogel of polyvinylpyrrolidone. Two pilot studies in 2001 and 2002 [237, 244] led to increased use of this product in Europe and it has been renamed PTQ implants (PTP implants in Australia). Malouf et al [237] studied 10 patients with passive incontinence injected circumferentially or at a single site with Bioplastique. At six weeks, 6 of 10 patients showed either marked improvement or complete cessation of leakage. However, after six months, only 2 of 7 had maintained marked improvement. Complications included anal pain and ulceration at the injection site.

Tjandra et al [238] randomized 82 patients with severe faecal incontinence to receive PTP implants either with or without endoanal ultrasound guidance for injection. All patients had a significant improvement in their Cleveland Clinic Continence scores (range 0-20). The ultrasound guided group had a decrease in score from 14.5 to 3 and the non-guided group had a decrease from 14.5 to 11 at 12 months. Six patients, two from the ultrasound guided group complained of pain at the injection sites. There were no other complications. The ultrasound guided group was also found to have a more significant improvement in resting pressures and quality of life scores. The same group injected PTQ in 7 patients with passive incontinence after hemorrhoidectomy and found significant improvement of Cleveland Clinic Continence scores and quality of life scores in all patients [245].

Only one report exists of long-term results for injectable agents and this was using Bioplastique. Maeda et al [246] reported the 5 year outcome of 6 patients injected with Bioplastique in 1999. The median St. Mark's incontinence score was essentially unchanged from 11 to 13 (range 9-20) and one patient had undergone a colostomy. However, four of the remaining five patients reported subjective improvement in their incontinence and quality of life scores.

The largest series of patients injected with silicone biomaterial included 20 patients with passive faecal incontinence of liquid or solid stool who had failed conventional therapy [239]. Ten patients had disruption of the internal anal sphincter; nine had degeneration of the sphincter. Patients were injected trans-sphincterically using an 18-gauge needle in the skin 2 cm from the anal margin and a finger in the anal canal to direct the injection above the dentate line in the submucosal plane. Three areas were injected with 2.5 ml of product. The Cleveland Clinic Continence score (0-20) decreased significantly from 13.5 to 4.5 at one month and slowly increased to 9.4 at two years, which was a still a significant improvement from the baseline score. Quality of life scores also improved, but there was no effect on resting and squeeze pressures measured at baseline and 3 months after injection. Of note, 70% of patients experienced pruritus ani and one patient developed an infection at an injection site. Post procedure endoanal ultrasounds found no evidence of migration of the product in 19 patients.

Pyrolytic carbon-coated zirconium oxide beads (Duraphsphere) are non-reactive and are not biodegradable. However, they are known to migrate within the tissues and require a large bore needle to inject the substance. Davis et al [240] assessed the short and long-term efficacy in 18 patients with an internal anal sphincter defect refractory to conservative management. It was injected in the submucosal plane at the site of the defect until adequate anal sphincter symmetry was restored. At 12 months, incontinence scores and patient satisfaction scores were significantly improved. Fifteen of eighteen patients reported improvement in their incontinence. An abstract presented by Weiss et al [247] demonstrated improvement in ten patients who were only followed for 3 months. Altomare et al [241] recently published a study of 33 patients with minor or medium severity faecal incontinence (Cleveland Clinic Continence score \( \leq 14 \) and/or American Medical Systems score \( \leq 89 \)) were injected with a mean of 8.8 ml (range 2-19 ml) of Duraphsphere into the submucosa at the level of the dentate line using an 18-gauge needle. After a mean follow-up of 21 months, the incontinence severity scores for the group decreased significantly but the faecal incontinence specific quality of life did not change. Resting and squeeze pressures were also increased 12 months after injection. Adverse events included anal pain in two patients, asymptomatic leakage of material in one patient, and distal migration of product in two patients.

Dextranomer-hyaluronic acid co-polymer (Zuidex) has been used to treat urinary incontinence [248] and a randomized placebo controlled trial is underway to assess its efficacy for faecal incontinence. Dextranomer microspheres are suspended in non-animal stabilized hyaluronic acid. There are no published reports of its use in faecal incontinence to date.
Another study of injectable agents for faecal incontinence involves two other products, cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (Bulkamid) [242]. Ten patients with passive faecal incontinence to liquid or solid stool who had failed conventional treatments received either of the two products. Injection was performed transsphincterically after injecting the skin 2 cm from the anal margin. The median volume to achieve closure of the anal canal under direct vision was 9 ml for Bulkamid and 15 ml for Permacol. There was a decrease in the St Mark’s incontinence score at 6 weeks for both groups and only a sustained decrease in the score for the Bulkamid group at 6 months. As this was a pilot study, there was inadequate power to assess the different in these treatments for faecal incontinence.

In summary, the data for injectable biomaterials incontinence involves two other products, cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (Bulkamid) [242]. Ten patients with passive faecal incontinence to liquid or solid stool who had failed conventional treatments received either of the two products. Injection was performed transsphincterically after injecting the skin 2 cm from the anal margin. The median volume to achieve closure of the anal canal under direct vision was 9 ml for Bulkamid and 15 ml for Permacol. There was a decrease in the St Mark’s incontinence score at 6 weeks for both groups and only a sustained decrease in the score for the Bulkamid group at 6 months. As this was a pilot study, there was inadequate power to assess the different in these treatments for faecal incontinence.

In summary, the data for injectable biomaterials comprises several small case series that in general show short term efficacy. [LEVEL OF EVIDENCE: 3]

**X. COLOSTOMY**

A permanent colostomy is usually formed as a last resort for severe faecal incontinence when all other interventions have failed. Because colostomy is generally regarded as a failure of treatment, its effectiveness, perioperative complications, and impact on the quality of life have never been properly evaluated except for patients with functional bowel disorders after spinal cord injury [249, 250]. For a specific role of colostomy for these patients, please refer to the specific chapter. Not only for patients with spinal cord injury, but also for the general population with severe faecal incontinence, colostomy is a frequently successful management strategy that restores dignity and allows them to regain social function.

No systematic reviews, randomized controlled trials or non-randomized cohort studies have been reported regarding colostomy for faecal incontinence, and only one case control study [251], two case series [252, 253], and one systematic review [146] were identified. [LEVEL OF EVIDENCE: 4]

Colquhoun et al [251] conducted a cross-sectional postal survey, comparing quality of life between 71 patients with faecal incontinence and 39 with a colostomy created for rectal cancer, complicated colonic diverticular disease or faecal incontinence. Analysis of the Short Form 36 General Quality of Life Assessment revealed significantly higher social function score in the colostomy group than in the faecal incontinence group (0 vs. -0.6, p=0.022). An age- and gender-adjusted regression analysis of the Faecal Incontinence Quality of Life score revealed significantly higher scores in the coping (2.7 vs. 2.0, p=0.005), embarrassment (2.7 vs. 2.2, p=0.014), and lifestyle scales (3.2 vs. 2.7, p=0.14) in the colostomy group compared to the faecal incontinence group.

The authors concluded that a colostomy is a good option for patients who suffer from severe faecal incontinence and offers a definitive cure with improved quality of life.

Tan et al [146] performed a systematic review specifically comparing the cost-effectiveness between end stoma (ES), artificial anal sphincter (AAS) and dynamic graciloplasty (DG). The quality-adjusted life years (QALYs) and the incremental cost-effectiveness ratio (ICER) were compared between the three procedures, by obtaining the probability estimates for patients with faecal incontinence from published data supplemented by expert opinion. The end stoma was the most cost-effective therapy at 5 years, with a QALY gain of 3.45 for 16,280 GBE and an ICER of £4,719/QALY, compared to AAS (4.38 for £23,569; £5,387/QALY) and DG (4.00 for £25,035; £6,257/QALY). After 10 years, AAS became the most cost-effective surgical intervention, with a QALY gain of 8.384 for £32,397 and an ICER of £3,864/QALY, compared to ES (6.9 for £27,910; £4,046/QALY) and DG (7.678 for £35,165; £4,580/QALY). The results of this study, however, must be interpreted with great caution, because it is not an intervention study but a systematic review with a rather complicated methodology and a variety of possible biases.

Norton et al [252] examined patients’ view of a colostomy by conducting a questionnaire study of patients who had a colostomy created to manage their faecal incontinence. Sixty-nine people (58 women) responded. When patients were asked to rate their ability to live with their stoma now on a scale of 0-10, the median score was 8 (range 0 – 10). The majority (83%) felt that the stoma, within the past month, restricted their life “a little” or “not at all”. Eighty-four percent answered that they would “probably” or “definitely” choose to have the stoma again. When they were asked the question “compared to when you were continent, how much change has having a stoma made to your overall quality of life?” on the scale of -5 (much worse) to +5 (much better), the median rating was +4.5 (range -5 to +5). The authors concluded that health care professionals should discuss the option of a stoma with incontinent patients because of the overwhelmingly positive outcomes.

An end sigmoid colostomy without proctectomy is usually recommended as a procedure of choice for patients who elect colostomy for the management of their refractory faecal incontinence. Creating such a colostomy, however, does not always solve all the problems of patients with faecal incontinence. Catena et al [253] reported a retrospective chart review of 44 patients (35 women) who underwent elective end sigmoid colostomy for faecal incontinence of various
etiolgies. After colostomy formation 19 patients (43%) were asymptomatic, while the other 25 experienced such problems with their rectal stump as diversion colitis and mucus leakage. Of the 25 patients, 12 (27% of the total) underwent a secondary proctectomy due to the rectal stump problems sufficient to warrant the operation. Histological examination revealed diversion colitis in 6 patients. The factor associated with proctectomy was age, with younger patients being more likely to require rectal excision. The authors concluded that data are insufficient to recommend primary proctectomy in patients with severe faecal incontinence warranting permanent end sigmoid colostomy.

### XI. ANTEGRADE CONTINENCE ENEMA

The concept of irrigation is to ensure emptying of the colon and/or rectum to prevent seepage of stool. It has been used for patients with neurogenic bowel dysfunction and those with symptoms of incontinence [254, 255].

Antegrade irrigation involves operative construction of an appendicostomy, cecostomy, or sigmoidostomy which will serve as a continent conduit for colonic enemas [254, 256-258]. The operation can also be done laparoscopically. There is a reported 65 to 78% subjective improvement in patients, but some studies have included patients with concurrent difficulty with defecation [259-261]. [LEVEL OF EVIDENCE: 3] The disadvantages of the procedure have been documented; the most common has been wound infection in up to 45% of patients [259]. This seems to be reduced by creating a so-called ‘neo-appendicostomy’ with a part of ileum [262, 263].

### B. SURGERY FOR PEDIATRIC FAECAL INCONTINENCE

Faecal incontinence is common in children who have anorectal malformations, Hirschsprung’s disease and spinal problems. Despite advances in technique for anatomic corrective surgery, many patients continue to suffer from persistent incontinence. This guideline mainly focuses on anorectal malformations and corrective surgeries along with their results and subsequent management in case of persistent incontinence. The latter is also applicable for treatment of patients suffering from incontinence after surgery for Hirschsprung’s disease and those with spinal problems. Other surgical interventions used less frequently were also reviewed.

Anorectal malformations occur one in 3000-5000 live births. Although the severity of malformation varies, it is invariably associated with defecatory problems including incontinence. The surgical advances have been most prominent in last few decades, particularly with the advent of posterior sagittal approach. [LEVEL OF EVIDENCE: 3] This technique has enabled surgeons to visualize the anatomy under direct vision and perform corrective surgeries more accurately [264, 265]. In brief, a mid-sagittal incision is performed and the sphincter mechanism is completely divided in the midline. The rectum is separated from the genitourinary tract and moved down to the perineum. The most challenging aspect of the operation is the separation of the rectum from the vaginal or urinary tract, which effectively requires creating two walls out of one septum without damaging each structure. This approach can also be used for reoperation in anorectal malformations [266] and can also be applied for reconstruction of severe perineal trauma [267].

For both male and female babies, urethral-perineal fistula is the simplest fistula to correct. These require the so-called ‘minimal posterior sagittal approach,’ which enlarges the stenotic orifice and relocates the rectal orifice posteriorly within the limits of the sphincter complex. For males with recto-urethral-bulbar fistula or recto-urethral-prostatic fistula and females with recto-vestibular fistula or cloaca with short (less than 3 cm) common channel, posterior sagittal approach is the main operation performed. For males with higher fistulas such as recto-bladder neck fistula and other complex and unusual defects and females with cloaca with long (greater than 3 cm) common channel and complex defects, the posterior sagittal approach needs to be coupled with abdominal access which can be either laparoscopy or laparotomy.

Cloacal repair is the most challenging amongst the corrective surgeries for anorectal malformations. A recent operative advance in cloacal repair is a maneuver called total urogenital mobilization, whereby the rectum is separated from the vagina and both vagina and urethra are then mobilized together. The advantage of this technique is to avoid separating rectum, vagina and urethra completely, which is not feasible all the time and risks damaging these structures during the procedure. This technique avoids the risk of urethrovaginal fistula and vaginal stricture (previously reported as complications in 10% of cloacal repairs) and also gives enough mobilization to allow more than 50% of all cloacal repairs without opening the abdomen [268, 269].

Functional outcomes depend on the severity of the malformations. A review of more than 1000 anorectal malformation cases showed 100% of babies who had perineal fistula repair achieved continence. Approximately 55% of patients who had been operated
for recto-vestibular fistula had bowel control. Any malformations more complicated resulted in only up to 30% achieving continence. All patients who had recto-bladder neck fistula repair were incontinent. In cloacal repair the length of common channel shorter or longer than 3 cm appears to be the distinct prognostic factor in terms of functional outcome [270]. Overall it is estimated that nearly 40% will have voluntary bowel movement and no soiling, but some of them may still lose bowel control in case of severe diarrhea, and 25% of all repairs will result in total incontinence [271].

For the group of patients with persistent incontinence following the corrective surgery, the next aim will be to keep the colon clean to avoid unpleasant accidents and improve their quality of life. A good option is implementation of a bowel management program whereby the patient and family are instructed in the use of daily enema, manipulation of diet, and medication to remain clean [272]. This is also a good treatment for constipation, which is the most common difficulty after corrective surgery [273].

Although most young children accept their parents administering enemas, when they get older they want privacy and rectal enemas on a daily basis becomes an unpleasant routine. In such cases, continent appendicostomy is a feasible option, whereby a conduit for the administration of an antegrade continence enema (ACE) is created. First described by Malone [274], it has become an important option in pediatric surgery for functional bowel disorders.

According to the initial description by Malone, appendicostomy was created by dividing the appendix at its base and reimplanting by a reverse manner into the cecum, which was then exteriorized through the right lower quadrant. Malone later revised it and the reimplantation of appendix is no longer considered necessary [275]. Levitt et al introduced utilizing the appendix in situ and added cecal plication to prevent reflux of stool and exteriorizing through umbilicus fold rendering it less noticeable [276]. This appears to yield good long-term results [277], though a recent study has shown that cecal fixation and wrap may be unnecessary for appendicostomy (44 patients, consecutive) [278]. The benefit of a variation called orthotopic continent appendicostomy stoma is not clear [279]. However, construction of appendicostomy with the cecum, which was then exteriorized through the right lower quadrant and reimplanting by a reverse manner into at its base and subsequently lead to overflow incontinence due to incomplete evacuation [299]. Once the rectum is dilated impaction, which can lead to development of a dilated segment of bowel called ‘megarectosigmoid’. This can subsequently lead to overflow incontinence due to incomplete evacuation [299]. Once the rectum is dilated it is refractory to conservative management, and resection of megarectum or megasigmoid has been associated with improvement [299-301]. A small minority of patients (5%) who fail these options may need colostomy [272].

### II. OTHER CAUSES OF Faecal INCONTINENCE

Some children with Hirschsprung’s disease following pull-through operations and severe constipation may also present with symptoms of incontinence [297]. Patients with spinal problems often lack bowel control due to paralysis and absence of sensation; 50% of children with spina bifida suffer from incontinence [298]. The majority of these cases can be successfully managed with the above mentioned bowel management program including appendicostomy, although wheelchair-bound children with spinal neuropathy is a predictive factor for poorer outcome with ACE [287].

The mechanism of incontinence after an operation for Hirschsprung’s disease, anorectal malformations and severe constipation is thought to be due to impaired bowel motility. Impaired bowel motility causes faecal impaction, which can lead to development of a dilated segment of bowel called ‘megarectosigmoid’. This can subsequently lead to overflow incontinence due to incomplete evacuation [299]. Once the rectum is dilated it is refractory to conservative management, and resection of megarectum or megasigmoid has been associated with improvement [299-301]. A small minority of patients (5%) who fail these options may need colostomy [272].

### III. OTHER SURGERIES

Sphincter augmentation by either palmaris longus transposition, gluteus muscle transposition, graciloplasty or levatorplasty has been used for children with faecal incontinence, albeit in small series[110, 302-309]. Dynamic graciloplasty has also been piloted and 50% of patients achieved complete continence, though the study only contained four patients [310]. [LEVEL OF EVIDENCE: 4]
Data regarding the surgical treatment of faecal incontinence are generally weak. Randomized, controlled studies are few, and practical considerations make the likelihood of such studies improbable. The quality of data reported in older studies was often poor. Problems included heterogeneous patient populations; variable definitions of "continence," "incontinence," "success," and "failure"; non-standardized and non-validated continence scales; underreporting of validated symptom-specific quality of life measures; variable patient follow up and lack of independent assessment of continence outcomes. However, there has been a notable improvement in the quality of studies reported in the past decade. The spectrum of surgery for faecal incontinence is broad and expanding. Interventions range from simple outpatient procedures to major reconstructive surgery. As the reported outcomes of these various operations are often similar, a sound general principle is to proceed first with the simplest and least invasive procedure. Major operations associated with more profound morbidity should be restricted to patients who have failed simpler measures.

1. Sphincter Repair (Grade B)
Sphincter repair is indicated for patients with acute traumatic sphincter disruption, such as following obstetrical injury, but many patients experience persisting symptoms.

2. Sphincteroplasty (Grade B)
Overlapping sphincteroplasty can be offered to patients with significant faecal incontinence and a documented sphincter defect. Most patients improve after sphincteroplasty, but outcomes deteriorate over time.

3. Postanal Repair (Grade C)
Postanal repair can be performed with modest success in carefully selected patients. However, this procedure is now rarely performed due to the advent of newer treatments.

4. Non-Stimulated Muscle Transposition (Grade C)
Non-stimulated muscle transposition repair can be performed with modest success in carefully selected patients, notably in children. However, this procedure is now rarely performed due to the advent of newer treatments.

5. Stimulated Muscle Transposition (Grade C)
Stimulated muscle transposition has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in selected patients with significant perineal tissue loss or in those who have failed other treatments.

6. Artificial Anal Sphincter (Grade B)
Artificial anal sphincter has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in carefully selected patients, particularly those who have failed other treatments.

7. Sacral Nerve Stimulation (Grade B)
SNS is an effective therapy for most patients with clinically significant incontinence who fail conservative management. The technique is safe, minimally invasive, and has the unique advantage of allowing a therapeutic trial prior to permanent stimulator implantation.

8. Posterior tibial nerve stimulation (Grade D)
Posterior tibial nerve stimulation is an investigational technique with few available data regarding efficacy and outcome.

9. Injectable Biomaterials (Grade C)
Most series of injectable biomaterials report reasonable success rates. However, the optimal injectable bulking agent and the technique for its insertion have not been established.

10. Colostomy (Grade C)
Formation of an end colostomy is a reasonable treatment option for patients with refractory faecal incontinence who are able to accept the associated alteration in body image. Colostomy provides restoration of a more normal lifestyle and improves quality of life. It also could be the most cost-effective in the short to medium term, compared to more complicated surgical procedures such as artificial anal sphincter and dynamic graciloplasty. Colostomy should not be regarded as a treatment failure but rather a reasonable treatment option for patients whose lives are restricted by faecal incontinence that is not amenable to other therapies. An end sigmoid colostomy alone, without proctectomy, is recommended. The minority of patients who develop significant symptoms from their retained rectal stump may eventually require proctectomy as a secondary procedure.

11. Antegrade Continence Enema (Grade C)
Antegrade continence enema is a useful technique to ameliorate faecal incontinence refractory to more conventional therapies. Patients must accept placement of a small stoma and be willing to adhere to a regular irrigation program.

12. Surgery for Pediatric Faecal Incontinence (Grade C)
Anorectal malformations should undergo surgical repair, most commonly by a posterior sagittal repair. An antegrade continence enema procedure can be considered for children with persistent or refractory faecal incontinence.

Fistulas in the Developing World

D. De RIDDER,

BACKGROUND

Obstetric fistulas destroy the lives of many young women in the developing world. While obstetric vesicovaginal fistulas have vanished from the industrialized world, despite the efforts of many charitable organizations, they continue to occur in epidemic numbers in developing countries. The national and local governments of these countries do not have either the resources or the political will to address this problem and help these outcast women. The number of vesicovaginal fistulas in a region reflects the quality and the level of perinatal care delivered by the local health systems. In regions where health care (particularly maternal health care) is poor or absent, the number of obstetric fistulas is likely to be high. Although the treatment of women with obstetric fistulas is a worthy endeavour, the ultimate goal should be to eliminate fistulas entirely by providing adequate maternal health services and perinatal care. As some Africans say: “Treating obstetric fistulas is like taking a serpent by the tail—you can only control the snake by taking it by the head.” The ultimate goal must be fistula prevention.

Only rough estimates can be given on the incidence and prevalence of fistulas and reliable data on cure rates and surgical complications are available only from a few authors. There is no internationally-accepted classification system for fistulas and the development of such a system has been hampered by the absence of prospective clinical research that could establish a relationship between fistula classification and surgical outcome.

LITERATURE SEARCHING STRATEGY

From the standpoint of evidence-based medicine, the literature on fistulas is disappointing. A total of 515 articles were identified using search engines such as Pubmed and Sumsearch, of which 149 were published during the last 5 years. Out of this literature, only 8 trials could be identified involving fistulas. Most of the published articles were simple observational studies. There are no evidence-based guidelines or well-designed randomized controlled trials. The major large-scale literature review is the last report of this committee [1].

Data are scarce on health economic issues as well. While there has been a gradual improvement in the number and quality of papers published on obstetric fistulas in the developing world over the last few years, none of these papers rises higher than “level 3” evidence. There is still a generalized lack of reliable data on obstetric fistulas. If the fistula problem is to be tackled successfully, this must change. The academic communities of both the industrialized and the developing worlds must work together to change this situation, thereby improving both maternal health care and the quality of services provided to women with obstetric fistulas.
A fistula is an abnormal communication between the vagina and the bladder (or rectum) of a woman that results in a constant leakage of urine and/or faeces. Most commonly fistulas develop as a result of obstetric trauma, hence the term “obstetric fistulas.” Obstetric fistulas have emerged as an international public health problem which is attracting increasing international attention [2, 3]. The aetiology and epidemiology of obstetric fistulas is reviewed in this section, along with the physical, psychological and social consequences suffered by those affected. This summary is based on recent literature reviews on the subject.

1. GEOGRAPHICAL DISTRIBUTION OF OBSTETRIC FISTULAS

Today, obstetric fistulas have vanished from the developed world and occur almost exclusively in the non-industrialized countries of Africa and Asia, where access to quality medical care is lacking for many (perhaps most) women. The disappearance of this condition from the developed countries is largely the result of universal access to emergency obstetric care. As will be seen later in this chapter, it is not possible at present to give a reliable estimate of the total number of obstetric fistulas in the developing world. Perhaps the most useful comparative health statistic in these countries is the maternal mortality ratio, which appears to be a reasonably accurate surrogate marker for obstetric fistulas. Obstetric fistulas are invariably found in regions where maternal mortality is high because both statistics reflect absence of effectively-functioning emergency obstetric services. Recent (2005) maternal mortality estimates by the World Health Organization indicate that there are half a million maternal deaths worldwide each year, and that 99% of those deaths occur in developing countries, with slightly more than half of those deaths occurring in sub-Saharan Africa, followed by South Asia. Maternal mortality in these two regions accounted for 88% of the world’s maternal deaths [4] (Figure 1).

2. DEVELOPMENT OF AN OBSTETRIC FISTULA

Obstetric fistulas usually develop from prolonged obstructed labour that occurs as the result of foeto-maternal disproportion during the course of delivery. The foetal head (or other presenting part) becomes wedged into the pelvis, through which it cannot pass, trapping the woman’s soft tissues between two bony plates. This in turn occludes the blood supply to the affected tissues, which then slough away to create the abnormal communication between the vagina and the bladder and/or rectum, leading to a fistula (figure 2). The foeto-maternal disproportion that causes obstructed labour is due either to a small pelvis (particularly in young, teenage primiparas who have become pregnant before they have reached their full adult pelvic growth), reduced pelvic proportions due to disease or injury, an abnormal foetal presentation (transverse lie, shoulder, breech, etc), or foetal macrosomia. AbouZahr has estimated that foeto-pelvic disproportion of this kind arises in 0.5% to 6.5% of deliveries [5], but no publications have been found to suggest what proportion of such deliveries actually result in the formation of a fistula. Harrison reported on 22,774 deliveries at the Amhadu Bello University Teaching Hospital in Zara, Nigeria [6]. He reported 70 cases of fistula in this series, giving a ratio of one fistula per 288 deliveries. In cases of obstructed labour, preventing the formation of a fistula depends on timely access to emergency caesarean delivery. In the needs-assessment carried out in 20 countries as part of UNFPA’s Campaign to End Fistula, caesarean section rate ranged from 0.1% to 3% [7], well below the absolute minimum rate of 5% recommended by WHO to meet maternal health needs. An analysis of data from Demographic and Health Surveys (DHS) has demonstrated that access to caesarean delivery is directly linked to the poverty level based on household goods, the poor having substantially less access to care than do the rich. Using DHS data, Ronsmans and colleagues [8] have shown substantial differences in caesarean rates between urban and rural areas. Not surprisingly women living in rural areas have less access to caesarean delivery than women who live in urban areas [9]. Additional factors including cultural beliefs, perceptions of disease severity, transportation issues, and restrictions on women’s social mobility may also reduce the access to caesarean section and other emergency obstetric services [10,11]. Thaddeus and Maine have suggested that there are three “stages of delay” which interact to produce maternal death and serious maternal morbidity: 1) delay in deciding to seek care; 2) delay in arriving at a health care facility, and 3) delay in receiving adequate care at that facility [12]. The cultural and biological elements that lead to obstetric fistula formation are summarized in figure 3 [3].

A second cause of fistula formation is iatrogenic injury sustained during the course of delivery such as at the time of laparotomy, caesarean section, or through the use of forceps. In many cases the relationship between the intervention and the fistula cannot be determined. Many fistulas develop in women who, after labouring for several days in a remote village, finally present for care at a medical facility. There the woman undergoes a very difficult caesarean delivery, often performed under less-than-ideal circumstances, with delivery of a stillborn baby and subsequent development of a fistula. There are many cases of this type reported in the literature [13-18]. In some cases the fistula is the result of direct injury
Figure 1: Maternal mortality map 2005

Figure 2: The foetal head is forced into the pelvis, trapping the bladder, urethra, and other soft tissues between the foetal head and the pelvic bones. This unrelenting pressure leads first to tissue ischemia and the to tissue necrosis with fistula formation. In most cases the bladder will not have been emptied as suggested by this picture, but will be markedly overdistended. The progressive thinning of the bladder wall from overdistention increases the likelihood of ischemic injury. The level at which labour becomes obstructed is directly related to the level at which the fistula occurs, as shown in the drawing on the right. (adapted from Elkins 1994)
under these difficult circumstances; in other cases the tissues involved were already avascular from obstructed labour. There is no doubt that a proportion of fistulas developing in these circumstances will be dependent on the qualifications of the persons performing the obstetric intervention and the nature of the facility where delivery takes place, but there are few data which would allow an accurate analysis of the proportion of fistulas that are the result of surgical misadventure. Because of the lack of trained gynaecologists and general surgeons in Africa, general medical doctors, nurses and midwives have been trained to perform caesarean sections in some areas, and some success has been reported with these programs [19-22]. The long-term success of such programs is uncertain and maintenance of adequate quality of care will depend upon close and continuing supervision of such programs by trained surgeons. This is an area that requires further study.

A third group of factors causing fistulas includes accidents, sexual abuse and rape [23]. A recent review on the subject of traumatic fistulas caused by violence against women documents the presence of such cases in war-torn areas of Africa such as the Democratic Republic of Congo, Sierra Leon, Sudan, and Somalia [24]. However, the prevalence of traumatic fistulas in these areas is sometimes difficult to determine with accuracy as the authors report that many women with fistulas claim a history of sexual abuse even when this does not appear to be the case. Two articles published in the Congo Medical Journal and included in the Acquire Project review demonstrate the importance of fistulas resulting from sexual violence [24]. The study by Kalume et al revealed that 17 of the 100 female victims of sexual violence developed a fistula as a result of their injuries [25]. At the Maternity Hospital in Kindu, 36 of the 2010 female victims of sexual violence developed a fistula as the result of sexual assault (28 vesicovaginal fistulas, 2 rectovaginal fistulas and 6 combinations of both fistula types) [26]. In a study in Ethiopia, Muleta et al [27] reported on 91 girls and women with fistulas resulting from sexual violence. A study in Kenya, Nduati and Muita [28] identified two cases of fistula (one rectovaginal, one vesicovaginal) among 21 sexual abused children. These data demonstrate both the variability in the prevalence of post-violence fistulas as well as the importance of this problem in war-torn parts of Africa. More detailed studies are needed in this area.

The last group of causes involved in fistula formation includes traditional cutting practices based on erroneous assumptions of disease aetiology or other cultural values. In northern Nigeria, a harmful practice called gishiri-cutting accounts for between 2-13% of vesicovaginal fistulas. Gishiri is the Hausa word for “salt.” It also refers to a disease state in the Hausa ethnomedical system. The belief exists that ingestion of too much salt, sugar or similar substances (especially during pregnancy) will result in the vagina becoming “encrusted,” narrowed, or “covered with a filmy membrane” that will prevent the child from being born. When this condition is diagnosed (obstructed labour) a traditional healer (barber, midwife) is consulted who makes a series of gishiri cuts in the vagina to “relieve” this obstruction. This often results in direct trauma to the urethra or bladder, causing a fistula.

The cut is usually made on the anterior vaginal wall. Repeated cutting over a period of time may extend the incision area to the posterior vaginal wall. Wall et al [29] identified among 932 cases of fistula 21 (2.3%) that might be caused by this practice. Tahzib found that gishiri-cutting was carried out in 12 of the 80 children (15%) with fistulas [30] and in 13% of the 1443 fistula patients treated at the University Hospital Ahmadu Bello between 1969 and 1980 [31].

Severe forms of female genital cutting such as like infilubations are often said to be possible contributors to the development of fistulas although there is little evidence in the world literature to support this belief. Direct injury to the urinary tract can, of course, occur at the time of “deinfibulation” or anterior episiotomy at the time of delivery (Andrew Browning, personal communication). There is evidence that women who have been subjected to female genital cutting have worse obstetric outcomes than women who have not had these procedures done. A recent study by the World Health Organization looking at the relationship between female genital cutting and obstetric outcome found that “deliveries to women who have undergone FGM are significantly more likely to be complicated by caesarean section, postpartum haemorrhage, episiotomy, extended maternal hospital stay, resuscitation of the infant, and inpatient perinatal death, than deliveries to women who have not had FGM ”[32]. The authors were unable to describe any clear mechanism to explain these findings, and the study was not able to look at long-term obstetric outcomes, including fistula formation. If genital cutting practices predispose women to fistulas, the most likely explanations would be direct injury to the genitourinary system at the time of the procedure as already noted, or scarring at the vaginal outlet that leads to prolonged labour. Since most cases of obstructed labour occur higher up in the pelvis than at the outlet, it seems unlikely that female genital cutting by itself is the sole cause of the obstruction that leads to a fistula. One study from Sweden—a highly industrialized country—compared the duration of the second stage of labour in “circumcised” immigrant and “nincircumcised” nulliparous women and found that those who had undergone female genital cutting actually had a shorter second stage than those who had not been “circumcised.” The authors concluded that prolonged labour does not seem to be associated with female genital cutting in an affluent society with high standards.
of obstetric care [33]. Similarly, an unpublished series of 2000 patients from Ethiopia compared those with and without female genital mutilation. There was no difference between the groups with respect to classification of fistula, length of labour, parity, age and outcomes implying that female genital cutting has little or no influence on the development of obstetric fistulas (A Browning, personal communication).

3. EPIDEMIOLOGY OF FISTULAS

a) Availability and quality of data

Two major shortcomings are present in the published papers on obstetric fistulas. The first is the overall paucity of reliable data on obstetric fistulas. The second is the fact that almost all studies have been done in a hospitals where fistula repair is carried out. Such studies are subject to considerable selection bias and do not provide reliable estimates of the true incidence of fistulas worldwide [34, 35].

b) Indicators for monitoring programs in the struggle against fistulas

In 2006 the WHO proposed indicators for monitoring and evaluating fistula treatment and prevention programs (table 1), [36, 37]. These indicators can be subdivided in four groups: epidemiologic indicators, service delivery indicators, training indicators, and markers of the quality of care provided. There is very little information on programmatic indicators of success in the social reintegration of fistula patients [38].

c) Population-based incidence and prevalence of fistulas

A review of the recent epidemiologic literature by Stanton et al [34] has demonstrated that our knowledge of the incidence (new cases) and prevalence (already-existing cases) of obstetric fistula is based on poor quality data. These authors organized the existing population-based estimates of obstetric fistula into three categories. The first category consisted of estimates reported in the scientific literature that did not specify the methods used to obtain the estimate. The most commonly quoted number was 2 million cases of obstetric fistula worldwide, with 50,000 to 100,000 new cases each year. The second group of estimates is those made by surgeons, again with no methodology clearly specified. Examples include estimates of fistula prevalence in northern Nigeria, the number of new cases each year in Ethiopia and Tanzania, the proportion of pregnant women with fistulas in Pakistan or other developing countries, and the proportion of married women with fistulas seen in Bangladesh. Although interesting, these estimates have low reliability when applied across national populations. The third group of estimates is those originating in population-based surveys where there is an adequate description of the methods used to obtain the estimates. Only four such papers could be

identified. The estimates were based on a cohort of pregnant women in western Africa, interviews of women concerning loss of urine or faeces one month after delivery in Bangladesh, model-based estimates of regional and age-specific fistula prevalence and incidence, and the lifetime prevalence of obstetric fistula from the 2005 Demographic and Health Survey (DHS) in Malawi. The cohort study of pregnant women identified only 2 fistula cases. Based solely on these 2 cases, the authors of this study reported an estimated incidence of 10.3 cases of obstetric fistula per 100,000 deliveries. The sample size of this study was clearly inadequate to generate meaningful estimates. In the study of post-partum incontinence in Bangladesh, all 3 women who responded “Yes” to the question on urinary/faecal leakage were examined by a female physician and none were found to have a fistula [34]. In 2007, Muleta and co-workers [39] found a prevalence of 1.5 non-treated fistulas per 1,000 women of reproductive age, based on interviews with 26,819 such women in Ethiopia. Since these reports of urinary and/or faecal incontinence were not confirmed by physical examination, these data are unreliable as incontinence may be due to factors other than a fistula.

The literature review by Stanton et al. suggests only 2 estimates of fistula incidence and 2 of fistula prevalence adequately describe the methods by which these estimates were obtained. These estimates vary from an empirical estimate of 124 obstetric fistulas per 100,000 deliveries for rural sub-Saharan Africa reported by Vangeenderhuyzen et al [40] to a model-based estimate of 18.8 fistulas per 100,000 women of reproductive age for all of sub-Saharan Africa reported by AbouZahr [5]. This latter estimate was only for rectovaginal fistulas and did not include vesicovaginal fistulas, which are more common than rectovaginal fistulas in all reported case series of obstetric fistulas. AbouZahr also estimated the global prevalence of obstetric rectovaginal fistulas at 654,000 cases in 1990, with 262,000 of these in sub-Saharan Africa. The only empirical estimate of the lifetime prevalence of obstetric fistula is the DHS estimate from Malawi [41], which suggested that 1 in 20 women of reproductive age were affected. The authors recommend the usefulness of the figures from the model-based estimate even when those date from 1990 because they result from a well-defined method based on the complete literature review and taking into account the age and the causes of women’s death [34]. None of these data are very convincing.

d) The estimated number of obstetric fistulas per 1000 deliveries

The estimated number of obstetric fistulas per 1,000 deliveries is a way of attempting to assess a woman’s risk of developing a fistula after any given delivery. Danso et al have reported the evolving trends in the number of cases of obstetric fistula per 1000 deliveries at Komfo Ankoye Teaching Hospital in Ghana, calculated over 5-year periods from 1977 to 2004. [42]. This indicator ranged from 0.78 for the years 1977-1981 to 0.66 for the years 2002-2004 and peaked between 1987-1991 at 1.46.

e) The number of women treated for obstetric fistulas per year

The number of women treated for obstetric fistulas per year is an indicator that takes into account the capacity of the health system to care for women with fistulas. Figure 4 demonstrates the impact of the presence of external funding to pay for the treatment of fistula patients in a rehabilitation centre in Nigeria between 1999 and 2006 [43]. Initially (1999-2002) this project (FORWARD) was funded by the UK Department of International Development. From 2003 onwards the project was funded by donations and by the government. The dependence on external funding is clearly shown by drop in cases treated when financial support was withdrawn.

f) Unmet need

This indicator takes into account the number of patients needing treatment who cannot get care. This would be the most useful information for policymakers to use in strategic planning, but this requires accurate information on the total number of fistula cases that exist in any given area. These data simply do not exist.

4. FACTORS PREDISPONING TO THE DEVELOPMENT OF FISTULAS

A woman’s obstetric history is the most salient element in the development of an obstetric fistula. It is often stated that fistula patients tend to be young women with small, immature pelves (most commonly primiparas), with an antecedent history of obstructed labour, prolonged delay in receiving emergency obstetric care, sometimes having undergone late caesarean delivery [44-51]. Creanga and Genardy [35] analysed the role of 5 socio-medical factors in the development of fistulas: age, parity, duration of labour, the place of delivery, and whether the delivery was attended by a qualified person along with the proportion of caesarean sections. The authors identified only 5 studies that included data on all these 5 factors, 7 other studies that reported data on 4 of these factors, and an additional 7 that reported data on only 3 of these factors. We have updated their work by including articles published in 2007 that reported data on these 5 socio-medical factors [52, 53]. The results of this enhanced review are presented in table 2. The proportions of young women, primiparas and caesarean deliveries are higher than in the general population. Moreover, the duration of labour in these cases is greater than 2 days, strongly suggesting that fistulas develop most commonly in young women with obstructed labour. Such predisposing factors were confirmed in a case-control study from Gombe Hospital.

Adapted from Creanga and Genadry, 2007 and completed with two new references
in Nigeria which compared 80 women with fistulas to 80 inpatients without fistulas who were recruited randomly as a control group. Major risk factors for the development of a fistula included early age at first marriage (average 14 years), short stature (average height of 146.2 cm), illiteracy, rural residence and living at more than 3.0 km from the nearest health care facility [54].

5. PHYSICAL, SOCIAL AND PSYCHOLOGICAL CONSEQUENCES

Recent publications [29, 55-61] and a review by Ahmed and Holtz [62] have documented the physical, social, economic, emotional and psychological consequences of fistulas in affected women. A meta-analysis of the literature published between 1985 and 2005 showed that 36% (95% CI: 27%-46%) of women afflicted with fistulas were divorced or separated and foetal loss occurred in 85% of cases in which a fistula developed. Low self-esteem, feelings of rejection, depression, stress, anxiety, loss of libido and loss of sexual pleasure were commonly reported by these women. It also appears that the rates of separation or divorce increases the longer a woman lives with a fistula, particularly if she remains childless [63]. Not surprisingly, successful fistula repair reduces the prevalence of these psychosocial pathologies [62].

Three recent articles further document the presence of these problems in women with fistulas. In their 2007 article on the health and social problems of women with fistulas in Ethiopia, Muleta et al [39] reported 69.2% of fistula victims were divorced, only 19.2% were members of a local community association, and 44.2% ate separately from other family members. Forty-eight of 52 women felt listless and 28 had suicidal thoughts. Goh et al [56] conducted a prospective observational study to screen women in Bangladesh and Ethiopia with fistulas for mental health dysfunction.

Of the 68 women with fistulas screened, 66 were at risk for mental dysfunction as measured by the General Health Questionnaire (GHQ-28) compared with only 9 of 28 controls. In a prospective interventional study, 51 women with fistulas in the north of Ethiopia were screened for mental health issues before and 2 weeks after surgery using the GHQ-28.

Prior to surgery, all women had signs of mental dysfunction, but two weeks after fistula surgery, only 36% still had signs of mental distress. Among the 45 women who were cured of their incontinence, only 27% had signs of mental dysfunction two weeks after surgery, whereas all of the six patients who remained incontinent continued to screen positive for mental distress on the GHQ-28 [55]. These studies highlight the importance of attending to mental health issues among women who have sustained an obstetric fistula.

II. DIAGNOSIS

1. SIGNS AND SYMPTOMS

Obstetric fistulas may develop early, either after vaginal delivery or after an emergency caesarean section. Even though these women may be under medical supervision, these early fistulas may not be detected by the local staff. Many of these women leave the hospital without a baby but with a fistula [64]. Once the fistula is established, the continuous leakage of urine will lead to a foul odour, skin deterioration, and a cascade of hygienic and social problems. In most cases these women will be poor. Women may present early or late after a fistula appears.

2. CLINICAL EVALUATION

A fistula patient often has more than just a fistula. When examining and treating a woman in whom a fistula is suspected, the clinician should look for evidence of the entire ‘obstetric labour injury complex’ [65]. Clinical evaluation should include the assessment not only of urologic and gynaecologic injury, but also for evidence of the presence of rectovaginal fistulas, orthopaedic trauma, neurologic and dermatologic injury as well. The psychological impact of the fistula should never be underestimated. (table 3)

After admission, fistula patients should undergo a thorough evaluation through the taking of a detailed history, general physical examination as well as a careful pelvic examination. The site of the fistula, the condition of the surrounding tissues, and the feasibility of a vaginal surgical approach should all be assessed. In many countries the absence of advanced technology will mean that careful clinical examination will be the only tool available to the surgeon in planning a repair.

a) Urologic injury

1. BLADDER

The loss of bladder tissue from pelvic ischemia during obstructed labour affects both the technique needed for, as well as the functional outcome of, fistula repair. Loss of bladder tissue is one of the main reasons why obstetric fistula repair is technically difficult. The surgeon must try to close large defects in the bladder often with only small remnants of residual bladder tissue with which to work. Although there are as yet no basic histological studies of the tissue surrounding obstetric fistulas, it seems clear that these tissues have themselves sustained significant damage during obstructed labour. The fistula itself develops in an area which becomes necrotic; but the tissues surrounding the fistula have also suffered varying degrees of ischemia. In some cases pressure necrosis may destroy virtually the entire bladder, so that if the defect can be closed at all, the afflicted woman is left with a remarkably small (30 - 50 ml) bladder that
remains virtually functionless. Because most of the innervation of the bladder runs through the base and trigone, ischemic injury to these areas probably also produces an element of neuropathic bladder dysfunction. Basic scientific studies confirming this hypothesis have yet to be undertaken.

Clinically it will be important to assess the number and size of the fistulas, their location, the amount of fibrosis present, and any involvement of the ureters and or the urethra.

Clinical experience also suggests that bladder compliance may be altered by the extensive fibrotic changes that often take place. To date there have been few urodynamic studies reported on patients who have undergone successful fistula closure [66, 67]. In the former study bladder compliance was not measured. In the latter study by Carey et al., of 22 women with severe urinary incontinence after fistula closure, 9 had urodynamic stress incontinence with normal bladder compliance, 3 had urodynamic stress incontinence with poor bladder compliance, 9 had mixed incontinence, and one had voiding difficulty with incomplete bladder emptying and overflow. There is a great need for further investigation of these issues; unfortunately, those hospitals most likely to see large numbers of patients with obstetric fistulas also usually lack the resources for more advanced urologic investigation.

A number of patients with vesicovaginal fistulas develop vesical calculi [68, 69]. Often these bladder stones develop in association with a foreign body in the vagina. In some cases a foreign body may have been the original cause of the fistula (such as an object used for masturbation or a container filled with traditional herbal medicines, placed in the vagina for an ostensibly therapeutic purpose). In other cases, the stone may form in association with an object that was placed into the vagina in an attempt to plug the fistula and prevent urine loss, which subsequently became stuck, eventually became calcified, and ultimately increased the overall misery of the afflicted woman. In other cases, no foreign body can be found. Frequently in these cases it is the increasing pain associated with stone formation that causes the suffering patient to present for care. In fistula cases complicated by the presence of vesical calculi, the stone is often located supratrigonally and the bladder may be able to hold at least a small amount of urine in the vicinity of the calculus (which allows for its continued growth) [69].

Removal of the stone (usually at a separate operation) is a prerequisite for successful fistula closure in such cases. After stone removal, the bladder should be allowed to heal prior to attempted fistula closure. If this is not done, there is substantial risk of post-operative infection and breakdown of the repair.

2. URETHRA

The ischemic changes produced by obstructed labour often have a devastating impact on urethral function. Complete urethral loss occurs in about 5% of fistula patients, with about 30% of fistula patients sustaining partial urethral injury. Goh et al. found that up to 63% of fistula patient have sustained some injury to the urethra [70]. The great Egyptian fistula surgeon Naguib Mahfouz was well aware of this problem [71].

Mahfouz stated [71] that fistulas “in which the whole urethra has sloughed” are “the most troublesome of
The experience of subsequent surgeons seems to bear this out. In a 1980 series of 1,789 fistula patients, Sister Ann Ward reported that only 26 cases were inoperable; but in all 26 urethral loss was present [72]. There are no comparative surgical studies that evaluate differing techniques of urethral reconstruction in patients with obstetric fistulas. There are no data on post-operative urethral function. Work of this kind is badly needed.

3. Ureters

Ureterovaginal fistulas from direct injury to the distal ureter during obstructed labour are uncommon, comprising only about 1% of fistula cases. Depending on the amount of tissue that is lost at the bladder base, the ureteral orifices can be found in bizarre locations, ranging from the lateral vaginal walls all the way up to the level of the vesico-urethral junction and the pubic arch (Figure 5).

Aberrant ureteral locations of this kind can easily be missed on clinical examination and are one cause of persistent incontinence after otherwise “successful” fistula closure. Standard urological tools such as ureteral stents are usually not always available in hospitals in the developing world, and most of the surgeons who work in such hospitals are not trained in “urologic” techniques such as ureteral reimplantation [73].

![Figure 5: Complex fistula with intravaginal ureters](image)

4. Kidneys

The incidence of secondary injury to the upper urinary tract in fistula patients has received little study, but this phenomenon appears to be clinically important. Clinical experience suggests that renal failure is a common cause of death in women with obstetric fistulas.

Upper tract damage could result from chronic ascending infection, obstruction from distal ureteral scarring, or even from reflux in very young patients. Lagundoye et al [74] found that 49% of fistula patients had some abnormality of the kidneys when intravenous urograms were performed. Most of the pathology that was detected consisted of minor calyceal blunting, but 34% of patients had hydro-ureter, 9.7% had ureteral deviation, four patients had bladder stones, and 10 patients had a non-functioning kidney. More research is needed in this field. Iatrogenic causes of hydronephrosis and renal insufficiency may also exist. Injury of the ureters during the surgery or scarring in the post-operative phase might play a role, but data to support this are currently missing.

b) Gynecologic injury

1. Vagina

An impaction of the foetal head serious enough to cause ischemic injury to the bladder will also cause ischemic injury to the vagina, which is likewise trapped between the two bony surfaces. These injured areas heal with varying degrees of scarring. A small sonographic study by Adetiloye and Dare [75] detected fibrotic changes in 32% of fistula patients and minor vaginal wall fibrosis in another 36%. Vaginal injuries in fistula patients exist along a spectrum that includes only small focal bands of scar tissue on one end all the way to virtual obliteration of the vaginal cavity on the other. Roughly 30% of fistula patients require some form of vaginoplasty at the time of fistula repair. The degree of vaginal injury has several important implications. In the first instance, severe vaginal injury results in loss of substantial portions of the vagina. In many instances the scarring is such that vaginal intercourse is simply not possible. There is very little information available on the sexual functioning of fistula patients, yet this is obviously an important concern in healthy marital relationships and undoubtedly contributes to the high rates of separation and divorce that appear common among these women. Browning et al. noted that among 240 fistula patients only 7.1% were having sexual intercourse prior to surgery and of those who were sexually active, 17.6% had dyspareunia. Six months after surgery 35% of patients were sexually active. Of those, 10.0% had dyspareunia. The main reasons for lack of sexual relations were divorce, anxiety about damaging the repair, widowhood or a scarred vagina [63].

Surgical repair of fistulas in women with extensive vaginal scarring often requires the use of flaps and tissue grafts in order to close the fistula. Little work has been done to assess whether or not sexual function normalizes in women who have had such operations. The presence of scarring that requires the use of plastic surgical techniques of this kind markedly reduces the effectiveness of surgical repair when fistula closure is attempted by surgeons who lack experience in reconstructive gynaecologic surgery. Although several papers have described various techniques for vaginoplasty that may be required in fistula patients [76-78], there is a pressing need to
investigate the role of vaginal plastic surgery at the
time of fistula repair and to evaluate subsequent
sexual functioning in patients who require surgery of
this kind [79].

Vaginal scarring impacts on more than just sexual
functioning. The presence of vaginal scarring appears
to be an important prognostic factor in determining the
likelihood both of successful fistula closure, and also
for the development of debilitating urinary stress
incontinence after otherwise successful fistula repair.
In one unpublished series of 26 fistula patients with
severe vaginal scarring, 57.7 percent suffered from
stress incontinence after fistula repair and 23.5 percent
had a persistent or recurrent fistula. This would
compare to an expected stress incontinence rate of
around 26% and a failed fistula closure rate of about
7% in the overall population of fistula patients
(Arrowsmith, personal communication). Kelly and
Kwast have also reported worsening surgical outcome
in fistula patients who have vaginal scarring than in
those without such findings [80].

2. CERVIX, UTERUS, AND FUTURE REPRODUCTIVE
PERFORMANCE

From an obstetric point of view, timely termination of
obstructed labour requires operative intervention,
most often by caesarean delivery. When timely access
to caesarean section is not available, prolonged
obstructed labour results in a high rate of uterine
rupture, usually with catastrophic consequences for
both mother and child. For example, Ekele and co-
workers reported one uterine rupture for every 79
deliveries in Sokoto, Nigeria, an impoverished rural
area with poor obstetric services [81]. Caesarean
delivery in such cases is often lifesaving, but in some
cases it may also be implicated in the formation of a
vesico-uterine fistula [82-84]. Vesico-uterine fistulas
can present in different ways, depending on their
location, size, and the degree of patency of the
endocervical canal. The least troublesome vesico-
uterine fistulas do not result in incontinence, but are
characterized by the absence of vaginal menstruation
in the presence of cyclic haematuria (“menouria” or
“Youssef’s syndrome”), whereby the menstrual flow
exits exclusively through the urinary tract [85-87].
Other vesico-uterine fistulas may be associated with
various combinations of altered menstruation and
either periodic or continuous incontinence. The finding
most characteristic of an uterovesical fistula is
a demonstrable loss of urine through the cervix (a
finding that also occurs with vesicocervical fistulas). In
the absence of operative intervention, uterovesical and
vesicocervical fistulas are relatively rare.

Many patients sustain severe cervical damage as well
as vaginal injury during the course of obstructed
labour. It is rare to see a completely normal cervix
when examining a fistula patient. In the worst cases,
prolonged obstructed labour may result in complete
cervical destruction, leaving the patient with no
identifiable cervical tissue at all. Unfortunately, detailed
descriptions of the condition of the cervix have not been
included in the case series of fistulas published to
date. Since cervical competence is such an important
factor in future reproductive performance, this is yet
another clinical area that demands further study. Other
studies have shown amenorrhea rates from 25% to
44% [88-90]. Many of these patients undoubtedly
have hypothalamic or pituitary dysfunction [89]. A
follow up study by Browning et al. showed that while
the amenorrhea rate was 58% pre-operatively, this rate
improved to 29% at 6 months after surgery, suggesting
a recovery of ovulation in a proportion of operated
women [63]. While the high incidence of amenorrhea
in vesicovaginal fistula patients is widely recognized,
only one unpublished study has been done to date
looking specifically at uterine pathology in the
vesicovaginal fistula population. Dosu Ojengbede of
the University of Ibadan (personal communication)
performed hysteroscopy on fistula patients in Nigeria
and found that intrauterine scarring and Asherman’s
syndrome were common in these women. The
combination of widespread amenorrhea, vaginal
scarring, and cervical destruction leads to a tremen-
dous problem of secondary infertility among these
patients. To date, there have been no serious scientific
efforts to explore treatment of cervical and uterine
damage in vesicovaginal fistula patients.

Subsequent reproductive performance of women who
have had an obstetric vesicovaginal fistula has been
analyzed in a few articles [88, 90-92]. Emembolu
analyzed the subsequent reproductive performance
of 155 fistula patients delivered at Ahmadu Bello
University Teaching Hospital in Zaria, Nigeria, between
January 1986 and December, 1990 [92]. This series
included pregnancies in 75 women who became
pregnant after successful fistula closure and 80 women
who became pregnant while still afflicted with an
unrepaired fistula that had occurred in a previous
pregnancy. The data presented do not allow one to
determine the subsequent fertility rates of women
who develop a fistula, but clearly indicate that women
can, and do, become pregnant after sustaining an
obstetric fistula. The proportion of booked pregnancies
receiving antenatal care was higher in the repaired
group (73%) than in the unrepaired group (51%),
and reproductive performance was better (but still dismal)
in those patients who had had a fistula repair. Of the
69 patients whose fistulas had been repaired, there
was a recurrence of the fistula in 8 (11.6%), and
among those undergoing a trial of vaginal delivery, the
fistula recurrence rate was nearly 27%. In women
with pre-existing, unrepaired fistulas who became
pregnant but who did not register for prenatal care in
the subsequent pregnancy, maternal mortality and
morbidity in those pregnancies was high, reflecting
continuation of the conditions that led to fistula
formation in the first place [92].
The commonest maternal morbidity, excluding recurrence of vesicovaginal fistulas, was haemorrhage requiring blood transfusion in 35 patients (27.3%). Others included ruptured uterus in 3 unbooked patients whose fistula had not been repaired, bladder injury at caesarean section in 1.6% and acute renal failure in 0.8%. Maternal complications occurred more frequently in the patients whose fistula had not been repaired and who were also unbooked.

The largest series is that of Aimakhu, who analyzed subsequent reproductive performance in 246 women who underwent successful fistula closure at University College Hospital in Ibadan, Nigeria, between 1957 and 1966 [88]. Only 48 patients became pregnant following fistula repair with a total of 65 pregnancies. All but 6 of these were managed at University College Hospital. Five patients aborted prior to the 16th week of gestation, leaving only 60 viable pregnancies. The plan was to perform elective caesarean section on all patients who became pregnant after fistula repair, but only 49 caesarean operations were carried out. The results of the vaginal deliveries were not encouraging. Patients who underwent caesarean delivery fared better. There were 49 babies delivered and 47 survived. There was no recurrent fistula among women previously repaired who became pregnant and had a subsequent caesarean section. There was one maternal death from pulmonary embolism in a woman who underwent an emergency delivery at 32 weeks gestation due to a prolapsed fetal umbilical cord.

c) The rectovaginal fistula

Rectovaginal fistulas appear to be significantly less common than vesicovaginal fistulas. In case series of patients presenting with vesicovaginal fistulas, between 6% and 24% have a combined rectovaginal and vesicovaginal fistula (Figure 6) [29-31, 49, 93-102]. In most series, isolated rectovaginal fistulas are less common than combined fistulas. Indeed, most series do not even mention isolated rectovaginal fistulas as a clinical phenomenon. In a series of patients from Turkey reported by Yenen and Babuna [103], 7.1% had rectovaginal fistulas and 6.5% had “combined” fistulas. From the report it is not clear if this latter figure was comprised solely of rectovaginal and vesicovaginal fistulas, or if it included other combinations of urinary tract fistulas as well (vesicocervicovaginal, urethrovaginal, etc.). Kelly and Kwast [80] reporting data from the Addis Ababa Fistula Hospital, noted a 15.2% pre-valence of combined fistulas, and a 6.8% prevalence of isolated rectovaginal fistulas in that population. Ethiopia appears to have one of the highest rates of rectovaginal fistulas reported in the literature. Whether this relates to specific obstetric characteristics of the Ethiopian population or whether this relates to other social factors — such as the cases of rape and sexual abuse of young Ethiopian girls reported by Muleta and Williams [27] — is unclear.

Figure 6 : rectovaginal fistula

Since the pubic symphysis poses an obstruction to delivery through the anterior pelvis, in normal birth mechanics the foetal head is normally forced posteriorly towards the rectum, anus, and perineum at the end of the second stage of labour. In non-obstructed labour, direct laceration of the perineum is not uncommon, occasionally resulting in a complete perineal tear with complete disruption of the anal sphincter. If this is not repaired, a complete perineal tear with sphincter disruption can create a rectovaginal fistula at the anal outlet [104]. This mechanism of fistula formation seems more likely to account for low rectovaginal fistulas, whereas rectovaginal fistulas higher in the pelvis would seem more likely to be caused by direct tissue compression from obstructed labour.

d) Orthopaedic trauma

Ischemic injury from obstructed labour not only affects pelvic organs, but also the pelvis itself. These changes are most pronounced in the pubic symphysis. The normal radiography of the symphysis pubis has been described in detail by Vix and Ryu [105]. In obstructed labour, the pubic bones are often directly involved as they form one side of the bony vice in which the vulnerable soft tissues are trapped. In fistulas where large amounts of bladder tissue are lost, the periosteum of the pubic arch can often be palpated directly through the fistula defect. It is these cases in which ischemic damage to the pubic bones is most likely to be demonstrable. In a study of 312 Nigerian women with obstetric vesicovaginal fistulas Cockshott [106] detected bony abnormalities in plain pelvic radiographs in 32 percent of these patients. The findings included bone resorption, marginal fractures and bone spurs, bony obliteration of the symphysis, and wide (>1 cm) symphyseal separation. Most of these changes appear to be the result of avascular
necrosis of the pubic symphysis. Their long-term significance remains uncertain and further study is required.

e) Neurologic injury

Another tragic injury associated with obstetric fistula formation is footdrop [107]. The relationship between difficult labour and neurological injury has been known for centuries, and the condition was traditionally called “obstetric palsy” [108]. Women with this condition are unable to dorsiflex the foot and therefore walk with a serious limp, dragging their injured foot, and using a stick for support (Figure 7). Sinclair’s paper on maternal obstetric palsy in South Africa [108], made the comment that “There are no records of this lesion associated with vaginal fistulas, where there has been prolonged pressure by the foetal skull in the lower part of the pelvis.” This statement is clearly wrong. In Waaldijk and Elkins’ review of 947 fistula patients, nearly 65% of those studied prospectively had evidence of peroneal injury either by history or physical examination [107]. The prevalence of clinical footdrop among patients seen at the Addis Ababa Fistula Hospital is about 20% [65].

Various theories have been proposed for the aetiology of this condition. In general clinical series of peroneal nerve palsy, the most common aetiologies appear to be direct trauma from ankle inversion, fractures of the hip, femur, fibula or tibia; knee injuries, alcoholic neuropathies, and a variety of miscellaneous or idiopathic causes. In obstetric patients the lesion most likely develops from one of three causes: prolapse of an intravertebral disk, pressure from the foetal head on the lumbo-sacral nerve trunk in the pelvis leading to direct compression of the peroneal nerve, or direct trauma to the peroneal nerve from prolonged squatting and pushing in the second stage of labour [108-110]. There is very limited experience with the performance of electromyography on fistula patients. Bademosi and colleagues performed EMG studies on 34 Nigerian women with obstetric neuropaxia at the University of Ibadan and found that 88% of the lesions were due to lumbosacral plexus injury high in the pelvis [111].

Footdrop has also been associated with trauma sustained in difficult forceps deliveries, particularly mid-pelvic rotations, but again, as others have emphasized “The peripheral nerve lesion following instrumental delivery may have developed in any case and forceps were but incidental or at the most a precipitating factor in border-line cases” (Sinclair 1952). The prognosis for recovery from this injury is unclear, as there are no proper prospective studies of women who have developed this condition. Waaldijk and Elkins suggest that most patients recover some or all of their nerve function spontaneously within two years of the injury [107]; however 13% showed persistent signs of nerve trauma. In some cases the affected women are almost completely crippled from bilateral lesions and suffer tremendously from the additional burden imposed by immobility on someone who already suffers from intractable urinary incontinence.

Physiotherapy and the use of posterior splints improve the condition of some patients. Others may require surgical intervention: the use of posterior tibialis tendon transfer is a well-established procedure for patients with footdrop from other causes (such as leprosy), and it may be that this method will be useful in treating women with unresponsive obstetric palsy as well [112, 113].

f) Dermatologic injury

Skin lesions can be variable, depending on the importance of the leakage, the duration of the leakage and the level of hygiene. The condition of the skin, which is in constant contact with a stream of urine and/or faeces, is one of the most bothersome problems for the fistula patient (Figure 8). In some women minimal skin damage will be noted, while in other extreme causes, the vulvar skin might be covered with uric acid crystals and salts or might be superinfected.

g) Psychological injury

The consequences of isolation, divorce etc… have been described in II.5. Depression has a high prevalence in patients with obstetric fistula. Care must be taken to acknowledge these factors. A significant improvement can be expected after successful surgery in many patients.

Figure 7 : Neurological injury

Figure 7 : Neurological injury
3. EVALUATION WITH ADVANCED TECHNOLOGY

The use of technology beyond simple physical diagnostic techniques in women with fistulas will depend entirely on the local availability of such resources. Cystoscopy, ureteral catheterisation, ultrasound or radiographic examination and urodynamic testing facilities are not always present. Utilization of modern diagnostic techniques might be especially useful in the evaluation of the upper urinary tract and in developing strategies for long-term follow-up of fistula patients. The ability to obtain some basic or advanced laboratory tests, would also be useful in many cases. At a minimum, it is desirable to have basic haematology and electrolyte testing available, if the data can be trusted. HIV testing is optional.

III. FISTULA PREVENTION

Preventing obstetric fistulas is an enormous task that will depend largely on continuous improvements in the maternal healthcare infrastructure of the countries where fistulas are prevalent. The magnitude of the needs in this part of the world is staggering. Waaldijk has stated that at least 75,000 new obstetric units should be built across Africa to deliver adequate perinatal care and to prevent new cases of fistulas [114].

Historical experience from Western countries suggests that fistula prevention can only be accomplished by providing good antenatal screening and surveillance of ongoing pregnancies, delivery in the presence of trained birth attendants, and prompt access to emergency obstetric services when problems arise during labour. In fistula-prevalent areas, basic emergency obstetric care is usually inaccessible due to problems with transportation and referral centres for advanced care are usually far away for women living in rural areas. A recent survey by UNFPA and UNICEF showed that each African country assessed had only one emergency obstetric unit per 500 000 inhabitants and none had the recommended number of facilities for the provision of basic emergency obstetric care. The unmet obstetrical needs were huge: only 8.2-35% of women with complications during labour received care at an appropriate facility [115]. Even when a woman with a complication arrives at such a facility, the receipt of good care is not guaranteed. In most countries the patient must pay for emergency care, including caesarean section and many families simply cannot afford the cost involved or are left in debt afterwards for many years [116].

In addition to creating centres for emergency obstetric care, adequate training for health care professionals has to be provided, financing mechanisms have to be established and access to these facilities has to be guaranteed for all patients who need these services. This is an enormous task and most governments in the developing world do not have the necessary resources for it (or the political will to carry such projects out). Western aid organizations are often more interested in funding the treatment of women with fistulas than with doing the hard work of constructing primary care obstetric units or funding the provision of emergency obstetric services [117]. What is clear is that perinatal care is grossly inadequate due to the large number of vesicovaginal fistulas that is being reported in many developing countries. It is also clear that there are multiple reasons that young mothers at risk of obstructed labour do not attend medical facilities, most of which have already been described. Even when patients in need arrive at a healthcare facility, they may not receive the care they need. This situation is described eloquently by Sundari in his paper on how health care systems in the developing countries contribute to maternal mortality [11]. The same problems are applicable to the prevention of fistulas. Thaddeus and Maine (1994) have elaborated on the three causes of delay that contribute to maternal mortality. These same causes of delay contribute to obstetric fistula formation once labour becomes obstructed.

1. PATIENT FACTORS
   - Delay in arriving at a healthcare facility
   - Non-use or non-availability of prenatal care
   - Transportation problems
   - Financial problems
   - Lack of women’s authority over decision-making regarding healthcare
   - Lack of information about risk factors, health problems, availability of services
2. QUALITY OF CARE FACTORS

- Shortage of trained personnel
- Lack of equipment
- Poor patient management

The lack of decent training is prevalent and is the result of the interaction of many different factors. There is wide high variability in the quality of training and in the curricula at many African universities and teaching hospitals. Once trained, local doctors may experience difficulties in maintaining their skills because of political issues, lack of equipment, and administrative decisions by local health authorities. In many developing countries poor staff training is compounded by the fact that only a ‘survival health economy’ exists, meaning that elective surgery is usually delayed until an emergency exists. Many pregnant women will have been warned about the risk of obstructed labour and its consequences, but simply do not have the money to undergo elective caesarean section even when it is advisable. Many local doctors depend on private income in order to survive in difficult economic situations. Inappropriate operations may compound the healthcare delivery problems that already exist. In India, where industrialisation is more advanced and the healthcare system is better than that of most African countries, caesarean sections are being misused for profit in the private sector of some of the states [118].

Ideally, therefore, fistula centres should be developed in collaboration with other maternal healthcare initiatives and they should also be prepared to provide services dealing with the entire obstructed labour injury complex and its consequences. A comprehensive approach that combines a curative setting with prevention is being advocated by many [119]. Doing this effectively will require the establishment of incentives at multiple levels throughout the healthcare system.

a) At the level of the patient

- Prenatal care is important because it plugs patients into the healthcare system and helps them access care when emergencies arise.
- “Maternity waiting homes” can be established for women at high risk of obstetric complications [120-123]. They then stay in the vicinity of the hospital until labour begins, at which time they are transferred to the hospital for monitoring and intervention. The success of such programs depends on multiple factors operating at the local level (D. De Ridder, personal observation, RD Congo 1987).
- Local radio or television shows involving former fistula patients can help create awareness about these problems and provide social mobilization.
- Young women and men should be educated about the risks of bearing children at too young an age.

Changing traditional customs of early marriage will require steady and prolonged pressure over time, but is one of the most important social interventions.

- These measures should be incorporated in a wider program that emphasizes education for girls and women. This is an extremely effective means of promoting maternal health [124] [7].

b) Professional level

Local midwives and doctors should be trained to screen for injuries associated with obstructed labour. It is not uncommon for a patient to undergo an emergency caesarean and to leave hospital later with a vesicovaginal fistula without any of the medical staff being aware of this problem (D. De Ridder, personal observation, Kisantu RD Congo 2007).

Several challenges are present:

- Continuing education on perinatal care
- Screening patients for risk factors
- Adequate and improved technical obstetrical skills
- Appropriate postoperative care
- Early detection of fistula formation
- Staff accountability for the quality of care provided
- Hospital level
- Careful record keeping
- Social accountability

c) Community level

At the community the level, awareness about the availability of antenatal care and the risk of obstetric fistula formation ought to be increased. Some fistula centres note that up to 30% of their patients are being referred by former patients who are now cured. Ways should be explored to use former patients as a mechanism to increase awareness of the problem and to organize prevention strategies, perhaps by monitoring women at the village level to detect prolonged labour early in its course.

Community-wide associations to promote maternal health should be encouraged, linking local farmers’ unions, women’s organisations, and religious associations, for example.

Patients often depend on their own finances or those of their relatives to be able to pay for health services. This is one of the main reasons for not undergoing timely caesarean sections in many countries. Local communities should be encouraged to embark on microfinance projects and revolving community credit schemes to help finance promote prompt access to emergency obstetric services when problems arise. Such projects could be facilitated within their catchment areas by fistula centres. Research in this area should be encouraged [125-130].
d) The Indian example

A national family health survey in India revealed that 65% of the births in rural areas took place in the homes of the women’s parents and that only one in seven deliveries was attended by trained health practitioners. According to the Indian government’s annual report in 2001-2002, maternal morbidity and mortality had not changed in the last four decades [131]. In the three years preceding the India’s National Family Health Survey 1998-1999 (NFHS-2), 35% of pregnant women received no antenatal care. This is only marginally better than the 36% in the 1992-1993 NFHS [132]. The government shifted its focus during the 1990s from contraceptive and fertility reduction targets and incentives for population control toward a broader system of performance goals and measures designed to encourage a wider range of reproductive and child health services. This approach seeks to address issues such as safe motherhood, safe abortion, and the quality of health services. Under this broader approach, the government initiated the Child Survival and Safe Motherhood Programme in 1992 in partnership with the World Bank and the United Nations Children’s Fund (UNICEF). In spite of such measures vesicovaginal fistulas and other urinary fistulas are still common. In rural areas, the majority of women with fistulas are not getting proper treatment. The results of surgery by surgeons who operate on these problems only rarely are so poor that many of them have abandoned the treatment of such cases altogether. Although the surgical results are good in hands of experienced surgeons, such practitioners are often more interested in procedures that have the potential for high financial gain, such as endo-urology and laparoscopy. Consequently, the majority of fistula patients are neglected. In urban areas where more surgeons are available, early caesarean delivery in cases of prolonged labour has reduced the obstetric causes of fistulas but there has been a concurrent increase in the number of fistulas resulting from gynaecological surgery (vesicovaginal fistulas, ureterovaginal fistulas, and uterovaginal fistulas).

In Kerala, one of the states of India that has achieved universal literacy, institutional deliveries have been made compulsory. This has resulted in a drastic reduction in maternal morbidity, and particularly in a reduction of obstetric fistulas [133]. In Kerala there is a more equitable distribution of health facilities and consequently better utilisation. Improved education has increase access to such services and there is also a higher degree of political awareness among the people in rural Kerala. Nag concluded that governments should give higher priority to social equity than to economic equity. In that state a rising trend in caesarean rates is seen and up to 28% of the first live births occurred by caesarean section [134]. The availability of these services is much appreciated by the local women and the use of the services was excellent (99% of a cohort of women participating in a survey visited a doctor at least 3 times during the pregnancy [135].

IV. CLASSIFICATION SYSTEMS

There is currently no uniform system for classifying fistulas and a wide variety of different systems have been proposed. Classification of fistulas is important only to the extent that the classification has a meaningful relationship to the prognosis of the injury. In recent attempts at fistula classification the size of the fistula and involvement of the urethral closing mechanism are taken into account. Some systems attempt to classify fistulas according to the anticipated degree of difficulty of the repair, while others classify them according to the type of surgical intervention that will be needed [36]. Systems based on the anatomical appearance of the fistula do not necessarily predict the difficulty of repair nor the post-operative prognosis [136]. Table 4 lists the most common classification systems in current use. Recently a large international multicenter study has started in an attempt to develop a prospectively-validated system for classifying fistulas (R. Genadry, personal communication 2008).

V. CONSERVATIVE MANAGEMENT

Little is known about the conservative treatment of vesico-vaginal fistula. As mentioned above, the diagnosis of a fistula is often missed by medical staff in the early phase after its development. This may be due to neglect by the staff or due to a patient who is eager to return home as soon as possible after delivery who simply thinks the initial urinary leakage is a normal consequence of her difficult delivery. Waaldijk published his personal experience with the conservative approach to fresh obstetric fistula [137-139]. He reported a series of 1716 patients with fresh obstetric fistulas, of whom 265 were treated conservatively with a CH 18 indwelling catheter. If there was no sign of healing after 4 weeks, a surgical approach was utilized. All but one of these women were cured by catheter drainage alone. Unfortunately, he provided no data on fistula size or location in this subgroup.

A recent evidence-based review by Bazi T. on the spontaneous closure of vesicovaginal fistula after bladder drainage alone came to the following conclusions [140]:

- It was not possible to correlate the aetiology of the fistula (obstetric or gynaecologic) with the likelihood of success

Failed previous repair | > 4cm |
- Most fistulas reported cured by catheter drainage alone are small, usually less than 1 cm in diameter.
- It was not possible to establish a relationship between fistula size and outcome, although a 5mm diameter has been set as an arbitrary cut-off limit.
- Duration of drainage utilized varies between 10 days and six weeks, but has not been studied properly.
- No data are available on which type of catheter drainage yields the best results.
- Fresh fistulas are more likely to close than those of longstanding duration.

The conclusion reached was that conservative management of a fresh fistula may be an option in small fistulas, but if healing has not taken place within a few weeks, surgical repair will likely be required for cure.

VI. SURGICAL MANAGEMENT

Fistula surgery requires some form of anaesthesia. The position used during fistula surgery depends on the nature and location of the fistula to be repaired. For the vast majority of fistulas a high lithotomy position with the buttocks pulled well over the edge of the operating table (in steep Trendelenburg position), with or without episiotomies provides excellent exposure (Figure 9). Surgery in this position can safely be performed under spinal anaesthesia, which is the cheapest and easiest form of anaesthesia for "low technology" settings in developing countries. Spinal anaesthesia can be administered by the surgeon which is an advantage over general anaesthesia [141].

Vaginal surgery for small fistulas can be attempted under local anaesthesia [142]. Larger or more complex fistulas can be treated under spinal anaesthesia, which is to be preferred over epidural or general anaesthesia [143]. Spinal anaesthesia will yield a better pain control than epidural anaesthesia in rural settings [144].

Alternative positions are the knee-chest position, which is uncomfortable for the patient and generally requires intubation. Operating by the abdominal route increases the cost and time of the operation, but is still often performed for some high fistulas where surgical access is problematic. Experienced fistula surgeons may be able to repair such defects vaginally. A retrospective study by Chigbu compared the outcome of juxtacervical fistula through the vaginal or abdominal approach [145].

Both approaches had similar cure rates and hospital stays, but the abdominal route was associated with a significantly higher need for blood transfusion. General anaesthesia is also more expensive, more complicated to administer, carries more risks, and should therefore be reserved for those patients who need an abdominal approach.

1. THE SIMPLE FISTULA

In practiced hands, skilled fistula surgeons routinely achieve a closure rate of over 80% for simple fistulas at the time of first operation. Multiple papers reporting large case series support this contention [29, 49, 71, 94-103, 146-161].

A fairly general consensus concerning the basic principles of fistula repair was reached at the first ‘Fistula Surgeons Experts Meeting’ at the WHO in Geneva 2004. These principles can be summarized as follows:

- The best chance for successful fistula closure is at the first operation and closure rates tend to diminish with each subsequent attempt at operative repair. In their large series of 2,484 obstetric fistula patients, Hilton and Ward (1998) reported successful fistula closure in 82.8% of patients at the first attempt. Successful closure was achieved in only 65% of those patients who required two or more operations. Another unpublished series of 400 patients from the Addis Ababa Fistula Hospital reported a successful closure rate of 92% and urethral incontinence of 33% at the first operation, a closure rate of 73% and urethral incontinence rate of 50% at the second operation and a closure rate of only 52% and urethral incontinence of 75% at the third operation (Browning, personal communication).
- The ureters should be identified and protected to ensure they are not cut or ligated during the fistula repair (if the site and size of the fistula puts them in proximity to the operative field).
- The fistula should be widely mobilized from the surrounding tissues at the time of repair.
• The fistula should be closed without tension on the site of repair.
• The repair must be ‘water-tight’. To ensure this, a dye test is performed intra-operatively and if there is still leakage, the repair is sutured again. There is one very experienced fistula surgeon who does not do this, preferring to drain the bladder continuously for up to 4 weeks postoperatively.
• After fistula repair the bladder should be kept on free drainage for 10-14 days. There is some weak evidence that 10 days of drainage is just as effective at six months follow up (for fistulas of less than 3 cm diameter with mild to moderate scarring) [162]. This change in catheter management could make a significant impact on the resources of hospitals where these operations are performed. If the time needed for postoperative bladder drainage could be reduced by 4 days, the capacity of the hospital to care for fistula patients would increase by 30% just from this gain in efficiency.
• There is debate as to whether or not a Martius bulbo cavernous flap or other graft should be used in fistula repair. The argument has always been that such practices bring in a new blood supply to help nourish the injured tissues surrounding the fistula. One retrospective paper compared the surgical outcomes of operations involving similar fistulas repaired with and without use of the Martius flap and demonstrated a higher successful closure rate when such a flap was employed [163]. Another more recent retrospective analysis evaluated 400 patients in which comparable fistulas were repaired with and without use of the Martius flap and demonstrated a higher successful closure rate when such a flap was employed [162].

What constitutes a “simple case?” This is a case that has a high chance of cure and is suitable for those without expensive experience in fistula surgery. Only about 20% of obstetric fistulas can be defined as simple. Simple fistulas are less than 3 cm in diameter, with no or only mild scarring and do not involve the urethra. The first pre-requisite for successful fistula repair is meticulous attention to detail. As Abbott aptly (if somewhat quaintly) noted [149], “There must be no attempt to operate on these cases with one eye on the clock and the other on the tea wagon”. In fact, the operator upon vesicovaginal fistulas should combine traits of daintiness, gentleness, neatness and dexterity of the English bulldog.”

After positioning the patient on the table the surgeon must obtain adequate exposure of the operative field. Figure 11 depicts a typically narrow, scarred vagina of the type that often develops after obstructed labour (Figure 11). For simple cases without scarring, the use of a weighted Auvard speculum should be sufficient. Sometimes an episiotomy is required to increase the exposure. The ureters should then be identified and catheterized. This can usually be done by passing the catheters through the fistula under direct vision (Figure 12). Note that for very small fistulas in the midline or for urethrovaginal fistulas well away from the ureters, this step may not be needed. Once the ureters have been catheterized, the ureteral catheters can be brought out of the bladder through the urethra, keeping them away from the operative field. Although some fistula surgeons leave the catheters in place for up to 14 days after surgery, most can be removed at the end of the operation or a few days afterwards.

Once the fistula is exposed and the ureters protected, the next step is to mobilize the bladder/urethra from their surrounding structures (Figures 13-17). The proximal margins of the fistula are incised and the incision is then extended laterally from the angles either side. Using traction and counter-traction the tissues planes are developed. The distal margins of the fistula are also incised. Two flaps are then developed, again using traction and counter-traction and sutured away to the labia. The fistula edges should now be fully exposed and mobilized. The mobilization should be adequate to be able to bring the margins of the bladder defect together under no tension. Often the angles of the fistula are adherent to the inferior pubic ramus either side. Releasing these attachments close to the bone gains much more mobility (Figure 17). This dissection can extend into the space of Retzius. It is also noted that the majority of the mobilization comes from the proximal dissection, not from the distal dissection and the amount of dissection reflects this. The distal dissection should really be only enough to secure a suture. It is best not to over dissect here and merely create scarring around the urethra.
Figure 10: a simple fistula

Figure 11: Exposure of the fistula. The illustration to the left shows a vagina that has been narrowed considerably by scarring, thus making the fistula difficult to see. Because adequate exposure of the operative field is the most important criterion for successful surgery, exposure must be improved in such cases. This is done by cutting a generous lateral episiotomy through the scar tissue on either side of the vagina. Although this is unavoidable in some case, the surgeon must remember that such incisions may bleed significantly and increase intraoperative blood loss. (Copyright Worldwide Fistula Fund, used by permission).

Figure 12: Catheterisation of the ureters. Knowledge of where the ureters are located is extremely important in fistula surgery, as closure of the fistula may inadvertently lead to ureteral injury. Particularly if the fistula is large, the surgeon should look for the location of the ureters in relation to the edges of the fistula. Giving the patient intravenous furosemide or indigo carmine dye, may help locate the ureteral orifices. When the fistula has been closed and the operation is over, the ureteral catheters may simply be removed. There is no benefit to keeping them in longer post-operatively, unless there are special circumstances. (Copyright Worldwide Fistula Fund, used by permission).

Figure 13: The initial incision. The initial incision should be made directly along the vesico-vaginal junction on the posterior edge of the fistula (see previous figure). The incision should be extended well out onto the lateral vaginal sidewalls. The purpose of the large incision is to allow wide mobilization of all tissues surrounding the fistula so that the fistula may be closed without any tension on the suture line. Very broad mobilization of tissues is especially important in more complicated fistulas and fistulas with extensive scarring. (Copyright Worldwide Fistula Fund, used by permission).
Figure 14: Extension of the initial incision. Once the incision has been made, it should be extended posteriorly, freeing the vagina from the underlying bladder. The initial opening of the incision is often facilitated using Thorek scissors, which have right-angled blades. Once the initial incision has been opened, the spaces can be widened using the Potts-Smith dissecting scissors. Blunt dissection with a finger to open these tissue planes is to be encouraged. (Copyright Worldwide Fistula Fund, used by permission).

Figure 15: Anterior extension of the incision around the fistula and into the anterior vagina. Again, the purpose of dissecting the fistula out from the surrounding tissues is to gain mobility so that the fistula can be closed with minimal tension. This involves mobilization of large areas of the vagina. (Copyright Worldwide Fistula Fund, used by permission).

Figure 16: Creation of anterior vaginal flaps. Once the initial incision around the fistula has been extended anteriorly, the dissection is carried out laterally to separate the vaginal skin from the underlying bladder. (Copyright Worldwide Fistula Fund, used by permission).

Figure 17: Entering Retzius' space. Mobility is further increased by penetrating the endopelvic fascia underneath the pubic rami and opening the space of Retzius. This further increases lateral mobility of the bladder and vagina. (Copyright Worldwide Fistula Fund, used by permission).
Once the fistula is adequately mobilized, it is closed. Traditionally, fistula closure was done by closing the bladder in two layers. Many surgeons now close the bladder in one layer using interrupted dissolvable sutures placed approximately 4 mm apart (Figures 18, 19, 20). The adage for the trainee is that a good tension-free closure with adequate good healthy tissue has no reason to fail.

The repair is then examined to ensure that ‘water-tight’ closure has been achieved by filling the bladder with 60-120 ml of coloured dye (dye test). Occasionally during this test a second fistula previously unknown will be found. If present, this, too, must be closed.

Once the fistula has been closed, the vagina is next repaired. When this has been finished, a vaginal pack is placed, and the urinary catheter is left in situ. The following day, the vaginal pack is removed and the patient is encouraged to mobilize and eat.

The bladder is left on continuous free drainage for 10-14 days. Each day the ‘3-Ds’ of post-operative fistula repair are checked. These are whether the patient is dry, drinking and the catheter is draining. The patient has to be dry; that is the fistula repair must be intact; drinking to ensure adequate irrigation of the bladder; and draining, that is, the catheter is not blocked. If the catheter does become blocked and the bladder fills, the repair is at risk of breaking from

Figure 18 : Placement of supporting stitches. Particularly in cases where the bladder neck and urethra are poorly supported, improved anterior vaginal support can be obtained by placing anchoring sutures into the tissues lateral to the edge of the fistula and then passing such sutures through the periosteum of the pubic arch (as shown in the inset). These sutures help decrease tension along the line of bladder closure. (Copyright Worldwide Fistula Fund, used by permission)

Figure 19 : Initial closure of the fistula. The defect in the bladder is closed using absorbable suture. Many surgeons prefer to close the bladder in two layers, so that the initial closure is reinforced; however, others do not do this. If any tension is encountered during bladder closure, this indicates that the initial dissection of the tissues around the fistula was inadequate and should be revised. (Copyright Worldwide Fistula Fund, used by permission).

Figure 20 : Closure of the fistula, second layer (if needed). A second set of sutures is placed to imbricate the second line of closure over the initial line of closure. This can be done either with interrupted sutures (shown here) or with a continuous running suture. When this line of closure is completed, the fistula should be “water tight.” Closure of the fistula can be tested by placing a trans-urethral Foley catheter and then filling the bladder with 100 – 200 mL of either colored water (indigo carmine, methylene blue, Gentian violet) or sterile infant feeding formula to check for the presence of leaks. If any leakage is noted, the repair should be reinforced with additional sutures until no leakage is demonstrated. If such leaks are not easily fixed it is better to take down the entire repair and start over rather than to struggle with repeated attempts to place additional sutures here and there. (Copyright Worldwide Fistula Fund, used by permission).
increasing tension on the repair site. If the catheter does become blocked and the repair ruptures, this may often be rectified by continuous prolonged catheter drainage. By ensuring an empty and relaxed bladder, the sides of the defect may come together and close, but this can take as long as 4 weeks to occur. The success rate is about 70% in such cases, less if the defect involves the urethra.

Following these principles in the repair of simple fistulas, the surgeon can anticipate successful closure in 90% of the patients and a postoperative urethral incontinence rate (“closed but still wet”) of 10%.

2. THE COMPLEX FISTULA

A complex obstetric fistula can be described being larger than 3 cm, involving the

- urethra, and associated with reduced vaginal capacity from significant scarring and/or a reduced bladder volume. Sometimes the defect may be urethrovaginal, but more commonly both the urethra and bladder are involved and therefore the fistula is called an urethrovesicovaginal fistula.

- Virtually all authors with extensive experience in the management of obstetric fistulas comment on the great difficulty in achieving postoperative continence in patients who have had extensive damage to the urethra, even if the defect itself has been closed successfully. Rates of postoperative urethral incontinence range between 6-50% (165) [37, 67]. Often the diagnosis of postoperative incontinence is given only if the patient suffers from severe incontinence while walking. If rigorous questioning is used to exclude any leakage with coughing or other exertion, the rate of postoperative incontinence increases dramatically.

- The four risk factors that lead to a high rate of incontinence following fistula repair are:
  - Urethral involvement. (Odds Ratio 8.4 for developing urethral incontinence post operatively.)
  - Large size of the fistula. (Odds ratio 1.34 for each cm increase in size of the defect.)
  - Severe vaginal scarring. (Odds Ratio 2.4 if the scarring is significant enough to prevent the introduction of a Sims speculum without relaxing episiotomies.)
  - Small bladder size. (Odds ratio 4.1 if the bladder capacity is less than 120 ml.) [166].

- In repairing complex obstetric fistulas, the principles for simple fistula repair still apply, but with the following additions:
  - Exposure is more difficult. In complex cases the fistula may be obscured from view due to the presence of severe vaginal scarring. Such scarring often consists of a thick band of scar tissue on the posterior vaginal wall. Occasionally, the vagina has been completely occluded. Wide bilateral episiotomies may be required and where possible the scar should be released from the lateral pelvic sidewalls. This will enable the fistula to be seen more clearly.
  - The ureters should be identified and protected against possible injury, as in the case of a simple repair.
  - The bladder and urethra should again be carefully mobilized. The tissues are often thin, scarred, and fragile in such cases. The mobilization often has to be extended along the lateral pelvic side walls and even on to the posterior aspect of the pubic symphysis in order to free the lateral and anterior bladder.
  - The mobilization of tissues should be wide to ensure a tension-free closure.
  - The utility of tissue flaps remains controversial.
  - Often destruction to the vagina has been so extensive that rotational flaps are required in order to cover the defect [167].

If these principles are applied, the success rate in fistula closure is high, but many women remain incontinent despite successful closure. In patients in whom all of the risk factors mentioned above are present, the postoperative incontinence rate may approach 100% [160]. In light of this dismal success rate, some surgeons now suggest that two further principles of repair be maintained:

Maintain the urethral length. It has been noted that post-repair fistula patients returning for further treatment of persistent urinary incontinence often have a shortened urethra. An unpublished series of 72 patients with post fistula repair incontinence found an average urethral length of 1.4 cm in these women. This suggests that continence might be improved if normal urethral length can be restored at the time of fistula closure. Vertical (as opposed to horizontal) repair of urethrovaginal fistulas has therefore been suggested. This appears to be possible in approximately 20% of such cases. In cases in which there is an urethrovesicovaginal defect, vertical repair of the urethral defect may improve success, while the vesical defect can be repaired either vertically or horizontally.

Support the urethra. For all urethral defects larger than 4 mm with a urethral remnant less than 2.5 cm, many fistula surgeons use an ‘anti-incontinence’ procedure during the initial repair. Currently there are two widely used procedures. The first sutures the urethra/bladder neck to the periosteum of the pubic ramus in a type of suspension operation. The fascia or muscle of the bladder is sutured on either side of the bladder neck area to the posterior aspect of the symphysis pubis or the arcus tendineus [141].
second procedure creates a sling of tissue to support the urethra. A pedicle of tissue is created on either side of the urethra from the lateral pelvic side wall. In theory this involves use of the pubococcygeus muscle, but more often it is simply a pedicle of fibromuscular tissue or scar that can be harvested. The pedicles created on either side are then sutured together in the midline [160, 166].

If either of these two extra steps are used, the incontinence rate after closure of complex fistulas can be reduced from 100% to 50% [160]. If all simple and complex fistulas are treated according to these extra principles, the postoperative incontinence rate can decrease from 33% to 18%.

a) The circumferential fistula

J. Chassar Moir, referred to the worst of obstetric fistula cases as “circumferential” fistula, which “involve a destruction of the bladder neck not only on the vaginal side, but in many instances, on the pubic side as well. The result is a circumferential sloughing with subsequent discontinuity of the urethra and bladder; the intervening tissue is merely the epithelium that has grown over, and become adherent to the periosteum of the back of the pubic bone.” [153]. This type of injury seems to occur more frequently in primiparous women, who tend to be younger. Such defects are more likely to be associated with severe vaginal scarring, the presence of a recto-vaginal defect, larger defects, and urethral involvement in 96% of cases [168].

In repairing these injuries, some fistula surgeons ignore the anterior defect in the bladder and merely repair the posterior section by suturing the bladder along the periosteum of the posterior symphysis pubis and then to the urethra. The anterior portion of the urethra will thus be pubic bone. These patients invariably suffer severe post-operative urethral incontinence, and the shorter the urethral remnant is to begin with, the more severe their incontinence is likely to be [169].

According to Moir, the three great problems involved in dealing with this type of fistula are: 1) extremely difficult exposure; 2) technical difficulty in dissecting the tissue remnants from the pubic bone; and 3) difficulty in joining the bladder neck to the urethral remnant or stump, if, indeed, any portion of the urethra is still intact. In order to deal with this type of injury, the bladder must be completely mobilized so that it can be drawn down low enough to create a tension free anastomosis with the urethral remnant. Freeing the urethral remnants and bladder from their adherence to the pubic bone may even require a suprapubic incision with the dissection from above in order to accomplish this. In such cases Moir took care to reinforce the bladder neck with buttressing sutures and generally brought in a Martius graft for support and a renewed blood supply. Today many experienced surgeon perform this operation entirely through the vagina and rarely use the Martius graft, but employ the continence saving steps to the procedure as described previously. The basic principles still apply, but emphasis is placed on completely releasing the bladder from any attachments to the posterior symphysis pubis. Once the bladder has been released, it is drawn down posteriorly to expose the plane of dissection between the bladder and pubic bone.

Once the bladder is mobilized circumferentially it is anastomosed to the urethra anteriorly with sutures at 12, 9 and 3 o'clock around the proximal section of the urethral remnant, usually anchoring it to the periosteum of the posterior pubic symphysis for stability. Often the distal defect in the bladder/urethra is much larger than the proximal defect in the bladder. To perform the anastomosis with this discrepancy in size, the bladder is pulled around the proximal part of the urethra and sutured. The remaining defect in the bladder is repaired vertically, again in an attempt to maintain the length of the urethra. (Figure 21).

The urethra is then suspended or supported with a sling as an anti-incontinence procedure. Despite these measures, post-operative incontinence is still high, with up to 45% of patients still incontinent in the immediate post-operative period [169].

The most difficult injury to repair is when the entire urethra has been sloughed. This may happen in up to 5% of cases [101]. If the urethra is only injured in its posterior aspect, the remaining urethral tissue can be mobilized and repaired vertically over an indwelling catheter with adequate results. More often, however, the whole circumference of the urethra is sloughed. To reconstruct a functional urethra is nearly impossible in such cases.

Figure 21: A circumferential fistula
(by courtesy of A. Browning)
In cases of complete destruction of the urethra and the anterior bladder neck, Hamlin and Nicholson recommended constructing a new urethra by creating a new "inner" urethra using the skin and fibrous connective tissue covering the pubic bones and the inferior border of the pubic symphysis. The neourethra thus created is then reinforced using a gracilis muscle flap taken from the thigh, preserving its neurovascular pedicle. Once this has been accomplished, additional grafting is necessary using a Martius flap which is then covered with skin flaps. Using this technique, the authors reported no deaths and only one ‘complete failure’ in 50 operations in which the blood supply to the gracilis flap failed. In some cases small urethrovaginal fistulas remained which were repaired at a subsequent operation. Surprisingly, only 8 women (16%) developed “severe” stress incontinence after this reconstruction, four of whom regained “satisfactory” continence over time, and four of whom required a subsequent operation for stress incontinence. In these latter four patients, only two operations were completely successful. Six patients (12%) developed a urethral stricture, three of whom were successfully treated by the passage of a sound and three of whom required surgical correction. The remaining 35 patients (70%) were discharged within six weeks of surgery cured or with mild residual stress incontinence which did not appear to be clinically bothersome [170]. There is no long-term follow-up on these patients, but anecdotally many patients who have had this procedure have returned for further care years after the operation with incontinence and complete stenosis of the neo-urethra.

Various authors have described neourethral reconstruction using bladder flaps [171, 172]. All of these operations are based upon transabdominal techniques such as that described by Elkins et al. [173]. In this technique, a neo-urethra is created by mobilizing a flap from the anterior bladder, which is then rolled into a tube. The anterior and lateral edges of the fistula are freed up and the space of Retzius is entered transvaginally beneath the pubic bone. The anterior bladder is pulled down into the vagina and mobilised. A 3cm incision is made into the bladder and the anterior bladder wall is then rolled around a 16 Fr. Foley catheter, creating a tube. The anterior surface of the neourethra is then sutured in two layers and the posterior edge of the fistula is closed transversely, also in two layers. The neourethra is reattached to the posterior edge of the pubic symphysis, and a Martius graft is placed before reapproximating the vaginal epithelium. In 18 of 20 cases, this technique resulted in fistula closure, but four women had severe stress incontinence post-operatively. It is not known how many had mild incontinence.

Neither of these surgical methods is ideal. Although they may create an anatomic urethra, often that urethra does not function normally. A further option in such cases is to create a ‘tube’ using either technique and then attempt to render the patient continent with the use of a urethral plug [24].

b) Additional advanced surgical techniques

Fistula centres in India tend to have more resources available to them than do fistula centres in Africa. In these situations it may be feasible to use more advanced surgical techniques on patients with fistulas. For example, the fistula centre at the Banaras Hindu University (Varanasi) has a substantial experience in managing more than 800 genito-urinary fistulas over a 15 year period. Fistula is common here: it was the most common diagnosis (40.5%) in female patients admitted for surgery in the past five years, followed by urinary stone disease (25.2%) and malignancy (14.6%). Vesicovaginal fistulas were the most common fistula encountered (66.6%) and vesico-uterine fistulas were the least common (5%) (174). Obstructed labour was the most common aetiology of fistulas (72.2%), followed by hysterectomy. Conservative management was successful in only 1-3% of the patients with vesicovaginal fistulas and the remaining cases were managed surgically with excellent results. A transabdominal approach was used for large, supravaginal vesicovaginal fistulas, associated ureterovesical fistulas or if bladder augmentation and bladder neck reconstruction was required. The transvaginal route was preferred for small sub-trigonal fistulas. A combined abdominal and vaginal approach was used for large fistulas involving the trigone or the bladder neck. The surgical approach varied in each patient. Interposition grafts or flaps were used when required [175]. The overall surgical failure rate was 4.3%. The average operative time for layered closure was 72 minutes (45-130 minutes) and that for graft or interposition tissue repair 100 minutes (90-165 minutes). The mean hospital stay was 9 days (6-17 days). There were no reported intra-operative complications. Postoperative complications were urinary tract infection, haematuria, wound infection and fever. None of the patients required blood transfusion. For the repair of small fistulas, surgeons did not use interpositional flaps but rather used the layered closure technique with a success rate of 97.1%. Complicated fistulas required repair by graft or tissue interposition and had a success rate of 94.8% which is similar to the experience of other Indian centres [176]. Risk factors for the failure of vesicovaginal surgery included previous failed repair, large-sized fistulas, fistulas involving the trigone or ureteral orifices, a small bladder capacity and unhealthy vesical urothelium at the time of surgery. Several techniques were used in addition to the standard layered closure:

1. **VESICAL AUTOPLASTY:** If the longitudinal diameter of the fistula was too large to allow simple layered closure and would put the bladder closure under
tension, a vesical autoplasty was performed based on the advancement flap technique used frequently by plastic surgeons. The initial steps are as in the layered closure technique. The vaginal layer is closed with interrupted 3/0 polygalactin sutures. Two incisions are made from either end of the proximal margin of the bladder defect and are extended proximally and laterally to make a wider based bladder flap. This flap is advanced over the vaginal layer and is sutured as in performing a layered closure. This technique avoids overlapping the suture line and also avoids tension [177].

2. O’Connor Repair. The majority of the large-sized fistulas were successfully repaired using the trans-abdominal technique described by O’Connor, with interposition of an omental flap (178). This technique works well except when the fistula extends up to the bladder neck or when its transverse diameter is too large to allow tension-free approximation.

3. Ileal Segment Interposition. This technique is used for fistulas which involve the entire posterior bladder wall or fistulas with a wide transverse diameter that extend up to the bladder neck, cases in which obtaining tension-free closure is difficult. Approximately 15-20 cm of the small bowel is isolated on its pedicle and opened at the anti-mesenteric border. The bladder wall is dissected away from the vagina, which is closed with interrupted sutures. This segment of small bowel is interposed posteriorly, along with an omental flap. This technique has yielded satisfactory results in complicated fistulas, and also augments bladder capacity (175, 179).

4. Bladder Mucosal Graft: This technique is an alternative to layered closure in cases where closure of the bladder may result in tension along the suture line. If sufficient pliable bladder wall is available, a vesical autoplasty may be performed. In a small-capacity fibrotic bladder, the fistula may be repaired using a free-graft taken from a healthy area in the dome of the bladder, as described by Vyas et al (180). A bladder mucosal graft is also a good alternative in fistulas where the ureteral orifices are close to the fistulous margin and might otherwise require ureteral reimplantation.

5. Combined Abdominal and Vaginal Approach. This technique may be required in complicated fistulas involving the bladder neck. In cases where urethral continuity is disrupted due to a fistula, a combined approach may be preferable. The fistula is repaired by the abdominal route and continuity of the urethra is established by anastomosing the urethra through the vaginal route.

c) Rectovaginal Fistula

Rectovaginal fistulas (RVF) are less common than vesicovaginal fistulas in developing countries. In one (unpublished) series of 75 obstetric fistula cases from Ethiopia, only 6.7% were isolated obstetric rectovaginal fistulas and 84% were associated with significant vaginal scarring. Two of the 75 required a temporary diverting colostomy prior to repair; both were high fistulas adherent to the sacral promontory. This compares to 15% needing a diverting colostomy prior to RVF repair in Addis Ababa [165].

The basic principles of vesico-vaginal fistula repair also apply to the repair of rectovaginal fistulas: wide mobilization of the fistula and a tension-free closure. The vaginal epithelium is incised around the circumference of the fistula and laterally from either angle. The vagina is reflected away and the bowel is mobilized, paying special attention to release of any lateral attachments. Severe bleeding can occur along the lateral aspect of the bowel. The bowel muscularis is repaired in 2 layers preferably in a horizontal plane to avoid creating strictures within the bowel lumen. The vagina is then repaired.

3. Urinary Diversion in the Developing World

Urinary diversion in developing countries is usually not a viable option since stoma appliances and catheters (in the case of continent urinary diversions) are often unavailable or are too expensive [79]. In such cases performing a diversion procedure merely moves the fistula to another part of the body and the end result of such surgery may be more stigmatizing in the local culture than the original injury!

Uretero-sigmoidostomy has been used as a surgical option in developing countries for many years. Long-term follow-up of a series of 65 Swiss oncology patients over a 20-year period showed early complications in 25 patients (pyelonephritis, anastomotic complications, wound problems) and late complications in 36 patients (pyelonephritis, electrolyte disturbances, ureteral stenosis, incontinence and colon tumour (3)). At 5 years 25 patients had survived: 23 of these (88%) were continent during daytime and 14 (54%) were continent at night as well [181]. These data show that both short- and long-term complications will arise and that surgeons must be prepared to treat them. This requires access to adequate diagnostic equipment. A series of 9 Tanzanian patients undergoing diversion found that results were acceptable and that patients had a marked improvement in their quality of life [182]. The Mainz II pouch or Sigma-rectum pouch was introduced by Fisch et al. to create a detubularized, low pressure, high capacity pouch that would protect the upper urinary tract and improve continence [183]. This technique has also been used in patients with vesico-vaginal fistulas. A series of 62 such patients was reported by Arrowsmith (184), 89% of whom were dry during the day and 66% were also dry during the night. Twenty-six patients had major complications, 35 had minor complications, and 6 patients died. The author does not mention the type of complications that occurred.
Urinary diversion with the creation of a sigmoid or rectal pouch is feasible in selected patients. Long-term data on outcome are not yet available. The risk of complications is rather high and managing complications adequately often requires diagnostic capabilities that are absent in developing countries. This situation requires that patients should be counselled extensively before they are offered this kind of surgery [185]. The risk of cancer has to be discussed as well. These discussions must take current life expectancy into account and balance the risk of complications (such as late occurrence of colon cancers) against any improvement in the quality of life. Current life expectancy in Africa is estimated to be 52.8 years, but such numbers vary substantially from country to country due to differing experiences with AIDS, poverty, malnutrition and war [186]. The decision to proceed with urinary diversion must be made jointly by the patient in consultation with the operating surgeon; it is not the surgeon’s choice alone. If a diverting operation is performed, it must be performed in a setting in which adequate post-operative follow-up is available. It is inappropriate for a visiting surgeon to perform a complicated operation of this kind and to leave the country without insuring that the patient has competent on-going care should complications arise.

4. COMPLICATIONS

4a) Urinary incontinence post fistula repair

1. The continence gap and urethral loss

Fistulas can be closed successfully in 72% to 92% of cases [187]. The definition of success, however, is often different when the perspectives of the patient and the surgeon are compared. “Success” to a fistula patient means complete restoration of urinary continence and control, whereas many surgeons define “success” as simply closing the fistula. It is essential to establish defined criteria that will allow meaningful comparison of treatment outcomes. The patient-oriented criterion of continence restoration should be the goal when the outcomes of various fistula treatments are compared. Persistent incontinence despite successful closure of the fistula has been termed “the continence gap” [188]. A patient whose fistula is closed but who remains incontinent may be just as wet as a patient whose fistula closure operation failed. The estimates of persistent urinary incontinence after a successful closure of the fistula come from case series, ranging from 16.3% in a large retrospective review of patients by Wall et al [29] to 33% in a small series of complex fistulas in which the proximal urethra was lost [189]. Adequate epidemiologic studies on the prevalence of fistula and its sequelae are scarce, and because long-term data on surgical outcomes are difficult to obtain, the prevalence of persistent incontinence after surgery appears to be severely underestimated. Techniques that are used in reconstructive urology in industrialized countries are seldom mentioned in the fistula literature [59, 190]. More research and training is needed in this field.

Persistent urinary incontinence in patients after fistula repair is due to multiple factors including scarring and location of the fistula as well as failure to perform a sling operation at the time of repair in patients likely to require such intervention. The goal of fistula surgery should be restoration of continence and resumption of a full and active life on the part of the patient, not just closing the fistula.

2. Pathophysiology of persistent urinary incontinence after fistula repair

Several possible etiological factors can be postulated in women who remain incontinent after successful fistula closure: massive damage to the mid-urethral continence mechanism, damage to the bladder neck, levator ani dysfunction, damage to the lateral attachments of the urethra, fibrosis and loss of compliance, neuropathy, etc. . . .

Although persistent incontinence tends to be blamed on urethral dysfunction, a few urodynamic studies suggest that bladder dysfunction may play a role as well [67, 191]. A small study of 22 women who underwent urodynamic studies to analyze post-repair incontinence revealed that 41% suffered from urodynamic stress incontinence, 41% had combined urodynamic stress incontinence and detrusor overactivity, 14% had a small non-compliant bladder, and 4% had a voiding disorder and overflow incontinence. In these cases the incontinence may be so severe that the urethra functions only as an open ‘drain pipe’ through which urine passes in a nearly-continuous stream. The result is little different from the leakage that occurred through the original fistula [67].

3. Assessment of urinary incontinence

A complaint of persistent leakage by the patient needs to be evaluated. The first step is to assure that the fistula has been closed successfully. This can be done by placing a balloon catheter into the bladder, occluding the bladder neck, and filling the bladder with a solution of water coloured with indigo carmine or another type of dye. If the fistula has not been closed successfully, the leakage should be readily apparent. If deflating the balloon or moving it away from the bladder neck produces incontinence, the question may be differentiating transurethral incontinence from a urethra-vaginal fistula. Where more advanced technological capabilities are available, diagnosing the presence of an urethrovaginal fistula may be facilitated by the use of a double-balloon catheter that allows occlusion of the urethra at each end and perfusion of the urethra through an opening between the two balloons. Most commonly, however, the diagnosis will have to be made on the basis of simple...
clinical testing by occluding the urethral meatus, asking the patient to strain, and seeing if there is leakage. Limited data from urodynamic studies by Hilton [191] and by Carey, Goh et al [67] suggest that detrusor overactivity and changes in bladder compliance are frequent causes of urinary incontinence in fistula patients with post-repair incontinence, in addition to the leakage resulting from successful closure but persistent intrinsic sphincter deficiency.

4. Management of urinary incontinence

1) Preventive management.

Assessment of host factors causing urinary incontinence following fistula repair:
The best approach to this problem is preventive and this starts with the assessment of host factors. The most important concept is the recognition of the differences between simple and complex fistulas.

Surgical techniques at the time of primary fistula repair to prevent urinary incontinence:
When the fistula involves the continence mechanism and is associated with moderate to severe scarring of the urethrovaginal junction, a sling procedure may be advisable to improve urethral closure. Several techniques have been used, including a sling or graft made of labial fat incorporating the bulbocavernous muscle, remnants of the pubococcygeus muscle, or a gracilis muscle flap [160, 189], as well as fascial grafting. The results obtained with this relatively simple low-cost operative procedure have not been replicated in other centres, nor are there long-term data on outcomes.

2) Initial management of urinary incontinence after fistula repair.

Pelvic floor muscle exercises have been proposed as a first step in the treatment of persistent incontinence after otherwise successful fistula closure. Some patients on a muscle exercise regimen improve after six months of therapy. A novel system for grading urinary incontinence has been proposed in an effort to predict which patients are likely to benefit from this type of therapy and which will not. This system is currently in use in only a handful of centres and prospective data are not yet available as to its general applicability.

Continence status after fistula closure can be graded as follows:

1. Cured, no incontinence leaks
2. Wet with exertion (coughing or physical exertion)
3. Wet when walking, but dry when sitting or lying down
4. Wet when walking, sitting, or lying down, but able to void some urine from the bladder
5. Wet all the time, no urine to void

After six months of physical therapy, in 50% of cases women with continence grades 2 or 3 were cured of their leakage, but only 18% of women with continence grades 4 or 5 were cured. Women in this latter group therefore seem likely to require further surgical treatment.

3) Secondary management for urinary incontinence after fistula repair.

If a patient with transurethral incontinence is still complaining of the leakage at follow-up, the treatment proposed must be cheap, effective and not dependent on expensive synthetic materials that are unlikely to be available in countries where obstetric fistulas are prevalent. Treating persistent incontinence after successful fistula closure requires good surgical skills. Some kind of bladder evaluation is essential prior to considering urethral support surgery. The type of repair proposed is based largely on analogies with other urethral operations such as those carried out to repair a urethral diverticulum, to attempt to achieve continence after radiation therapy, or the kinds of reconstructive operations carried out in patients who have extrophy or epispadias [79]. In these cases the use of tissue transposition techniques such as the Martius graft and various forms of sling operations are the mainstays of treatment. The traditional dissection required to place a sling may be difficult and may result in recurrence of the fistula and/or breakdown of the entire urethra. Thus, some authors have recommended using an in situ vaginal sling. Fascial slings are preferred; there is no place for a synthetic sling in these cases due to the levels of scarring found, the lack of vascularity in the surgical field, the high likelihood of infection, and the problems of sling erosion with little or no access to follow-up.

Several surgical methods have been described for treating fistula patients with post-closure stress incontinence; few have been successful and data are quite limited. A standard Burch-type retropubic bladder neck suspension operation combined with urethrolysis and tissue plication, may work in a few patients [141], but in general the results of this approach have been disappointing. Carey and co-workers reported a small series of patients who had undergone previous fistula closure and who later underwent re-operation for stress incontinence. After urodynamic testing, 9 women with severe urodynamic stress incontinence underwent a retropubic urethrolysis and pubovaginal sling procedure combined with placement of an omental J-flap. Four weeks after surgery, 78% were continent; however this fell to 67% at 14 months follow-up [67]. An operation described by Waaldijk involves urethralisation of the bladder neck as a neourethra in patients with a markedly shortened bladder neck. Following this, a fasciocolposuspension to the arcus tendineus is performed. Cure rates of 60-70% have been reported, but these results have not been replicated in other fistula centres [141].
An alternative approach for those patients who fail a surgical procedure or who are deemed unsuitable for an attempt at surgical repair is to use a urethral plug [24]. Although successful use of urethral plugs and various injectable materials has been reported, these technologies are not usually available in areas where obstetric fistulas are common. However, if an ongoing supply link can be arranged, urethral plugs seem to work well for many women with a high degree of patient satisfaction.

Urge-related bladder dysfunction can often be treated with low-cost antimuscarinic drugs. In cases where there has been extensive loss of bladder tissue or marked reduction in bladder compliance due to fibrosis, augmentation cystoplasty can be performed, usually using by interposing a segment of bowel. In some case, urinary diversion may be indicated, but only after careful discussion of the issues involved with the patient.

CONCLUSION

The vast majority of obstetric fistulas can be successfully closed using appropriate “low technology” surgical techniques; however, making these women completely continent and restoring their lives to normal functioning is the ultimate, but more difficult to achieve, goal. Persistent incontinence after fistula repair remains an underappreciated condition that requires further attention if overall outcomes are to be improved. There is a need for further research using clearly-defined outcomes and standardized data collection in this area.

VII. ORGANISATION OF FISTULA CARE IN THE DEVELOPING WORLD

1. LOCAL HOSPITAL OR A SPECIALIST FISTULA CENTER?

At the present time the care of fistula patients is not well-structured. Fistula centres are not networked with one another and most places where fistula surgery is performed carry out their work without much reference to the activities of other centres. Most fistula care is provided by individuals working alone, and by various charities and non-governmental organizations who largely “march to the sound of their own drums.” Funding for fistula initiatives is haphazard and frequently insecure. Around the world, the voices of women with fistulas are still not heard by most of the national healthcare systems that should be responsible for providing care to them. Wall has suggested that a fistula centre can survive and flourish only if three prerequisites are in place [192]. A fistula centre must have:

a) Adequate long-term funding

This funding usually must come from foreign donors, as local authorities often do not consider the care of fistula patients to be an important priority. Because fistula patients are largely destitute, they can rarely pay for the costs of care. This means that fistula surgery must be heavily subsidized in order to reach the maximum number of patients and this may breed resentment in hospitals where other patients are routinely charged for their care.

b) A dedicated fistula surgeon

A surgical program will only succeed if it is staffed by competent, responsible surgeons. Ideally the surgeon in charge of a fistula repair program should be someone who can treat both simple and complex fistulas, as well as with the complications of surgery (e.g., vaginal stenosis, persistent incontinence, etc). Surgeons must understand both their own limitations as well as the limitations placed on them by the environment in which they must operate. Maintenance of skills and improvements in data collection and research are likely to be improved by enabling the formation of networks of fistula surgeons who face similar problems in different parts of the world.

c) Adequate operating theatre time and adequate supplies

Surgical programs can only be successful if there is adequate time and adequate supplies to perform the necessary operations. General hospitals (especially rural hospitals) tasked with taking care of the entire range of medical and surgical problems—particularly obstetric emergencies and acute trauma—often lack the resources need to carry out large numbers of fistula repairs. Elective scheduled cases such as fistula repair are always in jeopardy of being bumped from the operating theatre schedule due to the arrival of victims of a road traffic accident, orthopaedic trauma or obstetric haemorrhage.

For these reasons many advocate that fistula programs be organized around a specialized fistula centre that focuses on these patients as its highest priority. Such a centre is optimized to deliver high quality specialized care for these women. Focused programs of this kind will be more difficult to operate in regions where transportation is difficult, making it difficult for people from remote areas to reach the centre.

It is also obvious that the small number of specialist centres that currently exist in Africa will never be able to treat all of the women currently living with fistulas. Whatever strategy is proposed, it must be based on a realistic assessment of local circumstances [193] [194]. Further research in this area is recommended.

Wherever possible, fistula care should be integrated into a broader preventive perinatal care program. A recent systematic review of inequalities in maternal health care in 23 developing countries showed a wide...
variation in the use of antenatal care [195]. In addition to factors related to the availability of health care services (distances travelled, clinic availability), user-related factors such as patient age, education, medical insurance, and clinical risk factors played a role in determining utilization. The interactions among these factors are also influenced by funding, organization, the structure of the local social system, and local cultural variations. The authors concluded that context-specific causes of variations in the use of maternal health care services need further investigation.

One overarching concern must be the standard of care provided in such programs: Poor quality antenatal care will almost certainly decrease the utilization of the services provided [196]. How fistula care should be organized must be seen within this larger context (Figure 22).

2. ETHICAL CONSIDERATIONS

There are many ethical issues intertwined with the epidemic of obstetric fistulas in developing countries. These issues range from the broadest human rights concerns arising from a devastating problem that only affects women to the most intimate issues involved in the responsibilities of individual surgeons for the care of individual patients to complex issues regarding clinical research. Everyone involved in caring for women with obstetric fistulas must realize the vulnerable nature of this patient population and the special needs they present for those entrusted with their care. Recently a code of ethics for the fistula surgeon was published with the aim of fostering common goals and a common ethical perspective as to how the campaign to eradicate fistulas ought to proceed [197]. This code of ethics emphasizes the following basic points: [197].

- The fistula surgeon should be dedicated above all else to providing the best possible care for women with obstetric fistulas permitted by the resources available and the local circumstances in which care is rendered.
- The surgeon must recognize the vulnerable nature of this population of patients, treat them with respect, and involve them in decision-making regarding important aspects of their care. Such patients should not be subjected to experimentation without their consent and research on fistula patients should be overseen by an appropriate ethical review board.
- The fistula surgeon must assume direct personal responsibility for the care of those patients on whom he or she operates and must provide them with access to competent ongoing care, particularly in the immediate post-operative period.
- The fistula surgeon should limit his or her practice to that which he or she is competent to deliver by education, training, experience, and available resources, and should not hesitate to refer complicated patients to a higher level of care.

Figure 22: The organisation of a fistula centre
The fistula surgeon should strive to improve his or her clinical skills through the regular collection and review of objective data on treatment outcomes.

The fistula surgeon should never take advantage of a patient for his or her own personal benefit or allow such patients to be abused by others.

Fistula surgeons must acknowledge the fundamental social inequalities that promote the development of obstetric fistulas and must help work to eradicate these injustices. They should actively support initiatives that seek to prevent fistulas and should work to remove barriers that hinder access to emergency obstetric care.

VIII. SUMMARY AND GOALS FOR FUTURE RESEARCH

The number of patients with obstetric fistulas in Africa cannot be estimated accurately at this time, but all authors agree that the number is high and that several million women may be affected by this terrible condition. Lack of adequate facilities for fistula repair prevents reduction of the backlog of women currently suffering with fistulas. Lack of adequate access to emergency obstetric services prevents the elimination of new fistula cases.

There is much that still needs to be learned about the optimal care for women with obstetric fistula. There is a great need for further research on both the best treatment of fistulas as well as on the types of programs that will be most effective in preventing fistulas from developing in the first place. There is almost no reliable data on how to develop and implement programs to rehabilitate women who have sustained a fistula and how to reintegrate them into their societies.

Repair of simple fistulas has a high success rate if the operation is performed by a trained surgeon. In cases of this kind, use of a Martius flap may not be required.

Complex fistulas remain challenging, sometimes daunting. A high proportion of women with complex fistulas will have persistent incontinence despite successful fistula closure. The number of women who will suffer from stress incontinence after successful fistula closure can probably be reduced by performing some type of autologous sling operation at the time of fistula repair. Exact protocols for doing this need to be developed.

In addition to their fistula, many patients also suffer from other components of the obstructed labour injury complex involving urological, gynaecological, gastrointestinal, musculoskeletal, psychological and social injuries. These comorbidities must also be taken into account during treatment planning.

The literature on fistulas in the developing world consists primarily of retrospective observational studies. Many fistula surgeons work for charitable organisations whose ultimate goal is the care of patients. Many surgeons are involved in fistula surgery only during short-term trips and leave without having any good idea about patient follow-up or the outcome of surgery. The organization of research in this field is therefore often complicated.

The development of partnerships between charitable organizations and academic institutions could help alleviate this problem. Joint programs between Western academic centres and local African hospitals would not only have a positive influence on the training and scientific expertise of the local staff, but would also be likely to improve the standard of care provided to patients. Several areas for future research can be suggested:

- Health economic studies
- Health organisation studies
- Studies on techniques for fistula closure and related surgical issues
- Urodynamic studies of patients following successful fistula closure
- Studies on long-term outcome, social reintegration, and the effect of fistulas on family life and child health

IX. RECOMMENDATIONS

All recommendations are based on articles with level of evidence 3 or 4. Hence all recommendations have grade C.

- Patients with vesicovaginal fistula should be treated as a person, and they deserve the right to adequate counselling and consent to the treatment they will eventually undergo, despite language and cultural barriers that may exist.
- Surgeons embarking on fistula surgery in the developing world should have appropriate training in that setting and should be willing to take a long-term commitment.
- Prevention of fistula is the ultimate goal. Collaboration between fistula initiatives and maternal health initiatives must be stimulated.
COMPLEX FISTULA

- Simple fistula, which have a less favourable outcome.
- Careful clinical examination will allow the distinction between both types of fistula, although no generally accepted classification system is available. Key items are the size and location of the fistula, the eventual involvement of the urethra and the urethral closure mechanism and the amount of vaginal scarring.
- Associated pathologies should be actively searched for and should be taken into account in the treatment plan: all components of the ‘obstructed labour injury complex’ should be examined.

TREATMENT

- The treatment for vesicovaginal fistula is surgical.

SIMPLE FISTULA

- A vaginal approach is preferred, since a single fistula can be reached vaginally and since spinal anaesthesia carries less risk than general anaesthesia needed for an abdominal approach necessitating. A trained surgeon should be able to manage these simple fistulas.
- After wide dissection a tension-free single layer closure of the bladder wall and closure of the vaginal wall in a separate layer are advocated. A Martius flap in primary simple obstetric fistula repair is not recommended.
- A care program for failed repairs and for persisting incontinence after a successful repair needs to be installed.

COMPLEX FISTULA

- Complex fistula should be referred to a fistula expert in a fistula centre.
- In principle most complex fistula can be dealt with by vaginal approach, but an abdominal approach can be useful in some cases (e.g. concomitant reconstructive procedures). Advanced training and surgical skills are prerequisites for treating this type of fistula.
- If the urethra and/or the urethral closure mechanism is involved a sling procedure, using an autologous sling, should be performed at the same time as the fistula correction. There is no place for synthetic sling material in that setting.

ASSESSMENT

- The majority of patients with as simple fistula will be cured after the repair. A proportion of them and an even larger proportion of the patients after complex fistula repair will remain incontinent. Depending on the local possibilities an after-care program should be installed.

INTRODUCTION

1. EVIDENCE ACQUISITION

The unrestricted, fully exploded Medical Subject Heading (MeSH) “interstitial cystitis” (including all related terms as “painful bladder syndrome,” “bladder pain syndrome”, or different terms such as “chronic interstitial cystitis,” etc.) were used to thoroughly search the PubMed database (http://www.ncbi.nlm.nih.gov/PubMed/) of the US National Library of Medicine of the National Institutes of Health; 1795 hits were retrieved. After exclusion of uncommon languages (other than English, French, German, Italian, Japanese, Spanish, Swedish) and by limiting the publications to the time period January 2004 to May 2008, 512 publications resulted.

Abstracts if available and titles of the 512 hits were reviewed, focusing on (but not limited to) clinical trials, randomised controlled trials, meta-analyses, scientific guidelines, and core clinical journals. The literature update thus achieved was added to the pre-existing database, covering the time period before and during 2004 (generated for the 2004 ICI Incontinence guideline, published 2005) that was established according to the same protocol.

Rating of the level of evidence and grade of recommendation was performed according to the Oxford Scale.

The committee believes that the Oxford system for categorizing levels of evidence is primarily relevant only for the sections on treatment, which follow. While the committee’s opinions will be expressed, where applicable, regarding evidence and conclusions for other areas, including diagnosis, aetiology, and pathophysiology, use of the Oxford system in this context is more open to interpretation.

2. DEFINITION

Bladder Pain Syndrome (BPS) is a clinical diagnosis that relies on symptoms of pain in the bladder and or pelvis and other urinary symptoms like urgency and frequency. Based on the evolving consensus that BPS probably is strongly related to other pain syndromes like Irritable Bowel Syndrome, Fibromyalgia and Chronic Fatigue Syndrome, the European Society for the Study of Bladder Pain Syndrome/Interstitial Cystitis (ESSIC) recently published a comprehensive paper on definition and diagnosis of BPS [1].

BPS was defined as chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded. Further documentation and classification of BPS might be performed according to findings at cystoscopy with hydrodistension and morphological findings in bladder biopsies. The presence of other organ symptoms as well as cognitive, behavioural, emotional, and sexual symptoms should be addressed.

This definition has been broadly accepted although actual wording differs somewhat [2]. Because omitting the name “Interstitial Cystitis” might cause serious problems in different health systems by affecting reimbursement, the possibility of patients gaining disability benefits, and so forth, the name Bladder Pain Syndrome/Interstitial Cystitis (BPS/IC) could be used in parallel with BPS for the time being. In this chapter the term Bladder Pain Syndrome largely replaces the older Interstitial Cystitis term, but the two are essentially interchangeable as there is no accepted definition that clearly delineates the interstitial cystitis syndrome from bladder pain syndrome. The Consultation believes the latter term more appropriately describes the disorder.
Historically, definitions of IC have moved from a severe inflammatory bladder disease to a condition described primarily by symptoms (Table 1) [2].

The International Continence Society [9] (ICS) used the term Painful Bladder Syndrome (PBS) defined as “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and nighttime frequency, in the absence of proven urinary infection or other obvious pathology”. ICS reserved the diagnosis Interstitial Cystitis (IC) to patients with “typical cystoscopic and histological features”, without further specifying these. It has however been shown, that only a fraction of patients believed by experts to have BPS fulfil this definition [10].

The condition will therefore in the remainder of this chapter be referred to as BPS. As the terminology is in flux, some of the older literature may be discussed using the original terminology in the interests of clarity. Logically “interstitial cystitis” should include some form of demonstrable inflammation in the bladder wall, while “bladder pain syndrome” should include pain in the region of the bladder. The diagnosis of BPS is based on exclusion of other diseases in the bladder, urethra, and other pelvic organs including the musculoskeletal system. As with other diseases without clear objective diagnostic criteria or pathophysiological explanation, countless theories have been put forward without adding much to the delineation or understanding of the disease.

In practice, patients with symptoms of BPS are screened to exclude other relevant diagnoses or confusable diseases [1], and a focused evaluation is performed at the discretion of the physician or centre. This evaluation might include cystoscopy under local or general anaesthesia, bladder distension with registration of bladder capacity and/or the presence of glomerulations and Hunner’s lesion. Bladder wall biopsies might be obtained and evaluated for inflammation, ulcer, fibrosis, mast cells etc. The evaluation might also include urodynamics with registration of bladder capacity, compliance and bladder stability [11]. One view of the relationship of BPS with OAB is graphically depicted in Figure 1 [12]. The 14% incidence of urodynamic detrusor overactivity in the BPS [13] patients is probably close to what one might expect in the general population if studied urodynamically [14].

In the end, these investigations might prove to be normal and the patients are identified as having BPS as a diagnosis of exclusion. The relevance of urodynamic, cystoscopic and histological findings is further obscured, because the methodology by which these results is obtained is rarely comparable and it is therefore recommended to use the standardisations described by ESSIC [1].

### 1. HISTORICAL NOTES

Recent historical reviews confirm that interstitial cystitis was recognized as a pathologic entity during the 19th century [15,16]. In his textbook Practical Observations on Strangulated Hernia and Some Diseases of the Urinary Organs, Joseph Parrish, a Philadelphia surgeon, described 3 problematic cases of recurrent, severe lower urinary tract symptoms in which he made repeated attempts to locate a bladder stone, which was the most common source for these symptoms in early 19th century America [17]. As Teichman et al have convincingly argued, these patients displayed all of the clinical hallmarks of IC including chronic frequency, urgency, dysuria and pelvic pain in the absence of demonstrable pathology [18]. Although he used the term repeatedly in his manuscript, Parrish did not elaborate upon the clinical definition of “tic doloureux,” likely because contemporaneous physicians would have been familiar with the concept. However, Parrish attributed the term Tic doloreux to his mentor, Dr. Phillip Syng Physick, who had applied it to patients with severe lower urinary tract symptoms with no discernible etiology, with the most common etiology during the 19th century being bladder stones.
A review of archival material from the Philadelphia College of Physicians indicates that by 1808 Physick had developed a concept of bladder inflammation, a “bladder ulcer,” that produced lower urinary tract symptoms in the absence of bladder stone [15]. Tic doloureux at its time represented a neurological irritation, most often associated with the trigeminal nerve but applicable to other sensory distributions as well, which produced pain and discomfort in the absence of injury or other specific physical findings. In applying the concept of tic doloureux to bladder sensation Parrish was ascribing the paroxysmal lower urinary tract symptoms occurring in patients to an idiopathic process affecting the nerves of the bladder. This sophisticated concept continues to be a prominent component of modern theories of BPS pathogenesis. Furthermore, Tic doloureux allowed him to formulate a diagnosis for those patients who chronically manifested the symptoms caused by a stone (severe frequency, urgency, dysuria and pelvic pain) but had no stone that could be detected. That is, he considered a neuropathic etiology in the absence of any other tangible causes of bladder pain. Clearly, this experience strongly resonates with the contemporary diagnosis of BPS.

50 years after Parrish’s first publication on the condition, Skene used the term interstitial cystitis to describe an inflammation that has “destroyed the mucous membrane partly or wholly and extended to the muscular parietes” [3]. Early in the 20th century, at a New England Section meeting of the American Urological Association, Guy Hunner reported on 8 women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years [4,19]. He drew attention to the disease, and the red, bleeding areas he described on the bladder wall came to have the pseudonym “Hunner’s ulcer”. As Walsh observed, this has proven to be unfortunate [20]. In the early part of the 20th century, the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall, he thought they were ulcers. For the next 60 years, urologists would look for ulcers and fail to make the diagnosis in their absence. The disease was thought to be a focal, rather than a pancystitis.

Hand authored the first comprehensive review about the disease, reporting 223 cases [21]. Many of his epidemiologic findings have held up to this day. His description of the clinical findings bears repeating. “I have frequently observed that what appeared to be a normal mucosa before and during the first bladder distention showed typical interstitial cystitis on subsequent distension”. He notes, “small, discrete, submucosal hemorrhages, showing variations in form...dot-like bleeding points...little or no restriction to bladder capacity.” He portrays three grades of disease, with grade 3 matching the small-capacity, scarred bladder described by Hunner. Sixty-nine percent of patients were grade 1 and only 13% were grade 3. Walsh later coined the term “glomerulations” to describe the petechial haemorrhages that Hand had described [20]. But it was not until Messing and Stamey discussed the “early diagnosis” of IC that attention turned from looking for an ulcer to make the diagnosis to the concepts that 1) symptoms and glomerulations at the time of bladder distention under...
anesthesia were the disease hallmarks, and 2) the diagnosis was primarily one of exclusion [6,20]. However, this description was not suitable for defining this disease in a manner that would help physicians make the diagnosis and set up research protocols.

The National Institute of Diabetes, Digestive, and Kidney Disorders (NIDDK) held a major meeting in 1987 with researchers and clinicians from around the world [22]. This ultimately resulted in the 1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and, glomerulations or Hunner’s ulcer on cystoscopy under anesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc [7].

In order to validate the criteria, which were designed not for clinical diagnosis, but rather to ensure that patients enrolled in research trials could be agreed upon to have the disease, a database with broad entry criteria was created. The 1997 NIDDK Interstitial Cystitis Database Entry Criteria: unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable etiologies [23]. Urgency was not defined in the protocol. Participants were given a 10 point scale, and those who scored 2 or higher on self report satisfied the urgency criteria. The protocol was written in 1992, a time when the definition of “urgency” was not a particularly controversial topic. When a comparison of the NIDDK revised criteria with the database entry criteria was performed, it was apparent that up to 60% of patients clinically believed to have interstitial cystitis by experienced clinicians were being missed when the NIDDK research criteria were used as a definition of the disease [24]. The last decade has been an active one from an international standpoint in terms of wrestling with the issues of diagnosis and definition [25-27].

2. NOMENCLATURE AND TAXONOMICAL CONSIDERATIONS

There is currently no agreement how this complex syndrome should be referred to. The literature over the last 170 years has seen numerous changes in description and nomenclature of the disease. The syndrome has variously been referred to as tic doloureux of the bladder, interstitial cystitis, cystitis parenchymatosa, Hunner’s ulcer, panmural ulcerative cystitis, urethral syndrome, and painful bladder syndrome [3,5,16,18,19,28,29]. The term “interstitial cystitis,” which Skene is credited with coining and Hunner for bringing it in to common usage, is a misnomer; in many cases not only is there no interstitial inflammation, but also, histopathologically, there may be no inflammation at all [30-33].

By literally focussing exclusively on the urinary bladder, the term interstitial cystitis furthermore does not do justice to the condition from both the physician’s and the patient’s perspective. The textual exclusiveness ignores the high co-morbidity with various pelvic, extra-pelvic and non-urological symptoms [34] that frequently precede the onset of the bladder condition [35].

With the formal definition of the term “painful bladder syndrome” by the ICS in 2002, the terminology discussion became an intense international focal point [9].

- In Kyoto at the ICICJ in March 2003, it was agreed that the term “interstitial cystitis” should be expanded to “interstitial cystitis/chronic pelvic pain syndrome” when pelvic pain is at least of 3 months duration and associated with no obvious treatable condition/pathology [36].

- The European Society for the Study of Interstitial Cystitis (ESSIC) held its first meeting in Copenhagen soon after Kyoto. Nomenclature was discussed, but no decision was reached, as the meeting concentrated on how to evaluate patients for diagnosis [11].

- At the 2003 meeting of the NIDDK titled, “Research Insights into Interstitial Cystitis,” it was concluded that “interstitial cystitis” will inexorably be replaced as a sole name for this syndrome. It will be a gradual process over several years. At the meeting it was referred to as “interstitial cystitis/painful bladder syndrome” in keeping with International Continence Society nomenclature [37].

- At the 2004 inaugural meeting of the Multinational Interstitial Cystitis Association in Rome, it was concluded that the syndrome should be referred to as “painful bladder syndrome/interstitial cystitis” or “PBS/IC” to indicate an intellectual and taxonomical hierarchy within the acronym [37].

- The International Consultation on Incontinence in 2004, cosponsored by the ICS and Societe Internationale d’Urologie in association with the World Health Organization, included the syndrome as a part of its consultation. The chapter in the report was titled, “painful bladder syndrome (including interstitial cystitis),” suggesting that the IC formed an identifiable subset within the broader syndrome. Because such a distinction is difficult to define, within the body of the chapter, co-authored by nine committee members and five consultants from four continents, it was referred to as PBS/IC (one inclusive entity) [38].

- In June 2006 Abrams and colleagues published an editorial focussing on the nomenclature problem [39]. They noted that: “It is an advantage if the medical term has clear diagnostic features that translate to a known pathophysiologic process so that effective treatment may be given. Unfortunately, the latter is not the case for many of the pain
syndromes suffered by patients seen at most pain, gynecological, and urological clinics. For the most part these “diagnoses” describe syndromes that do not have recognized standard definitions, yet infer knowledge of a pathophysiologic cause for the symptoms. Unfortunately the terminology used to describe the condition may promote erroneous thinking about treatment on the part of physicians, surgeons and patients. These organ based diagnoses are mysterious, misleading and unhelpful, and can lead to therapies that are misguided or even dangerous. The editorial went on to note that a single pathologic descriptive term (interstitial cystitis) for a spectrum of symptom combinations ill serves patients.

The umbrella term “painful bladder syndrome” was proposed, with a goal to define and investigate subsets of patients who could be clearly identified within the spectrum of PBS. It would fall within the rubric of chronic pelvic pain syndrome. Sufferers would be identified according to the primary organ that appears to be affected on clinical grounds. Pain not associated with an individual organ would be described in terms of the symptoms.

One can see in this the beginnings of a new paradigm that might be expected to change the emphasis of both clinical and basic science research, and that removes the automatic presumption that the end-organ in the name of the disease should necessarily be the sole or primary target of such research.

• At the major biannual IC research conference in the fall of 2006, held by the National Institute of Diabetes, Digestive, and Kidney Disorders (Frontiers in Painful Bladder Syndrome/Interstitial Cystitis), the ESSIC group was given a block of time with which to present their thoughts and conclusions. Because PBS did not fit into the taxonomy of other pelvic pain syndromes such as urethral or vulvar pain syndromes, and because IC is open to different interpretations, ESSIC suggested that Painful Bladder Syndrome be redesignated as Bladder Pain Syndrome (BPS), followed by a type designation. BPS is indicated by two symbols, the first of which corresponds to cystoscopy with hydrodistention findings (1, 2, or 3, indicating increasing grade of severity) and the second to biopsy (A, B, and C, indicating increasing grade of severity of biopsy findings) (Table 2). Although neither cystoscopy with hydrodistention nor bladder biopsy was prescribed as an essential part of the evaluation, by categorizing patients as to whether either procedure was done, and if so, the results, it is possible to follow patients with similar findings and study each identified cohort to compare natural history, prognosis, and response to therapy [40].

As Baranowski et al. conceived it in early 2008, BPS is thus defined as a pain syndrome with a collection of symptoms, the most important of which is pain perceived to be in the bladder [41]. IC is distinguished

1465
as an end-organ, visceral-neural pain syndrome, whereas BPS can be considered a pain syndrome that involves the end-organ (bladder) and neuro-visceral (myopathic) mechanisms. In IC, one expects end-organ primary pathology. This is not necessarily the case in the broader BPS.

A didactically very demonstrative way to conceptualize the dawning shift in conception of the condition is with the drawing of a target (Figure 2). There may be many causes of chronic pelvic pain. When an aetiology cannot be determined, it is characterized as pelvic pain syndrome. To the extent that it can be distinguished as urologic, gynecologic, dermatologic, and the like, it is further categorized by organ system. A urologic pain syndrome can sometimes be further differentiated on the site of perceived pain. Bladder, prostate, testicular, and epididymal pain syndromes follow. Finally, types of BPS can be further defined as IC, or simply categorized by ESSIC criteria. Patient groups have expressed their concerns with regard to any nomenclature change that potentially drops the term “interstitial cystitis” because the U.S. Social Security Administration and private insurances recognize IC but not the term BPS, and benefits potentially could be adversely affected. Whether the term “interstitial cystitis”, as difficult as it is to define and as potentially misleading as it is with regard to aetiology and end-organ involvement, should be maintained, is a subject of ongoing controversy.

II. EPIDEMIOLOGY

Figure 2: Conceptual Diagram of Pelvic Pain

It has been estimated that the prevalence of chronic pain due to benign causes in the population is at least 10% [42]. Numerous case series have, until recently, formed the basis of epidemiologic information regarding BPS. Farkas and associates [43] discussed IC in adolescent girls. Hanash and Pool [44] reviewed their experience with IC in men. Geist and Antolak [45] reviewed and added to reports of disease occurring in childhood. A childhood presentation is extremely rare and must be differentiated from the much more common and benign-behaving extraordinary urinary frequency syndrome of childhood, a self-limited condition of unknown etiology [46,47]. Nevertheless, there is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of BPS. In Close and colleagues’ review of 20 such children [48], the median age of onset was younger than 5 years, and the vast majority of patients had long-term remissions with bladder distention.

A study conducted at the Scripps Research Institute [49] included 374 patients at Scripps as well as some members of theInterstitial Cystitis Association, the large patient support organization. A more recent, but similar study in England [50] concurred with the Scripps findings of urgency, frequency, and pain in the vast majority of these patients, devastating effects on quality of life, and often unsuccessful attempts at therapy with a variety of treatments. Although such reviews provide some information, they would seem to be necessarily biased by virtue of their design.

Epidemiology studies of BPS are hampered by many problems [51]. The lack of an accepted definition, the absence of a validated diagnostic marker, and questions regarding etiology and pathophysiology make much of the literature difficult to interpret. Overlapping patterns of lower urinary tract symptoms and pelvic pain are common and present challenges for clinical practice and research [52]. This is most apparent when one looks at the variation in incidence reports in the United States and around the world. These range from 1.2 per 100,000 population and 4.5 per 100,000 females in Japan [53], to a questionnaire based study that suggests a figure in American women of 20,000 per 100,000 [54]. Certainly, bladder pain symptoms are more common than suggested by coded physician diagnoses [55].

Several population-based studies have been reported in the literature, and these studies tend to support the reviews of selected patients or from individual clinics and the comprehensive follow-up case-control study by Koziol [56]. The first population-based study [57] included “almost all the patients with interstitial cystitis in the city of Helsinki”. This superb, brief report from Finland surveyed all diagnosed cases in a population approaching 1 million. The prevalence of the disease in women was 18.1 per 100,000. The joint prevalence in both sexes was 10.6 cases per 100,000. The annual incidence of new female cases was 1.2 per 100,000. Severe cases accounted for about 10% of the total. Ten per cent of cases were in men. The disease onset was generally subacute rather than insidious, and full development of the classic symptom complex occurred over a relatively short
time. IC does not progress continuously, but usually reaches its final stage rapidly (within 5 years in the Koziol study [49]) and then continues without significant change in symptomatology. Subsequent major deterioration was found by Oravisto to be unusual. The duration of symptoms before diagnosis was 3-5 years in the Finnish study. Analogous figures in a classic American paper a quarter of a century earlier were 7-12 years [21].

Another early population study, this in the United States, first demonstrated the potential extent of what had been considered a very rare disease [58]. The following population groups were surveyed: 1) random survey of 127 board-certified urologists 2) 64 IC patients selected by the surveyed urologists and divided among the last patient with IC seen, and the last patient with IC diagnosed 3)904 female patients belonging to the Interstitial Cystitis Association 4) random phone survey of 119 persons from the US population. This 1987 study reached the following conclusions:

1. 43,500 to 90,000 diagnosed cases of IC in the USA (twice the Finnish prevalence)
2. Up to a five-fold increase in IC prevalence if all patients with painful bladder and sterile urine had been given the diagnosis, yielding up to half million possible cases in the USA
3. Median age of onset 40 years
4. Late deterioration in symptoms unusual
5. 50% temporary spontaneous remission rate, mean duration 8 months
6. 10 times higher incidence of childhood bladder problems in IC patients vs controls
7. 2 times the incidence of a history of urinary tract infection vs. controls
8. Lower quality of life than dialysis patients
9. Costs including lost economic production in 1987 of $427 million

Other population studies followed. Jones et al [59] obtained their data from self-report of a previous diagnosis of IC in the 1989 National Household Interview Survey. The survey estimated that 0.5% of the population, or >1,000,000 people in the United States reported having a diagnosis of IC. There was no verification of this self-report by medical records. Bade et al [60] used a physician questionnaire-based survey in the Netherlands yielding an overall prevalence of 8-16 per 100,000 females, with diagnosis heavily dependent on pathology and presence of mast cells. This prevalence in females compares to 4.5 per 100,00, in Japan [53]. The Nurses Health Study I and II [61] showed a prevalence of IC between 52 and 67 per 100,000 in the USA, twice the prevalence in the Held study [58] and three-fold greater than the Netherlands [60]. It improved on previous studies by using a large sample derived from a general population and careful ascertainment of the diagnosis. If the 6.4% confirmation rate of their study were applied to the Jones et al National Health Interview Survey data, the prevalence estimates of the two studies would be nearly identical. Ibrahim and colleagues [62] studied prevalence among community-dwelling women in Michigan, comparing survey responses from 215 established BPS cases with 823 age-matched controls of 3.7% to 4.4%., a figure that corresponds with other symptom-based assessments around the world [63-65].

1. POPULATION BASED STUDIES AND THE NEED FOR A BETTER QUESTIONNAIRE: (Figure 3)

Increasingly epidemiological studies of BPS are being conducted on large populations. This is the best way to evaluate risk factors, as well as obtain more accurate measures of disease prevalence. However, in population based studies, disease assessment is done by symptom-based questionnaires. Warren, et al [66] combined a mail-in survey with randomly selected telephone surveys to determine the prevalence of BPS amongst first degree relatives in comparison to that of the general population. They concluded that adult female first degree relatives of patients with BPS may have a prevalence of BPS 17 times that found in the general population. This suggests but does not prove a genetic susceptibility to BPS. The O'Leary Sant (OLS) and the Pelvic Pain and Urgency/Frequency (PUF) questionnaires were compared by Rosenberg and Hazard [67] in the same general practice population of 1218 patients. The prevalence of BPS with the OLS was determined to be 0.57%, with the PUF the prevalence was determined to be 12.6%. This indicated the need for a more accurate screening tool/questionnaire to be used with population based studies. When Nickel, et al [68] utilized the OLS in outpatient urology practice populations of 65 urologists, the prevalence of IC was determined to be 2.8%. This is strikingly similar to studies using the OLS in Finland, Austria, and Taiwan [63-65]. Again this demonstrates the need for a more refined symptom based questionnaire which can be used by epidemiologists and non-urologists to get an accurate determination of prevalence in population studies.

Leppilahti, et al [64,69] studied a general population of women, in Finland, using the OLS. These urologists estimated the prevalence of BPS in the general Population of Finland to be 6.8%. However, when a sample of those women was examined by one of the urologists, the more accurate prevalence approached that reported by Nickel, et al: 3.0%. This demonstrates the variability of the OLS questionnaire, and how the
estimates can differ when confirmed by clinical examination.

The need for a more general symptom based questionnaire specific for epidemiological studies was again demonstrated by Clemens et al. [70]. They administered the OLS questionnaire to 5000 women and men that a clinician had determined not to have IC. Their results demonstrated that the OLS questionnaire, when utilized as a screening tool in a general population estimated IC to be 30 to 50 fold higher in women than the prevalence of a coded physician diagnosis. These findings suggest that the current population based studies conducted using either the OLS or PUF questionnaires tend to report a much higher prevalence of BPS than confirmed by physical exam. This increasingly becomes a problem as population based studies are conducted by epidemiologists and findings are not confirmed by clinical examination. It indicates the pressing need for development of a validated symptom based questionnaire with documented sensitivity and specificity to identify not only prevalence, but also risk factors and associated disorders.

An estimation of the prevalence at this time, recognizing that a consistent definition of the condition has not been used in epidemiologic studies, appears to be about 300 per 100,000 women, and a male prevalence of 10% to 20% of the female estimate. Level of Evidence: 1 Grade of Recommendation: A

2. OTHER CONSIDERATIONS

The Interstitial Cystitis Database Cohort (ICDB) of patients has been carefully studied, and the findings seem to bear out those of other epidemiologic surveys [71]. Patterns of change in symptoms with time suggest regression to the mean and an intervention effect associated with the increased follow-up and care of cohort participants. Although all symptoms fluctuated, there was no evidence of significant long-term change in overall disease severity. The data suggest that BPS is a chronic disease and no current treatments have a significant impact on symptoms over time in the majority of patients. Quality of life studies suggest that BPS patients are 6 times more likely than individuals in the general population to cut down on work time owing to health problems, but only half as likely to do so as patients with arthritis [72]. There is an associated high incidence of comorbidity including depression, chronic pain, and anxiety and overall mental health [38, 73, 74]. There seems to be no effect on pregnancy outcomes [75].

Most studies show a female to male preponderance of 5:1 or greater [38, 76]. In the absence of a validated marker, it is often difficult to distinguish BPS from the chronic pelvic pain syndrome (nonbacterial prostatitis, prostatodynia) that affects males [77], and the percentage of men with BPS may actually be higher [78-80]. Men tend to be diagnosed at an older age and have a higher percentage of Hunner's lesion in the case series reported [80, 81].

3. ASSOCIATED / OVERLAPPING DISORDERS

Until recently bladder pain syndrome was investigated by urologists and urological scientists focusing predominantly on the bladder. This can be attributed at least in part to the fact that the NIDDK Diagnostic Criteria, and other BPS definitions focused almost entirely on the bladder symptomatology. In 1994, a biostatistician at the Scripps Research Institute [56] reported that there was a significant association of IC with irritable bowel syndrome, as well as sinusitis, allergies and other inflammatory and autoimmune disorders. In the following year Dan Clauw, a rheumatologist, [82] published a novel unifying hypothesis which linked many chronic pain disorders such as BPS, irritable bowel syndrome, chronic fatigue syndrome, fibromyalgia, and others, to a common central pathogenesis and pathophysiology. Dr. Clauw concluded that “a multidisciplinary approach which examines a number of symptoms and systems concurrently is likely to be much more effective than examining one aspect at a single point in time”. In 1997, Clauw, et al [83] reported on the symptom overlap between two cohorts of patients, one with fibromyalgia and one with IC. In the same year an analysis of a survey by Alagiri, et al [84] of over 6,700 persons who had a physician diagnosis of Interstitial Cystitis reported that individuals with BPS were 100 times more likely to have inflammatory bowel disease, and that allergies, irritable bowel syndrome, sensitive skin, and fibromyalgia also have an increased association with IC. The investigators concluded that “IC, which at present has neither a specific nor a curative treatment, has an increased association with certain chronic disease and pain syndromes, and raises the question of whether these dysfunction syndromes should be investigated for a common
biochemical defect”. Unfortunately over a decade has passed and these concluding statements remain relevant, and the investigation of associated symptoms has not been a significant focus of investigation by BPS treating physicians.

Erickson, et al [85] reconfirmed the data reported by Clauw, et al 4 years earlier, in which BPS and fibromyalgia cohorts were compared. The Erickson group concluded that BPS patients had significant occurrence of symptoms of aches in joints, abdominal cramps, headache, other pelvic discomfort, etc. They concluded that the pathophysiology that affects BPS symptoms may affect other organ systems besides the bladder. An analysis of a co-twin control study in Seattle, Washington assessed the association of numerous chronic pain disorders including BPS, irritable bowel syndrome, fibromyalgia, chronic fatigue syndrome, etc. and concluded that there was a high rate of association between these disorders [86,87]. It went on to suggest that treating physicians should examine affected patients for comorbid clinical conditions. They concluded that this multisystem assessment will help in determining a temporal relationship between the disorders as well as develop strategies for early intervention.

Peeker, et al [88] sub-classified BPS into classic (with ulcer) and non-ulcer and then evaluated for concurrent systemic and autoimmune disorders. Their findings supported the co-occurrence of associated disorders but did not see any significant differences between findings in the two categories of BPS patients. Weissman, et al [89] reported from a case-control and family history study the association of panic disorder with confirmed BPS and suggested there might be a subset of BPS patients with a genetic linkage to a possible syndrome associated with panic disorder, thyroid disorder and other disorders of autonomic or neuromuscular control.

There are very few studies reported by urologists using a patient sample. The study reported by Erickson, et al [85] is, perhaps, the most complete patient centered investigation reported by a urologist. Clemens, et al [90] reported a medical record survey at Kaiser Permanente Northwest in Portland, Oregon. They confirmed that BPS is associated with multiple other unexplained physical symptoms. They also confirmed previous findings of Peters, et al [91] that BPS is also associated with a history of child abuse.

Recent literature strongly suggests that these associated symptoms must be assessed in both BPS patients as well as patients with related disorders.. Brand, et al [92] have published “The Fibromyalgia Bladder Index” which is a validated fibromyalgia-specific instrument that captures information about the sensory bladder symptoms in a patient with fibromyalgia. Aaron and Buchwald [93] developed a series of multidisciplinary screening questions which address the more common associated/overlapping conditions. This is an excellent start to a complex problem.

The study of the associated symptoms and disorders must be continued and expanded utilizing cohorts of BPS diagnosed patients. A screening questionnaire must be developed by a multidisciplinary team of clinical specialists so that IC and its co-morbidities can be more effectively evaluated and treated by urologists, gynecologists, rheumatologists, general practice physicians and other clinical providers.

### III. AETIOLOGY

The aetiology of BPS is still an enigma. Hypotheses abound with sparse evidence to support them. Studies on all aspects of BPS are hampered significantly because there is no general consensus on how to define and classify this condition.

#### 1. INFLAMMATION

Inflammation is a non-disputable feature only in the classic or ulcerative form of BPS. Histological examination of bladder lesions has revealed pancystitis and perineural inflammatory infiltrates of lymphocytes and plasma cells [94,95]. **Level of Evidence: 1 Grade of Recommendation: A**

#### 2. MAST CELL ACTIVATION

Mast cells are thought to have a role in the etiology and/or pathogenesis of BPS. They are multifunctional immune cells that contain highly potent inflammatory mediators such as histamine, leukotrienes, serotonin, and cytokines [96]. These cells are the repositories of many potent inflammatory factors. Many of the symptoms and findings in ulcerative BPS such as pain, frequency, oedema, fibrosis, and the production of new vessels in the lamina propria, could possibly be ascribed to the release of mast cell-derived factors. Hence, the mast cell-IgE system and its interaction with other inflammatory cells and the nervous system[97] seems to be of importance when it comes to pathogenesis.

There is a ten-fold increase in mast cell count in bladder tissue from patients with ulcerative BPS as compared to controls. In non-ulcer BPS, however, the mast cell count is normal or only slightly increased [96,98,99].

Other mechanisms have also been put forward. Bouchelouche [100] compared the urinary excretion of leukotrienes E4 and eosinophil protein X in patients in IC and noted detrusor mastocytosis and increased urinary leukotrienes E4 and eosinophil protein X. **Level of Evidence: 1 Grade of Recommendation: A**
3. UROTHELIAL DYSFUNCTION/GAG-LAYER DEFECTS

A defect in the glycosaminoglycan (GAG) layer has been proposed by Parsons and co-workers [101]. With such a defect the sub-mucosal nerve filaments might become accessible to noxious substances in the urine and this might explain bladder pain and urinary frequency. In ulcerative BPS there is granulation tissue indicating a reparative process following repeated disruption of the mucosa [102]. Widened tight junctions and increased permeability have been demonstrated by scanning electron microscopy and other techniques [103,104].

A more recent study by Parsons et al [105] has shown that Tamm-Horsfall protein is quantitatively different in BPS patients as compared to controls. Tamm-Horsfall protein is synthesized in the kidney and excreted into the urine. It has been suggested to have a role in immune defense and in preventing damage to the urothelial cells by injurious urinary constituents. Level of Evidence: 2 Grade of Recommendation: B

4. INHIBITION OF UROTHELIAL BLADDER CELL PROLIFERATION

One explanation of the bladder epithelial dysfunction might be the fact that the cells produce an inhibitor of heparin-binding epidermal growth factor-like production in BPS [106]. It was shown that explanted urothelial cells from BPS patients differ from controls not only as to production of epithelial growth factors but also in the rate of proliferation and the production of an antiproliferative factor (APF). Keay and co-workers [107] studied gene expression patterns in normal bladder urothelial cells treated with APF and with mock APF as compared to patterns expressed by BPS urothelial cells. The results indicate that the mechanism of APF inhibition of urothelial cells may involve both down-regulation of genes that stimulate cell proliferation along with up-regulation of genes that inhibit cell growth. The same group of researchers has indicated that APF seems to be specifically elevated in the urine of patients with BPS but not in persons with no or other conditions. These findings might open up new avenues for identification and development of urine markers for BPS [108]. Level of Evidence: 2 Grade of Recommendation: B

5. AUTOIMMUNE MECHANISMS

There are numerous reports on autoantibodies in patients with BPS [109-112]. The precise identity of these autoantibodies has yet to be determined. Some of the common clinical and histopathological characteristics present in BPS patients show certain similarities with other known autoimmune disturbances. Studies on autoantibodies in BPS have shown that these mainly consist of antinuclear antibodies [111] and these findings are in turn similar to the autoantibody profiles in some systemic diseases like Sjögren syndrome, which is known to be of autoimmune origin [88,113,114]. Only a portion of BPS patients have auto-antibodies. It has been proposed that the presence of auto-antibodies in these patients could be a reflection of disease severity [115].

Vascular immunopathology with immune deposits in the bladder wall was found by Mattila [116]. Further studies also suggest activation of complement [117]. By means of immunophenotyping and flow cytometric analyses of the bladder mucosa and peripheral blood, differences between ulcerative and non-ulcer BPS patients have been demonstrated. In the former group intense T-cell infiltrates and B-cell nodules were seen, compared to far less T-cell infiltrates in non-ulcer BPS [118]. Involvement of the immune system is one feature found in some individuals with BPS, but findings are conflicting and have not been helpful in explaining the aetiology. The lack of thorough descriptions of patients in many published studies has made classification and comparison between series impossible. Level of Evidence: 2 Grade of Recommendation: C

6. INFECTION

No microorganism has ever been revealed as the cause of BPS. Lynnes and coworkers did not find any evidence of recent or remote Gram negative or Gram positive infections in patients with BPS, nor did they find increased urinary IgA and IgG elevation [119]. This makes infection by an untested organism unlikely. Warren et al [120] in a case control study of women with recent onset of BPS symptoms, reported that documented evidence of UTI at symptom onset was found in only a minority of patients. Polymerase chain reaction techniques to amplify bacterial 16S rRNA genes that would be present if there were bacteria in bladder tissue or urine in BPS patients despite negative cultures have been without success [121]. Contrary to what was demonstrated for chronic gastritis, there is no evidence for helicobacter in BPS patients [122]. The possibility of a microbial contribution to the etiology of BPS remains an open question. Level of Evidence: 1 Grade of Recommendation: A

7. NEUROBIOLOGY/PELVIC CROSS-TALK

Several authors have described autonomic nerve changes [123-125], but the findings are far from uniform. An increase of sympathetic innervation and activation of purinergic neurotransmission has been reported. The S-100 family of proteins appear in Schwann cells of the peripheral nervous system [126,127]. Decreased levels of S-100 protein in the non-ulcer group as compared to controls has been found [128], which is consistent with a decreased nerve content in patients with non-ulcer BPS, a finding conflicting with the results of Hohenfellner [124] who used polyclonal antihuman protein gene product 9.5 antibody and found the overall nerve content increased.
in BPS patients as compared to controls. However, their study did not include subtyping of the disease into ulcerative and non-ulcer type. A distinctive ultrastructural appearance of specimens from patients with non-ulcer BPS prompted Elbadawi and Light to propose neurogenic inflammation as a trigger to a cascade of events taking place in this disease [129]. In this context it should be noted that afferent nerves release transmitters like substance P which could activate immune cells, or vasoactive intestinal polypeptide. These events may constitute a link to the immune cell system and promote a decrease of lymphocyte proliferation.

A prominent increase of tyrosine hydroxylase immunoreactivity in bladder tissue of BPS patients, as compared to controls, has been described [130]. This can presumably be interpreted as a sign of generally increased sympathetic outflow. This lends support to the notion of a neurogenic etiology and or pathogenesis.

Malykhina and others [131-135] have demonstrated in innovative animal studies that there is a bidirectional neural cross-sensitization of the colon and lower urinary tract. Acute colitis sensitized lumbosacral spinal neurons receiving input from the urinary bladder result in spinal neuronal hyperexcitability that may be involved in central cross-organ sensitization of visceral nociception between the colon and urinary bladder. This provides information which not only supports a neurogenic etiology but also may account for the substantial overlap of BPS with other chronic pelvic pain disorders, especially the inflammatory bowel disorders [84]. Rudick and Colleagues have shown in a murine model organ cross talk in pelvic pain and modulation of pain responses by visceral inputs distinct from the inflamed site [136]. Level of Evidence: 2 Grade of Recommendation: B

8. NITRIC OXIDE METABOLISM

Regulation of urinary nitric oxide synthase activity has been proposed to be of importance for immunologic responses in BPS. The oral administration of L-arginine, the substrate for nitric oxide production [137] has been shown to increase nitric oxide related enzymes and metabolites in the urine of patients with BPS [138].

It has been reported that differences in NO evaporation between ulcerative and non-ulcer BPS allows for subtyping of cases meeting the NIDDK criteria. This could negate the need for cystoscopy [139]. Level of Evidence: 2 Grade of Recommendation: C

9. TOXIC AGENTS

There are a few publications which have suggested that toxic substances in the urine may cause injury to the bladder resulting in symptoms consistent with BPS. One published hypothesis is that heat labile, cationic urine components of low molecular weight may exert a cytotoxic effect [140]. Another group of investigators has suggested that defective constituent cytokine production may decrease mucosal defense to toxic agents [141]. Level of Evidence: 3 Grade of Recommendation: D

10. HYPOXIA

Decreased microvascular density has been reported to be a feature of bladders from some individuals with BPS [142] One group of investigators has reported that bladder perfusion decreased with bladder distension in some PBS patients compared to the opposite effect in control subjects [143] Despite these observations, the investigators have noted that bladder ischemia alone would not account for the symptoms associated with BPS. Level of Evidence: 4 Grade of Recommendation: D

11. THE ROLE OF GENETICS IN BPS

Warren et al [144] report findings from a small cohort of twins which demonstrated a greater concordance of BPS among monozygotic that among dizygotic twins. This finding suggested that there could be a genetic susceptibility to BPS. A later study by the same research group [66] suggested that adult female first-degree relatives of patients with BPS may have a prevalence of IC 17 times that found in the general population. This coupled with the previously reported twin data suggests, but does not prove, a genetic component adds to the susceptibility for BPS.

The report by Weissman et al [89] of the increased frequency of BPS in patients and their first degree relatives with panic disorder and other seemingly disparate disorders, has suggested that there is a familial syndrome consisting of BPS and other disorders of possible autonomic or neuromuscular dysfunction. More recent studies by the same group [145] from a case control study, suggested that this syndrome might include other anxiety disorders as well, and that families with and without this collection of symptoms were genetically distinguishable on chromosome 13. Level of Evidence: 1 Grade of Recommendation: B

CONCLUSIONS

There have been no significant conclusive advances made in understanding either the etiology or pathogenesis of BPS. It is now believed that the aetiology of BPS is more complex than has been previously envisioned [84,86,90,146-148]. The consideration of BPS as a part of a generalized somatic disorder should open new pathways to the study of BPS. Investigators should continue to explore central neurological mechanisms of pathogenesis, as well as genetic/familial, immunological and infectious etiologies of this puzzling, complex disorder.

An algorithm that attempts to illustrate an etiologic schema is presented below (Figure 4).
Figure 4: Proposed Pathogenesis of Bladder Pain Syndrome
IV. PATHOLOGY

One can have pathology consistent with the diagnosis of BPS, but there is no histology pathognomonic of this syndrome. The role of histopathology in the diagnosis of BPS is primarily one of excluding other possible diagnoses. One must rule out carcinoma and carcinoma-in-situ, eosinophilic cystitis, tuberculous cystitis, as well as any other entities with a specific tissue diagnosis [102,149,150].

Level of Evidence: 1 Grade of Recommendation: A

While earlier reports described a chronic, edematous pancytisitis with mast cell infiltration, submucosal ulcerations and involvement of the bladder wall and chronic lymphocytic infiltrate [151,152], these were cases culled from patients with severe disease and not representative of the majority of cases currently diagnosed. The pathologic findings in BPS are not consistent. There has been a great variation in the reported histologic appearance of biopsies from BPS patients, and even variation among biopsies taken from the same patients over time [22].

Lepinard and colleagues [153] reported a pancytisitis affecting the 3 layers of bladder wall. In nonulcerative disease the vesical wall was never normal, epithelium being thinned and muscle being affected. Johansson and Fall [102] looked at 64 patients with ulcerative disease and 44 with nonulcerative IC. The former group had mucosal ulceration and hemorrhage, granulation tissue, intense inflammatory infiltrate, elevated mast cell counts and perineural infiltrates. The nonulcer group, despite the same severe symptoms, had a relatively unaltered mucosa with a sparse inflammatory response, the main feature being multiple, small, mucosal ruptures and suburothelial hemorrhages that were noted in a high proportion of patients. As these specimens were almost all taken immediately after hydrodistention, how much of the admittedly minimal findings in the nonulcer group were purely iatrogenic is a matter of speculation.

One can see completely normal biopsies in the nonulcerative BPS group [154]. Transition from nonulcerative to ulcerative BPS is a rare event [98], and pathologically the two types of IC may be completely separate entities. While mast cells are more commonly seen in the detrusor in ulcerative BPS[155], they are also common in patients with idiopathic bladder instability [156]. Mastocytosis in BPS is best documented by tryptase immunocytochemical staining [157]. Larsen and colleagues recommend taking biopsies from the detrusor of patients with suspected BPS and examining them with tryptase-stained 3 micron thick sections, with every seventh section used for quantification. They consider 27 mast cells/mm² indicative of mastocytosis [158]. Despite attempts to develop a diagnostic algorithm based on the detrusor to mucosa mast cell ratio and nerve fiber proliferation [97], mast cell counts per se have no place in the differential diagnosis of this clinical syndrome.

Mast cells could be valuable in clinical phenotyping, but as yet that is unproven. Mast cells trigger inflammation that is associated with local pain, but the mechanisms mediating pain are unclear. In a murine model of neurogenic cystitis, Rudick and colleagues [159] demonstrated that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and tumor necrosis factor respectively. Therefore, pain is independent of pathology and inflammation, and histamine receptors may represent direct therapeutic targets for the pain of BPS and other chronic pain conditions.

Lynes and coworkers [32] concluded that biopsy specimens are often not helpful in confirming the diagnosis. Although BPS patients in his study had a higher incidence and degree of denuded epithelium, ulceration, and submucosal inflammation, none of these findings was pathognomonic. In addition, these “typical” findings occurred only in BPS patients with pyuria or small bladder capacity. Epithelial and basement membrane thickness, submucosal edema, vascular ectasia, fibrosis, and detrusor muscle inflammation and fibrosis were not significantly different in the BPS and control patients.

Attempts to definitively diagnose BPS by electron microscopy have also been unsuccessful. Collan’s group [160], in the first such study, wrote that the similarity of the ultrastructure of epithelial cells in controls and IC patients makes it improbable that the disease process originates in the epithelium. Other investigators found no differences in the morphologic appearances of the glycocalyx and of urothelial cells in patients with IC when compared with controls [161]. Anderstrom and colleagues [104] saw no surface characteristics specific for IC, but believed that the mucin layer covering the urothelial cells seemed reduced in IC compared with controls, a fact disputed by Nickel in a very elegant paper [162]. Elbadawi and Light [129] observed ultrastructural changes sufficiently distinctive to be diagnostic in specimens submitted for pathologic confirmation of nonulcerative interstitial cystitis. Marked edema of various tissue elements and cells appeared to be a common denominator of many observed changes. The wide-ranging discussion of the etiology of IC in his paper is fascinating, but the pathological findings are potentially marred by the methodology, in that specimens were obtained after diagnostic hydrodistention [163].

So what is the place of pathologic examination of tissue in BPS? Attempts to classify the painful bladder by the pathoanatomical criteria described by Holm-Bentzen [164] are of questionable value. There is a
group of patients with what she describes as “nonobstructive detrusor myopathy” [165]. In her series, these patients with degenerative changes in the detrusor muscle often had residual urine, a history of urinary retention, and an absence of sensory urgency on cystometry with bladder capacities over 400cc. Most would not be clinically confused with BPS. A similar English series [166], however, included patients who met NIDDK research criteria and associated detrusor myopathy with diminished detrusor compliance and ultimate bladder contrac-

The Interstitial Cystitis Database (ICDB) study worked backwards from symptoms to pathology, and concluded that certain symptoms are predictive of specific pathologic findings [30,167]. Denson et. al. [33] analyzed forceps biopsies from 65 females and 4 males with BPS. Ten per cent of specimens showed vasodilatation or submucosal edema. Inflammation was absent in 30% of patients, and mild in another 41%. Cystoscopic changes did not correlate with degree of inflammation. Hanus and colleagues [168] studied 84 biopsies from 112 BPS patients and reported a linear relationship between the mean bladder capacity under anesthesia and severity of glomerulations. They did not find a correlation between severity of symptoms and histopathological changes observed by light or electron microscopy.

Rosamilia reviewed the pathology literature pertaining to BPS in 2 recent publications and presented her own data [31,38]. She compared forceps biopsies from 35 control and 34 PBS/IC patients, 6 with bladder capacities less than 400cc under anesthesia. Epithelial denudation, submucosal edema, congestion and inflammatory infiltrate were increased in the BPS group. Submucosal hemorrhage did not differentiate the groups, but denuded epithelium was unique to the BPS group and more common in those with severe disease. The most remarkable finding in her study was that histological parameters were normal and indistinguishable from control subjects in 55% of BPS subjects. Method of biopsy can be important in interpreting findings, as transurethral resection biopsies tend to show mucosal ruptures, submucosal hemorrhage and mild inflammation [102], while histology is normal approximately half the time with cold-cup forceps biopsies [31,32,169].

Histopathology plays a supportive diagnostic role at best [170]. Major reconstructive procedures appear to have better outcomes in patients with pathology consistent with Hunner’s lesions [171]. Inflammatory features can be seen in 24% to 76% of patients without a visible Hunner’s lesion [172]. While recent studies suggest that a severely abnormal pathology may be associated with poor prognosis [173,174], this is not necessarily the case [175]. At this point in time, excluding other diseases that are pathologically identifiable is the primary utility of bladder biopsy in this group of patients.

V. DIAGNOSIS

Much work has been put into the attempt to define objective diagnostic criteria based on, among other factors, cystoscopy under local or general anesthesia, bladder distention with registration of bladder capacity and/or possible presence of glomerulations and Hunner’s lesion, bladder wall biopsies evaluated for inflammation, ulcer, fibrosis, mast cells, etc. and urodynamics with registration of bladder capacity, compliance and bladder stability. Results have, however, been frustrating. It is more fruitful to establish a broad clinical diagnosis, mainly on the basis of symptoms and exclusion of other diseases, and then stratify patients by urodynamic, cystoscopic, histological, and other tests on the basis of the significance of these findings for results of treatment and prognosis of disease. Current efforts to phenotype the disorder by the presence or absence of associated syndromes and diseases may also prove useful in the same way.

What follows is based solely on expert opinion. Level of Evidence:4 Grade of Recommendation:C

It is hoped that future Consultations will have the data to base such suggestions on more a more firm foundation.

1. HISTORY

A general thorough medical history should be taken. Special emphasis should be given to:

- Previous pelvic operations
- Previous UTI
- Bladder history/urological diseases
- Location of pelvic pain (referred pain) and relation to bladder filling/emptying.
- Characteristics of pain: onset, correlation with other events, description of pain
- Previous pelvic radiation treatment
- Autoimmune diseases
- Physical examination

A common physical examination should be performed including palpation of the lower abdomen for bladder fullness and tenderness:

- Standing: kyphosis, scars, hernia
- Supine: abduction/adduction of the hips, hyper-aesthetic areas

In females physical examination should include a vaginal examination with pain mapping of the vulvar region and vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor. Tenderness might be graded as mild, moderate or severe.
2. PAIN MAPPING

Inspection:
- Vulva
  - exclusion of vulvar/vestibular diseases (vulvitis, dermatosis etc.)
  - evaluation of introital area (endometriosis)
  - tenderness of vestibular glands or vulvar skin (Touch Test: use wet cotton stick or finger tip)
- Vagina
  - tenderness during insertion and opening of speculum
  - cervical pathology
  - vaginal fornices (endometriosis)
- Bimanual physical examination
  - tenderness of urethra, trigone and bladder
  - superficial/deep vaginal tenderness
  - tenderness of pelvic floor muscles (levator, adductor)
  - tenderness in adnexal areas

In males digital rectal examination (DRE) should be performed with pain mapping of the scrotal–anal region and palpation of tenderness of the bladder, prostate, levator and adductor muscles of the pelvic floor and the scrotal content.

3. LABORATORY TESTING

- Urine dipstick (ABS, pH, leucocytes, nitrate), urine culture in all. If sterile pyuria culture for tuberculosis.
- Urine cytology in risk groups.
- Investigations for vaginal Ureaplasma and Chlamydia in females and prostatitis in men are optional.

4. SYMPTOM EVALUATION

- Voiding diary with volume intake and output for 3 days at initial evaluation. Patient sensation at voiding might be recorded (see chapter outcome assessment, Hanno).
- At follow-up only number of voidings during day and night time is necessary. Morning volume might be recorded as a help to monitor highest functional capacity.
- The O’Leary–Sant Symptom Score supplemented should be used as basic symptom score supplemented with the Quality of Life Score from the International Prostate Symptom Score (see chapter symptom scales, Hanno3).
- Pain should be recorded using a Visual Analogue Scale (VAS) for pain during the last 24 hours (to fit with the voiding diary). Separate scores for the average, mildest and worst pain should be obtained (see symptom scales)

5. URODYNAMICS

Level of Evidence: 4 Grade of Recommendation: C

The NIDDK criteria excluded patients with detrusor overactivity at filling cystometry in order not to confuse the picture in clinical trials [22]. This does not however mean that detrusor overactivity can not coexist with bladder pain syndrome. In the interstitial cystitis database approximately 14% of BPS patients had overactive bladders [13]. Whether these patients respond better to antimuscarinics than BPS patients with stable bladders has never been systematically investigated. If so, a rationale for routinely employing urodynamics as a part of the evaluation would follow. In males, infravesical obstruction might be a differential diagnosis [176], and it is recommended to do flowmetry in all males and pressure-flow studies in men with a peak flow rate below 20ml/seconds.

There are no data to support the following recommendations:

In females, flowmetry, post void residual urine volume and pressure- flow study are optional. In males, a flowmetry should be done in all, and if maximum flow rate <20 ml/s a pressure-flow study and measure of residual urine volume should be done. It is recommended to perform filling cystometry with a filling rate of 50 ml/s (to comply with the revised Potassium Test - see below) to look for overactivity, volume at first desire to void and cystometric capacity.

6. POTASSIUM TESTING

Level of Evidence: 1 Grade of Recommendation: -A (not recommended)

Parsons has championed an intravesical potassium chloride challenge, comparing the sensory nerve provocative ability of sodium versus potassium using a 0.4 M potassium chloride solution. The test has proved controversial [177]. Pain and provocation of symptoms constitutes a positive test. Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients, or hypersensitivity of the sensory nerves is unclear. Normal bladder epithelium can never be absolutely tight, and there is always some leak, however small [178]. The concentration of potassium used is 400meq per liter, far exceeding the physiologic urinary concentrations of 20-80meq/liter depending upon dietary intake [179]. Healthy controls can distinguish KCl from sodium chloride, though they don’t experience severe pain [180]. The hope is that this test may stratify patients into those who will respond to certain treatments (perhaps those designed to fortify the glycosami-noglycan layer), but to date this information is lacking [181].

Used as a diagnostic test for interstitial cystitis, the potassium chloride test is not valid [182]. The gold standard in defining BPS for research purposes has been the NIDDK criteria. These criteria are recognized
to constitute a set of patients that virtually all researchers can agree have BPS, though they are far too restrictive to be used in clinical practice [24]. Thus, this group of patients should virtually all be positive if the KCl test is to have the sensitivity needed to aid in diagnosis. Up to 25% of patients meeting the NIDDK criteria will have a negative KCl test [183]. In the group it should perform the best in, it is lacking in sensitivity. When we look at the specificity side of the equation, in the universe of asymptomatic persons, it performs relatively well and is rarely positive, although a recent study reported a 36% false positive rate in asymptomatic men [184]. It is in the patient population with confounding conditions for which we would want help in sorting out BPS from other disorders. Twenty-five percent of patients with overactive bladder test positive and virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive [183,185]. The results with chronic prostatitis / chronic pelvic pain syndrome in men are variable, but 50-84% of men have been reported to test positive [184,186,187]. In women with pelvic pain results are similar [188], and based on these findings, Parsons has expressed the view that BPS may affect over 20% of the female population of the United States [189]. Others have reported prevalence in unselected female textile workers in Turkey using similar methods at 32.8% [190]. Another way to interpret the findings would be that the KCl test is very nonspecific, missing a significant number of BPS patients and over-diagnosing much of the population.

Prospective and retrospective studies looking at the KCl test for diagnosis in patients presenting with symptoms of BPS have found no benefit of the test in comparison with standard techniques of diagnosis [182,191,192]. A recent modification of the test using 0.3 molar potassium chloride for potential differentiation between patients with IC and detrusor overactivity (DO) showed that the 0.3 M KCl reduces maximum cystometric capacity in BPS and DO, the effect being more pronounced in DO. Urothelial hyperpermeability was not specific to IC. Comparative cystometry using NS and 0.3 M KCl does not help to differentiate BPS from DO [193,194].

The development of a painless modification of the potassium chloride test [195] using cystometric capacity and a 0.2M solution may improve acceptability among patients. The so-called revised or Comparative Potassium Test has shown prognostic value in bladder irrigation studies, [196] but is considered optional by ESSIC. If performed it should be performed according to Daha et al. [195]: A Foley balloon catheter (14F) is inserted and the bladder drained. Instill into the bladder 500 ml saline (0.9%) at a rate of 50 ml/min via an infusion set until the maximum capacity is reached. Drain the bladder and measure the saline filling volume. Repeat the instillation and measurement with 500 ml 0.2 M potassium chloride at a rate of 50 ml/min (taking care that filling lines are emptied of all saline before KCl instillation), and calculate the filling volume difference. A difference in bladder capacity > 30% is considered positive. Besides reduction of bladder capacity with 0.2 M KCl there is a stronger feeling of urgency in IC patients compared to the saline filling, which is also clinically relevant.

7. CYSTOSCOPY

Level of Evidence:2 Grade of Recommendation:B

The classic cystoscopic picture of BPS as an “elusive” bladder ulcer with a corresponding cystoscopic appearance of patches of red mucosa exhibiting small vessels radiating to a central pale scar was described by Hunner in 1914 [4]. Since then, glomerulations, described as punctuate petechial hemorrhages and observed after hydrodistention, have become the primary cystoscopic feature of BPS [6]. But not all patients with symptoms of BPS have glomerulations, [24,33,197] and not all patients with glomerulations have symptoms of BPS [198-200]. Neither presence nor severity of glomerulations correlate with any of the primary symptoms of BPS, [30] although the presence of a Hunner’s lesion is significantly associated with bodily pain and urinary urgency [199]. The finding of a Hunner’s lesion or glomerulations has been somewhat subjective. Some researchers find a Hunner’s lesion in 50% of their BPS patients, while others rarely see one [201].

No study comparing individual perceptions and variations in reporting or classifying glomerulations has ever been reported. Bladder capacity during hydrodistention has not drawn much attention, although it is strongly associated with increased urgency [199].

Because considerable variation in the duration of distension, repetition of distension, the pressure used for distension, and the measurement of bladder capacity have been described [202], the ESSIC has suggested a standardized procedure for cystoscopy and hydrodistention [11]:

A rigid cystoscope is preferred to facilitate taking of adequate biopsies. Glycine or corresponding filling fluid should be used to allow for coagulation after biopsies. Infusion height should be approximately 80 cm above the Symphysis Pubis. A dripping chamber is used and the bladder is filled until fluid dribbling stops. If necessary, a digital block is applied around the urethra to prevent leakage. Pre-distension inspection includes observation for radiating vessels, coagulum or fibrine deposits, white spots, hyperaemia, oedema, cracks, scars or any other mucosal changes. Continuous inspection while filling the bladder is advised. When maximum capacity is reached, the distension is maintained for 3 minutes. The bladder is emptied and the colour of the fluid checked for the
degree of bleeding. The total volume drained is the measured maximum bladder capacity. During a second filling, the bladder is filled to approximately 1/3rd to 2/3rd of the bladder capacity to achieve optimal vision for inspection and biopsies. The bladder should not be filled to maximum capacity or distended again to avoid further provocation of changes with doubtful reproducibility.

a) Inspection

Describe lesions in anterior wall, posterior wall, lateral quadrants and fundus. At the fundus one should be alert for possible artefacts if there is blind introduction of the scope. Bladder mapping by drawing is mandatory. Photographs are recommended but optional.

b) Classification

Grade 0 = normal mucosa  
Grade I = petechiae in at least two quadrants  
Grade II = large submucosal bleeding (ecchymosis)  
Grade III = diffuse global mucosal bleeding  
Grade IV = mucosal disruption, with or without bleeding/oedema

c) How useful is hydrodistention?

Hydrodistension results fail to identify any statistically significant differences in post-distention objective findings (anesthetic capacity, glomerulations) or therapeutic benefits when patients are categorized according to presenting symptoms [203]. Cystoscopy with hydrodistention may provide little useful information above and beyond the history and physical examination findings. In one study, 56% of 84 patients reported symptom improvement, but the duration was short lived with a mean of 2 months [204].

Damerau and colleagues examined the relationships between symptoms and cystoscopic findings in 12 women newly diagnosed with BPS who had not previously received treatment. Pain symptoms had consistent positive correlations with the cystoscopic findings. An increase in pain with bladder filling was associated with inflammation (P = 0.011), ulceration, and smaller bladder capacity. Pain relief after voiding correlated with smaller bladder capacity (P = 0.019), hematuria, and total cystoscopic score. Pain intensity in the urethra was related to ulceration and hematuria, and pain in the lower abdomen was related to a smaller bladder capacity (P = 0.047), glomerulations, and a larger total cystoscopic score. Daytime frequency correlated negatively with most cystoscopic findings, and nocturnal frequency had a positive relationship with most cystoscopic findings and was significantly associated with a smaller bladder capacity (P = 0.010). Urgency showed no strong associations with any cystoscopic findings. The results of this study contradict those of previous studies that found no relationship between symptom reports and cystoscopic findings suggesting possible effects of treatment on pain perception and therapeutic influence on cystoscopic findings [205].

It is important to keep in mind that the cystoscopic appearance of the bladder wall after hydrodistention may not be constant over time, and the absence of initial findings of glomerulations or terminal hematuria does not preclude further development of these hallmarks of the disease on subsequent evaluation [206]. Rare cases of hydrodistension induced bladder necrosis have been described [207].

d) Morphology

Pathological changes in light microscopic and electron microscopic features in patients with BPS have been described including infiltration with inflammatory cells in all or specific parts of the bladder wall. Although these findings are important in our attempt to understand the disease and perhaps as an aid to stratification of patients, there are at this time no pathognomonic findings on biopsy in terms of diagnosis [30]. Expert opinion as per the ESSIC suggests the following procedures when biopsy is planned for BPS evaluation:[11]

1. Biopsies

During cystoscopy the bladder is distended to full capacity. After draining the bladder, bladder biopsies are taken at roughly half full bladder capacity: Biopsy procedures should be performed by using large forceps and include detrusor muscle; alternatively double punch biopsies or resections of lesions can be used.

2. Number of Biopsies

At least 3 biopsies from the two lateral walls and bladder dome should be taken in addition to biopsies from visually abnormal areas. The biopsies are to be immediately fixed in neutral buffered 4% formalin.

3. Biopsy Handling

Biopsies are treated conventionally. Six adjacent 3 mm sections are cut and placed with 3 specimens on each of two specimen slides. The first slide is stained with H&E, the next with a connective tissue stain suitable for the individual institute. Twenty-four 10 mm sections are then cut and every third section is mounted on a specimen slide for mast cell counting. The specimens are stained by Lederstain (naphthol-lesterase) according to routine procedures. Finally, a 3mm section is obtained to ensure the presence of detrusor muscle in the specimens.

4. Mast Cell Counting

The use of a measuring grid (e.g. Leitz periplan 6F 10_N ocular containing a standardized grid) is necessary. Only mast cells containing nucleus are included. When counting the cells those covering or touching the bottom should be excluded whereas those covering the upper and left line are included. At least 3 biopsies must be the subject of mast cell counting and if possible one including a lesional area.
Biopsies for mast cell counting should contain detrusor muscle.

5. The Pathology Report

- Epithelium
- Not present
- Present
- Dysplasia with grading
- Abnormal but no dysplasia: description is mandatory.
- Propria
- Normal
- Inflammation: description with a grading
- Other findings are described
- Detrusor muscle. Abnormal muscle cells: describe
- Intrafascicular fibrosis
- Not present
- Present
- Mast cell count: At least three biopsies should be included in the counting. Only the biopsy with the highest number of mast cells per mm2 should be reported.

Larsen recommends examining the detrusor biopsies with tryptase-stained 3 micron thick sections, with every seventh section used for quantification. 27 mast cells/mm2 is considered indicative of mastocytosis [158].

e) Biomarkers

The lack of universally accepted clinical diagnostic criteria for BPS affects all aspects of making progress in understanding this disease. Insights into risk factors, pathogenesis, trials for effective therapy, prognosis, and outcome criteria for treatment are all affected by this lack of diagnostic criteria. A major factor affecting the controversy over accepted clinical diagnostic criteria is that the current criteria are predominantly symptom specific. An objective biomarker would advance the establishment of reproducible diagnostic criteria for BPS and also aid in monitoring effects of treatment.

A biomarker for any disease needs to demonstrate high sensitivity and high specificity. In addition, the marker assay needs to be reproducible in many laboratories and should be suitable for use in a clinical diagnostic laboratory.

Many of the published studies on biomarkers for BPS have been on biomarkers isolated from urine. Erickson et al has published excellent reviews of urine markers for BPS [08,209]. The most thoroughly investigated marker is antiproliferative factor (APF). This factor has been identified and characterized by Dr. Susan Keay and her colleagues at the University of Maryland [210,211].

APF seems an ideal candidate for a biomarker for symptomatic BPS. There need to be additional studies to determine if it can serve as a BPS marker for patients in remission or for those who have not yet become symptomatic. As of 2008, the findings on asymptomatic patients have yet to be replicated by laboratories around the world, and the biologic assay has not proven suitable for commercial development as it currently exists.

GP-51 is a glycoprotein present in both the transitional epithelium and urine of humans and other mammals. Moskowitz et al have shown that bladder biopsies of BPS patients had decreased staining for GP-51 [221]. The same laboratory also demonstrated that although GP-51 demonstrates a high specificity for BPS, it is not as sensitive as APF [222].

There have also been many published studies on heparin-binding epidermal growth factor-like growth factor (HB-EGF) [107,213,214,223,224]. HB-EGF is a growth factor found in normal urine. It has been shown that APF inhibits the production of HB-EGF. There have been no large population studies focusing solely on HB-EGF as a biomarker for BPS.
f) Confusable Diseases

Criteria for a diagnosis are needed only if the target disease may be confused with other diseases (confusable diseases) because of overlapping features [225]. For a diagnosis, the target disease has to be recognized in a pool of confusable diseases in one of two ways: by recognition of the specific combination of features of the target disease or by exclusion of confusable diseases. For the diagnosis of BPS both methods might be used because:

- Confusable diseases are more common than BPS, so recognition is mandatory because many can be treated.
- Failure to diagnose a confusable disease would automatically incorrectly yield a diagnosis of BPS.
- Patients may have a confusable disease plus BPS. The diagnosis of BPS can thus be made on the basis of exclusion of confusable diseases and confirmation by the recognition of the presence of the specific combination of symptoms and signs of BPS. If the main urinary symptoms are not explained by a single diagnosis (confusable disease or BPS), the presence of a second diagnosis is possible. Symptoms and signs for use in diagnostic criteria do not need to be specific for the target disease. On the contrary, if a specific symptom or sign existed for the target disease, a diagnosis would only require the presence of the specific feature and diagnostic criteria would not be necessary.

In evidence-based medicine, diagnoses are based on medical history, physical examination, and appropriate clinical investigations to eliminate diseases from a list of differential diagnoses (confusable diseases) and to confirm the final diagnosis. BPS may occur together with confusable diseases such as chronic or remitting urinary infections or endometriosis. Cystoscopy with hydrodistension and biopsies might in this situation document positive signs of BPS thereby making a double diagnosis more probable. For therapeutic studies it makes sense to exclude patients who also have a confusable disease because symptoms and signs may be caused by BPS, the confusable disease, or both. For prevalence studies of BPS, on the other hand, all cases with BPS should be included, also those with a confusable disease. This approach eliminates the need for separate diagnostic criteria for clinical practice and scientific studies. Table 3 summarizes confusable diseases related to BPS and their mode of exclusion based upon the aforementioned diagnostic proposals and procedures [11,40].

* The diagnosis of a confusable disease does not necessarily exclude a diagnosis of BPS.

VI. CLASSIFICATION

Interstitial cystitis was originally described as bladder disease with severe inflammation of the bladder wall described by Hunner as an ulcer [4]. The lesion is however not an ulcer but a vulnus (weakness) that can ulcerate on upon distention, and the name of the bladder lesion has consequently been changed to “Hunner’s lesion” [1]. The finding of a Hunner’s lesion could therefore originally be regarded as a diagnostic criterion for IC. Messing and Stamey introduced glomerulations as another typical finding for IC and this was included in the NIDDK criteria [7]. Magnus Fall proposed, that patients with Hunner’s lesion (classic IC) and patients with glomerulations (non-ulcer type) represented two different subtypes [98] with different clinical pictures, different outcomes, and different responses to treatment [226] meaning that patients fulfilling the NIDDK criteria represents at least two different patient populations. Moreover up to 60% of patients clinically believed to have BPS by experienced clinicians do not fulfil the NIDDK criteria [24] and whether or not these patients are comparable to the patients fulfilling the NIDDK criteria is unknown. Finally Japanese urologists consider that “interstitial cystitis” should be preserved as a disease name for patients with urinary symptoms and cystoscopic findings of glomerulations or Hunner’s lesion as outlined in the NIDDK criteria [227].

In an attempt to unite these different philosophies into a coherent schema, ESSIC proposed a classification of BPS based on findings during cystoscopy with hydrodistension and morphological findings in bladder biopsies [1]. (Table 2) The classification includes groups not having had cystoscopy with hydrodistension (group X) as well as groups not having had morphological investigation of bladder biopsies (group XX). By using this classification future research will be able to identify if findings of glomerulations and/or Hunner’s lesion as well as morphological changes in bladder biopsies does have significant importance for disease prognosis and/or treatment outcome.

VII. CONSERVATIVE TREATMENT

1. BEHAVIORAL MODIFICATION

A PubMed search (performed in June, 2008) using the keywords, “interstitial cystitis” and “behavioral therapy” identified 6 articles. One English-language article focused on behavioral therapy [1] has been summarized with two additional articles [2,3]. Level of evidence: 3 Grade of recommendation: C

Despite a low level of evidence, behavioral therapy has become the cornerstone of treatment for patients with BPS. Some efficacy has been reported in the treatment of motivated patients with urinary frequency and urgency. No problematic side effects have been identified.

Behavioral therapy includes timed voiding (scheduled voiding time and interval), controlled fluid intake, pelvic floor muscle training and bladder training (gradually extending voiding interval).

Chaiken et al [228] reported that when they conducted behavioral therapy consisting of frequency-volume chart, timed voiding, controlled fluid intake and pelvic floor muscle training for the treatment of 24 female patients, 50% of the patients showed improvement in the number of urinations and bladder capacity. At the same time, they considered that as the data was collected from 12 weeks’ intensive therapy conducted by skilled therapists for selected patients whose main symptom was urinary frequency, it should not be generalized.

Parsons and Koprowski [229] reported that when 21 patients with the main symptom of urinary frequency underwent bladder training using a frequency-volume chart, 15 patients showed improvement. In 15 patients, the mean voided volume after one month increased by 65cc, whereas a persistent sensation of bladder fullness remained unchanged.

2. PHYSICAL THERAPY

A PubMed search (performed in June, 2008) using the keywords, “interstitial cystitis” and “physical therapy” identified 60 articles. Three usable English-language articles [230-232] focused on physical therapy were examined with 4 additional articles [233-236]. Level of evidence: 3 Grade of recommendation: C

Some efficacy has been reported in the treatment of motivated patients with urinary frequency, urinary urgency and coital pain. No problematic side effects are reported.

Physical therapy for the pelvic floor is said to be effective for genitourinary and anorectal disorders [235]. Biofeedback and soft tissue massage may stimulate the relaxation of the pelvic floor muscles [233,234].

Lukban et al conducted a direct myofascial release treatment on 16 BPS patients with high-tone pelvic floor dysfunction and sacroiliac dysfunction. The treatment was effective for urinary frequency and suprapubic pain. Fifteen patients (94%) showed improvement in the O’Leary & Sant symptom score. Coital pain relief was observed in 15 of 16 patients, with 9 patients becoming able to resume sexual intercourse [231,236]. Transvaginal Theile massage was also reported to be effective for 9 of 10 patients of the same group [232]. Mendelowitz showed a 69% success rate when treating 16 patients using electromyographic biofeedback [233]. However, it was suggested that a placebo effect may have occurred because the effect did not correlate with the improvement in patient’s...
awareness of the pelvic floor muscle movement and position before and after the therapy. Weiss [230] reported that 70% of 10 patients with IC showed symptomatic improvement, rating from “effective” to “remarkably effective”. ??

3. STRESS REDUCTION

A PubMed search (performed in June, 2008) using the keywords, “interstitial cystitis” and “mental health” identified 7 articles. Four articles [73,74,237,238] which are focused on interstitial cystitis have been summarized with 5 additional articles [49,239-242 here. Level of evidence: 4 Grade of recommendation: C

Stress reduction is believed to contribute to an overall improvement in quality of life. No problematic side effects are reported.

It is known that mental stress is one of the factors which aggravate the symptoms of BPS. Kozol et al [49] reported, in a survey of 374 patients, that more than half of the patients experienced intensified pain due to stress. Rothrock et al [241] reported that when comparing patients with BPS and healthy people, increased pain and urgency caused by stress were observed only in patients with BPS.

It is believed that exercise and bathing favorably influence the quality of life by reducing stress, [242] however, behavioral therapies may not provide sufficient effect [49]. It can be beneficial, when possible, to shorten working hours, choose a job with less stress or create a less stressful home environment. At the same time, involvement in patient education programs and patient support groups are considered to be beneficial [239,243].

World-wide patient support groups, including the Interstitial Cystitis Association (ICA) [240], http://www.ichelp.com/welcome.htm, are important sources of information for patients with IC. In Japan, there is an IC patient support group, “TOMONOKI” http://www.tomonoki.org/. Another good source of information is the International Painful Bladder Foundation http://www.painful-bladder.org/. Psychiatric support is important because IC patients often suffer depression, which may negatively impact upon the quality of life. Effective self-care strategies taught by psychiatric nurses are considered to be useful [73,74,238,244].

4. DIETARY MANIPULATION

A PubMed search (performed in June, 2008) using the keywords “interstitial cystitis” and “diet” identified 17 articles. Nine English-language articles [245-253] which are mostly focused on dietary manipulation have been summarized with additional 5 articles [49,56,242,254,255] here. Level of evidence: 4 Grade of recommendation: C

No problematic side effects have been reported. Acidic beverages, coffee, spicy food, and alcohol may aggravate the symptoms of most patients with BPS [49,56,242,247]. The symptoms of the majority of BPS patients can be improved by dietary manipulation [242,246,247,249,255]. On the other hand, Nguan et al [256] reported that there was no statistically significant difference in pain and other symptoms, when they evaluated the influence of the changes in urinary pH on the symptoms of 26 patients with BPS by instilling pH5.0 and pH7.5 saline solutions into the bladder.

Although dietary manipulation has no proven scientific basis, it was ranked in the top five frequently used treatments in a cohort study of the Interstitial Cystitis Data Base (ICDB) [251]. As the influence of diet is variable with regard to food, beverage, and patient, there is no reason for patients to be uniformly on a strict diet. It is advised that each patient experiment to find out the foods that tend to aggravate their symptoms and avoid them. The ICA home page, (http://www.ichelp.com/welcome.htm) introduces the foods often avoided by patients with IC.

VIII. ORAL THERAPY

Several categories of medication have been used in the management of patients with bladder pain syndrome including analgesics, antidepressants, antihistamines, immunosuppressants, and glycosaminoglycans. Many of these drugs are used empirically. Only a few of them have been studied in randomized controlled trials and none have a grade A recommendation (Table 4).

1. ANALGESICS

The long-term, appropriate use of pain medications is indispensible in the treatment of bladder pain syndrome. Many nonopioid analgesics including acetaminophen and the nonsteroidal anti-inflammatory drugs (NSAIDs) and even antispasmodic agents [257] have a place in pain therapy. Patients with more severe symptoms can often be helped with medical pain management using medications commonly used for chronic neuropathic pain syndromes including antidepressants, anticonvulsants, and opioids.

Gabapentin, introduced as an anticonvulsant, has found efficacy in neuropathic pain disorders including diabetic neuropathy [258] and postherpetic neuralgia [259]. It demonstrates synergism with morphine in neuropathic pain [260]. Sasaki et al reported that 10 of 21 male and female patients with refractory genitourinary pain had subjective improvement of their pain following treatment with gabapentin [261].

Pregabalin has similar structure as gabapentin and also has been shown to reduce the pain of diabetic neuropathy [262]. Prebabalin was proved effective for treating pain associated with fibromyalgia [263].
Pregabalin might be worthwhile to try for bladder pain syndrome, particularly for those with concurrent fibromyalgia, though studies are lacking.

Opioids are seldom the first choice of analgesics in chronic pain states, but they should not be withheld if less powerful analgesics have failed [264]. Chronic opioid therapy can be considered as a last resort in selected patients, who have disabling pain and often receive inadequate doses of short-acting pain medications, which put them on cycles of short-term relief, anxiety, and pain.

The major impediment to the proper use of opioids when they are prescribed for long-term nonmalignant pain is the fear of addiction. Some studies suggest the risk is low [265], but not zero [266]. Using opiates is a difficult decision that requires much thought and discussion between patient and urologist, and a pain specialist. They are best administered in a pain clinic setting, requiring frequent reassessment by both patient and physician [267].

In addition to narcotics, concurrent usage of nonsteroidal anti-inflammatory drugs, cyclooxygenase inhibitors, acetaminophen, and tricyclic antidepressants may provide better pain control [268]. The common side effects of opioids include sedation, nausea, mild confusion, and pruritis. These are generally transient and easily managed. Respiratory depression is extremely rare if they are used as prescribed. Constipation is common and a mild laxative is generally necessary. The long-acting narcotic formulations that result in steady levels of drug over many hours are preferable.

### 2. ANTIDEPRESSANTS

#### a) Amitriptyline

Amitriptyline is a tricyclic antidepressant with the
property of blocking H1-histaminergic receptors [269]. It stabilizes mast cells and inhibits mediator stimulated vascular leakage. It inhibits synaptic reuptake of serotonin and norepinephrine, thus inhibiting painful nociception from the bladder at the level of the central nervous system. Its nighttime sedation can be therapeautic in the BPS population and its purported beta-adrenergic receptor stimulation in the bladder may facilitate urine storage [270].

Using a dose titration of up to 75mg taken before bed, Hanno and Wein reported success in about half of 20 patients who could tolerate the medication. Twenty percent of the initial 25 patients dropped out because of fatigue, weight-gain, or dry mouth. In a follow-up report [271], 18 of 28 patients who could tolerate the drug had major relief of symptoms within 3 to 6 weeks of onset of therapy with a mean follow-up of 14.4 months. However, about one-third of patients initially placed on the drug could not continue on it because of side effects. Kirkemo et. al [272] treated 30 patients and 90% had subjective improvement in 8 weeks. Pranikoff and Constantino [273] reported improvement in 16 of 22 patients with urinary frequency and pain who did not have a diagnosis of interstitial cystitis, noting that 5 of the 22 could not tolerate the drug.

van Ophoven et al performed the only reported prospective, double-blind, placebo-controlled study of amitriptyline. Fifty patients were randomized to placebo or a titrated dose of amitriptyline up to 100mg daily. Forty-two percent of patients initially placed on the drug could not continue on it because of side effects. Wammack et al used the combination of doxepin and piroxicam, a cox-2 inhibitor. Twenty-six of 32 patients (81%) experienced remission of symptoms [276]. One study reported satisfactory outcome with desipramine [277]. Duloxetine, a serotonin-norepinephrine reuptake inhibitor has also been tried but without therapeutic effects [278].

b) DOXEPIN, DESIPRAMINE, DULOXETINE

Other tricyclic antidepressants that have been used for bladder pain syndrome are doxepin and desipramine. Wammack et al used the combination of doxepin and piroxicam, a cox-2 inhibitor. Twenty-six of 32 patients (81%) experienced remission of symptoms [276]. One study reported satisfactory outcome with desipramine [277]. Duloxetine, a serotonin-norepinephrine reuptake inhibitor has also been tried but without therapeutic effects [278].

3. ANTIHISTAMINES

Simmons first proposed use of antihistamines in 1955 [279]. His findings of mast cells in the wall of a normal bladder and the edema and increased vascularity seen in the IC bladder suggested that histamine may be responsible for the development of interstitial cystitis. He reported on 6 patients who had some improvement with pyribenzamine for limited periods [280].

a) Hydroxyzine

Hydroxyzine is the most widely used antihistamine for bladder pain syndrome. Its ability as an H-1 receptor antagonist, to inhibit bladder mast cell activation, along with its anticholinergic and anxiolytic properties and good safety profile, have made it a reasonable candidate for use as a therapeutic agent for bladder pain syndrome [281]. In 1933, Theoharides first reported significant benefits of hydroxyzine in reducing pain and urinary symptoms [282]. His two subsequent reports of uncontrolled series further suggested the therapeutic effects of hydroxyzine [283 284]. However, in an NIDDK randomized controlled trial, the global response rate for hydroxyzine was only 31% compared to a 20% response to those not treated with hydroxyzine. When looked at by itself the response was 23% vs. 13% on placebo. None of the results in this under-powered trial reached statistical significance [285].

a) Cimetidine

Cimetidine, a H2 histamine receptor antagonist, has been explored for treatment of bladder pain syndrome. In a pilot study [286], 9 patients were treated with a dose of 300mg orally twice daily for one month. At follow-up 26 to 42 months later, 4 patients had complete relief of urinary symptoms and suprapubic pain. Lewi [287] reported 31 patients given 200mg three times daily with mean followup of 6.6 months. Seventy-one per cent experienced varying degrees of symptomatic relief, 45% were pain free, and 26% went into remission of all symptoms. In a later report [288] of 69 patients treated over a 4 year period, 67% of patients had complete relief of all symptoms. A small, prospective, placebo-controlled RCT studied 36 patients who either received oral cimetidine or placebo [289]. Median suprapubic pain and frequency scores improved significantly, but the publication does not state exactly how many patients in each group improved.

4. IMMUNOSUPPRESSANT

a) Cyclosporine

Cyclosporine, a widely used immunosuppressive drug in organ transplantation, was the subject of a novel bladder pain syndrome trial [290]. Eleven patients received cyclosporine for 3-6 months at an initial dose of 2.5-5 mg/kg daily and a maintenance dose of 1.5 to 3mg/kg daily. Micturition frequency decreased, and mean and maximum voided volumes increased significantly. Bladder pain decreased or disappeared in 10 patients. After cessation of treatment, symptoms recurred in the majority of patients.

In a longer-term follow-up study, 20 of 23 refractory IC patients on cyclosporine therapy followed for a mean of 60.8 months became free of bladder pain. Bladder capacity more than doubled. Eleven patients
subsequently stopped therapy, and in 9, symptoms recurred within months, but responded to reinitiating cyclosporine [291]. Sairanen et al further found that cyclosporine A was far superior to sodium pentosanpolysulfate in all clinical outcome parameters measured at 6 months [292]. Patients who responded to cyclosporine A had a significant reduction of urinary levels of epidermal growth factor (EGF) [293].

b) Suplatast Tosilate

Suplatast Tosilate (IPD-1151T) is an immunoregulator that selectively suppresses IgE production and eosinophilia via suppression of helper T cells that produce IL-4 and 5. It is used in Japan to treat allergic disorders including asthma, atopic dermatitis, and rhinitis. Ueda et al reported a small study in 14 women with interstitial cystitis [294]. Treatment for one year resulted in a significantly increased bladder capacity and decreased urinary urgency, frequency, and lower abdominal pain in 10 women. Concomitant changes occurred in blood and urine markers suggesting an immune system response. Larger, multicenter, randomized controlled trials in the United States and Japan are planned.

c) Azathioprine and Chloroquine derivatives

In a single report in 1976, Oravisto et al used azathioprine or chloroquine derivatives for BPS patients not responding to other treatments [295]. About 50% patients responded.

5. SODIUM PENTOSANPOLYSULFATE

Sodium pentosanpolysulfate (PPS), a synthetic sulfated polysaccharide, is available in an oral formulation, 3-6% of which is excreted into the urine and theoretically may replenished the damaged glycosaminoglycan (GAG) layer overlying transitional epithelium of the urinary bladder of BPS patients. An intact urothelial GAG layer has been proposed to be essential to keep the urothelium impermeable to urinary components. A defective bladder GAG layer is hypothesized to be one important cause for BPS [296].

PPS’s mechanism of action has been attributed not only to correction of a putative defect in the GAG layer, but also its ability to inhibit histamine release from mast cells, [297] and a possible effect mediated by nonspecific binding of the molecule with the inflammatory stimulants of urothelial activation, an action that would occur in the urine rather than at the mucosal membrane [298].

PPS is the most intensively studied treatment ever proposed for BPS. It is the only medication approved by the Food and Drug Administration for the pain of interstitial cystitis. Parsons initially administered the drug at a dosage of 50mg 4 times daily or 150mg twice daily in an open trial involving 24 patients [299]. Twenty-two of 24 patients experienced a good or excellent response within 8 weeks. In a subsequent randomized, placebo-controlled trial using a dose of 100mg three times daily in 62 patients, pain and urgency improved in 44% vs. a placebo response of 15%. Urgency improved by 38% vs. 18% on placebo. The average number of daily voids was unchanged [300].

Five randomized controlled trials for pentosan polysulfate have yielded conflicting results of efficacy. Holm-bentzen et. al [301] reported the first multicenter double-blind placebo controlled trial in 1987 looking at 115 patients with bladder pain syndrome. Patients were randomized to a dose of 200mg twice daily vs. placebo for 4 months. The results showed no difference between pre and post trial values with regard to symptoms, urodynamic parameters, cystoscopic appearance, or mast cell counts in the two groups. The study concluded that the drug had no clinically significant effect.

The first of two pivotal studies for the FDA was performed in the United States in 1990 [302] A total of 110 patients in 5 medical centers were studied for 3 months on a dosage of 100mg three times daily. Twenty-eight per cent of patients on PPS reported “more than slight improvement” versus 13% of those on placebo. Pain and pressure to urinate were the main parameters to show benefit with PPS.

The FDA asked for a second study which was reported 3 years later [303]. In a multicenter, placebo-controlled RCT 148 patients were randomized to 100mg three times daily of pentosanpolysulfate vs. placebo. In the primary endpoint of patient self-evaluation of global improvement, 32% of those on PPS reported 50% or more overall improvement vs. 16% on placebo at 3 months. Pain, urgency, and pressure showed significant improvement with drug. Frequency, nocturia, and volume voided showed no significant changes between study groups.

The NIDDK performed their own 2 X 2 factorial study to evaluate PPS and hydroxyzine [285]. Each drug was used alone and in combination and compared to a placebo group. Patients were treated for 6 months. There were 121 participants in 7 centers. No statistically significant response to these medications was documented. A non-significant trend was seen in the PPS treatment groups (34%) compared to non-PPS groups (18%). Of the 29 patients on PPS alone, 28% had global response (primary endpoint) of moderately or markedly improved vs. 13% on placebo, very similar in this 6-month study to improvement rates in the 3-month pivotal studies, though not reaching statistical significance in the longer study.

In summary, of 5 RCTs 2 had unfavorable and 3 had favorable results for PPS. Such conflicting results might suggest that a minority of patients do respond to PPS, but currently there is no reliable method to identify such patients.
Long-term, open-label studies with PPS have been reported. Populations of patients receiving extended treatment for up to 90 months or more in the compassionate use program showed no further improvement in symptoms after 1-2 years, though there seemed to be little tachyphylaxis [305,304]. A total of 2809 patients had begun treatment with a 3 month supply of PPS and 21% continued with treatment beyond this point and reordered medication. This seems to correlate with the 28-32% improvement rate previously reported. The dropout rate in the first 6 months was extraordinarily high with only 178 active patients out of 1742 who initially ordered the drug. There was an overall improvement in symptoms in 62% of the patients who did remain in treatment for 6-35 months.

PPS appears to be a very well-tolerated medication [304] with no common central nervous system side effects, and appears to be beneficial with regard to improving the pain associated with interstitial cystitis in up to one-third of patients, a standard often expected with a placebo. A 3-6 month course is required to see an effect in most patients. Claims suggesting greater efficacy and claims urging its use in patients who do not meet the standard definition of bladder pain syndrome should be regarded with caution.

6. OTHER ORAL MEDICATION THAT HAVE BEEN USED FOR BPS

a) L-Arginine

Foster and Weiss were the original proponents of L-arginine in the therapy of interstitial cystitis [305]. Eight patients with IC were given 500mg of L-arginine 3 times daily. After one month, urinary nitric oxide synthase activity increased 8-fold and 7 of the 8 patients noticed improvement in IC symptoms. An open-label study of 11 patients showed improvement in all 10 of the patients who remained on L-arginine for 6 months [306].

An open-label study of 9 women in Sweden failed to find any change in symptom scores or in nitric oxide production in the bladder [307]. A placebo-controlled randomized controlled trial of 53 IC patients could find no difference on an intention to treat analysis between drug and placebo-treated patients [308]. A smaller randomized placebo-controlled crossover trial of 16 IC patients found no clinically significant improvement with L-arginine and concluded that it could not be recommended for IC treatment [309].

Data does not support the use of L-arginine for the relief of symptoms of interstitial cystitis.

b) Quercetin

Quercetin, a bioflavanoid available in many over-the-counter products, may have the anti-inflammatory effects of other members of this class of compounds found in fruits, vegetables, and some spices. Katske et. al [310] administered 500mg twice daily to 22 BPS patients for 4 weeks. All but one patient had some improvement in the O’Leary/Sant symptom and problem scores as well as in a global assessment score. Further studies are necessary to determine efficacy.

c) Antibiotics

Warren et. al [311] randomized 50 patients to receive 18 weeks of placebo or antibiotics including rifampin plus a sequence of doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin and ciprofloxacin for 3 weeks each. Intent to treat analysis demonstrated that 12 of 25 patients in the antibiotic and 6 of 25 patients in the placebo group reported overall improvement while 10 and 5 respectively noticed improvement in pain and urgency. The study was complicated by the fact that 16 of the patients in the antibiotic group underwent new BPS therapy during the study as did 13 of the placebo patients. There was no statistical significance reached. What was statistically significant were adverse events in 80% of participants who received antibiotic compared to 40% in the placebo group. Nausea and/or vomiting and diarrhea were the predominant side effects. Most patients on antibiotics correctly guessed what treatment arm they were in, and those that guessed correctly were significantly more likely to note improvement after the study. No duration in improvement after completion of the trial of antibiotics was reported.

Burkhard et. al [312] reported a 71% success in 103 women presenting with a history of urinary urgency and frequency and chronic urethral and/or pelvic pain often associated with dyspareunia and/or a history of recurrent urinary tract infection. This was a large, inclusive group and one that is probably broader than the bladder pain syndrome we are focusing on. Nevertheless, he recommended empiric doxycycline in this group. The overwhelming majority of BPS patients have been treated with empiric antibiotics prior to diagnosis.

At this time there is no evidence to suggest that antibiotics have a place in the therapy of BPS in the absence of a culture-documented infection [313].

d) Methotrexate

Low dose oral methotrexate significantly improved bladder pain in 4 of 9 women with BPS, but did not change urinary frequency, maximum voided volume, or mean voided volume [314]. No placebo-controlled, RCT has been done with this agent.

e) Montelukast

 Mast cell triggering releases 2 types of proinflamma-tory mediators, including granule stored pre-formed types such as heparin and histamine, and newly syn-
thesized prostaglandins, and leukotriene B4 and C4. Classic antagonists, such as montelukast, zafirlukast and pranlukast, block cysteinyl leukotriene 1 receptors. In a pilot study, [315] 10 women with IC and detrusor mastocytosis received 10mg of montelukast daily for 3 months. Frequency, nocturia, and pain improved dramatically in 8 of the patients. Further study would seem to be warranted, especially in patients with detrusor mastocytosis, defined as > 28 per mm².

e) Nifedipine

The calcium channel antagonist nifedipine inhibits smooth muscle contraction and cell-mediated immunity. In a pilot study, [316] 30mg of an extended release preparation was administered to 10 female patients and titrated to 60mg daily in 4 of the patients who did not get symptom relief. Within 4 months five patients showed at least a 50% decrease in symptom scores, and 3 of the 5 were asymptomatic. No further studies have been reported.

f) Misoprostol

The oral prostaglandin analogue misoprostol was studied in 25 patients at a dose of 600 micrograms daily [317]. At 3 months 14 patients were significantly improved, and at 6 months 12 patients still had a response. A cytoprotective action in the urinary bladder was postulated.

IX. INTRAVESICAL / INTRAMURAL THERAPY (Table 5)

Intravesical therapies form one of the staples of BPS therapy, though regulatory approvals and availability throughout the world differ from nation to nation. What follows are treatments that have been reported in the recent literature, some of which are commonly used. Older therapies that are rarely used now include silver nitrate [44,330-333] and chlorpactin WCS90 [6,334-338]. These have not been included in this current edition of the Consultation, but have level 3 evidence to support a grade C recommendation based on original reports.

1. DMSO (Dimethyl sulfoxide)

Grade of Recommendation: B
Level of evidence 2

• A small number of significant side effects.

Not approved in Japan.

DMSO is believed to reduce inflammation, relax muscles, eliminate pain, dissolve collagen, and degranulate mast cells. It has long been used as a therapeutic agent for BPS. Its mechanism of action, however, has not been clarified. Ten articles on DMSO for the treatment of IC were retrieved. Peekar et al [339] reported that in a randomized study, frequency and pain were improved in ulcer-type IC patients, although no improvement was observed in maximum bladder capacity. Perez-Marrero et al [340] reported that in a non-randomized controlled study, 53% of the patients showed remarkable improvement in subjective evaluation (placebo 18%), and 93% in objective evaluation (placebo 35%). Around an 80% improvement rate has been reported in case series and retrospective studies [341-348].

With regard to side effects after instillation of DMSO, most patients recognize a garlic-like odor, which disappears within a day, and about 10% of patients report bladder irritative symptoms which resolve with or without symptomatic treatment [349]. It is hypothesized that these transient exacerbations occur as the result of mast cell degranulation. The number of significant side effects is considered to be small [348]. Cataracts have been reported in animal studies, [350,351] though not in humans. Negative effects on bladder compliance have been noted in rat detrusor [352]. DMSO may accelerate the absorption of other drugs instilled simultaneously, which could be a source of side effects.

The instillation method has not been standardized. Generally, 50cc of a solution of medical grade 50% DMSO is instilled into the bladder. If pain occurs immediately following instillation, local anesthesia (e.g. 20ml of 2% lidocaine solution) may be instilled. Average retention time is considered to be 10 to 20 minutes [349]. The instillation is performed weekly for 6-8 weeks. After an initial course, treatment is suspended until symptoms recur. If a good result was obtained, another 6 week course (often followed by monthly maintenance) can be initiated. The long-term effect is unknown, although there is no upper limit for the duration of the treatment. DMSO is medically approved in the US, while it has not been approved yet in Japan.

2. HEPARIN
Grade of Recommendation: C
Level of Evidence: 3

Side effects primarily related to effects intravesical catheterization and slight chance of bladder hemorrhage.

The glycosaminoglycan (GAG) layer on the bladder urothelium is a kind of muco-polysaccharide, working as a non-specific defense mechanism. It is believed that a deficiency or abnormality of GAG secondarily causes inflammation of the bladder by increasing the permeability of the bladder mucosa, leading to the pathologic cascade of BPS. Heparin has similarities to the GAG layer of the bladder. When instilled into the bladder, theoretically it might replace the damaged GAG layer. Kuo [353] reported that the International Prostate Symptom Score, as well as bladder capacity at initial desire to void and maximum bladder capacity, improved significantly. According to the report by Parsons et al [354] symptoms were reduced in 56% of patients treated 3 times weekly for 12 weeks. These reports suggest the efficacy of heparin, however, there is no randomized comparative study to give conclusive evidence. One study indicated that intravesical heparin instillations may prolong the response to dimethyl sulfoxide treatment [355].

No significant side effects have been reported, as it does not affect systemic coagulation parameters. In the case of patients with hematuria, however, it may exacerbate local hemorrhage.

The instillation method has not been standardized. Generally, 10,000-40,000 units of heparin are instilled. It is unusual to have pain or irritation as a result of instillation, and retention times can be 30 minutes or more. Instillation frequency can be up to every other day and is often administered at home by the patient. Parsons et al [356] recently reported that when 40,000 units of heparin combined with 1 to 2% lidocaine was instilled 3 times a week for 2 weeks, about 80% efficacy was obtained. There is no upper limit for the duration of the treatment, but a long-term effect is unknown.

A bleeding tendency may occur. Heparin for intravesical use is not approved by drug regulatory authorities.

3. HYALURONIC ACID
Grade of Recommendation : D
Level of Evidence: 1

- No significant side effects.

Hyaluronic acid, like heparin, is a mucopolysaccharide, that could theoretically repair a damaged GAG layer of the bladder mucosa. Six reports have indicated efficacy [357-362]. In the summer of 2003 Bioniche Life Science Inc http://www.medicalnewstoday.com/articles/112053.php and in the spring of 2004 Seikagaku Corporation reported double-blind, placebo-controlled, multicenter clinical studies of their hyaluronic acid preparations (40mg or 200mg per cc respectively) and neither showed significant efficacy of sodium hyaluronate compared to placebo. These negative studies have not been published in peer reviewed literature. Neither preparation has been approved for use for BPS in the United States. At the same time, no significant side effects were observed.

4. CHONDROITIN SULFATE
Grade of Recommendation: D
Level of Evidence: 4

- No significant side effects.

Chondroitin sulfate is another mucopolysaccharide. Its efficacy was suggested in one article when used alone [363] and in another trial when used in combination with hyaluronic acid [364]. A randomized comparative study has not been reported.

5. PENTOSAN POLYSUFATE
Grade of Recommendation: D
Level of evidence: 4

- No significant side effects are considered to be present.

Pentosan polysulfate (PPS) is a mucopolysaccharide similar to heparin, with a similar postulated mode of action when used locally. Like other mucopolysaccharides, it has not been well-studied clinically. Bade et al in a randomized controlled trial found benefit in 4 patients out of 10 on PPS versus 2 of 10 on placebo [365]. A more recent placebo-controlled study of 41 patients found the addition of a 6 week course of intravesical PPS to a regimen of oral PPS significantly improved results [366].

6. CAPSAICIN, RESINIFERATOXIN
Grade of Recommendation: -A (ineffective)
Level of Evidence: 1

- Significant side effects: local irritation possible.

It would seem reasonable that capsaicin, a C-fiber
afferent neurotoxin, could alleviate the pain of BPS by desensitizing bladder afferents. Resiniferatoxin (RTX) is considered to have a stronger action than capsaicin, by desensitizing C-fibers more quickly, and causing less initial irritation. Efficacy was indicated in five relatively small clinical trials [367-371]. No severe side effects were reported. A randomized multicenter placebo-controlled clinical trial of RTX failed to demonstrate benefit over placebo [372].

7. BACILLUS CALMETTE-GUERIN (BCG)
Grade of Recommendation: -A (ineffective)
Level of Evidence: 1

• Potential serious complications

Seven articles reported on a BCG instillation therapy. Zeidman et al first reported that 5 patients who did not respond to other therapies showed symptomatic improvement [373]. Peters et al conducted a randomized double blind study showing a 60% improvement compared to 27% [374] placebo response with good long-term results at 27 months [375]. Sixty-five percent of the patients experienced burning sensation, 41% irritation of the bladder, and 35% pelvic pain. One patient was reported to have dropped out due to joint pain.

Peeker et al conducted a randomized double blind study comparing intravesical BCG and DMSO and failed to find any efficacy with BCG [339]. A very large, multicenter randomized placebo controlled trial conducted by the National Institute of Diabetes, Digestive, and Kidney Disorders failed to identify benefit from BCG, although the side-effect profile was surprisingly similar to that of placebo [376].

8. OXYBUTYNIN
Grade of Recommendation: D
Level of Evidence: 4

• Side effect profile is unknown

Barbalias et al observed significant improvement when combining intravesical instillation of oxybutynin with bladder training [377]. Randomized trials are lacking.

9. LIDOCAINE
Grade of Recommendation: C
Level of Evidence: 2

• No significant side effects.

Lidocaine is a local anesthetic that relieves pain by blocking sensory nerves in the bladder. Four articles [378-381] reported on the electromotive drug administration (EDMA) of lidocaine. Using EDM, ionized lidocaine is actively introduced into the bladder using an electrical current. Three articles reported that lidocaine and dexamethasone were instilled following hydrodistention. According to the report by Rosamilia et al [381], 85% of the patients had a good result, with the effect persisting for 6 months in 25%.

There are two other case reports [382,383]. A report on a pharmacokinetic effect, demonstrated safe levels of lidocaine absorption into the bladder [384]. Randomized, placebo-controlled trials are needed to ascertain efficacy, optimal treatment parameters, and length of response to intravesical lidocaine preparations [385]. Advantages seem to be immediate response, low-cost of generic medication, and ability of patients to self-administer at home.

10. BOTULINUM TOXIN
Grade of Recommendation: D
Level of Evidence: 4

• Side effects include dysuria, incomplete bladder emptying

In a study using rats, botulinum toxin inhibited pain response induced by acetic acid and calcitonin gene related peptide release from afferent nerves, which indicates the possibility of relieving pain and other symptoms of BPS [386]. Smith et al observed symptom improvement in 9 of 13 BPS patients treated with 100-200 units of botulinum toxin injected into 20 to 30 sites under general anesthesia [387]. Giannantoni and colleagues [388] noted improvement in 13 of 15 patients at 1 and 3 months after injection of 200units diluted in 20cc injected into the lateral bladder walls and trigone. By the 5 month mark only 26.6% of patients had any benefit, and at 12 months all patients had baseline symptoms. Dysuria occurred in a majority of patients and persisted in a minority for several months after initial injection. Three patients required clean intermittent catheterization for 2-3 months following therapy. Further studies will be needed to obtain conclusive evidence for its efficacy, duration of effect, and side-effect profile.

X. NEUROMODULATION

Level of Evidence: 3
Grade of Recommendation: C

Sacral nerve stimulation (SNS) involves implanting permanent electrode(s) to stimulate S3 or S4 roots. As early as 1989, Tanago et al showed that stimulation of S3 may modulate detrusor and urethral sphincter function [389]. FDA approved the usage of sacral neuromodulation for treating refractory detrusor overactivity in 1997 and for urinary urgency and frequency in 1999. Although the effectiveness of SNS for detrusor overactivity is largely confirmed by a good number of papers, only a few papers report the effect of SNS in treating BPS.

Zerman et al reported significant improvement in a 60-year-old woman treated for severe BPS pain using sacral nerve stimulation implant. Pain and accompanying bladder dysfunction were improved by temporary and permanent sacral nerve stimulation for up to six months [390].
Maher et al showed that temporary stimulation was effective in 73% of 15 women with refractory BPS [391]. Mean voided volume during treatment increased and mean daytime frequency, nocturia and pain decreased significantly. As indicated by the Short Urinary Distress Inventory and SF-36 Health Survey, the quality of life parameters of social functioning, bodily pain and general health significantly improved during the stimulation period.

Chai et al found that percutaneous S3 nerve root stimulation improves symptoms and normalizes urinary HB-EGF levels and antiproliferative activity in patients with BPS [213]. In their report in 2003, Comiter et al prospectively investigated the effect of SNS on a series of 17 patients with refractory BPS. At an average of 14 months follow-up mean daytime frequency, nocturia and mean voided volume improved significantly.

The average pain decreased from 5.8 to 1.6 points on a scale of 0 to 10 and Interstitial Cystitis Symptom and Problem Index scores (ICSI and ICPI) decreased from 16.5 to 6.8 and 14.5 to 5.4, respectively. Of the 17 patients 16 (94%) with a permanent stimulator demonstrated sustained improvement in all parameters at the last postoperative visit [392].

Whitmore et al applied percutaneous sacral nerve root stimulation on 33 patients with refractory interstitial cystitis. Statistically significant improvements were seen in pain and urinary symptoms.

Significant improvements were also seen in ICSI and ICPI scores [393]. Peters et al reported a reduction of narcotic usage in 18 BPS patients following SNS for a mean of 15.4 months, although the dose reduction was modest (36%) and only 4 of 18 discontinued the narcotics [394]. However, Elhilali and colleagues found that both of two patients with interstitial cystitis reported no improvement following sacral neuromodulation [395].

Zabihi et al more extensively stimulate S2-S4 by implanting electrodes into epidural space through sacral hiatus. 23 of 30 (77%) patients had successful trial stimulation and were permanently implanted. Among these patients, the symptom score was improved by 35% (p=0.005). The pain score improved by 40% (p=0.04). Patients reported an average of 42% improvement in their symptoms [396].

Sacral nerve modulation is still considered an investigational procedure for BPS by the Consultation. Its therapeutic benefits appear to be significant in selected cases.

Strict patient selection and detailed discussion with patients prior to surgery is mandatory. Long-term results should be collected and reported, and trial results discussed with patients before employing this treatment modality.

**XI. PAIN EVALUATION AND TREATMENT**

**Level of Evidence:** 4  
**Recommendation:** C

As is evident in the information presented in this section, studies on the use of analgesics for bladder pain syndrome are sparse, and the majority of data is inferred from non-BPS types of pain and expert opinion

Health professionals should ask about pain, and the patient’s self report should be the primary source of assessment. Clinicians should assess pain with easily administered rating scales and should document the efficacy of pain relief at regular intervals after starting or changing treatment. Systematic evaluation of the pain involves the following:

- Evaluation of severity
- Detailed history of the pain including assessment of pain intensity and character
- Evaluation of the psychological state of the patient, including assessment of mood and coping responses
- Physical examination emphasizing the neurologic examination
- Diagnostic workup to determine the cause of the pain
- Re-evaluation of therapeutic strategy and response.

The initial evaluation of pain should include a description of the pain, PQRST characteristics serve well for this purpose:

- **P:** Palliative or Provocative factors, ‘what makes it less intense?’
- **Q:** Quality, ‘what is it like?’
- **R:** Radiation, ‘does it spread anywhere else?’
- **S:** Severity, ‘how severe is it?’
- **T:** Temporal factors, ‘is it there all the time, or does it come and go?’

**1. PAIN MEASUREMENT**

A number of different rating scales have been devised to attempt to methodically measure pain and to allow patient follow-up. These have been used in research, audit and in clinical practice. They all rely on a subjective assessment of the pain and therefore make inter-individual comparisons difficult. Additionally, pain is a multidimensional complex phenomenon and is not adequately described by unidimensional scales, however there is value in making some sort of an assessment to aid clinical practice.
• Categorical scales e.g., verbal rating scales: mild, moderate, severe pain
• Visual analogue scale (VAS)
• Complex pain assessment compendiums e.g., Brief Pain Inventory (BPI), McGill Pain Questionnaire [397-399].

The BPI consists of several visual analogue scales grouped together assessing pain at rest, on movement, and other aspects of the pain including interference with function and effect on work.

2. BASICS OF CHRONIC PELVIC PAIN MANAGEMENT

a) Analgesia

1. NON-ACIDIC ANTIPYRETIC ANALGESICS

Paracetamol (acetaminophen) is the main representative of this group. It has antipyretic activity and is a simple analgesic. There is very little evidence about its role in chronic pelvic pain. Further studies need to be considered. Paracetamol should be considered for mild pain.

2. ACIDIC ANTIpyRETIC ANALGESICS

The classical non-steroidal anti-inflammatory drugs (NSAIDs) fall into this group and include salicylic acid. They are known to act on the cyclooxygenase (COX) enzyme. The early NSAIDs tended to have little selectivity for COX2 over COX1, and are therefore said to be associated with more side effects than the newer COX2 selective inhibitors. The COX1 enzyme is mainly involved in normal ‘housekeeping’ functions, such as mediating gastric mucosal integrity, and renal and platelet function. Blocking the COX1 enzyme is the cause of the platelet, gastric and renal complications that can occur with NSAIDs. It has been suggested that the COX2 enzyme is inducible as a result of tissue damage, and that it is the main enzyme involved in inflammation and peripheral sensitization of nociceptors. As a result, the analgesic efficacy of COX2 selective drugs should be as good as that of the nonselective drugs. This, however, has been disputed [402-405]. The selective COX2 agents should be used with caution as an alternative to the non-selective drugs where there is an increased risk of gastric complications. They should be avoided in patients with known cardiovascular disease. NSAIDs should be taken with food and consideration must be given to the use of gastric protective agents. The benefits of the NSAIDs must be demonstrated to outweigh the risks. All NSAIDs are contraindicated in active gastrointestinal ulceration/bleeding and renal disease. They may seriously exacerbate asthma and produce fluid retention. Even if stronger analgesics such as opioids are added, the NSAIDs can be continued as they are likely to have a synergistic action improving pain control above and beyond that obtained with opioids alone [409].

b) Opioids

There is now a general acceptance that opioids have a role in the management of chronic non-malignant pain [410]. The use of opioids in urogenital pain is poorly defined. The following guidelines are suggested by the European Association of Urology [408].

General guidelines for the use of opioids in chronic/non-acute urogenital pain

1. All other reasonable treatments must have been tried and failed.
2. The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with another physician (preferably the patient’s family doctor).
3. Where there is a history or suspicion of drug abuse, a psychiatrist or psychologist with an interest in pain management and drug addiction should be involved.
4. The patient should undergo a trial of opioids [410]
5. The dose required needs to be calculated by careful titration.
6. The patient should be made aware (and possibly give written consent):
   I. that opioids are strong drugs and associated with addiction and dependency
   II. the opioids will normally only be prescribed from one source
III. the drugs will be prescribed for fixed periods of time and a new prescription will not be available until the end of that period

IV. the patient will be subjected to spot urine and possibly blood checks to ensure that the drug is being taken as prescribed and that non-prescribed drugs are not being taken

V. inappropriate aggressive behaviour associated with demanding the drug will not be accepted

VI. hospital specialist review will normally occur at least once a year

VII. the patient may be requested to attend a psychiatric/psychology review

VIII. failure to comply with the above may result in the patient being referred to a drug dependency agency and the use of therapeutic, analgesic opioids being stopped.

7. Morphine is the first-line drug, unless there are contraindications to morphine or special indications for another drug. The drug should be prescribed in a slow release/modified release form. Short-acting preparations are undesirable and should be avoided where possible. Parenteral dosing is undesirable and should be avoided where possible.

1) Morphine. There is no compelling evidence that one opiate is better than another [410]. Morphine is the traditional gold standard. In an acute situation, the daily morphine requirement may be calculated by titration of the drug with progressively increasing doses of 4-hourly rapid-release morphine. However, in most cases, starting with a low dose of slow-release morphine and confining the increments to occur at intervals of no less than 3 days to 1 week is adequate.

2) Diamorphine is not generally available orally, because of its high first-pass metabolism within the liver. It should not be used routinely for long-term pain because of its high first-pass metabolism within the liver. It should not be used for long-term pain because of its high first-pass metabolism within the liver.

3) A fentanyl patch is used when oral absorption is restricted or when the patient suffers with nausea and vomiting. Patches are generally changed every 72 hours. The problem with the currently available patches is that the dosing increments between patches are large. Care needs to be exercised when increments in dose are undertaken.

4) Methadone is a strong analgesic which has a long track record [411]. It may have a useful role in the management of urogenital pain, though there is very little science to support this. Methadone has the tendency to accumulate with repeated dosing and cause delayed respiratory arrest. Therefore, whereas it may be a very useful drug, it should only be prescribed by a practitioner familiar with its use as an analgesic. Methadone as an analgesic is usually prescribed 6 hourly as its analgesic action is relatively short-lived compared with the longer benefits seen from using the drug in drug addiction.

5) Pethidine 100 mg intramuscular (i.m.) is about as effective as tramadol 100 mg i.m [412] or morphine 10 mg i.m. Its oral bioavailability is, however, poor. Pethidine has a short duration of action and is therefore not an ideal drug for use in chronic/non-acute pain.

6) Other opioids. Oxycodone and hydromorphone are now both available as slow/modification-release preparations. They may be useful for opiate rotation if side effects or tolerance is a problem. They are powerful opioids. Phenazocine is effective in severe pain. It may be administered sublingually if nausea and vomiting are a problem. Buprenorphine and pentazocine both have agonist and antagonist properties and can induce withdrawal symptoms in patients used to opioids. Naloxone may only partly reverse respiratory depression. Buprenorphine topical patches are now available. Codeine and dihydrocodeine are effective for the relief of mild-to-moderate pain. However, dihydrocodeine is a drug that is frequently abused.

7) Opioid-like agents. Tramadol produces analgesia by two mechanisms: an opioid effect; and an enhancement of serotoninergic and adrenergic pathways [413,414]. It has fewer of the typical opioid side effects (notably, less respiratory depression, less constipation and less addiction potential).

c) Neuropathic analgesics

- Tricyclic antidepressants. Tricyclics have a definite analgesic effect on neuropathic pain compared with placebo [415]: 30% of patients should obtain more than 50% pain relief; 30% will have minor adverse effects; and 4% will have to stop treatment because of side effects. Tricyclics are said to work in doses that are too low to affect mood. They may work by increasing levels of norepinephrine and/or serotonin. They also have actions at sodium channels. They are extensively used for pelvic pain and good evidence exists to justify their usage (see oral therapy) [416,417].

- Serotonin reuptake inhibitors. Selective serotonin reuptake inhibitors appear to be less effective for the management of pelvic pain [418]. Fluoxetine can increase plasma levels of amitriptyline and induce toxicity, and therefore care must be exercised if the drugs are combined.

- Anticonvulsants have been used in the management of pain for many years. Gabapentin and pregabalin have recently been introduced for pain management. There is evidence to show that both compounds are effective in neuropathic pain [419]. There is limited evidence to show that gabapentin is effective in acute pain [420]. Whereas there is little evidence to support the use of anticonvulsants in the management of genitourinary pain, they should be considered if there
is a suggestion of neuropathic pain or central sensitization [421,422].

- **N-methyl-D-aspartate (NMDA) antagonists.** The NMDA receptor channel complex is known to be an important channel for the development and maintenance of chronic pain. It is felt to be particularly important when there is evidence of central sensitization and opioid tolerance [423]. Ketamine has been used as a general anaesthetic for over 30 years. It has also been used as an intravenous analgesic in burn units, and accident and emergency units. Ketamine is thought to act primarily at the NMDA receptor, though it may also have actions at sodium channels, as well as opioid (kappa and mu) receptors [424]. Ketamine has been shown in both human and animal models of neuropathic pain to reduce central sensitization and wind-up [424-426]. These phenomena alter signal transmission within the nervous system so that non-painful stimuli may become painful (allodynia) and pain from a painful stimulus is magnified (hyperalgesia). Ketamine has been found to be useful in a number of chronic pain states including: peripheral neuropathies with allodynia, stump and phantom pain, central pain, and cancer-related pain with and without a neurological component [427]. Difficult urogenital pains may therefore be helped by ketamine if there is evidence of nerve injury or central sensitization [428-431]. Ketamine may be useful in opioid-resistant pain in which it may restore the opioid dose-response curve towards normal [428,432]. Oral ketamine has a bioavailability of about 17%. A test dose given by intravenous infusion is a quick way of establishing whether oral ketamine may be viable. Ketamine is a street drug of addiction and great care must be exercised if a patient is to be managed at home on parenteral ketamine. Ketamine should only be used by an experienced practitioner trained in its use.

### XII. SURGICAL THERAPY

**Bladder Pain Syndrome (BPS) is a chronic and debilitating disease. Major surgical options should be considered only when all conservative treatment has failed.** The patient should be informed of all aspects of surgery and understand consequences and potential side effects of surgical intervention. An experienced surgeon familiar with the particular surgical technique should perform the procedure.

#### 1. HYDRODISTENTION

Bladder distention has been used for many years [433] not only as a diagnostic/ classification tool but also for treatment of BPS. In 1957 Franksson reported on a retrospective series of 33 patients, with symptom improvement in all, and lasting up to 1 year in 7 patients [434]. Reports from the seventies were contradictory. Using the Helmstein method [435], Dunn reported complete absence of symptoms in 16 of 25 patients [436], while Badenoch found no improvement in 44 of 56 patients [437]. More recent literature reports poor results with only a minority of patients reporting a small improvement in symptoms for a relatively short period of time [203,204,215,438]. Most studies are retrospective and uncontrolled. **Level of evidence 3; recommendation C**

#### 2. TRANSURETHRAL RESSECTION

In his first papers Hunner described open resection of the bladder ulcer in the treatment of patients with IC[4]. He later abandoned this treatment due to operative morbidity and recurrence of symptoms. Results of transurethral resection were originally reported by Greenberg et al. [439] and Fall [440]. The retrospective results of this treatment in 116 patients with Hunner’s lesion from Fall’s Swedish clinic was later reported by Peek et al [441]. Hunner’s lesion was first recognized by bladder distension under general anesthesia. All lesions were then resected including at least half of the underlying muscular coat. Large areas of the bladder might be treated to resect all diseased tissue. Ninety-two of the 116 patients experienced amelioration of their symptoms. Average duration of symptom alleviation was 23 months ranging from 0-180 months. Up to 16 re-resections were performed if symptoms recurred. This is the only center having reported a large clinical series of patients with BPS treated in this manner. Shanberg and Malloy reported in 1987 on laser fulguration of 39 patients with BPS [442]. Nineteen of 39 had Hunner’s lesion. Of the 19 patients with Hunner’s lesion 17 reported good pain relief lasting between 6 and 18 months. In the 20 patients without Hunner’s lesion, reddened areas in the bladder were photoagulated with the Neodymium:Yag laser.

Thirteen felt marked improvement of symptoms but time to symptom recurrence was not reported. Small bowel perforation in 2 patients was the most important complication in this series. This series was extended to 76 patients [443] where 21 of 27 patients with Hunner’s lesion (BPS ESSIC type 3X) experienced symptom improvement; 12 had relapse within 18 months. Of patients with BPS ESSIC type 1 or 2, 20 of 49 improved but 10 required further therapy within 1 year. Rofeim et al [444], reported on Nd:YAG laser ablation of Hunner’s lesion in 24 patients with BPS type 3X. All had symptom improvement within days without complications. Pain, urgency, nocturia, and frequency were improved after 23 months, but relapse in 11 patients required up to four additional treatments. **Transurethral resection, coagulation, or laser ablation of Hunner’s lesions is a recommended treatment for patients with BPS type 3X.** **Level of Evidence: 3** **Grade of Recommendation: C**
3. CYSTOLYSIS – PERIPHERAL DENERVATION

Hunner [4] simply dissected bladder from surrounding tissue. Initial results were encouraging, however after 3 years of follow-up, symptoms recurred. Worth and Turner-Warwick [445] attempted to do more formal cystolysis and were more successful with regard to symptoms. Worth [446] followed patients up to 7 years and found bladder areflexia to be a significant complication of this procedure. Patients had to use Credé technique or even be on intermittent self-catheterisation. Albers & Geyer [447] reported symptom recurrence after 4 years in most of the patients.

- Cystolysis – peripheral denervation is not indicated for BPS; Level of Evidence: 3 Grade of Recommendation: -A (not recommended)

4. SYMPATHETIC DENERVATION

Visceral pain is transmitted in most cases by the sympathetic nervous system. Gino Pieri [448] applied this principle to the bladder pathology and suggested resection of the superior hypogastric plexus (presacral nerves), paravertebral sympathetic chain, and gray rami from S1-3 ganglia (Level 4). This was repeated by Douglass [449] a few years later. Immediate results were very good; however Nesbit [450] showed that the long term results were short lived.

- Sympathetic denervation is not indicated for BPS
  Level of Evidence: 4
  Grade of Recommendation: -A (not recommended)

5. PARASYMPATHETIC DENERVATION

Based on the contribution of S2-S4 segments to bladder innervation, Moulder and Meirowsky [451] used S3 neurectomy in 3 patients with good long term follow-up. Larger series were reported by Milner [452] and Mason [453] but results after five years were not encouraging. To improve results selective dorsal sacral root neurectomy, unilateral or bilateral, was introduced encouraging. To improve results selective dorsal sacral root neurectomy, unilateral or bilateral, was introduced by Douglass [449] a few years later. Immediate results were very good; however Nesbit [450] showed that the long term results were short lived.

- Parasympathetic denervation is not indicated for BPS
  Level of Evidence: 4
  Grade of Recommendation: -A (not recommended)

6. BOWEL SURGERY

a) Bladder augmentation-cystoplasty has been commonly used for refractory BPS for 50 years. First reports of ileocystoplasty from 1958 were very promising [455]. Later publications were less sanguine with good results varying from up to 100% 456,457 to 25% [458,459]. Cystoplasty is usually done with or without bladder resection.

Cystoplasty alone was reported as early as 1967 by Turner-Warwick and Ashken [460], advocating augmentation with removal of the diseased tissue. Several subsequent studies indicated that cystoplasty with subtrigonal cystectomy offers better results than without subtrigonal cystectomy [457,461-463]. These were all retrospective studies and conclusions should be taken with reservation. Cystoplasty with partial or total removal of the bladder requires bowel tissue substitution. Different bowel segments are used to enlarge the bladder. It is the general consensus that the intestine segment used for bladder augmentation should be detubularized [464]. Experiences with different bowel segments have been reported in numerous articles with level 4 evidence:

- ileum [456-458,463,465-469]
- ileocecum [330,457,459,461,470,471]
- cecum [456,472,472]
- right colon [457,458,473]
- sigmoid colon [461,463,466,470]
- gastric segments [474,475]

There is no significant different between different bowels segments with regard to outcome except for gastric tissue substitution which is associated dysuria and persistent pain due to production of acids

b) Cystoplasty with Supratrigonal Resection

(i.e. trigone-sparing) has been reported in various studies. Von Garrelts [456] described excellent results in eight of 13 patients with a follow-up of 12-72 months. Bruce et. al [463] reported satisfactory relief of BPS symptoms by ileocystoplasty and colocystoplasty in eight patients. Dounis and Gow [476] reported improvement in pain and frequency in seven BPS patients after supratrigonal cystectomy with ileocecal augmentation. Kontturi et. al [461] used segments of colon and sigmoid colon in 12 cases with 100% symptom-free outcome in five patients augmented with sigmoid colon over 4.7 years of follow-up. Two of seven cases augmented with colon required ileal conduit and cystectomy. Linn et. al [477] followed six BPS patients for 30 months, and reported that all were symptom-free and voided spontaneously. The report by Nielsen et. al [459] was less favorable. Six out of eight patients had good results. Van Ophoven et. al [478] reported the long-term (mean 5 years) results of orthotopic substitution enteroplasty in 18 women with BPS, using ileocecal (n = 10) or ileal (n = 8) segments with only two failures. In the group [479] augmented with ileum, three patients required self-catheterization and one a suprapubic catheter. Peeker et. al [480] found that patients with end-stage ulcerative BPS had excellent results following ileocystoplasty but not so the patients with non-ulcer disease. A follow up on this paper was recently published [171] with the same conclusion for the
patients with end stage BPS ESSIC type 3C, while both continent diversion and iliocystoplasty were unrewarding in patients with type 2X BPS. Patients with low cystoscopic capacity (<200 ml) under general anaesthetic have achieved better results [6, 21, 481,482].

**c) Cystoplasty with Subtrigonal Cystectomy** — orthotopic continent bladder augmentation (i.e. with trigone removal but preservation of the bladder neck) in the management of BPS has been reported less often [479,483-485]. Because of the need of ureteral reimplantation, it is associated with some risks of urine leakage, urethral stricture and reflux [484]. Linn et. al [477] had three failures in 17 patients and half of the patients with good symptomatic response required self catheterization. Nielsen et. al [459] had better results following orthotopic substitution with low bladder capacity (200 mL versus 525 mL, respectively). Orthotopic continent bladder augmentation, particularly when removing the trigone, may cause incomplete voiding requiring intermittent self catheterization. Therefore patients considering such procedures should be advised accordingly and must be considered capable of performing, accepting and tolerating self catheterization. Nurse suggested that the decision on whether to due a subtrigonal or supratrigonal cystectomy be based on the results of trigonal biopsy, with the former procedure indicated in the patient with trigonal inflammation [486].

There is no compelling evidence that subtrigonal cystectomy with cystoplasty has any outcome advantage over supratrigonal cystectomy but it tends to be associated with more complications and poorer functional bladder rehabilitation. Level of evidence: 3; Grade of Recommendation: C

**d) Urinary Diversion with or without Total Cystectomy and Urethrectomy**

This is the ultimate, final and most invasive option. It should be used as a last therapeutic resort in selected patients. Techniques include simple or continent urinary diversion. Continent diversion may be preferable for cosmetic reasons in younger patients.

Simple urinary diversion with formation of an ileal conduit is the most common surgical treatment for BPS/IC [487]. Initially, diversion can be done without cystectomy and only when bladder pain is persistent, cystectomy may be considered. Bladder de-functionalization alone produced symptom-relief in several reports [6,21,458,488,488,489]. Often diversion is performed as a next step after unsuccessful bladder augmentation. To avoid further bowel resection, a bowel segment used for cystoplasty can often be converted to a conduit [490]. In some patients chronic inflammatory changes have been seen in the cystoplasty pouch resembling interstitial cystitis [6,458,491,492], preventing one from using this technique. Similar bowel changes however have been described when cystoplasty is performed for pathology other than interstitial cystitis, suggesting that these pathologic findings are not a direct result of the exposure of bowel to BPS urine [493]. Relatively good responses to diversion with or without cystectomy have been reported in small series [459,494].

Urinary diversion with and without cystectomy may be the ultimate option for refractory patients. Continent diversion may have better cosmetic and life style outcome but recurrence of pain in the pouch is a real possibility. Level of Evidence: 3; Grade of Recommendation: C

**XIII. CLINICAL SYMPTOM SCALES**

Symptom scales have enabled patients to be categorized by symptom severity and have also served to follow results of treatment in patients with bladder pain syndrome. Their future development may enable a presumptive diagnosis of the syndrome but at this time that is not possible. A brief survey that reliably segregates BPS from other urologic disorders would make the ability to diagnose the syndrome reliable, inexpensive, and available to all healthcare providers. It would aid in epidemiologic studies as well. Currently such work sponsored by NIDDK is ongoing (http://www.niddk.nih.gov/fund/other/niddkfrontiers/frontiers%20PBS%20Summary%20Report.pdf). The goals of the RAND Interstitial Cystitis Epidemiology (RICE) study are to: (1) develop a case definition for IC in women for patient screening and epidemiological studies; (2) develop and validate a symptom questionnaire to identify female IC patients through self-report; (3) develop IC specific self-report measures of functional status and disease burden; (4) conduct first and second stage screening for IC; and (5) describe the impact of IC on quality of life compared to other disease.

A process for development of a case definition for IC has been developed by adapting the RAND/University of California, Los Angeles Appropriateness Method. This involves a panel consisting of nine experts with experience in BPS and related diseases, literature review of case definitions of BPS, initial ratings of symptoms as indicators of the BPS diagnosis, and discussion and a second set of ratings to establish criteria for diagnosis through patient reports. Symptom questionnaire development, based on the results of the case definition exercise, and validation are the following steps to identify populations of women with
symptoms of BPS who do or do not meet NIDDK criteria, which allows determination of the specificity and sensitivity of the case definition for use in population screening.

Questionnaires and symptom scales are currently utilized to measure treatment outcome and are especially valuable in clinical research studies as well as for guiding therapy for individual patients.

There are 3 published BPS symptom questionnaires: the University of Wisconsin IC Scale (figure 5), the O'Leary-Sant IC Symptom Index (ICSI) and IC Problem Index (ICPI) (figure 6), and the Pelvic Pain and Urgency/Frequency (PUF) Scale (figure 7).

1. The University of Wisconsin IC Scale includes 7 BPS symptom items and has not been validated for identification or diagnosis of BPS. It captures severity of symptom expression [495,496]. Unlike the other two instruments, it addresses some quality-of-life issues, and this is an advantage when such issues are subject of investigation. Its most attractive aspects are its clinically apparent face validity and its ease of implementation.

2. The O'Leary-Sant indexes are validated questionnaires that were originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to BPS patients and asymptomatic controls [497,498]. The questionnaires center on 3 questions related to urgency/frequency and one on bladder-associated pain. It does not address generalized pelvic pain or symptomatology associated with sexual activity. This is not because these questions were not considered in the formulation of the questionnaire.

Of 73 questions in the preliminary instrument covering domains of urinary symptoms, pain, sexual function, menstrual variability, and general health, only the four questions now in the instrument were needed to reliably and validly describe the illness experience of those with IC and distinguish these patients from those without the disorder [499].

3. The most recently published instrument is the Pelvic Pain, Urgency, Frequency (PUF) questionnaire [189].

It was specifically designed to include questions that directly reflect a wide variety of the symptoms experienced by patients who are affected by this disorder. One-third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum. A large study utilizing the PUF questionnaire has concluded that up to 23% of American females have BPS [189]. This makes one wary as to the utility and face-validity of the PUF [500]. A total score of 10-14 =74% likelihood of positive potassium test (PST); 15-19=76%; 20+=91%. To the extent that the PST is suspect, the reliability of PUF data comes into question.

4. Discussion

Neither the PUF nor O'Leary Sant questionnaires have been shown to be of value in diagnosis of the individual patient [501]. In an interesting epidemiologic study in Finland, Leppilahni and colleagues randomly selected 2000 participants from the Finnish population registry and administered the O'Leary Sant IC symptom and problem index [64]. Women with symptom scores 7 or higher with no history of urinary tract infection in the preceding month were invited to undergo clinical examination. Of these 32 women, 21 underwent examination of whom 3 had probable interstitial cystitis and 4 had possible interstitial cystitis. Based on this specificity, a population prevalence in Finnish women of 230/100,000 probable interstitial cystitis and 530/100,000 possible interstitial cystitis was calculated. Thus, one can get some idea as to O'Leary Sant specificity. For probable BPS it would be about 14% using a parameter of 7 or greater on the symptom index.

The O'Leary-Sant and University of Wisconsin instrument correlate strongly in a large population of patients with BPS [502]. Clemons and co-workers administered the ICSI to 45 patients scheduled to undergo laparoscopy for pelvic pain. Seventeen were diagnosed with BPS based on the finding of glomerulations on bladder distention associated with urgency, frequency, or nocturia. A score of 5 on the ICSI had a 94% sensitivity and a 93% negative predictive value in this enriched population of patients with pelvic pain [503]. However, Clemons and colleagues have found a high degree of overlap in International Prostate Symptom Scores, the O'Leary Sant Symptom Index, and the Chronic Prostatitis Symptom Index in a random sample of over 1400 men and women with urologic symptoms, underscoring that we should be cautious in using these questionnaires as a basis for diagnosis in epidemiologic studies [504].

Rosenberg and Hazzard [67] surveyed 1218 consecutive patients presenting to their primary care office and found 7 (0.6%) who had a 7 ICSI score. Likely BPS was noted in 12.6% of patients on the PUF scale, a figure 21 times higher, suggesting that either the PUF drastically overestimates BPS, or the ICSI lacks sensitivity. Based on the correlation of the potassium sensitivity test and the PUF questionnaire, Parsons [54] stated that 30.6% of 3rd year female medical students at his California institution had probable BPS. Sahinkanat and coworkers [190] in Turkey administered the PUF questionnaire to all 442 female textile workers in two local factories. Eighty-six per cent of those with a PUF score 7 or greater had an 86% positive rate of PST testing versus 9% positive in the group with PUF less than 7. They extrapolated that bladder epithelial permeability dysfunction was present in 32.8% of these unselected women. The ICSI estimate seems much more in line with current epidemiologic data.

*Figure 6: O’Leary Sant Symptom and Problem Indexes*
While perhaps not ideally suited for epidemiologic studies, these questionnaires can reveal important epidemiologic data. Porru and colleagues [505 compared University of Wisconsin scores including both urinary and non-urinary symptoms, for 30 BPS female patients and 30 female controls. While the IC group had significantly higher scores for the urinary symptoms, they did not appear to indiscriminately report higher scores than controls for different somatic and general complaints, as might be expected if this disease is a manifestation of a more generalized disorder. Diggs and colleagues [506] used the ICSI to investigate how interstitial cystitis patients interpret urgency. The ICSI question regarding: “the strong need to urinate with little or no warning” consistently underestimated the response to the International Continence Society definition of urgency: “the compelling urge to urinate that is difficult to postpone.

Treatment outcome studies have also used the Global Response Assessment (figure 8): a balanced patient self-report on overall response to therapy, developed for NIDDK sponsored multicenter therapeutic trials [285]. The O’Leary Sant and University of Wisconsin questionnaires are responsive to change over time in patients with BPS and have been recommended as secondary endpoints in future clinical trials of the disorder. Propert and colleagues in the Interstitial Cystitis Clinical Trials Group determined that a 1.2 point change in the O’Leary Sant indexes and a 3.1 point change in Wisconsin IC inventory corresponded to a one-category change in the GRA. Individual symptoms were also responsive [507].

Figure 7: Pelvic Pain, Urgency, Frequency Scale

Figure 8: Global Response Assessment (GRA)

1. THE PROBLEM

BPS/IC has been a difficult condition for which to assess therapeutic impact. There is a 50% incidence of temporary remission unrelated to therapy, with a mean duration of 8 months [58]. A somewhat surprising finding from the Interstitial Cystitis Database was that although there was initial improvement in symptoms partially due to regression to the mean [508] and the intervention effect, there was no evidence of a long-term change in average symptom severity over the four year course of follow-up [71]. In a chronic, devastating condition with primarily subjective symptomatology, no known cause, and no cure, patients are desperate and often seem to respond to any new therapy. A
skeptical view of outcomes is essential (figure 9), as patients can be victims of unorthodox health care providers using unproven forms of therapy, some medical, some homeopathic, and some even surgical.

2. THE PLACEBO ISSUE

Where possible, the results of randomized controlled studies should be used for decision making. Placebo, double-blind studies are optimal in this disorder for which there is no generally effective standard therapy.

Placebo effects influence patient outcomes after any treatment which the clinician and patients believe is effective, including surgery. Placebo effects plus disease natural history and regression to the mean can result in high rates of good outcomes, which may be misattributed to specific treatment effects [71,509-511]. Unfortunately, few BPS treatments have been subjected to a placebo-controlled trial. This is not to say that what seems effective is not, but rather that a high index of skepticism is healthy, even in treatments tested in controlled trials [512].

While in many diseases an argument can be made against using a true placebo control as opposed to an orthodox treatment of approved or accepted value [513], a good case for true placebo comparison can readily be made for BPS. The vagaries of the natural history, the general lack of progression of symptom severity over time, and the fact that it is not life threatening, mean that there is little to lose and much to gain by subjecting new treatments to the vigorous scrutiny of placebo control. Many patients who volunteer for such trials have already run the gamut of accepted (though generally unproved) therapies. It has long been recognized in protocols that use subjective criteria for assessment that "improvement" may be expected in up to 35% of placebo-treated patients [514]. As the spontaneous remission rate (though temporary) for BPS is 11% [295] to 50% [58], combined with the placebo improvement it can be difficult to prove efficacy.

Even in placebo controlled trials, it is reasonable to surmise that some degree of unblinding may occur as a result of somatic or psychological side effects of the active arm, impairing the validity of the trial results and giving the active arm a slight edge over placebo [515,516]. Failure to recognize unblinding can easily bias results of a study and has not been routinely measured in clinical trials [517]. When occurring late in a study after one would expect onset of a therapeutic effect, unblinding could be the result of side effect profile or drug efficacy. Early in the trial it reflects poor placebo or study design. The degree of blinding needs to be ascertained throughout the trial. This is of specific concern in BPS and any disorder where primary outcomes may be subject to patient-specific psychological and physiological factors.

The ethics and necessity of placebo-controlled trials have been questioned, especially in situations in which an effective treatment exists and also where delay in treatment has been shown to result in disease progression [518-520]. However, there are methodological concerns with equivalence and non-inferiority active agent comparison trials [521]. These include an inability to determine if the treatments are equally good or equally bad, and the possibility that successive non-inferiority trials can lead to a gradual decrease in treatment efficacy. Although the use of placebo-controlled trials raises ethical concerns when proven effective treatment exists for the condition under investigation, they are ethically justified, provided that stringent criteria for protecting research subjects are satisfied [522].

The value of placebo-controlled trials is aptly illustrated by the recent decisions by pharmaceutical manufacturers not to pursue FDA approval in the United States for seemingly promising intravesical therapies for BPS [523,524] after placebo-controlled trials failed to establish efficacy. These include low concentration hyaluronic acid (Bioniche, Canada), high concentration hyaluronic acid (SKK, Tokyo), and resiniferatoxin (iCOS, Bothell, Washington, USA). Nalmefene, an initially promising oral therapy in the 1990's, [326] also failed phase 3 trials (iVAX, Miami). Placebo trials are impractical in surgery and it can be difficult to evaluate surgical reports. The many older medications currently used off-label might not meet success if tested in the stringent manner in which new molecular entities are tested. The expense of testing therapies currently used off-label often requires dependence on the largesse of government agencies like the National Institute of Health [285,376,525].

2. OUTCOME INTERPRETATION

As has been discussed with regard to rheumatologic disorders [526], the interpretation of measurements of physical functioning in clinical trials should consider the composition of the study sample, with attention to the stage of disease and the heterogeneity in disease duration. Patients with long-standing disease or compromised bladder capacity or central sensitization can be expected to be less responsive to treatments directed toward the bladder itself. Finally, when considering objective changes, the concept of statistical versus clinical significance is paramount. Investigators should, but rarely do, point out differences between statistical improvement and what they consider to be clinically significant improvement [527]. As Gertrude Stein reportedly stated, "A difference, to be a difference, must make a difference". An increase in bladder capacity of 30cc may be statistically significant but clinically irrelevant. Number needed to treat and number needed to harm data [528] may be particularly important in BPS and have not typically been included in efficacy analysis.
Figure 9: Selected reported treatment outcomes in uncontrolled studies in IC literature: Percentage of patients initially improved.
3. IMMPACT RECOMMENDATIONS

The core outcome domains for chronic pain clinical trials have been published [399,529]. The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) recommendations indicate that core outcome domains should be considered in all clinical trials of the efficacy and effectiveness of treatments for chronic pain. These domains include:
1. Pain
2. Physical functioning
3. Emotional functioning
4. Participant ratings of improvement and satisfaction with treatment
5. Symptoms and adverse effects, participant disposition

CONCLUSIONS

Currently for BPS/IC there are no accepted biologic disease markers that can be used for the assessment of response to therapy. The O’Leary Sant, University of Wisconsin, and Global Response Assessment are well-validated questionnaires to follow disease progression and response to therapy. The IMMPACT recommen-dations suggest that as well as symptoms scores, any future study on a pain syndrome must involve more general assessments of psycho-physical functioning. There is limited experience in BPS/IC for the use of well-validated measures available for the study of chronic pain. Future NIDDK research initiatives may help to rectify this. http://grants.nih.gov/grants/guide/rfa-files/RFA-DK-07-003.html http://www.nih.gov/news/health/sep 2008/ niddk-05.htm.

International recognition of an agreed upon definition and inclusion and exclusion criteria of BPS/IC will help future studies to fulfill the highest standards available, and placebo-controlled, double-blind, randomized controlled trials, where possible, will provide the highest level of evidence to move the field forward.

XV. PRINCIPLES OF MANAGEMENT

The information currently available in the literature does not lend itself to easily formulating a diagnostic or treatment guideline. Different groups of “experts” would undoubtedly create different “best practices”. The compromise approach devised by an experienced cross-section of urologists and gynecologists from around the world at the International Consultation on Continence 2004 meeting in Monaco [38] has been reviewed and updated by the committee and allows for significant latitude to reflect varying individual practice patterns and to account for patient preference.

An underlying principle is that, where possible, treatment decisions of bladder pain syndrome should be evidence based. Unfortunately, high level evidence of efficacy is lacking for many common treatments, either because such studies have not been done, or were done and failed to demonstrate efficacy [530,531]. The previous Consultation reported that only oral amitriptyline and intravesical dimethyl sulfoxide had supporting evidence to have a B level of recommend-ation in the Oxford system [38]. A subsequent review by Karsenty and colleagues added oral cimetidine to that list [532].

Another principle is that we should be guided by patient perceived and driven outcomes for bladder pain syndrome, which is, after all, diagnosed on the basis of symptoms after exclusion of confusable diseases. Many patients prefer noninvasive therapies [533], and it would seem reasonable to start with oral therapies if conservative non-medical interventions fail to result in significant symptom amelioration. Use of surgical therapies should be approached with some caution. Ingber and coworkers reported that women with BPS have significantly more pelvic surgeries than controls, and the majority were performed prior to diagnosis of BPS, possibly for pain related to undiagnosed BPS [534].

1. HISTORY / INITIAL ASSESSMENT

Men or women with an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes [535] should be evaluated for bladder pain syndrome. The initial assessment consists of a frequency/volume chart, focused physical exam, urinalysis, and urine culture. Cytology and cystoscopy are recommended if clinically indicated.

Patients with infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and/or hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms are they diagnosed with BPS.

2. INITIAL TREATMENT

Patient education and support, dietary manipulation, nonprescription analgesics, and pelvic floor relaxation techniques comprise the initial management of BPS. It is important to address the patient’s pain, and understand that at some point in the progression of treatment, referral to a pain specialty clinic may be desirable.

When the conservative approach fails, or symptoms are severe and conservative mana-gement unlikely to succeed, oral medication, physical therapy, and/or intravesical treatment can be prescribed.
3. SECONDARY ASSESSMENT

If oral or intravesical therapy fails, or before beginning such therapy at the discretion of the clinician, it is reasonable to consider further evaluation which can include urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anesthesia. Laparoscopy may be indicated if there is a suspicion of gynecologic disease. Findings of bladder overactivity suggest a trial of antimuscarinic therapy. Findings of a Hunner’s lesion suggest therapy with transurethral fulguration or resection of the ulcer. Distention itself can have therapeutic benefit in up to one-third of patients, though benefits rarely persist for longer than a few months.

4. REFRACTORY PBS/IC

Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities, generally in the context of clinical trials. These might include neuromodulation, intravesical botulinum toxin, and/or experimental pharmacologic protocols of promising new treatments. The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urine stream. Augmentation (substitution) cystoplasty and urinary diversion with or without cystectomy have been used with good results in very well selected patients.

It is the opinion of the committee that, because of the natural history of the disorder, it is best to cautiously progress through a variety of treatments. Whereas the shotgun approach, starting newly diagnosed patients on a variety of simultaneous medications, seems to have many adherents, employing one treatment at a time makes the natural history of the disease itself an ally in the treatment process. If a treatment has no efficacy, it should be stopped. It a treatment results in modest improvement, it should be continued and another treatment option employed in an attempt to further improve symptoms. The goal is to maximize quality of life and dispense with ineffective treatments in a somewhat controlled fashion. The patient and clinician must remember that “perfect is the enemy of good” and expectations should be realistic. One should encourage patients to maximize their activity and live as normal a life as possible, not becoming a prisoner of the condition. Although some activities or foods may aggravate symptoms, nothing has been shown to negatively affect the disease process itself. Therefore, patients should feel free to experiment and judge for themselves how to modify their lifestyle without the guilt that comes from feeling they have harmed themselves if symptoms flare. Dogmatic restriction and diet are to be avoided unless they are shown to improve symptoms in a particular patient. Level 4 Grade C

XVI. FUTURE DIRECTIONS IN RESEARCH

There are five major recommendations for future directions in research on BPS that the committee believes will lead to a greater understanding of the condition and will have a major impact on its management.

1. EPIDEMIOLOGICAL STUDY

1. Develop a reliable screening tool with adequate sensitivity and specificity to conduct epidemiologic research in the general population to study the incidence, prevalence and identify risk factors for the development of BPS.

2. Establish patient data bases in different regions and conduct longitudinal follow up to understand the natural history of the disease and to examine the differences in disease natural history among regions.

2. SUB-GROUPING/PHENOTYPING PATIENTS

Patients who have or develop additional pain syndromes, such as vulvodynia, temporomandibular disorder, irritable bowel syndrome, fibromyalgia and chronic fatigue syndrome, or autoimmune diseases such as lupus erythematosus and Sjögren’s syndrome might have different pathophysiology, natural history and treatment response from those patients without co-morbidities. Sub-grouping patients not only allows us to develop better treatment strategy but also may answer the question: Is BPS an end-organ disease of the bladder or a systemic condition? However, to properly phenotype patients, it is necessary to develop an easy-to-use tool for non-specialists to identify those with co-morbidities. It is also important to validate the concept that categorizes all types of pelvic pain into one “chronic urological pelvic pain syndrome”, as some patients’ symptoms involve multiple pelvic organs, concurrently or sequentially along with other body systems.

3. DEVELOPING A SIMPLE, NON-INVASIVE DIAGNOSTIC TEST FOR BPS

This will most likely involve urinary markers. Urinary markers may help to sub-classify various types of BPS. This test will determine the diagnosis of BPS in the female population, as well as determine the subset of men currently diagnosed with non-bacterial chronic prostatitis/chronic pelvic pain syndrome who may actually have BPS.

4. COMPREHENSIVE STUDY ON HYDRODISTENTION

Hydrodistention is still a popular practice in many places around the world simply due to the limited effective therapeutic armamentarium that can be
offered to the patients. It is necessary to standardize the technique and conduct international cooperative studies to verify the true value of this treatment modality. Some important information can be gathered from these studies, such as identifying the patient variables that lead to a good therapeutic response.

5. DEVELOP A PRACTICAL MULTI-DISCIPLINARY CARE MODEL

In addition to physical morbidities (urinary frequency, pain), many BPS patients have associated psychological co-morbidities [537]. These can often be managed by psychological intervention. BPS patients also need help from dietitians and physiotherapists. A practical multi-disciplinary care model, which includes physicians, dietitians, physiotherapists, pain specialists, psychologists, psychiatrists and patient support groups, should be developed and tested in various settings.

XVII. SUMMARY (figure 10)

1. DEFINITION

Bladder Pain Syndrome (in the absence of a universally agreed definition, the European Society for the Study of Interstitial Cystitis –ESSIC definition is given along with a slight modification made at a recent international meeting held by the Society for Urodynamics and Female Urology – SUFU

ESSIC: Chronic pelvic pain, pressure or discomfort of greater than 6 months duration perceived to be related to the urinary bladder accompanied by at least one other urinary symptom like persistent urge to void or urinary frequency. Confusable diseases as the cause of the symptoms must be excluded.

Consensus Definition from SUFU International Conference (Asia, Europe, North America) held in Miami, Florida February 2008: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes.

2. BLADDER PAIN SYNDROME (BPS)

a) Nomenclature (Figure 11)

The scientific committee of the International Consultation voted to use the term “bladder pain syndrome” for the disorder that has been commonly referred to as interstitial cystitis (IC). The term painful bladder syndrome was dropped from the lexicon. The term IC implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. Painful Bladder Syndrome, as defined by the International Continence Society, is too restrictive for the clinical syndrome. Properly defined, the term Bladder Pain Syndrome appears to fit in well with the taxonomy of the International Association for the Study of Pain (IASP), and focuses on the actual symptom complex rather than what appears to be long-held misconception of the underlying pathology.

b) History / Initial Assessment

Males or females with pain, pressure, or discomfort that they perceive to be related to the bladder with at least one urinary symptom, such as frequency not obviously related to high fluid intake, or a persistent urge to void should be evaluated for possible bladder pain syndrome. The presence of commonly associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms also suggests the diagnosis. Abnormal gynecologic findings in women and well-characterized confusable diseases that may explain the symptoms must be ruled out.

The initial assessment consists of a frequency/volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology and cystoscopy are recommended if clinically indicated. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms, are they diagnosed with BPS. Grade of recommendation: C

c) Initial Treatment

Patient education, dietary manipulation, nonprescription analgesics, and pelvic floor relaxation techniques comprise the initial treatment of BPS. The treatment of pain needs to be addressed directly, and in some instances referral to an anesthesia/pain center can be an appropriate early step in conjunction with ongoing treatment of the syndrome. When conservative therapy fails or symptoms are severe and conservative management is unlikely to succeed, oral medication, intravesical treatment, or physical therapy can be prescribed. It is recommended to initiate a single form of therapy and observe results, adding another modality or substituting another modality as indicated by degree of response or lack of response to treatment. Excellence can be the enemy of good. Grade of recommendation: C

d) Secondary Assessment

If initial oral or intravesical therapy fails, or before beginning such therapy, it is reasonable to consider further evaluation which can include Urodynamics, pelvic imaging, and cystoscopy with bladder distention...
**Bladder Pain Syndrome**

**Symptoms**
- Pain, pressure, or discomfort perceived to be related to the bladder with at least one other urinary symptom (e.g., frequency, nocturia, urgency)

**Basic Assessment**
- History
- Frequency/volume chart
- Focused physical examination
- Urinalysis, culture

**1st Line Rx**
- "Simple BPS" Conservative Therapy
- Patient Education
- Dietary Manipulation
- Nonprescription Analgesics
- Pelvic Floor Relaxation
- Address Treatment of Pain

**Complicated BPS**
- Urinary infection
- Incontinence
- Urinary infection
- Hematuria
- Gynecologic signs/symptoms

**Treatment**
- Consider:
  - Urine cytology
  - Further imaging
  - Endoscopy
  - Urodynamics
  - Laparoscopy

**Treat as indicated**

---

**Paradigm Change**

**Inflammatory Bladder Disorder**

**Interstitial Cystitis**

**Painful Bladder Syndrome**

**Chronic Pain Syndrome**

**Old Paradigm IC:**
- Identify marker
- Determine pathophysiology
- Modify pathophysiology

**New Paradigm: BPS**
- Chronic Pain Syndrome
- Treat the Pain
- Local causes in bladder
- Prevent Central Sensitization

---

*Figure 11: The new perspective of Bladder Pain Syndrome From Hanno, PM: Proceedings of the International Consultation on Interstitial Cystitis, Japan; Comfortable Urology Network, pages 2-9, 2008*
and possible bladder biopsy under anesthesia. Findings of bladder overactivity suggest a trial of antimuscarinic therapy. Findings of a Hunner’s lesion suggest therapy with transurethral resection or fulguration of the lesion. Distention itself can have therapeutic benefit in 30-50% of patients, though benefits rarely persist for longer than a few months. Grade of recommendation: C
e) Refractory BPS

Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. Many of these are best administered within the context of a clinical trial if possible. These may include neuromodulation, intravesical botulinum toxin, or newly described pharmacologic management techniques. At this point, most patients will benefit from the expertise of an anesthesia pain clinic. The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urinary stream. Urinary diversion with or without cystectomy has been used as a last resort with good results in selected patients. Augmentation or substitution cystoplasty seems less effective and more prone to recurrence of chronic pain in small reported series. Grade of recommendation: C

I. INTRODUCTION

Not all incontinence can be cured completely and even those who are ultimately successfully treated may have to live with incontinence for a time, for example, whilst they wait for surgery or for pelvic floor muscle training to yield its benefits. Still others – depending on their frailty, severity of incontinence and personal priorities – may not be candidates for treatment or may choose management over attempted cure. For all such people, the challenge is to discover how to deal with their incontinence so as to minimise its impact on their quality of life. This usually involves using some kind of continence product(s) to control or contain leakage of urine and/or faeces, and/or to manage urinary retention. In short, the possible role of continence products should be considered at each stage of patient assessment and treatment and, if treatment is not available, appropriate, acceptable or (fully) successful – subsequent management. Managing incontinence successfully with products is often referred to as contained incontinence, managed incontinence or social continence, in recognition of the substantial benefits it can bring to quality of life even though cure has not been achieved [1].

This chapter is aimed primarily at healthcare professionals seeking to make informed decisions as they choose – or help their patients to choose - between continence product categories and then select a specific product within their chosen category. We have also aimed to make this information accessible to the user, particularly in the summary and recommendation sections. The chapter includes a section for each of the major product categories, each section reviewing published data and – where possible - identifying evidence-based recommendations for product selection and use. Products designed to deal with skin and odour problems caused by incontinence are also addressed.

The sections on the major product categories are preceded by two others. The first provides overall guidelines for product selection, describing the key elements of patient assessment and suggesting a classification of people with incontinence into a number of broad groups based on gender, age (adult or child) and the nature and severity of their incontinence. A table is provided for each group summarising the user characteristics, priorities and contexts which commonly favour or discourage the use of each of the major product categories available to them. Following these overall guidelines and preceding the sections on the major product categories, a review is provided of the methodological challenges of conducting continence product evaluations and interpreting the results.

Unfortunately, much of the evidence base for product selection and effective use is patchy and, where there is little published data to provide confident evidence-based advice on an issue commonly raised by patients and caregivers, an expert opinion is offered as the best advice available. The hope is that highlighting knowledge gaps in this way will help stimulate the research necessary to provide more robust evidence-based advice in the future.

The literature search strategy to identify material for this chapter additional to that reviewed for the third consultation [2] was conducted as follows. MEDLINE and CINAHL databases were searched from 2003 – 2008 for English language publications. Detailed search strategies were developed for each electronic database searched. Consideration was given to variations in terms used and spellings of terms in different countries so that studies were not missed. Relevant abstracts were examined and then pertinent articles were retrieved and reviewed, and the reference lists searched for further studies. For product categories associated with little or no research literature, analysis relied on expert opinion from clinical practice papers.

The following main search terms were used: incontinence AND device*, toilet* AND facilities, commode*, urinal*, bedpan*, urinary AND sheath*, condom AND catheter*, incontinence OR absorbent pad*, urinary AND catheter* (in title), urinary AND leg bag* OR legbag* OR drainage bag, faecal OR fecal AND incontinence AND plug OR pouch OR bag OR manage* system, flatus AND odour OR odor AND device, incontinence OR perineal AND dermatitis OR inflammation OR skin damage.
Selecting suitable continence products is critical for the well-being and quality of life of patients and carers. The ability to contain and conceal incontinence enables individuals to protect their public identity as a "continent person" and avoid the stigma associated with incontinence [3]. Failure to do so can result in limited social and professional opportunities, place relationships in jeopardy and detrimentally affect emotional and mental wellbeing [4]. The ability to contain and conceal incontinence enables carers to feel confident that the person(s) they care for will not be embarrassed publicly. It reduces the level of care required in relation to maintaining hygiene, skin care and laundry for the person who is dependant upon continence products [5].

Fortunately there is a diverse range of different products to choose from. However, without comprehensive and current information on the products available, this plethora of choice can be overwhelming and confusing [5]. Furthermore, the range of products actually accessible to users can vary enormously between and within countries, depending on the funding available, healthcare policy and the logistics of supply [5].

The choice of appropriate products for an individual with incontinence is influenced by the resources and care available and patient / carer preference, as well as assessment of specific client characteristics and needs [6,7].

The stigma associated with incontinence means that another measure by which the success of products is judged is their ability to conceal the problem [8]. Such concealment may involve compromises: for example, in order to prevent leakage from a product, those with a larger capacity than strictly necessary may be preferred but this can in itself introduce issues to do with discretion when the product is worn. The intimate and stigmatised nature of incontinence means that issues relating to self-image can affect some patients’ preferences. This may be especially marked in younger people for whom body-image may be particularly important and for whom disruption to normal social and interpersonal development may result in isolation or lack of access to normal experiences [9,10].

1. PRODUCT CATEGORIES

The continence products considered in this chapter may be divided into those that are intended to assist with toileting and those to manage urinary retention and / or contain incontinence (urinary and / or faecal) (Fig II-1).

II. OVERALL GUIDELINES FOR SELECTING CONTINENCE PRODUCTS

Selecting suitable continence products is critical for the well-being and quality of life of patients and carers. The ability to contain and conceal incontinence enables individuals to protect their public identity as a “continent person” and avoid the stigma associated with incontinence [3]. Failure to do so can result in limited social and professional opportunities, place relationships in jeopardy and detrimentally affect emotional and mental wellbeing [4]. The ability to contain and conceal incontinence enables carers to feel confident that the person(s) they care for will not be embarrassed publicly. It reduces the level of care required in relation to maintaining hygiene, skin care and laundry for the person who is dependant upon continence products [5].

Fortunately there is a diverse range of different products to choose from. However, without comprehensive and current information on the products available, this plethora of choice can be overwhelming and confusing [5]. Furthermore, the range of products actually accessible to users can vary enormously between and within countries, depending on the funding available, healthcare policy and the logistics of supply [5].

The choice of appropriate products for an individual with incontinence is influenced by the resources and care available and patient / carer preference, as well as assessment of specific client characteristics and needs [6,7].

The stigma associated with incontinence means that another measure by which the success of products is judged is their ability to conceal the problem [8]. Such concealment may involve compromises: for example, in order to prevent leakage from a product, those with a larger capacity than strictly necessary may be preferred but this can in itself introduce issues to do with discretion when the product is worn. The intimate and stigmatised nature of incontinence means that issues relating to self-image can affect some patients’ preferences. This may be especially marked in younger people for whom body-image may be particularly important and for whom disruption to normal social and interpersonal development may result in isolation or lack of access to normal experiences [9,10].

1. PRODUCT CATEGORIES

The continence products considered in this chapter may be divided into those that are intended to assist with toileting and those to manage urinary retention and / or contain incontinence (urinary and / or faecal) (Fig II-1).

2. IDENTIFYING THE NEEDS

The algorithms below (Figs II-2 and II-3) are designed to provide guidance for determining broadly which product(s) is likely to be of benefit to a particular patient. There are three main questions:

• Is there urinary retention (with or without incontinence)?
• Are there problems with toilet access (e.g. the proximity or design of the toilet; mobility or urgency problems for the patient)?
• Is there urinary incontinence or faecal incontinence or both?

Answers to these questions will determine which one (or both) of the algorithms is most appropriate for an individual and help identify the category(s) of products most likely to help.

Figure II-1: Products for toileting (top) and for managing incontinence and / or urinary retention (bottom). CIC = Clean intermittent catheterisation; IDC = Indwelling catheter.

All toileting products can be useful for dealing with urine and / or faeces except for handheld urinals which are just for urine. Containment / control products are subdivided into three overlapping classes: those for urinary retention, urinary incontinence, and faecal incontinence. So, for example, someone with urinary retention is most likely to benefit from one of the products in the red ellipse, while someone with urinary incontinence will most likely benefit from one in the blue ellipse. A patient experiencing both problems will need two products (one from each ellipse) or one product from the intersection of the two ellipses.
Figure II-2: Algorithm to help identify the category(s) of products most likely to help a patient with urinary incontinence and / or urinary retention. (Y = Yes; N = No; U = unsatisfactory ie considered and deemed unsuitable or tried and found not to work satisfactorily). * Consideration should be based on assessment of the patient’s physical characteristics, cognitive ability and personal preferences, as well as the nature of their incontinence. (CIC = Clean intermittent catheterisation; IDC = Indwelling catheter).

Figure II-3: Algorithm to help identify the category(s) of products most likely to help a patient with faecal incontinence. (Y = Yes; N = No; U = unsatisfactory ie considered and deemed inappropriate or tried and found not to work satisfactorily). * Consideration should be based on assessment of the patient’s physical characteristics, cognitive ability and personal preferences, as well as the nature of their incontinence.
3. PATIENT ASSESSMENT FACTORS

A careful patient assessment is an important part of the process of product selection and Table II-1 summarises the key elements to be considered.

The choice of appropriate products for an individual with incontinence is dependent upon the resources and care available. It must also be influenced by patient and carer preference as well as assessment of specific client characteristics and needs [6,7].

Assessment of physical characteristics such as anthropometrics, level of independence, mobility and dexterity, mental acuity and the nature of the incontinence will determine which products may be appropriate. In addition to these factors, successful product choice and effective use involves other practical and psychosocial considerations. Product effectiveness depends upon the same factors as any assistive device intended to address a disability or impairment: patient participation in device selection [11] provision of adequate instructions for use [12] and the need for products to fulfil their function reliably and not be difficult to use [9-12,13].

While Table II-1 provides general guidance on patient assessment relating to product selection, later sections in the chapter provide further discussion on assessment issues specifically related to the various product categories.

In addition to selection of appropriate and effective products following patient assessment, education and training of users or carers in the correct use of the devices is of importance if product use is to be optimal. This may be a simple matter of instruction in the effective fitting and changing of absorbent products, or may involve more in-depth training in the ongoing care of, for example, a suprapubic catheter.

Incontinence is often a long term condition and so monitoring and periodic reassessment is essential to maintain effective management with products.

4. MAIN USER GROUPS

Although needs, priorities and preferences vary between people with incontinence it is useful to divide patients into major user groups to help identify the category(s) of products most likely to benefit an individual. Seven primary groups are identified in this chapter:

- People with urinary retention.
- People who need help with toileting / toilet access.
- Females with light urinary incontinence.
- Males with light urinary incontinence.
- Females with moderate / heavy urinary incontinence.
- Males with moderate / heavy urinary incontinence.
- People with faecal incontinence.

An individual may belong to more than one group. Each group includes children and young people: the products available for them are broadly similar to those for adults.

5. CHOOSING BETWEEN PRODUCT CATEGORIES

Figs II-4 to II-9 summarise the user characteristics, priorities and contexts which favour or discourage the use of each of the categories of products available for six of the seven user groups identified in section II.4. Assistance with choosing appropriate products for the first group (people with urinary retention) is given in the section on catheters (Table XII-1) as all the product options for these people are in the same category (catheters).

The recommendations given in these charts are based on the evidence presented in the sections of the chapter dedicated to different product categories and they are intended to help identify which product category (categories) are most likely to help an individual. However, it should be remembered that the same product will not suit all people, even if they have very similar assessment outcomes on the factors summarised in Table II-1. Different people prefer different products and where possible patients should be given access to a range with which to experiment to determine the most satisfactory product(s). Similarly, the balance of priorities varies between users; for example, some pad users will opt for a bulky and, therefore, less discreet product to achieve an acceptably low risk of leakage while others will see the balance differently. It should also be noted that a mix of products from different categories may provide the best solution; for example, needs may vary between day / night and home / away. Once a product category of interest has been identified the corresponding chapter section should be consulted for further help.

6. SUMMARY

In conclusion continence products find an important role in enhancing the quality of life and reducing stigma of incontinence of those who: are awaiting treatment; are waiting for treatment to take effect; elect not to pursue cure options; are unable to be fully cured and are living with an ongoing bladder / bowel problem.

7. RECOMMENDATIONS

- Incontinence should be actively managed with products to minimise the impact of incontinence on quality of life (Grade of Recommendation C).
- Patients should be carefully assessed (and reassessed) to select the most appropriate products (Grade of Recommendation C).

1524
<table>
<thead>
<tr>
<th>Element</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nature of the continence problem</td>
<td>The frequency, volume and flow rate of the incontinence influences product suitability. Generally smaller, more discreet products should be tried before larger bulkier products. If catheterisation is necessary, intermittent catheterisation is a less invasive option than indwelling catheterisation.</td>
</tr>
<tr>
<td>Gender</td>
<td>Males may consider and prefer sheaths as a more masculine option to pads. Females may be attracted to products that are more feminine in design and presentation. Some ‘unisex’ products such absorbent pads have different designs that work better for men (or women).</td>
</tr>
<tr>
<td>Physical characteristics</td>
<td>Anthropometrics (e.g. height and waist, thigh, penile circumference) will influence the comfort and effectiveness of a product.</td>
</tr>
<tr>
<td>Mental acuity</td>
<td>Mental impairment can affect the person’s ability to manage the product. Products that resemble usual underwear (e.g. some absorbents) may be easiest to manage. Products which have health implications if used incorrectly (e.g. mechanical devices or catheter valves) should be avoided if mental impairment is present.</td>
</tr>
<tr>
<td>Mobility</td>
<td>Impaired mobility may make some product choices impractical or require toilet or clothing modification to allow effective use of the product.</td>
</tr>
<tr>
<td>Dexterity</td>
<td>Problems with hand or finger movement can make it difficult to use some products (e.g. taps on leg bags, straps with buttons).</td>
</tr>
<tr>
<td>Eyesight</td>
<td>Impaired eyesight limits effective application and management of some products.</td>
</tr>
<tr>
<td>Leg abduction problems</td>
<td>Difficulty with abduction can make the use of some products impractical or ineffective.</td>
</tr>
<tr>
<td>Lifestyle and environments</td>
<td>Daily activities and environments can influence the choice of product and a mixture of products may provide optimum management. Different products may be most satisfactory for daytime and going out (when discreetness may be a priority) and night-time or staying in (when comfort may be a priority), for holidays (when large quantities of disposables may be a problem) or for use at work. The proximity and accessibility of a toilet in the various environments may be a key factor.</td>
</tr>
<tr>
<td>Independence / assistance</td>
<td>If a carer is required to apply or change the product then it may be important to involve them in the selection of the product and to establish their willingness and ability to use it.</td>
</tr>
<tr>
<td>Laundry facilities</td>
<td>Washable pads and bed linen may be very heavy when wet and take a long time to dry. It is important to check that the person doing the laundry has the ability and facilities to cope.</td>
</tr>
<tr>
<td>Disposal facilities</td>
<td>Ability to appropriately, safely and discreetly dispose of the selected products needs to be considered.</td>
</tr>
<tr>
<td>Storage facilities</td>
<td>Some products – notably, pads for heavy incontinence – can be bulky. Adequate space to store supplies between deliveries / purchases needs to be available.</td>
</tr>
<tr>
<td>Personal preferences</td>
<td>Different people like different products and where possible patients should be given a choice of products with which to experiment to determine the most satisfactory product.</td>
</tr>
<tr>
<td>Personal priorities</td>
<td>Everyone wants to avoid leakage but other factors such as discreetness may be more or less important to individuals.</td>
</tr>

III. PRODUCT EVALUATION

METHODOLOGY

This section aims to assist those planning clinical trials of products. There have been relatively few large clinical trials of continence products (with the exception of urinary catheters) and for most product categories research evidence to guide the selection of individual products / designs / features is limited and in some cases absent.

Measuring the performance of continence products is methodologically challenging. Manufacturers modify and change their products regularly - in terms of both materials and designs - and this limits the long-term validity of research results. There are also complex issues regarding research questions, study design, product representation, blinding and sample size [14] which are discussed below.

It is common for practitioners to be asked (by their employers or by companies) to do a small evaluation or trial – sometimes to ‘test out’ a new product and sometimes to help choose between competing brands for bulk-buying. Such trials should be approached with caution; they can be very demanding but their results may be of very limited value even for local use. The methodological challenges identified below still apply but are compounded by small sample size and restricted product selection. These studies are likely to be helpful only for identifying gross product short-comings or benefits.

1. RESEARCH QUESTIONS

a) Comparisons

Part of the complexity of product evaluations is the sheer number and type of products which means that many different comparisons could be made. Table III-1 shows an example range of questions that may be asked about one particular product category (absorbent pads – following question 1) and many combinations and permutations of products / designs / feature are possible.

In the field of absorbent products the practitioner and / or patient wishes to know whether to use an underpad or a bodyworn product, a reusable or a disposable, a diaper or an insert (if they select a bodyworn), a diaper with internal elasticity (standing gathers) or without and, finally, which of the many diaper brands is likely to be most effective. Attempting to answer this final question is the most pertinent question for the practitioner (who may already have made decisions about questions 1-4) but is particularly problematic because of the high rate of product change. By the time the results of a clinical trial of product brands are known many of the test products will have been modified and the results will have limited value for product selection. However, these ‘single design’ studies do have value in demonstrating the range of performance within the group of product brands, and where objective measurements can be made (for example, of leakage performance) can allow for comparisons between groups of products. Single design studies are also helpful in promoting product improvement by revealing common problems experienced by patients and exposing particularly poor products or poor product features which are amenable to change by manufacturers.

Basic product designs, features and materials change much less frequently and attempting to answer questions 1-4 (Table III-1) is therefore likely to lead to more long-lasting results. Such studies have been attempted by many researchers, but these have frequently been confounded by problems with product representation.

b) Product representation

The single greatest (and most frequently overlooked) threat to the validity of clinical trials of products is the selection of the products entered into the study. Studies of single groups of similar product brands have shown that patient ‘overall opinion’ scores vary by as much as 70 percentage points [15] and the selection of products to represent the group of interest is therefore crucial. Studies that have purported to compare different designs or materials have often included a small number (most often just one) of arbitrarily selected product(s). Generalizing the results of such studies to whole product groups (e.g reusable underpads, or disposable bodyworns) is meaningless and misleading. It is perfectly possible to select (either by accident or design) a particularly ‘good’ product from one group and a particularly ‘poor’ product from another. A well-designed study will therefore be seriously flawed if there is no clear process or pilot study to determine and justify the choice of particular products. Even with a systematic process of product selection (or preferably a pilot study) it is unwise to select a single product to represent a whole group of products and selection of a small group of products (e.g, three) is preferable. This allows for any ‘within group’ differences to be detected and helps to demonstrate the ‘representativeness’ of the products selected.
The most controlled method of testing different designs, materials or features of products is to make up experimental batches which differ only in the aspect of interest (e.g. the material or the feature) and a small number of studies have attempted this [16,17]. However, experimentally made products are not usually identical to those available on the market which impairs the validity of such studies.

2. RESEARCH DESIGN

A randomized controlled trial is not possible for clinical trials of products in most categories simply because a ‘control’ product does not usually exist. Nor is there a ‘standard or reference’ product to act as a control and comparisons with ‘standard practice’ (i.e. the product currently in use) are prone to bias.

Although it is methodologically simpler (and more robust) to compare only two different product groups, it is more clinically relevant to compare several competing groups, using a multiple cross-over design, where there are valid comparisons. For example, there are four main design groups of disposable bodyworn pads for moderate / heavy incontinence (inserts, diapers, pull-ups and T-shaped). Evaluation of all four groups together is much faster (and therefore gives more long-lasting results) and more cost-effective than several serial studies. Cross-over trials are vulnerable to order effects and randomization of the order of testing should be carried out using Latin squares [18] to ensure balance.

It is important that clinical trials of single designs of products (which aim to enable selection of particular product brands) are comprehensive (i.e. cover all the available products) because otherwise manufacturers can justifiably claim that although their product may be similar to one of those tested even subtle distinctions may lead to clinically important differences.

A further problem with research design is the blinding of products. Different products have different appearances and it is impossible to blind subjects or staff to the product in use. Products can be repackaged to assist anonymising but this may have unwanted effects on the products and is expensive.

Previous product experience can also affect study results, particularly if a substantial proportion of subjects are currently using a product included in the study. It is therefore important to record which products are in current use in order to add this data to the model used in the analysis.

a) Sample size and study power

Studies that include more than two products (or two small groups of products) will need to be powered so that multiple comparisons can be made. As the number of products included in the study increases the number of possible comparisons of pairs of products rises. This requires a corresponding reduction in the significance level (e.g. by using the Bonferroni method) for each pair-wise comparison to retain the overall level of significance (usually p<0.05). Thus as the total number of pair-wise comparisons increases the likelihood of a type 2 error (accepting the null hypothesis when it is false) also increases.

Sample sizes therefore need to be calculated to allow for each pair-wise comparison. Sample size requirements rise rapidly if each subject does not test each product and the number of products entered into a study must therefore be limited by subject fatigue. As an example, a clinical trial of four product groups where the primary outcome variable will be binarised (e.g. satisfactory / unsatisfactory) will require a sample size of approximately 80 subjects with an alpha of < 0.05 and d (difference) of 20%.

b) Outcome variables

Studies of product performance have most frequently used self-report questionnaires at the end of the product test period to assess participant ratings of product performance. Diaries of product-related events such as leakage, laundry generation and product consumption are also commonly included. Subjects in some absorbent pad studies have been asked to identify and prioritise items of product performance [19, 21] to inform questionnaires and Table III-2 shows the most common items of high priority to women with light urinary incontinence identified by Getliffe and colleagues [20].

or other design features commonly encompass measures of urinary tract infection, tissue trauma and recurrent catheter encrustation leading to blockage (see Section XII-2).

Questionnaire items vary depending on the products being tested and for product groups where few studies have been carried out it is particularly important to tailor questionnaires to patient needs by asking study subjects to prioritise items and to assess final questionnaires for content and face validity. One study [22] has measured the test re-test reliability of a questionnaire to assess sheath performance and found moderately good Kappa scores (around 0.7) when assessing the same sheath twice with four weeks between measurement periods.

Skin health, urinary tract infection, pain or discomfort are the main physical health consequences of containment products and skin health (which can be rated by self-report or by skin inspection) has sometimes been used as the primary outcome variable (e.g.[23]). Urinary tract infection is an important outcome for invasive devices such as catheters. Although leakage performance is most frequently rated as the top priority for users, good leakage performance is not adequate as a sole measure of patient satisfaction with performance. A single (or multiple) fatal flaw such as poor comfort, bulkiness, or poor fit may cause a product that performs well for leakage to be unacceptable to the patient. For this reason aggregate measures - which assumes that the overall performance of a product can be calculated using a weighted sum of the scores for specific aspects of performance (like comfort and freedom from leakage) - are ill-advised. Patient overall opinion or satisfaction with the product should therefore be used as the primary outcome variable[14].

There are no quality of life measurement tools specifically designed for clinical trials of products, but there is a need for such tools to measure the impact that good or bad product performance has on people’s lives. Existing incontinence-specific quality of life tools are designed to measure change after interventions to improve incontinence and include urinary symptoms. These tools are therefore likely to be insensitive to changes in quality of life brought about by products which are designed to contain incontinence rather than reduce or prevent it. The first stage in the development of a quality of life tool for absorbent product users has been reported by Getliffe et al. [20] and a similar tool for catheter users is known to be under development.

3. SUMMARY AND RECOMMENDATIONS

- There is little published evidence on which to base summary and recommendations regarding methodology and so the following summary points / recommendations are all Level of Evidence 3 / Grade of Recommendation C.

- Evaluation of continence products is methodologically complex and many attempts at providing robust evidence for product selection have been hampered by methodological weaknesses.

- Product representation is critical to providing robust and generalisable data. Selection of products for inclusion in a study needs to be transparent and systematic and several products should preferably be included to represent a product group.

- Multiple crossover designs are likely to be more efficient than randomised controlled trials for many products (e.g. pads) and therefore sample sizes estimation needs to take into account the multiple comparisons that will be made.

- Outcome variables should include patient (or carer) questionnaire including items that have been established as important to patient users.

- Diary data should be included to determine leakage performance, skin health, laundry and product consumption.

- Incidence of urinary tract infection should be included when testing invasive devices such as catheters, but “significant” UTI/ bacteriuria needs to be carefully defined (see Section XII.2.8).

- The primary outcome variables should be patient overall opinion / satisfaction and patient preference.

- Health economics should be measured alongside product performance.

4. RESEARCH PRIORITIES

- The development of Quality of Life tools for users of continence products.

### IV. HANDHELD URINALS

Handheld urinals are portable devices designed to allow a person to empty their bladder when access to a toilet is not possible or convenient, often due to limited mobility, hip abduction or flexibility. They can be especially helpful for those suffering from frequency and / or urgency.

An effective hand held urinal must enable its user to empty his / her bladder in comfort and be confident of no spillage. It should not require excessive physical effort on their part and should be easy to empty without spillage.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of patient assessment particularly important for handheld urinals are user postures (in bed, on side of bed, back in
chair, on edge of chair, standing/crouching/kneeling), leg abduction, approach of urinal (from front, side, behind, above), ability to initiate void, dexterity and strength to position and remove urinal, level and availability of assistance, user preference.

There has only been one clinical trial [24] of female urinals and there are no published trials of male urinals. However, much helpful guidance and expert opinion has been published [25-28].

1. FEMALE HANDHELD URINALS

Female handheld urinals come in a variety of shapes and sizes (Fig IV-1). Most are moulded in plastic but they may be made from metal or (for single use items) cardboard. Some are designed for use in particular postures, like standing, sitting or lying down – (see below). Some have handles to facilitate grip and positioning. Some are intended to empty into a drainage bag during or after use.

![Figure IV-1: A variety of female handheld urinals.](image)

Although female handheld urinals are often described and discussed in general nursing articles on continence products they have only been the subject of one published (cross-over) evaluation. Fader et al. [24] carried out a multi-centre study in which each of 37 community-based women (age range 33-89y; mean age 61y) was invited to evaluate all 13 products on the UK market in 1997. No product suited everybody but each was successful for at least some subjects. The key requirements for success were that the user should be able to position the urinal easily and feel confident that it would catch urine without spilling (Level of Evidence 2). Many products were successful when used in the standing / crouching position or when sitting on the edge of a chair / bed / wheelchair. Fewer worked well for users sitting in a chair / wheelchair. Only one worked even reasonably well when users were lying / semi-lying (Subaseal). In general, subjects with higher levels of dependency found fewer urinals to be suitable for their needs.

Recently the development of a powered urinal designed to pump urine into a reservoir has been described [29]. The aim of the device was to provide active removal of urine without leakage and without the need for gravity-assisted drainage. The urinal was tested by 80 women from six countries. Although evaluated as ‘good’ or ‘okay’ by more than three-quarters of the women, nearly half the women found the device ‘poor’ for weight and size. Problems with reliability of the device were also common and the authors concluded that the current device needed further refinement but may have potential as an alternative to conventional urinals. Although this device is not currently on the market, at least one other powered device is available. However, there are no published reports on efficacy.

2. MALE HANDHELD URINALS

Most handheld urinals for men are somewhat similar, involving a narrowed neck opening into which the penis is placed. Some products come with a detachable or integral non-spill adaptor containing a flutter valve to impede back-flow of urine from the urinal. There are no published trials of such products.

A review paper by Vickerman [28] makes recommendations for selecting suitable urinals for men. A flat bottom urinal may be more stable (and less likely to spill) for those using a urinal in bed. Urinals made from soft plastic (jug-style or with a funnel) may be easier to grip for those with poor manual dexterity. Urinals designed to be attached to a drainage bag (for emptying the urinal) may also be helpful to men living at home with limited support.

Vickerman also suggests that home-made devices (such as empty wide-mouthed containers with a handle and lid (for example, those used for clothes-washing liquid or conditioner) may be a practical (and cheap) option for some men. For those with a retracted penis female urinals may be easier to use than male products.

3. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

The literature [25-28] suggests that successful use of urinals depends on many factors which are summarised below.

- Experimentation is often needed to find the optimum urinal for an individual. A ‘library’ of urinals (i.e. a collection of different types of urinals to be lent out to users for experimentation) has therefore been recommended [27] but rigorous cleaning methods are needed (see below).
- Clothing alterations can aid quick and easy use of a urinal. For men, extending the fly opening of trousers or replacing zips with Velcro can be helpful, as can boxer shorts. For women drop-front pants may be needed, particularly if mobility is limited.
- Disposable and reusable ‘travel’ hand-held urinals are available for both men and women. These
urinals fold away to fit into a pocket and may therefore be more discreetly portable than conventional urinals.

- Some disposable urinals include superabsorbent polymer in their reservoirs which turn urine into a gel and help to prevent spillage. Sachets of superabsorbent polymer may also be added to reusable urinals.

- Use of a urinal is not always free from leakage and provision of absorbent chair or bedpads to protect bedding, clothes and furniture (particularly when testing out urinals) may be necessary.

- The limited range of urinal options in acute settings, where often only bedpans are available, has been criticised and the process of introducing hand-held urinals to hospital services has been described and recommended [30].

- When used by one individual in the home, urinals can be cleaned with soap and water between uses. But where urinals are shared (i.e. cleaned and used by others), or if a library of urinals is used then robust methods are necessary. Some urinals can be cleaned in a bedpan washer but cleaning methods vary with different designs and materials and compliance with local infection control procedures will be needed.

4. RECOMMENDATIONS

- There is a wide range of female urinals and experimentation is likely to be necessary to identify the best one for an individual (dependent on their individual needs and abilities).

- A library of female urinals (used with robust cleaning methods) will help to facilitate experimentation (Grade of Recommendation B).

- Male urinals are less varied than female urinals, but may be supplemented by use of less conventional receptacles (e.g. jugs, home-made devices); experimentation will help to identify best options.

- Section IV.3 addresses other more general recommendations regarding urinal use.

5. PRIORITIES FOR RESEARCH

- Further development of female urinals is encouraged, particularly for supine users and those unable to move to the edge of a chair.

- The range of male and travel urinals need to be evaluated to provide guidance for users and carers.

V. COMMODES AND BEDPANS

Toilets can be difficult to use by people with mobility problems and other disabilities. Toilet adaptations such as raised toilet seats, padded seats, and grab rails can be very helpful in enabling individuals to access the toilet easily and comfortably. Bottom wipers and bidets can also be useful. However, if access to the toilet is impossible, commodes and other toileting receptacles should be considered.

Commodes are devices that comprise a frame supporting a toilet seat with a pan (disposable or washable) beneath to receive urine and faeces. They are used independently of a toilet and may be static or mobile. Mostly, they are used by people with reduced mobility who find it difficult to access a conventional toilet. Bedpans are portable receptacles that may be used for passing urine or faeces while in bed or chair. Some female urinals (see Section IV) may also be used to collect faeces.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding commodes and bedpans begin with appropriate indications for their use since Matsumoto and Inoue [31] reported that incontinent elderly persons or their caregivers misunderstand indications of commode use for incontinence. Other patient assessment elements include: a) physical characteristics of the person with incontinence (e.g. can an obese person fit on a commode and use its handrails?); b) mental acuity (e.g. will a person with dementia recognize a commode or bedpan as a device to be used for defecation?); c) need for supervision or foot supports whilst on the commode (what is the risk of falling?); d) mobility (e.g. does the person need a commode or bedpan?), ability to transfer and method of transfer to the commode (e.g. hoist, carer help, independent with transfer board), need for static or mobile commode (particularly when considering using commode over a toilet), postural stability and need for supportive commode, e) level of assistance needed and physical burden to caregiver involved; and f) personal preferences (e.g. comfort of bedpan type) including need for ‘non-commode-like’ appearance (e.g., particularly when used in own room, particularly the living room). Patient assessment findings need to be evaluated in terms of the safety and stability properties of a commode. The proximity of the area for waste disposal, storage facilities (i.e., the location / visibility of the commode in the household), the availability of privacy during defaecation, and length of time likely to remain on the commode (is there a need for a pressure-relieving commode cushion?), are additional factors to be considered.
Commodes (or better still toilets) are preferable to bedpans (which are relatively difficult to use and do not permit appropriate posture for passing urine/faeces). Bedpans are generally reserved for people who are confined to bed (e.g. post-operatively) and for whom safety (risk of falling) is an important assessment issue.

1. RESULTS

Fader [32] has reviewed the little work that has been done to evaluate existing commodes and bedpans and to identify the needs of users. An investigation of commode design by Nazarko [33] highlighted the problem of commodes providing poor trunk support for elderly and disabled people. Prolonged periods of sitting alone (for privacy) to enable defecation resulted in a risk of falls. Nazarko worked with a manufacturer to produce a design specification for a commode. Consultation with patients indicated that many would prefer to use a toilet. As a consequence, attention was focused in designing a shower chair which could also be used as a commode or could be wheeled over a toilet.

An evaluation of the four main types of commodes (standard; with adjustable height; with removable / drop-down arm; with adjustable height and removable / drop-down arm combination) was published by the UK Medical Devices Agency [34]. One third of the 150 commodes on the UK market at the time were found to have backwards instability, and most of them scored poorly for aesthetics and comfort. A discussion of the results of this evaluation and its application to nursing was subsequently published by Ballinger et al. [35].

The maintenance of hospital commodes can be a problem and Gillan [36] complained about the poor condition of commodes in wards for elderly people. Dassut [37] has recommended a commode cleaning and identification system, to help overcome this problem.

Naylor & Mulley [38] investigated the use of commodes in community-dwelling patients and the attitude of carers and users towards them (115 subjects and 105 carers). The main reasons for commode use were impaired mobility, difficulty climbing stairs and urinary incontinence. Main concerns were lack of privacy and embarrassment about using the commode, unpleasant smells and the poor physical appearance of the commode. Carers tended to view them negatively, particularly with regard to cleaning. Where commodes were used for defecation in a living area the authors highlighted the problem of odour that lingered even after a commode had been emptied, and recommended the use of a chemical toilet.

Thorough cleaning of commodes or bedpans after every use is necessary for hygienic purposes and to eliminate odours. Naylor & Mulley [38] report that typically a caregiver rather than the commode user empties and cleans a commode. No recommendations for cleaning a home commode or bedpan were found in the published literature. In institutional settings, large sinks with spray hoses or special sanitizing equipment are available. The size and shape of a bedpan or commode receptacle may be difficult to fit under a standard sink basin in the home. Whether certain commode cleaning products reduce any residual odour more than others is not known. Toilet bowl cleaning products are suitable for cleaning a commode or bedpan; many contain bleach or antibacterial ingredients but their effect on reducing odour of commodes or bedpans has not been studied. Gel formulations are advertised by manufacturers as being better able to cling to hard-to-reach surfaces than liquid agents. Use of a deodorizer can be considered (Level of evidence 4).

Nelson and colleagues [39] surveyed 147 spinal cord injured patients regarding their satisfaction and safety with the shower chairs (used for bowel care) used in the home. They found that around a half of patients were dissatisfied with their chairs and concerns expressed related to lack of hand access to the perianal area, difficulty in turning and rolling the chair and problems with keeping the chair clean. One third of patients experienced chair related falls and nearly a quarter reported pressure ulcers. Two-thirds of subjects felt that their safety was compromised.

The same group of researchers evaluated three shower chairs using video-taping, photography and questionnaires and produced performance criteria for the design of an optimal shower chair [40]. Pressure mapping devices were used to measure seat pressures on three subjects who tested all three bowel / shower chairs to inform seat design [41].

These researchers [42] then set about designing a more advanced commode-shower chair. It had lockable, swing-away armrests and lever activated brakes to facilitate transfers. To prevent pressure ulcers a chair frame and padding combination was designed to facilitate a seating position that distributed body weight and reduced pressure on pressure points. Cupped edgeless footrests were designed to reduce the risk of heel ulcers. An adapted version of this chair is now commercially available in the USA.

Matsumoto and Inoue [31] examined whether use of a commode in the home might prevent or delay nursing home admission of elderly people who were incontinent. A five-year follow-up of multiple predictors of institutionalization in elderly people in a rural town in Japan showed that 40% of incontinent men and only 17% of incontinent women used a commode. Use of a commode was not associated with institutionalization. The authors suggested several possible reasons: misunderstanding of appropriate indications for a commode based on the type of incontinence; physical
burden in assisting a care recipient to use a commode that seemed no different than for cleansing after an incontinence episode; and inadequate muscle strength of the elderly for using either a Japanese-style or Western commode.

Bedpans and other portable receptacles are not well described in the literature. Wells and Brink [43] describe three general shapes of bedpans: concave, cutaway, and shovel. The concave pan has a rounded triangle shape that slopes back to front and a curved seat. The cutaway has a rounded triangle shape with a flatter seat and rolled edges that allow for handgripping. The shovel shape, commonly called a “fracture pan” is a wedge or rectangle shape that has a flattened end that goes under the individual and a handle at the distal end. Generally bedpans are considered to be unsuitable for defecation for safety and acceptability reasons. However, for individuals with specific needs (e.g. frequency and urgency of defecation) a portable receptacle may be beneficial. Although many portable urinals are now available for both men and women, very few are recommended for defecation [44] and they have yet to be formally evaluated.

Privacy and dignity need to be given high priority when patients need to use a bedpan or commode, in particular in institutional settings. Care needs to be taken when transporting patients on a shower chair to maintain dignity and avoid revealing the patient’s bottom.

Bottom wiping and cleaning can be difficult for people with disabilities, particularly manual dexterity problems, or caregivers. Simple moist wipes may be helpful and are widely available. Devices designed to assist with bottom wiping problems are on the market and portable bidets are also available, however there are no published trials of these products. Bedpans have other disadvantages including difficulty removing the bedpan from under an individual without spilling (particularly if the individual is obese), risk of spilling and odour when transporting the contents for disposal since none have lids, and lack of privacy during use.

2. SUMMARY
• There are major defects in most of the current designs of commodes, especially: poor aesthetics; poor trunk support; instability (i.e. a tendency to tip over easily); poor comfort; difficult to clean; poor pressure relief (Level of Evidence 3).
• If direct transfer to a toilet is impossible or unsafe a sani-chair / shower chair is usually preferable to a commode (Level of Evidence 3).
• The main concerns of users about commodes and bedpans are: lack of privacy; embarrassment over use; odour; poor aesthetics; poor perineal cleansing accessibility; and inadequate facilities for cleaning the devices in the home (Level of Evidence 2).
• Defaecation on a bedpan or other portable receptacle presents problems of safety and unacceptability to users (Level of Evidence 2).

3. RECOMMENDATIONS
• If at all possible, access to a toilet should be made available for defaecation (Grade of Recommendation C).
• If direct transfer to a toilet is impossible or unsafe, a sani-chair / shower chair should be offered in preference to a commode wherever possible (Grade of Recommendation C).
• If a commode is used, care should be taken to ensure good trunk support; that the chair is stable; and that methods of reducing noise and odour are offered (Grade of Recommendation C).
• With commodes and sani-chairs / shower chairs, the user’s bottom should never be visible to others and transportation to the toilet and use of the toilet or commode should be carried out with due regard to privacy and dignity (Grade of Recommendation C).
• Bedpans and other portable receptacles should be avoided for defaecation purposes (Grade of Recommendation C).
• Patients vulnerable to pressure ulcers should not sit on a commode / sani-chair / shower chair for prolonged periods (Grade of Recommendation C).
• The person should be given a direct method of calling for assistance when left on the toilet / commode / sani-chair / shower chair (Grade of Recommendation C).
• Cleaning of bedpans and commodes should be carried out after each use following local infection control policies (in institutional settings) (Grade of Recommendation C).
• For individual’s at home there are no published guidelines regarding frequency of cleaning or type of cleaning product. However, thorough cleaning after bowel evacuation (to avoid odour and maintain aesthetics) is important, together with rinsing after urine has been passed. Cleaning needs may vary according to personal hygiene standards and offensiveness of urine/ faecal smells (Grade of Recommendation C).

4. PRIORITIES FOR RESEARCH
• Studies are needed to determine how to make toilets accessible to as many users as possible. These may lead to improved designs for toilets and associated equipment and / or strategies for toileting.
• Studies are needed to determine which commode / sani-chair / shower chair designs best meet performance and safety requirements.
• Development of better commodes designed to overcome the limitations identified.
VI. ABSORBENT PRODUCTS

1. INTRODUCTION

Absorbent products (commonly known as pads) are available in a wide range of sizes and absorbencies encompassing light through to very heavy incontinence. Most pads are bodyworn but some are used on the bed or chair (underpads, see Section VI.2); in this section the term ‘pad’ refers to bodyworn absorbent products. Broadly speaking, absorbent products can be divided into two main sub-groups: those suitable for light incontinence (usually smaller products) and those suitable for moderate-heavy incontinence (usually larger products). Manufacturers generally indicate the severity of incontinence that each product is designed to accommodate, but see the discussion in Section VI.4. Although absorbent pads are most commonly used for urinary incontinence they are also used by individuals for both faecal and urinary / faecal incontinence; however, there have been no published studies which specifically address this issue.

Incidental findings from evaluations of products indicate that absorption capacity alone does not determine whether a user will choose to use a product. Some users may have frequent, low flow-rate loss of small volumes of urine (“dribble”), whilst others may be dry for days but then have a higher volume, higher flow-rate incontinence incident (“gush” or “flooding”). Both may prefer to use pads for light incontinence. Mobile and independent community-dwelling women of all levels of incontinence are reported to generally prefer small pads and are often willing to change them frequently rather than use larger products and change them less often [45]. Conversely, dependent, immobile individuals may prefer the security of larger products despite relatively low urine volumes due to their dependence on others for pad changing.

Studies that have collected and weighed used pads to measure urine volume have found overlap between the quantities contained by pads from different sub-groups; thus in a study of insert pads for moderate-heavy incontinence used by older people in residential care around 15% of insert pads for moderate-heavy incontinence contained less than 100g of urine [46] and in a study of older women with light incontinence living in the community about 10% of insert pads for light incontinence were found to contain more than 100g of urine [47].

It is possible that a proportion of patients are simply provided with inappropriate products that exceed or fall short of the absorption capacity they require. One study investigated this issue [48] and found that patients were more satisfied with their products once their urine loss had been determined by pad weighing and appropriately absorbent products were provided. But many of these patients were using inadequate products to start with (such as pads comprising tissue paper) and firm conclusions could not be drawn. In practice, it is probably hard to justify the need for pad weighing to determine which absorbents should be provided and if there is doubt about which group a patient falls into then the patient should be offered small pads for light incontinence in the first instance and the size of pad titrated upwards as necessary.

General guidelines on patient assessment for product selection are discussed in Section II.

Aspects of assessment that are particularly important regarding absorbent pads are frequency / severity of leakage, day / night incontinence, gender (some products are designed for or are better for men / women than others), ability to change pad independently / need for carer, pad changing position (standing / lying), laundry / drying facilities, individual priorities (e.g. need for discreetness), personal preference for design / materials (washable / disposable), lifestyle (at home / travel / work etc).

Aspects of absorbent pad performance have been identified and prioritised (during interviews) by men and women taking part in a series of clinical trials of such products [20]. There was considerable consistency across patient groups (light / heavy, men / women) with the ability of a product to hold urine without leakage being the top priority, and the following aspects also being considered to be of high priority: discreetness, containment of smell, ability to stay in place, comfort when wet and ability to keep skin dry.

2. ABSORBENT PRODUCT CATEGORIES

Absorbent products may be classified into two broad categories - disposable (single-use) and washable (reusable) - with each category dividing into two sub-categories: bodyworn products (worn on the person) or underpads (placed under the person). Within each sub-category are different design groups such as diapers and pull-ups which are sub-divided by size (to fit users of different sizes) and / or absorbency (to cater for different severities of incontinence). Some designs are further subdivided into those intended for men, women or children. This classification is shown in Table VI-1.

- **Bodyworn** absorbent products can be divided into four main design groups:
  - **Inserts** (sometimes called liners or, in the case of small pads, shields) are held in place by close-fitting underwear or stretch mesh briefs (Fig VI-1). Some patients experience problems with keeping pads in place using the commonly supplied net pants. As a result, many use more robust stretch pants purchased privately (i.e. cotton / Lycra, etc). Many disposable inserts (Fig VI-2 and Fig VI-3) have an adhesive strip on the back to help secure them and may have an indicator that changes colour when the pad is wet to...
Figure VI-1: Mesh pants with (right) and without (left) legs, for securing incontinence pads in position.

Figure VI-2: Disposable inserts for light incontinence.

Figure VI-3: Disposable inserts with (right) and without (left) standing gathers, for moderate / heavy incontinence.
signal the need for a change. They may have longitudinal, elasticated standing gathers of hydrophobic material intended to impede lateral leakage of urine and faeces. They are sometimes rectangular but are more usually shaped to fit the body more snugly. Elastication at the legs may also be used to enhance fit. Washable inserts (Fig VI-4) are usually more simply designed than disposable inserts, with no elastication and are either shaped or a simple rectangle. Inserts are made in a wide range of sizes suitable for light through to very heavy urinary incontinence. For light faecal incontinence, the liner may be a small cotton gauze dressing placed against the anus and held in place by the cheeks of the buttocks (Fig VI-5).

- **Diapers** (sometimes called all-in-ones or briefs) are adult-size versions of babies’ diapers. Disposable diapers (Figs VI-6) usually have elasticated waist and legs and self-adhesive tabs (usually resealable), and often a wetness indicator and standing gathers. More recently modified diapers have been introduced that fasten round the waist before the front is pulled up pant and is either limited to the crotch area or as well as the designs described above. In particular terry-towelling squares may be used by those with heavy incontinence. These may be formed into briefs by folding into different configurations and fastening with pins and covered with plastic pants as a waterproof barrier. It is known that superabsorbers hold much more urine – weight for weight – than fluff pulp and retain it far more tenaciously under pressure. They are usually based on cross-linked salts of polyacrylic acid whose chemistry can be varied according to the balance of properties such as absorption capacity and absorption speed desired. Some thermoplastic fibres are also sometimes included in absorbent cores to reduce core break up and the collapse of the structure when wet. It is increasingly common for absorbent cores to comprise

two or more layers, each designed to perform a different function. For example, an upper layer might comprise low absorbency fibres engineered to receive and distribute urine efficiently and maintain a dry layer next to the skin, while lower layers provide absorption capacity. Some disposable products have ‘breathable’ plastic backings designed to reduce skin occlusion.

Washable absorbent cores are usually made from a needlefelt or knitted fabric comprising rayon and / or polyester fibres. A variety of polymers are used for the water-proofing. In general, the thicker, stiffer materials are more durable (the durability of the plastic backing often determines the lifetime of the product) but less comfortable. Topsheets are usually made from either cotton – which is hydrophilic and intended to have good dry comfort – or polyester – which is hydrophobic and intended to have good wet comfort.

Concern for the environment and also for controlling costs has led to an increase in the number of washable products available on the market. An important consideration in the comparison of washable and disposable designs is the relative environmental cost, particularly disposal (landfill) costs of disposable designs and energy costs associated with laundering the washables. A recent report on baby diapers concluded that there was no significant difference in environmental impact between three diaper systems

This means that, like pad performance, users' needs cannot be easily quantified. However, a number of studies have been published on work with pad users described as having moderate-heavy urinary incontinence have yielded corresponding figures of about 250ml and 600ml [51]. Accordingly, in this chapter the material is divided – somewhat simplistically – into that which relates to light incontinence and that which relates to moderate-heavy.

But the published work also makes it clear that some products work better for users whose incontinence is towards the lighter or the heavier end of the spectrum within each of these two groups and so, where necessary in the text and tables that follow, these distinctions are made by dividing light incontinence into “light LIGHT” and “heavy LIGHT”; and moderate-heavy incontinence into “light HEAVY” and heavy HEAVY”.

5. ABSORBENT PRODUCTS FOR WOMEN WITH LIGHT URINARY INCONTINENCE

There are four main product designs for women with light incontinence (Table VI-2). In addition menstrual pads are known to be frequently used for light urinary incontinence. The disposable pull-up group are relatively expensive, single-use items and are seldom used for light incontinence except as ‘emergency’ items. Underpads are not commonly used for light incontinence.

Aspects of assessment that are particularly important regarding pads for women with light incontinence include frequency / severity of leakage, day / night incontinence, individual priorities (e.g. need for discreetness), personal preference for washables / disposables, lifestyle (home / travel / work).

a) Quality of data

A small number of robust comparative evaluations of absorbent pads for lightly incontinent women have been published and there has been a Cochrane review [52]. A recent study has compared the most common designs: disposable inserts, menstrual pads, washable
inserts and washable pants with integral pad. One study has compared a range of disposable inserts and menstrual pads and there have been comprehensive single group studies of disposable inserts and washable pants with integral pads. A further study has compared specially made experimental products that have differed from one another in carefully controlled ways enabling more specific questions about product materials and design to be addressed.

b) Results

Using a crossover design, Fader et al [51] compared disposable inserts, menstrual pads, washable pants with integral pad, and washable inserts. Three products were selected (based on previous study results) to represent each design and each product was tested for one week (three weeks for each design block, total 12 weeks). Order was randomised. Product performance was characterised using a validated questionnaire to evaluate pad performance (leakage, discreetness etc) with a five point scale (very good – very poor) at the end of each week of product testing.

A pad change and leakage diary was used to record severity of leakage from pads (three-point scale: a lot, a little, or no leakage), and numbers of laundry items and pads used were recorded to estimate costs. Skin health changes were recorded weekly. At a final interview preferences were ranked (with and without costs), acceptability of the design recorded (highly acceptable – totally unacceptable) and overall opinion marked on a visual analogue scale (VAS) of 0-100 points (worst design – best design). This VAS score was used to estimate cost-effectiveness.

Eighty-five women (mean age 60) completed the study and 8691 used pads were weighed. The disposable insert was significantly better than the other designs on most variables except for discreetness. For leakage prevention, overall acceptability and preference, disposable inserts were found to be significantly better than menstrual pads, which were better than washable pants with integral pad, which were better than washable inserts. There was no clear benefit for skin health using either washable or disposable designs. Most women preferred the disposable insert pad but some preferred the other cheaper designs (6/85 preferred menstrual pads; 13/85 preferred washable pants), both of which were >50% cheaper to use than disposable inserts. Washable inserts were significantly worse than the other designs (72/85 found them unacceptable). Overall there were generally more practical problems with washables, particularly when away from the home (Level of Evidence 1).

The authors concluded that allowing women to choose their preferred design of absorbent product (or combination of different designs for different circumstances) would be more cost-effective and provide better patient satisfaction than provision of disposable insert pads (the most expensive product) alone.

Clarke-O’Neill et al. [19] compared the range (12 products) of disposable inserts for lightly incontinent women available in the UK in 2000. Products were tested by 60 community-based women aged 50 years or older who currently used products similar to those to be evaluated. Products were evaluated using a pad performance questionnaire and a pad leakage diary. As a group, the products performed well in terms of their ability to hold urine without leakage. However, the ‘overall opinion’ scores of the testers showed large differences between products with 88% of subjects scoring the most successful insert as Good or OK compared with 51% for the least successful product (p<0.001) (Level of Evidence 2).

A similar study by the same research group [53] compared all 10 washable pants with integral pad for lightly incontinent women available in the UK in 1999. Seventy-two community-based women who usually used absorbent products for light incontinence tested each product for one week each. Leakage performance was found to be disappointing with 69% (CI: 59-78) of the best performing product not leaking at all with 10g of urine, compared to 40% (CI: 29-51) for the least successful product. Again subjects’ ‘overall opinion’ scores showed wide differences between products with the best performing product scoring 85% Good or OK compared with 34% for the least successful product (Level of Evidence 2).

Baker and Norton [54] evaluated six small disposable inserts and two menstrual pads (available in the USA in 1991) with 65 community dwelling women. The products were rated using an evaluation questionnaire and daily diary of pad use. The two menstrual pads (which were the least expensive pads in the study)
scored significantly higher than many of the incontinence products although neither was the most popular pad. The authors concluded that women should try a ‘maxi’ menstrual pad first and then move onto a higher capacity (incontinence) pad if this was inadequate. However, this study was carried out more than 10 years ago and products have changed considerably since then (Level of Evidence 2).

Thornburn et al. [17] studied ‘wet comfort’ using small disposable pads that had been experimentally made using different combinations of materials in an attempt to reduce ‘wetback’ (the tendency of pads to allow urine to escape back on to the wearer’s skin). Twenty women tested the pads. Whenever differences in wet comfort, absorbency or overall performance were found they were in the expected order but differences were small and few reached statistical significance. The clinical value of including technically superior materials was not strongly supported. However this was a small study and may have had insufficient power to detect significant differences (Level of Evidence 2).

c) Summary

There is robust evidence that disposable inserts are more effective in terms of leakage and more acceptable than menstrual pads, washable pants and washable inserts (Level of Evidence 1). Menstrual pads are cheaper and washable pants cheaper still (on a per-use basis) and are acceptable to many, particularly those with lighter incontinence and particularly when used at home. Washable inserts are not acceptable to most women. The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Fig VI-16.

d) Recommendations

- Disposable inserts are recommended as the most effective and preferred absorbent product for women with light incontinence (Grade of Recommendation B).
- Menstrual pads or washable pants may be sufficient for some patients with very light incontinence and are cheaper (Grade of Recommendation B).
- Washable inserts are not recommended (Grade of Recommendation B).
- Combinations of designs for different situations (e.g. disposable inserts for going out, washable pants with integral pad for staying at home) are likely to provide optimum management in terms of patient needs and cost-effectiveness, and product advice and provision (where purchased by institutions / services) should reflect this (Grade of Recommendation B).
- See also the general recommendations relating to pad selection in Section VI.11 and to washable pads in Section VI.12.

e) Research priorities

- Because the performance of washables was generally poor (particularly for leakage) compared to disposables, the development of better washable products is a priority.
- The use of combinations of designs for different situations needs to be evaluated.

6. ABSORBENT PRODUCTS FOR MEN WITH LIGHT URINARY INCONTINENCE

There are five main product designs for men with light urinary incontinence (Table VI-4). However, disposable and washable insert pads are often unappealing to men as they are frequently marketed specifically at women and bear a strong resemblance to menstrual pads. Anatomical differences are also likely to mean that they are less effective for men. Pouch, shield and leaf products (Figs VI-12 and VI-13) are designed to be more suitable for men by containing the penis or penis and scrotum.

Aspects of assessment that are particularly important regarding pads for men with light incontinence include frequency / severity of leakage, day / night incontinence, retraction of penis, individual priorities (e.g. need for discreetness), personal preference for washables / disposables, and lifestyle (home / travel / work).

Only one study has been published which has evaluated absorbent products for men with light urinary incontinence (55). It compared the four main absorbent designs of products available in the UK in 2003:

disposable insert pads, pouches and leaves and washable pants with integral pad. All six leaf products (five disposable and one washable) and all six pouches (all disposable) on the UK market in 2003 were evaluated, together with a selected disposable insert pad and a selected washable pant with integral pouch (chosen to represent their respective designs).

Seventy men with light urinary incontinence completed the 14 week study and filled out product performance questionnaires at the end of testing each product for a week. Products were supplied in random order within their design group and the design group order was also randomised. Pad leakage diaries were used to record product performance and used pad weight. At the end of testing each design a design performance questionnaire was completed.

‘Overall opinion’ was used as the primary outcome variable. Results showed that the pouch design performed significantly worse than the leaf and the insert design. The most common problems with the pouch were staying in place and difficulties re-inserting the penis in the pouch once the pouch was wet. The leaf designs had the best leakage scores, but one product was significantly better than the other leaves (Tena). The disposable insert was also effective for leakage prevention and was substantially cheaper than the leaf designs. The washable leaf was the least successful of the leaf designs. The washable pants with integral pad received polarised overall opinion scores (loved or hated) and scored well for staying place but poorly for leakage (Level of evidence 2). The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Fig VI-17.

a) Recommendations

- Disposable leafs are recommended as the most acceptable and effective design for men with light incontinence, but some men prefer other designs which should be considered as alternatives (Grade of Recommendation B).
- Simple insert pads are cheaper and may be acceptable to some men (Grade of Recommendation B).
- Washable pants with integral pad are likely to be most suitable for men with very light incontinence who have difficulties keeping an insert or pouch in place (Grade of Recommendation B).
- See also the general recommendations relating to pad selection in Section 6.11 and to washable pads in Section VI.12.

b) Research priorities

Because the performance of washables was generally poor (particularly for leakage) compared to disposables, the development of better washable products is a priority.

7. ABSORBENT PRODUCTS FOR MEN AND WOMEN WITH MODERATE-HEAVY URINARY INCONTINENCE

There are 12 absorbent product designs for men and women with moderate-heavy urinary incontinence (Table VI-5). The most commonly used products are disposable bodyworn inserts and diapers (Figs VI-3 and VI-6). More recently, modified diapers (T-shaped diapers, Fig VI-7) have been introduced which can be applied by the wearer whilst standing. Pull-ups are also a relatively new innovation and comprise an absorbent pad integrated into a disposable elasticated pant (Fig VI-9). Washable counterparts to most disposable bodyworn designs are available but they have a much smaller market, where they are available. They are made from a variety of natural and synthetic materials. Disposable and washable bedpads are used on the bed at night with or without the support of a bodyworn product. Disposable and washable chairpads are used either without a bodyworn product (in which case the individual must sit directly on the pad with no underpant on) or in combination with bodyworn products to protect chairs from any leakage from the bodyworn. Both practices place an underpad on display and mark the individual as being incontinent and are therefore to be discouraged. Aspects of assessment that are particularly important regarding absorbent pads for moderate / heavy UI are frequency / severity of leakage, day / night incontinence, gender (some products are better for men/women than others), ability to change pad independently / need for carer, pad changing position (standing / lying), laundry / drying facilities, individual priorities (e.g. need for discreetness), personal preference for design / materials (washable / disposable) and lifestyle (at home / travel / work etc).

a) Quality of data

There have been two recent clinical trials comparing the main designs of disposable bodyworn pads (one also included washable designs). There have been no trials of underpads for the last 15 years. There have also been a large number of comparative studies of absorbent products for moderate-heavy incontinence but most are more than 10 years old and evaluated products that are no longer available. Furthermore, changes in materials and design features mean that it is impossible to generalise any particular findings to products of today. Brink (56) identified 30 studies of absorbent products published between 1965-1990. Some robust multi-centre international studies have examined the correlation between laboratory testing and the leakage performance of products clinically.

b) Results

1. Evaluations comparing different designs of disposable and / or washable body worn absorbent products for urinary incontinence

Fader et al. [51] carried out two clinical trials of absorbent products for moderate-heavy incontinence; one involving subjects in the community and the other subjects in nursing homes. In the community-based trial 85 moderate / heavily incontinent adults (urinary or urinary / faecal) living in their own homes (49 men and 36 women) were enrolled, and tested three (or two) products from each of five design categories (total of 14 test products): disposable inserts (with mesh pants); disposable diapers; disposable pull-ups; disposable T-shape diapers; and washable diapers. All products were provided in a daytime and a (mostly more absorbent) night-time variant. Products were selected based on having similar scores for absorbency across the designs (Rothwell scores, (50) see below) and performance data from pilot studies. In the nursing-home-based trial 100 moderate / heavily incontinent adults (urinary or urinary / faecal) living in a total of 10 nursing homes (27 men and 73 women) evaluated one product from each of the four disposable design categories above. Products were selected on the basis of product performance from the community-based trial and, again, day and night-time variants were provided.

Product performance was characterised using validated questionnaires which asked the participants (in the community-based trial) or carers (in the nursing home based trial) to evaluate various aspects of pad performance (leakage, ease of putting on, discreetness etc) using a five point scale (very good – very poor) at the end of the week (or two weeks for the nursing-home-based trial) of product testing. In addition, participants / carers were asked to save individual used pads in bags for weighing and to indicate the severity of any leakage from them on a three-point scale (none, a little, a lot). These data were used to determine differences in leakage performance. Numbers of laundry items and pads used were recorded to estimate costs, and skin health changes were recorded by the participant or by the researchers. At the end of testing participants were interviewed and ranked their preferences (with and without costs), stated the acceptability of the design (highly acceptable – totally unacceptable) and recorded their overall opinion on a visual analogues scale (VAS) of 0-100 points (worst design – best design). A pad changing experiment was conducted with 12 women from the nursing home based trial to determine any differences between product designs. Under idealised conditions the different designs were applied (by the same carers) in random order for each patient and the speed of pad changing was timed using a stop-watch.

Findings from the community-based and nursing home trials were broadly similar. The leakage performance for the disposable inserts was worse than the other designs for day and night and disposable pull-ups were preferred over inserts for the daytime. The new T-shape diaper was not better overall than the traditional disposable diaper. But there were important differences in performance and preference findings between men and women from both trials and the men (in the community) had more severe urinary incontinence than the women - mean daytime urine mass 375 g for men and 215.g for women (difference148g, CI: 79.8, 217.7).

Pull-ups (the most expensive design) were better overall than the other designs for women during the day and for community-dwelling women during the night too. Although disposable diapers were better for leakage than disposable inserts (the cheapest), women did not prefer them, but for men (in the nursing homes and the community) the diapers were better both overall and for leakage and were the most cost-effective design. No firm conclusions could be drawn about the performance of designs for faecal incontinence and there was no firm evidence that there were differences in skin health problems between designs (Level of Evidence 1).

In the nursing home trial the carers found pull-ups and inserts significantly easier to apply (in the standing position) and significantly quicker in the pad change experiment (mean time 35.2 and 37.9 seconds for inserts and pull-ups respectively and 53.2 and 62 seconds for diapers and T-shaped diapers respectively) and ability to stand was associated with preference for pull-ups or inserts. Despite being designed for ease of changing the T-shape diaper was not found to be easier or quicker to change than the diaper.

The washable products (used in the community-based trial) gave diverse results. Two of the products were made from cotton terry-towelling (one a simple square, folded and pinned in a diaper shape; the other a shaped diaper-like design, both worn with plastic pants) while the third product had a felt absorbent core, with an integral plastic backing and was fixed by poppers. This third product performed significantly worse for leakage than the other two washables and was therefore excluded from the final data analysis. The terry-towelling washables were better for leakage at night than the other disposable designs, but were less popular overall for daytime use than the other disposable designs. Three quarters of the women (27/38) found them unacceptable, but nearly two thirds of men (31/49) found them highly acceptable at night.

Findings from the community-based trial showed that there were many practical problems dealing with washable products particularly when out of the house, but that they were more acceptable at home.

Macaulay et al, [21] carried out a pilot study of 19...
washable products with 14 community dwelling subjects. The products included a mixture of washable insert and brief designs and two disposable bodyworn products. Product performances varied widely: the most popular was rated as good (for overall performance) by 78% of testers, while the least popular scored 22%. Although most of the washable products performed poorly for leakage, one washable product made of cotton towelling (used with plastic pants), scored better than both the other washable and disposable products (Level of Evidence 3).

Seven older trials have compared disposable with washable bodyworn products for moderate-heavy incontinence [57-63]. The trials varied in size and design from a large controlled trial with 276 subjects [57] to a small trial of eleven subjects [60]. In addition some trials have compared disposable and washable bedpads and body-worns. Brown [23] [64] undertook a large trial of this kind. The fact that no systematic method of product selection was used for these studies limits the utility of the results since particularly good or poor products may have been selected to represent the disposable or washable groups.

Skin condition was used as an outcome measure in five of the above trials. However, only three used an experimental design and statistical methods of analysis. Beber [57] and Grant [58] both reported that they did not find statistically significant differences between their washable and disposable products in terms of an adverse change in skin condition. But Hu et al. [65] reported a statistically significant improvement in the skin condition of their disposable product users as compared to their users of washable products (See Section XIV).

Other parameters frequently investigated in these studies were staff preference, product leakage and laundry. Overall, the disposables in the studies were considered to have performed better than the washable products in terms of preventing leakage (often measured by quantity of laundry) and staff preference.

Four studies attempted to measure costs [58, 59, 64,66]. Of these, three used statistical methods of analysis. Hu et al. [66] and Brown [64] reported that although there were no statistically significantly differences in terms of per-day product costs of washable and disposable products, the laundry costs associated with the disposable product (ie for laundering soiled bed linen and clothes) were significantly lower than those associated with the washable product (ie for laundering the products as well as soiled bed linen and clothes). Brown [64] found no significant differences between daily costs of the washable and disposable products. However, statistically significant differences were found between the groups in terms of incontinence-related laundry, with the disposable group producing less laundry than the washable group. Grant [58] reported that the cost of washable products was significantly lower than that of disposables, but laundry costs were not taken into account. (see committee 22)

2. Disposable absorbent products for urinary incontinence: studies of single designs, laboratory tests and studies of materials

Clancy and Malone-Lee [67] compared versions of the same pad experimentally engineered to have different combinations of fluff pulp and topsheet materials. Forty-five heavily incontinent older adults participated. The main valuable finding from this study was that pads were more likely to leak if they were not held in place by pants (p<0.0001) and that, if there was any leakage from a pad, this tended to be less severe if the supplied mesh pants were worn than if normal pants were worn (p<0.05) (Level of Evidence 2). The mesh pants probably held pads more firmly to the body.

There have been two single design group studies of bodyworn products for moderate-heavy incontinence [68,69], both carried out in nursing homes. A study of shaped insert pads involved 228 subjects from 33 nursing / residential homes who tested 20 ranges of insert pads (74 products in total). A similar study of diapers involved 192 subjects from 37 nursing / residential homes who tested a total of 36 products. These studies showed the wide range of product performance that can exist within single product groups. For example, the least successful diaper (based on 'overall opinion') was found to be unacceptable to 100% of the test subjects while the most successful was unacceptable to only 6% (Level of Evidence 2).

In addition, there have been a number of studies on the impact of wet pads on skin health and these are reviewed in Section XIV.

Because clinical evaluations are expensive and time-consuming, laboratory evaluation procedures are in widespread use. Few have been clinically validated but there is a clinically-validated International Standard relating to the leakage performance of disposable bodyworn pads for moderate-heavily incontinent adults in institutions [50]. It describes a simple method for measuring the absorption capacity of pads in the laboratory that was shown to correlate well with the leakage performance of 18 different products evaluated in an international multi-centre clinical study involving 112 heavily incontinent adults [70] The strength of the correlation between technical and clinical data data depended on the exact parameters being compared, but typically r = 0.9 (Level of Evidence 2). This laboratory test (the Rothwell method) is now in common use in the UK, Sweden and other countries and provides a basis for selecting similar products with which to make direct comparisons (for cost purposes) or to select promising pads for inclusion in clinical trials.
The ability of ISO 11948-1 to predict the leakage performance of more recent bodyworn pads (138 diapers and inserts) for heavy incontinence was investigated by Cottenden et al. [71]. Correlations were poorer than in the original 1993 study (r<0.87 compared with r>0.95) but still strong enough to make the method useful. For a given Rothwell capacity, the leakage performance of diapers was far superior to inserts, but no evidence was found for any other design feature of the test products (inserts and diapers) having a significant impact on their leakage performance (Level of Evidence 2).

The repeatability and reproducibility of the ISO 11948-1 was investigated by Cottenden and co-workers [72] in three laboratories (UK, Spain and Sweden). Repeatability (precision between repeats in the same laboratory) was found to be very good with the coefficient of variation for five repeats rarely exceeding 5%. However, the reproducibility (precision between laboratories) was poorer, revealing systematic differences: results from the Swedish and Spanish laboratories typically exceeded those from the English laboratory by 13% and 8%, respectively. Efforts to identify the source(s) of this poor reproducibility have so far been unsuccessful but it seems likely that minor variations in interpretation of the standard when constructing the apparatus and/or executing the test are to blame (Level of Evidence 2).

c) Summary

Results from these studies indicate that there is no single best design (i.e. one design that is significantly better than all other designs for all users) (Level of Evidence 1). There is evidence that different designs are better for men and women, and that men leak substantially higher volumes of urine than women (Level of Evidence 1). Of the disposable designs, the more expensive pull-up and T-shaped diaper designs are not better overall than the cheaper diaper for men, indicating that the diaper is the most cost-effective design for men. For women pull-ups are better overall than the other designs (except for night-use in those living in nursing homes), but they are expensive (Level of Evidence 1). Unlike men, women in the community do not favour diapers over insert pads and of these cheaper designs, inserts may be preferred for women. There is also evidence that the leakage performance of inserts is worse than other designs, but that they leak significantly less if they are held in place by mesh pants than by ordinary pants, and using no pants at all is associated with significantly more leakage than if either kind of pant is worn (Level of Evidence 3). There is evidence that pads containing superabsorber leak less, are more comfortable, and keep the skin drier than those without (Level of Evidence 2). The leakage performance of inserts and diapers for heavy incontinence can be predicted with reasonable precision using an international standard laboratory tests (Level of evidence 2). This test has been shown to have very good repeatability and adequate reproducibility (Level of Evidence 2). Washable products are very varied in design and materials, and also in performance. There is evidence that terrycloth products (used with plastic pants) have good leakage performance, however they have limited acceptability - confined mainly to some men at night. There is no firm evidence regarding the performance of different designs for faecal incontinence and no firm evidence that any particular design or type of material (washable or disposable) is better or worse for skin health.

The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Fig VI-18.

d) Recommendations

- **Gender** should be considered when products are prescribed/purchased for users. As men often have substantially higher incontinent urine volumes than women, men may require more products and/or more absorbent products than women (Grade of Recommendation B).

- **Gender** should also be considered when products are prescribed/purchased for users because men and women are likely to prefer different designs. Men generally prefer disposable diapers to inserts (Grade of Recommendation B).

- Women generally prefer disposable pull-ups to other designs, but these are expensive. Disposable inserts are a cost-effective alternative (Grade of Recommendation B).

- **Caution** is recommended if washable designs are being considered. Heavy bulk confines their use mainly to the night-time (where they may be particularly useful for users who lie on their side). They are unacceptable for most people during the daytime and for most women at any time and for this reason a blanket policy of health services providing washables alone is not recommended. If washables are being considered refer to points below (Grades of Recommendation B).

- **Freedom from leakage**: Where possible, international standard laboratory tests should be used to rank the likely leakage performance of different pads for heavy and light incontinence (Grade of Recommendation B). In general, diapers should be selected in preference to inserts to minimise leakage (Grade of Recommendation B).

- **Carer application**: When products are applied by a carer to a patient who can stand for pad changing, disposable inserts or pull-ups are
Figure VI-18: Designs of pads for adults with moderate-heavy urinary incontinence. For definitions of light HEAVY and heavy HEAVY, see Section VI.4.
e) Research priorities

- Comparison of absorbent products (disposable and washable) when used by carer-dependent users in the community.
- Development of more effective and aesthetically acceptable washable products, particularly for night-time use and for women.
- Development of more effective and acceptable disposable designs specifically for men.

8. DISPOSABLE UNDERPADS

There have been no published studies examining the use of bedpads during the last 15 years. This probably reflects the recognition of their limited role in long-term management of incontinence. Disposable underpads on chairs declare their user to be incontinent and require clothes to be pulled up (or absent) which is unacceptable for dignity. In the bed disposable underpads easily become displaced, folded and creased under the patient which inhibits their performance and comfort, and may potentially be a threat to skin health. Large disposable underpads with wings to tuck into the bed may have a role as bed protection ‘back-up’ to bodyworn pads. The main role of disposable underpads should be confined to temporary bed or chair protection such as during clinical procedures (e.g. enemas) or when using a urinal.

Published trials comparing different disposable bedpads are few [23] [73,74] and it is not possible to draw firm conclusions from them on the effectiveness of different product design features and materials. Some useful work has been done to highlight the risks of infection from disposable bedpads and to validate clinically some laboratory tests to assist with product selection by predicting pad leakage performance.

Bedpads are generally supplied as non-sterile items and Bradbury [75] has drawn attention to the risk of infection, particularly from products containing recycled paper. Leigh and Petch [76] and Sprott et al. [77] have conducted microbiological tests on a range of products. Both studies identified low levels of bacterial contamination but concluded that the risk to patients was minimal unless they were immunocompromised in some way. More recently, Stansfield and Caudle [78] reported an outbreak of wound colonization on a surgical orthopaedic hospital ward which they attributed to the use of disposable underpads containing virgin wood pulp.

Due to the paucity of published clinical data many technical tests have been devised to evaluate products in the laboratory. The only tests with published clinical validations are described by Cottenden et al. [70] who subjected six different bedpads to a variety of laboratory tests and to a multi-centre clinical evaluation in which 95 incontinent subjects tested each product in turn for a week, in random order. A combination of two laboratory tests (one to measure the absorption capacity and the other the absorption time of bedpads) gave a strong correlation with the percentage of subjects finding the leakage performance of a product acceptable when used as their sole protection (r = 0.94) and predicted the acceptability scores of all six products accurate to within ± eight percentage points. A different absorption capacity test produced a strong correlation for the leakage performance of bedpads used as back-up to bodyworn products (r = 0.96) and predicted the acceptability scores of all six products to within ± five percentage points.

a) Summary

No robust data are available on the effectiveness of current disposable bedpads or of their various design features or constituent materials. There is a risk of infection from bedpads made from recycled paper for immunocompromised users (Level of evidence 2). The leakage performance of bedpads (used alone or as back up to bodyworn pads) can be predicted with reasonable precision using clinically-validated laboratory tests (Level of Evidence 2).

b) Recommendations

- Disposable underpads should not be used for long-term management of incontinence, but have a useful role as temporary protection for chairs and beds during clinical procedures (Grade of Recommendation C).
- Immunocompromised people should not use bedpads made from recycled paper because of the risk of infection (Grade of Recommendation B).
- Where possible, clinically-validated laboratory tests should be used to rank the likely leakage performance of different products (Grade of Recommendation B).
c) Research priorities

Disposable underpads have a limited role in continence management but are known to be widely used. An exploration of patient views regarding their use may help demonstrate their limitations.

9. WASHABLE UNDERPADS

Aspects of assessment that are particularly important regarding washable underpads are patient acceptability and preference, particularly with regard to willingness to be naked below the waist (if sole use intended) and availability of laundry and drying facilities.

Cottenden [79] has reviewed comparative evaluations of different washable bedpads up to about 1990. Leiby and Shanahan [80] have since published a study. Some evaluations have found significant differences between products relating, for example, to leakage performance and impact on skin health but none of the products evaluated is still available in the variant tested. In addition, compared products always differed from one another in many respects making it impossible to draw reliable generic conclusions relating to the products now available. However, the choice of topsheet material and the presence or absence of features like tuck-in flaps and integral water-proofing appear to be, primarily, matters of personal preference.

In institutional settings washable bedpads are commonly used by multiple patients and questions are often asked about the risk of cross-infection. Cottenden et al. [81] assessed the risk by determining the microbial content of 145 bedpads of five different designs after a night’s use by incontinent adults, followed by laundering using a standard foul wash procedure which included heat disinfection at 71°C for three minutes. Laundering destroyed all known pathogenic organisms, although some commensal flora were isolated in small numbers. It was concluded that foul wash laundry had left bedpads safe for multiple patient reuse with no demonstrable risk of cross-infection.

a) Summary

The literature contains insufficient robust data on which to base guidelines for choosing between washable bedpads. Choice of topsheet material and the presence/absence of design features like tuck-in flaps and integral/separate water-proof backing appear to be, primarily, matters of personal preference (Level of evidence 3). Provided an approved foul wash procedure is used, the risk of cross-infection between different users of a bedpads is very low (Level of Evidence 2).

b) Recommendations

- If considering using washable underpads for sole use (ie without a bodyworn product) the patient will need to be naked below the waist.

Patient consultation and approval will therefore be needed (Grade of Recommendation C).

- Personal preferences of users with regard to topsheet material, tuck-in flaps and integral waterproof backing should be considered in making product selections (Grade of Recommendation C).

- Provided an adequate foul laundry wash cycle is used, the risk of cross-infection between successive users of washable bedpads is low and not a contra-indication for their use (Grade of Recommendation B).

c) Research priorities

Comparison of washable underpads with bodyworn products when used at night.

10. ABSORBENT PADS FOR CHILDREN WITH URINARY AND / OR FAECAL INCONTINENCE

Most children are expected to achieve daytime dryness by the age of three [82]. However, some children take longer to become dry and some (e.g. children with learning and physical disabilities) may never reach this goal. These children usually require absorbent products to contain leakage. (see committee 9)

Aspects of assessment that are particularly important regarding bodyworn products for children are presence of faecal incontinence, day / night incontinence, level of independence with toileting, and use of aids (e.g. callipers).

To date there has been only one study of absorbent products for children and this has compared the diaper design with the newer pull-up design (83). Sixty-one children with physical and / or learning disabilities tested five diaper products and five pull-up products, each testing each product for one week. The children were randomised to receive either the pull-up or diaper group first and individual products were tested in random order within each design arm. Parents completed a product performance questionnaire and a pad leakage diary to record wet weights and severity of leakage. Parents were asked to state their preference for a design for day and night use.

Findings indicated that generally, the diaper products performed similarly to each and so did the pull-up products, although there were some statistically significant differences between products within each of the two design groups. Overall diapers were preferred for night-time use by the majority of parents. By contrast, 40% of parents preferred pull-ups for daytime use and these were found to be particularly appropriate for older children and those who were attempting independent toileting, provided they did not have faecal incontinence and did not wear callipers or adapted footwear. Diapers were more suitable for
children who were dependent on carers and / or had faecal incontinence, and wore callipers or adapted footwear. The authors recommended that both diapers and pull-ups should be supplied for children, with pull-ups (which are about 50% more expensive than diapers) being provided for selected children during the daytime.

a) **Summary and recommendations**

Diapers and pull-ups meet different needs of children and both should be made available to children with disabilities, dependent on assessment (Level of Evidence 3 / Grade of Recommendation C).

b) **Research priorities**

Comparison of washable and disposable bodyworn products.

11. **PADS FOR FAECAL INCONTINENCE**

Most absorbent products are designed for urinary incontinence. No studies comparing available absorbent products for faecal incontinence were found. Bliss et al. [84] reported preliminary findings of a survey of the use and evaluation and suggested modifications of absorbent products for faecal incontinence by 188 community-living persons with the problem. Forty-five percent of persons used an absorbent product for FI. Ninety-eight percent of those with UI and FI used the same type of product for both. Suggested improvements in product designs included having better odour control, fit, and ability to stay in place; a clearer distinction between the front and back of a pantiliner or pad; adding wings for greater absorbency; and making them flushable, cooler feeling, wider and longer in the rear and more absorbent but less bulky. For mild faecal incontinence, especially when faeces remain between the buttocks without soiling underwear, persons have used a small disposable gauze surgical dressing placed between the buttocks. This product was more acceptable than a pantiliner or pad to some men [84] (Level of Evidence 2).

a) **Recommendations**

- A disposable gauze dressing that can be placed between the buttocks maybe acceptable for men with light faecal incontinence (Level of Recommendation C).

b) **Research priorities**

- Better designs of products are needed for light and moderate FI (with and without UI).

12. **GENERAL RECOMMENDATIONS ON PAD SELECTION**

- **Individuality:** No study has ever identified one product that worked best for all testers: needs and priorities vary. Accordingly, users are advised to try a variety of products when possible (Grade of Recommendation B).

- **Brand differences:** The individual product brands within a design group often exhibit a wide range of performance and acceptability for individuals, and it cannot therefore be assumed that pads of different brands but broadly similar design will be equally acceptable or effective (Grade of Recommendation B).

- **Combinations of designs:** Absorbent products vary greatly in price and performance and suitability for individual needs. Users may therefore find combinations of designs preferable and cost-effective. For example, women might use pull-ups (expensive, but discreet and good for leakage) for going out, and inserts (cheap, less good for leakage) for staying at home. Men might use disposable diapers for daytime, and washable terry-towelling products for night-time (Grade of Recommendation B).

- **Freedom from leakage:** In general, pads containing superabsorber should be selected in preference to those without (Grade of Recommendation B). Nobody wants their pad to leak but compromises have to be made: the pad needed to contain a person’s most severe accident may be substantially more bulky and expensive than is needed most of the time. Some users choose to tolerate a higher risk of pad leakage in exchange for being able to use cheaper, smaller (more discrete) pads. The balance of priorities for a given user should be investigated in making product selections (Grade of Recommendation C).

- **Comfort and skin health:** In general, pads containing superabsorber should be selected in preference to those without (Grade of Recommendation B). Shaped pads should usually be selected in preference to unshaped (Grade of Recommendation C).

- **Staying in place:** No product is effective if it slips from position. Inserts should be used with pants, preferably mesh pants (Grade of Recommendation B). Robust, stretch (e.g. cotton / lycra) pants may also help to provide a snug fit and minimise leakage. Shaped pads are preferable to rectangular (Grade of Recommendation C).

- **Ease of putting on and taking off:** The ease of putting pads on and taking them off should be considered, especially for caregivers and for incontinent users with reduced mobility or dexterity (Grade of Recommendation C).
13. RECOMMENDATIONS RELATING TO WASHABLE PADS

- **Laundry issues:** Access to good, reliable washing and drying facilities should be checked before washable products are introduced (Grade of Recommendation B). Laundry – especially of bedpads – can be heavy work, beyond the capability of frail incontinent people or their caregivers. The number of washable products needed per user depends on laundry turn-around times. Drying times for washables can be long and expensive, especially for bodyworns for heavy incontinence and for bedpads.

- **Personal preferences:** Personal preferences (of both users and caregivers) with regard to choosing between washable and disposable products should be taken into account carefully (Grade of Recommendation C). Some users prefer the chore of laundering washables to anxiety over whether their next consignment of disposables will be delivered on time. Washables generally require less storage space than disposables. Discreet disposal of disposables can be a challenge. The possibility of using a mix of disposable and washable products should be considered (Grade of Recommendation C).

- **Aesthetics and discretion:** A possible preference for small, more discrete pads (even if they are more likely to leak) should be considered, especially for those wishing to wear close fitting clothing (Grade of Recommendation C). The possibility of plastic backing materials rustling noisily should be considered (Grade of Recommendation C).

- **Independence and lifestyle:** The ability of a user to change his / her own pad should be considered (Grade of Recommendation C); those able to change their own pad can often manage with a smaller (less absorbent) one than those reliant on a caregiver. Users who travel should consider in their choice of product(s) the practicalities of carrying a supply of pads, disposing of used ones, and dealing with laundry (Grade of Recommendation C).

- **Costs:** Cost issues should be approached with caution (Grade of Recommendation C). Expensive pads do not necessarily work better than cheaper ones. Cheaper pads do not necessarily save money. If pads leak more they may have to be changed more frequently and / or lead to higher laundry costs. More pad changes will mean increased caregiver workload. However, more absorbent pads will not necessarily reduce pad consumption rates: pads are often changed according to ward or personal routine.

Some users who choose disposables when at home prefer washables when travelling because of the space that disposables occupy in luggage and the possible inconvenience of disposal. Others use washables at home and disposables when away as they see the balance of disadvantages and advantages differently.

- **Personalisation of products:** In institutions, the chore of personalizing washable products and sorting them after each laundry cycle should be considered before they are introduced (Grade of Recommendation C). Washable bodyworns are often personalised to particular users. In institutions this means marking products with users’ names and sorting them after laundry, an extra task for caregivers. Washable bedpads are not usually personalised.

- **Staining:** Washable products should not usually be used by those with faecal incontinence – beyond occasional light smearing – because of staining (Grade of Recommendation C). Skin sprays and ointments may stain washables too.

- **Costs:** Cost comparisons between washable and disposable products should be made with caution (Grade of Recommendation C). Key factors are: local arrangements (mostly laundry and transport costs); the durability of the products (which depends on how carefully they are used and the criteria for deciding when they should be replaced); the costs of ordering, transporting and disposing of disposables; and product purchase costs. Much of the cost of washables is encountered with the initial capital outlay for stock. This also represents a commitment to use the products for an extended period and so expensive mistakes can be made if it transpires that a better product was / has become available. It will usually be wise to experiment with samples of a variety of alternative products before committing to major purchases.

### VII. SHEATHS

Close-fitting penile sheaths (sometimes called condom catheters, urodomes or external catheters) are commonly used male incontinence devices and they are used in combination with a urine drainage bag. They are suitable for males who are experiencing moderate to heavy urine loss, or have limited mobility and are experiencing frequency and urgency and may even be considered in combination with intermittent catheterisation (IC) for males who are leaking urine as a consequence of bladder emptying problems. Sheaths may not be suitable for males who are experiencing confusion, considered psychologically
vulnerable or have decreased sensation through spinal cord injury [85-87]. There is strong opinion expressed in the literature that suggests assessment, selection and use of penile sheaths and the accompanying urine drainage systems needs to be undertaken with the guidance, education and monitoring of health professionals who have a knowledge of continence products. Failure to do so, according to this expert opinion [86-87], may result in serious penile trauma, impaired penile skin integrity and leakage of urine.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important in relation to sheaths include: physical, mental, cultural, gender and socio-economic factors. This incorporates assessment of the cognitive and dexterous ability of the male or carer to apply the sheath and empty the drainage bag, the integrity of the penile skin, length and circumference of the penis and whether it is retracted, or retracts on sitting or bending down, history of latex or adhesive allergy and, most importantly, recognition that the assessment from the health professional needs to be ongoing. It is also important to assess factors known to encourage or discourage sheath usage. Expert opinion [86, 89,90] suggest factors that encourage usage include: level of reimbursement, cultural expectation, resonance with masculine image, and ability to keep urine off the skin when the skin integrity is at risk because of incontinence. Factors which they suggest discourage usage include: ignorance of product efficacy by professionals and consumers and embarrassment between carer and client.

An effective sheath is one that stays securely in place for an acceptable period of time, is leak-free, comfortable to wear, easy to apply and remove, avoids skin damage and channels the urine effectively into a urine drainage bag.

1. PRODUCT CATEGORIES AND FEATURES

Sheaths come with a variety of features (Fig VII-1) of which the following are the most important to consider in making selections:

- **Material**: sheaths may be made from latex, silicone rubber or other synthetic polymers. Some men will be allergic to latex.
- **Size**: most sheaths are supplied in a range of lengths and sizes. Most companies supply them with diameters in the range of about 20 – 40 mm, in 5-10 mm increments.
- **Adhesive**: the adhesive may be integral to the sheath (one-piece systems) or come as a separate strip or spray (two-piece systems). Some men will be allergic to some adhesives.
- **Applicator**: some sheaths come with an applicator intended to help users and carers to put the sheath on.
- **Anti-kinking / twisting features**: some sheaths come with features intended to improve drainage by reducing kinking and twisting at the distal end, near the connection to the drainage bag tube.
- **Anti-blow-off features**: some sheaths come with features intended to reduce the likelihood of the sheath blowing off at high urine flow rates; for example, at the beginning of a void (eg the distal end of the sheath may be thickened and bulbous to stop the internal walls sticking to one another between voids).
- **Connection to the drainage bag**: some sheaths come with features intended to increase the ease and security of connection to the drainage tube (eg a push ring or ridge at the end of the outlet tubing)
- **Retracted penis features**: with or without specific features intended to accommodate a retracted penis (eg a shorter sheath or a wider adhesive seal).
- **Durability**: some sheaths are intended for use over a limited time period (eg 24 h) while other (generally, more robust) designs are intended for extended wear.
- **Transparency**: some sheaths are transparent allowing for observation of the condition of the skin along the shaft and glans of the penis.

2. QUALITY OF DATA

Some controlled comparative evaluations of different sheaths have been performed; one extensive market survey to identify the needs and priorities of sheath users; and one study to compare a sheath with an indwelling urethral catheter. Other studies report on the problems encountered by various groups of sheath users.

3. RESULTS

Although many men use sheaths successfully, problems have been reported in the literature. In a study on an unspecified number of spinal cord injured men, Goli [91] found that 15% experienced side effects or complications when using sheaths. These were irritative, allergic or compressive in nature. Jayachandran et al. [92] reported similar experiences with six incontinent men of widely varying aetiology and highlighted the importance of ensuring that the sheath does not become twisted near the distal end to avoid stagnation of urine and the risk of UTI. They also stressed the importance of good genital hygiene to avoid problems with infections. In a study of 94 men on medical / surgical wards, Hirsh et al. [93] found that none of the 79 who were judged as cooperative and able to manage their sheaths properly developed UTI (mean period of use, 21.2 days). By contrast, eight of 15 patients who tended to tug and kink the drainage tube attached to their sheath.
developed UTI within a mean of 9.6 days. In a retrospective study, Johnson et al. [94] compared the frequency of UTI in users (mean period of use, 35 months) and non-users of sheaths amongst 64 elderly men on an extended care unit. He found that 63% of users but only 14% of non-users developed UTI. No difference was found between men who did and did not tug and kink their tubing. Ouslander et al. [95] reported that 40% of 30 nursing home sheath users (mean period of use, 35.9 months) developed at least one UTI. The need for proper fitting of the sheath and regular monitoring of the skin integrity of the penile shaft, glans penis and prepuce of males who are regular sheath users has been highlighted in two articles that report a combined total of eight cases of fibropithelial polyps of the glans penis and prepuce of which six had a history of long term sheath use [88] [96].

A trial to compare sheaths and indwelling catheters in terms of infection, risk and patient satisfaction has been reported by Saint et al [97]. This was a prospective, randomised unblinded controlled trial which compared one type of sheath drainage with one type of indwelling urethral catheter using a small group of participants (N=75) across several locations in one hospital. There are important limitations of the study, including the low numbers drawn from a specific population, and the lack of comment on the changing / care routines associated with the sheaths and catheters. After making adjustments for age, mental score, history of UTI and history of catheterisation the conclusions of the study were that for males without dementia the use of sheaths has the potential to reduce infection compared to indwelling catheters and is more acceptable to patients in terms of comfort and pain. For males with dementia no significant difference in infection rates was found.

Nichols and Balis [98] reported the results of a survey undertaken for marketing purposes of an international cohort of 216 men who had used sheaths for at least three years, and their carers. Their responses to 19 brands of sheath were gathered using a questionnaire in the form of a Likert scale. It was found that catheter security (presumed to mean staying in place and freedom from leakage) was the most important issue for both wearers and carers, followed by comfort and ease of application and removal.

There have been a number of comparative evaluations of different sheaths. Peifer and Hanover [99] reported on an evaluation in which 20 men compared a new branded sheath system, that consists of three parts: a tubular sheath impervious to urine with a drainage tube connection at one end and a ring at the other; an undergarment with a frontal opening through which the penis is extended; and a ring-like collar which is used to keep the sheath and penis in the correct position, with the variety of external sheaths they had previously been using. The participants were a convenience sample identified through pharmacy medication files. In all 32 men were approached and

Figure VII-1: A variety of sheaths (top left and bottom right), a sheath applicator (top right) and an external fixation strip (bottom left).
20 consented, all experienced users of urinary sheaths. A questionnaire was developed to test the participants pre and post intervention. The new sheath – which was used for a week - proved more popular with the participants: it was judged to provide superior security (13/20 experienced increased dryness by day; 10/20 by night), and considered easier to apply (19/20) and remove (20/20).

In a multi-centre study involving 35 men (age range 22-87y; mean age, 54y; 34 living in their own homes), the UK Medical Devices Agency [100] compared four latex sheaths: two with integral adhesive; and two in which the adhesive was supplied as a separate strip. They found the products with integral adhesive to be more successful in both overall performance and ease of application. Fader et al. [101] conducted a multi-centre study to compare all six sheaths with integral adhesive on the UK market in 1998. Five were made from latex, one from silicone rubber. Four were supplied with an applicator, two without. Fifty-eight men (age range 26-88y; mean age 53y) were given the opportunity to try each sheath in turn for one week. The silicone rubber sheath was found to be significantly better than four of the other sheaths in overall performance (p<0.01). The ease with which a sheath could be put on was found to be the best predictor of overall performance. Surprisingly, sheaths with an applicator were found to be unacceptable to a significantly higher proportion of subjects than sheaths without an applicator (p<0.0001). Subjects found that the silicone sheath fell off / blew off significantly less frequently than two of the other products (p<0.01).

Pemberton et al [90] report a randomised prospective open crossover design trial to test user preference for an established one-piece silicone rubber self-adhesive sheath with a new one-piece silicone rubber self-adhesive sheath in a study sponsored by the distributor of both products. To be included the males had to be currently using at least one, one-piece urinary sheath, per day. Fifty three males from seven centres participated in the trial and were each given 10 sheaths of each product. Data from the 44 participants who had evaluated at least three of each product were analysed. No reason was given for why nine males did not complete the trial. The data shows that there were some problems with both products, however, it is difficult to understand why the new product was preferred, as the report does not mention any differences in the features of the two products.

Watson & Kuhn [102] describe a crossover study with six male participants that found the choice of leg bags may influence the performance of penile sheaths. Goldyn, Buck and Chenelly [103] conducted an exploratory study on 10 patients in an extended care hospital to consider the efficacy of a brand name external sheath and a hospital constructed sheath. The brand name sheath was found to be more secure and the preferred nursing choice but it was recognised that the hospital-constructed sheath was useful for patients with fragile skin and limited mobility. A study by Saint et al. [104] provided further evidence (although low level) to support the importance of security and comfort to sheath users. Using questionnaires, they interviewed a convenience sample of 104 older men (response rate = 90%) and surveyed 99 nurses (response rate = 92%) about the relative merits and problems of sheaths and indwelling catheters. The study population was drawn from a university-affiliated Veterans Affairs Medical Centre in the USA.

The patients using the sheaths were more likely to believe their product was comfortable (p = 0.04) and less likely to believe it was restrictive (p = 0.002) or painful (p = 0.008) than those using an indwelling catheter. This viewpoint was supported by the nurses surveyed, the majority of whom (no numbers given) believed that sheaths were more comfortable and less restrictive than indwelling urinary catheters for male users, but required more care time because they fell off or leaked.

4. SUMMARY

For incontinent males, sheath drainage can provide a good alternative to pads. However, the increased risk for complications such as local skin breakdown, bacteriuria and infection - especially in the frail confused elderly male – should be borne in mind (Level of Evidence 2). Also, there is the risk of urinary retention if the condom twists or the external band is too tight, leading to poor drainage to the urine bag (Level of Evidence 3). Sheaths with integral adhesive are more popular with users and easier to apply than those with separate adhesive strip (Level of Evidence 2/3). Secure fixation and the ease with which a sheath can be put on are the best indicators of its overall performance (Level of Evidence 2). Sheath applicators are often ineffective and unpopular (Level of Evidence 2). There can be considerable differences in performance between products with somewhat similar designs (Level of Evidence 2).

5. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

- Prior to applying the sheath, ensure any remaining adhesive or barrier cream is removed from the penis and that it is thoroughly washed with soap and water and thoroughly dried.
- Trim long pubic hairs to prevent them being caught up in the adhesive.
- Protective skin wipes can be used to protect the skin, but make sure the skin has dried properly before applying the sheath.
- Leave a gap at the end of the sheath between the glans penis and the drainage tube to avoid trauma to the glans / prepuce. However, make sure the gap is not too large such as to cause kinking or twisting of the sheath [105].
• After the sheath has been applied, snip any reinforced ring or unrolled section of sheath sitting at the bottom of the shaft of the penis.

• Penile sheath removal should not be rushed and is made easier by gently rolling it off while bathing the penis in warm soapy water.

6. RECOMMENDATIONS

• Since there can be considerable differences in performance between products of similar design, men should be given the opportunity to experiment with different products before making a final selection (Grade of Recommendation B).

• The key performance characteristics which should be considered in selecting products are: security (ie ability to keep a leak-proof seal and channel urine to the drainage bag without leakage) and ease of putting the sheath on and taking it off (Grade of Recommendation B).

• In general, sheaths with integral adhesive (one-piece systems) should be selected rather than those in which the adhesive is supplied separately (two-piece systems) (Grade of Recommendation C).

• It should not be assumed that a sheath applicator will make sheath application easier: often it does not (Grade of Recommendation B).

• Potential sheath users should be asked if they have an allergy history and regular users should be routinely checked as their latex allergy status can change over time and with continued use. (Some health settings are moving to reduce or eliminate latex usage whenever possible and some manufacturers have moved to offer non-latex sheaths) (Grade of Recommendation C).

• Sheath users should be monitored for skin health, tissue damage and UTI (Grade of Recommendation C).

• When possible the external sheath rather than indwelling urethral catheter should be the urinary collection device of choice. (Grade of recommendation B).

7. PRIORITIES FOR RESEARCH

• Although products are continually being developed, changed, withdrawn and released, comparison studies that are controlled and use multiple sites to achieve larger numbers are recommended to further evaluate the effectiveness of the variety of sheaths available.

• Comparison studies of the risks of complications between the use of sheaths, pads and catheters are required.

• Since leg bag features may influence the performance of the sheath, further evaluation of design features claimed to reduce twisting and kinking at the drainage bag connection site and increase ease and security of connection to drainage bags is required.

• Well designed studies to generate and validate procedures to help identify the type of sheath most likely to suit an individual are needed.

VIII. URINE DRAINAGE BAGS AND ACCESSORIES

Urinary drainage bags are attached to an indwelling catheter or penile sheath to collect and store urine. Features of effective drainage bag systems include ease of operation of all components (connectors, taps, and support devices), comfort and discreetness.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding urine drainage bags are patient / carer dexterity (86;106), and eyesight. Both are necessary to manage the urinary drainage bag system, including using the outlet tap to empty the drainage bag. It is also important to assess the patient’s preferred and usual mode of dress (86;106); for example, a male whose preferred mode of dress is shorts will want a drainage system that is not visible and allows easy access for emptying.

1. PRODUCT CATEGORIES AND FEATURES

Urine drainage bags fall into two major categories: leg/ body worn bags for day-time usage; and large capacity body-free bags for night-time use (night drainage bag) which are suspended from a stand or bed hook.

Leg / body worn bags come with a variety of features of which the following are the most important to consider in making selections:

• Volume: most bags have a volume in the range of 350-750 ml, but some are bigger.

• Material: most bags are made from transparent PVC (polyvinyl chloride) but PVDF (polyvinylidene fluoride ) (less noise from rustling), polyethylene or rubber / latex may be used.

• Sterility: bags may or may not be supplied sterile.

• Wear position: bags may be designed for wearing over the knee, across or down the thigh, down the calf, or against the abdomen.

• Attachment / suspension system: most leg bags are attached to the leg with straps, which are usually made from latex or a (usually elasticated) fabric. A variety of hooks, loops, buttons / button holes and Velcro may be used to secure straps and to attach bags to straps. Some bags are designed to be
suspended around the waist. Some straps and suspension devices can be bought separately from bags, but they are generally not suitable for use with all bags (Fig VIII-1).

- Connecting tube: bags come with a variety of connecting tube lengths (eg the length required for wearing a bag on the calf will be greater than that for the thigh). With some products the tube can be cut to the preferred length.
- Drainage tap: Drainable bags come with a variety of drainage tap designs (Fig VIII-2).
- Sampling port: bags may or may not have a sampling port in the drainage tubing for taking urine specimens.
- Comfort features: some bags come with features intended to increase comfort – most commonly, a fabric backing against the skin to reduce sweating.
- Discretion features: some bags come with features intended to increase discretion – most commonly, internal welds between the front and back faces to reduce bulging and / or sounds caused by a large volume of liquid moving about as the user mobilises.
- Anti-kinking / twisting features: some bags come with features intended to improve drainage by reducing kinking and twisting in the connecting tube.
- Infection reduction features: some bags come with features intended to reduce the risk of infection for the self-carer and cross-infection between bag users by care givers. Such features may include; a non return flap valve, designed to help reduce reflux of urine up the tubing when the bag is moved by users or carers, a sampling port and / or a tap with an outlet sleeve which allows the overnight bag to be connected to the body worn bag. This linkage provides a mechanism to maintain a closed catheter drainage system designed to minimise the risk of cross-infection by reducing the handling of the catheter. Having connected the night bag to the leg bag sleeve, the leg bag tap is opened and urine flows freely from the sheath or catheter through the leg bag into the night drainage bag. Pre-sealed drainage systems to prevent breaking the closed system are also available.

Night drainage bags are usually held on a suspension system away from the body. They may be connected directly to the catheter or sheath or they may be connected to the drainage tap of the leg / body worn bag to avoid the need for repeated connections and disconnections with the catheter or sheath (Fig VIII-3). They usually have a capacity of 2000-4000 ml and come with a variety of design features many of which are similar to those for leg / body worn bags. Night drainage bags are available without a tap for single use as well as with a variety of drainage tap designs for emptying and reuse. Glass bottles are also available for high volume or overnight urine drainage.

2. QUALITY OF DATA

Several controlled comparative evaluations of urine drainage bags and suspension systems have been performed, as well as a small number of studies addressing infection and cross-infection issues. There is also one case controlled study which has investigated the purple urinary bag syndrome.

3. RESULTS

a) Evaluations of urine drainage bags

Kennedy et al. [108] tested the performance of ten different drainage bags in a simulation study involving 40 subjects (mostly health-care staff) which focused particularly on taps. Significant differences (p<0.05) were found between many pairs of bags with regard to each of the performance aspects studied: ease of tap opening and closing, ability to empty the bag without urine wetting fingers; and how easy the tap mechanism was to understand. Taps comprising caps or bungs were found to be particularly fiddly and messy to use.

In a study which focused primarily on the cross-infection risks associated with leg bags, Wilson and Coates [109] evaluated four leg bags. Each of ten long-term catheterised patients was invited to try each bag for a week in turn. The authors concluded that no one bag suited every patient; rather, each was liked by some users. The popularity (or otherwise) of many features was a matter of personal preference. Adverse comments mostly related to the tap (difficult to operate, opened accidentally, causing leakage) and the straps.

The UK Medical Devices Agency [110] evaluated all 14 sterile 500 ml leg bags on the UK market in 1995 in a multi-centre study involving 83 test subjects (58 men, 25 women). About half [44] lived in their own homes and almost all the rest in nursing / residential homes. Subjects were divided into pairs matched for each) to try for a week in turn. Preferences varied but the main concerns of users consistently focused on taps (many subjects found many taps difficult to operate), straps (discomfort was common) and the minimisation of leakage (through faults in bags and / or connectors; onto the fingers when emptying; or by the tap accidentally opening in use). The most popular bags tended to perform well in these three respects.

In a multi-centre study involving 34 men (age range 27-84y; mean age 55y; all sheath users) Fader et al. [111] evaluated all seven non-sterile 500-700 ml leg bags on the UK market in 1997. Twenty-five of the men lived in their own homes and the rest in residential/

nursing homes or long stay wards. Conclusions were substantially similar to those for the earlier MDA study.

Some international standards have been developed which provide general advice on bag performance and test methods [112]. These standards can be useful to laboratories asked to advise on bulk buying choices.

b) Urine drainage bag suspension systems

Little research has been undertaken on urinary drainage bag suspensions apart from a study by Thelwell et al. [113]. Thelwell et al. conducted a cross-over study using 52 subjects (20 men, 32 women). This study compared four suspension systems for fastening leg bags with the leg straps they had used prior to the study. Each subject evaluated each product for a week in turn and recorded their findings on a weekly questionnaire. Again, difficulty of application, comfort, discreetness and cost were key issues. However, there is suggestion in the literature that urinary drainage bag suspensions have an important role to play not only in the comfort and security of the wearer but in the prevention of urinary tract infection regardless of whether the drainage system is connected to a sheath or an indwelling catheter.

Munnings and Cawood [114] report the findings of a pilot study designed to evaluate the use of a belly bag of 1,000ml capacity and worn 24 hours a day, thus eliminating the need to use two separate bags and reducing the number of times the closed system is broken. Twenty-nine patients from a variety of areas from within an acute care setting who were using continuous catheter drainage systems were invited to participate, with 27 of the participants completing the study. All agreed to wear and then compare the belly bag with their previous leg and night drainage bag system. Worn around the waist, the belly bag is not positioned below the bladder: the manufacturers claim that the pressure of the bladder muscles is sufficient to ensure that urine flows through the catheter from the bladder into the bag. The residual pressure of the bladder is reported to be around 10-25cm H₂O, while the manufacturer asserts that a pressure of only 6cm H₂O is necessary to ensure the urine drains into the bag. Following education of how to use the drainage bag, users were given a questionnaire designed to facilitate comparison between the previous drainage system used and the belly bag. This was followed up with a telephone call. All agreed the belly bag was an improvement over their previous system of leg and overnight drainage bags, and found it more convenient, comfortable and less likely to cause pain with movement.

It has been suggested that current standard drainage tubing / bag designs evacuate the bladder sub-optimally, leading to retention of residual urine. Outflow obstruction can be caused by the development of airlocks in the dependent curls of tubing. A new drainage tubing design which incorporates a coiled downward spiral shaped configuration has been reported to eliminate air-lock obstruction (107) in experimental and clinical studies. However the importance of this in relation to infection requires further study.

There is opinion in the literature that positioning standard drainage bags below the bladder in a manner that averts kinking will prevent reflux of urine, and associated infection[115-117]. When doing so care must be taken not to increase traction or friction [106]. This can be achieved with the use of supports especially designed to divert accidental pulling on the catheter or sheath. When using these support systems allowance should be made for penile erection and tumescence [106].

The drainage system for indwelling catheters should be positioned off the floor to reduce the risk of cross infection[115-117]. Some sterile and unsterile leg bags come with a variety of tubing lengths or tubing that can be cut according to the needs of the individual, and leg straps that can be adjusted to allow positioning of the bag on the thigh or calf. Night bags - even if the tubing can be cut - rely on uniform stands or hangers to ensure that they are off the floor. Roe et al [118] raised the issue of poorly designed support systems for night bags. Expert opinion suggests that this still remains an issue.

c) Infection and cross-infection issues for management of urine drainage systems for indwelling catheters

Usage of urinary catheters and their drainage systems increases the risk of urinary tract infection and cross infection (See Section XII.2.h). There is evidence to suggest that catheter associated infections are reduced with the use of closed urinary drainage systems. A randomised controlled trial was reported by Platt et al [119]. This trial compared the incidence of infection (measured as 10^5 cfu/ml in catheter urine or drainage bag urine) between sealed junction catheters and unsealed junction catheters in a hospital setting with a median period of catheterisation of three days. For subjects not taking antibiotics there was no difference in infection rates between sealed junctions and unsealed junctions. The infection rate appeared to be consistently lower in the subjects taking antibiotic than the ones not taking antibiotic (p=0.01). For subjects taking antibiotics there was no difference in infection rates between sealed junctions and unsealed junctions.

There is little research to support the common practice of changing drainage bags every five to seven days (or any other particular change regime). The practice appears to be based upon expert opinion, anecdotal evidence and manufacturers’ recommendations. Of interest is the study outlined by Keerasuntongpon et al. [120] which was a randomized controlled study that compared the incidence of catheter-related urinary tract infections in a group of 79 hospitalised patients
whose catheter bag was changed every three days with that for a group of 74 patients who had their bag changed at the time of the catheter change or if the bag became faulty. A urine sample for culture was obtained for each participant every seven days, on the day the catheter was removed or on the day the participant was suspected of having an infection. The findings suggest that urinary drainage bags could be left for longer than three days but the authors were reluctant to define how long as the sample size was considered too small to rule out a false-negative result. They recommended additional study.

There is no evidence to support the practice of adding in situ antiseptic agents to drainage bags to reduce catheter-associated infection. A paper by Thompson et al. [121] which was primarily looking at the effectiveness of hydrogen peroxide instilled into closed drainage bags in reducing infection in drainage bags and in catheters also raises the question of whether catheters are infected primarily via drainage bags or vice versa. This prospective randomised study in a hospital setting involved daily sampling for bacteriuria (See Section XII.2.h for further discussion of outcome measures for catheter-associated infection) in catheters (≥10^5 cfu/ml) and drainage bags (≥10^3 cfu/ml) and identifying the infecting bacteria species.

In a sample size of 688, infection was found in 68 catheters and 78 bags. Although bag contamination was 8% in the H2O2 group and 16% in the control group (p<0.001) there was no significant difference in catheter bacteriuria (11% and 9%, respectively). One of the reasons given in the paper for questioning whether the drainage bag is the main source of catheter infection was that 77% of the bags in this study were contaminated later than the catheters.

Best practice guidelines to prevent infections associated with short term indwelling urethral catheters are available. The most recent of these, the EPIC 2 guidelines, were revised in 2005 and reported by Pratt et al. [117]. Designed to prevent short term, indwelling urethral catheter associated infection in NHS Hospitals in England, the guidelines are based upon a series of systematic reviews that include the best available evidence (experimental and non-experimental research as well as expert opinion). These guidelines recommend a closed catheter system where drainage bags are changed according to the manufacturer’s recommendations (5-7 days) or the patient’s clinical need. The guidelines also recommend that antiseptic or antimicrobial solutions are not added to urinary drainage bags.

The quandary for health professionals involved in the education and support of clients, who are self-managing and often financing their long term indwelling catheter drainage systems while living at home, is that they are aware that many of them are leaving the bags on for much longer than the manufacturers recommend and are often washing the bags out with a variety of solutions and reattaching the bags directly to the indwelling catheter. There is a paucity of studies that have explored long-term self-management of urinary catheter drainage systems in a community setting.

Madigan & Neff [122] undertook a literature review (50 studies) that explored the complications and long term management of long term indwelling catheters used for urinary retention and incontinence. Their recommendation in relation to management of drainage bags was that closed drainage systems were preferred best practice. However they also indicated that leg and bed bags may be used for up to four weeks if the system is broken daily to allow daily bag decontamination with a diluted (1:10) bleach solution. This recommendation appears to be based on the following two trials, one of which involved 54 participants sampled from an acute care rehabilitation centre and one involving 14 community dwelling participants.

Dille et al [123] report a randomised group parallel study with a pre-test and multiple post-tests utilised to determine the safety of a 4 week re-use of vinyl leg and bed bags compared to the usual practice of one week when de-contaminated daily with a procedure that utilised dilute bleach (sodium hypochlorite). Set in an acute rehabilitation unit, 54 participants (18 female and 36 males) completed the four week data collection period. Randomised by the flip of a coin, 28 participants were in the experimental group and 26 in the control group.

All participants had an indwelling catheter and were using a leg bag during the day and a bed bag at night. Both groups received identical daily bag decontamination and weekly bag and urine cultures. A standard of 0 to 100 cfu/mL was used to measure bag decontamination effectiveness and the urine cultures were processed by the Associated Regional and University Pathologists Inc. No significant differences were found between groups and the authors concluded that it is safe and cost effective to reuse vinyl bags for four weeks as opposed to the previous practice of one week, if the protocol for daily decontamination described is used. This study does not compare the practice of washing out the drainage bags with the chlorine solution either weekly or for a period of four weeks with a closed urinary catheter system to determine if that would result in fewer UTI’s.

Rooney [124] reported a study of 14 people with neurogenic bladders living at home. They changed from using daily sterile leg bags to non-sterile leg bags which were washed out after use each day with a dilute chlorine solution. Nine participants were on Foley catheter drainage and five were using sheaths. Bedside urine collection bags were used by all participants at night and there was no change made
to the standard practice of rinsing the overnight bag with water each morning and recapping the drainage tubing. The study ran for three months including a preliminary baseline phase of one month. No comment was made on whether the non sterile bags were changed. There were no symptomatic UTI infections during the study and urine samples with bacteriuria (>10^5 cfu/ml) did not increase. However the sample was very small and no statistical tests were applied to the results.

d) Urinary drainage bag features intended to reduce the risk of cross infection

The cross-infection risks of leg bags (particularly via the tap or sampling port) have been studied by Glenister [125] and by Wilson and Coates [109]. In her study Glenister [125] concluded that designs in which the tap and outlet spouts were most widely separated were most effective at preventing contamination of the hands with urine. Wilson and Coates [109] studied sampling ports and contamination of leg bag spouts. They suggested that the night connector tubing attached to the taps on the four leg bags in their study made decontamination difficult.

A small comparative study of two sets of closed system bags with a double non-return valve and two set of bags with a single non-return valve - all inoculated with Escherichia Coli and using simulated laboratory conditions in two separate microbiological laboratories blinded to each other - found that the colonisation of a simulated bladder was significantly delayed when the double non return valve was used [126].

e) Purple urine bag syndrome

There are occasional reports in the literature of purple discolouration in urine drainage bags - termed, purple urinary bag syndrome (PUBS) – and there is considerable debate and diversity of opinion over the cause and significance of the phenomenon. Mantani et al [127] conducted a case controlled study on 26 patients in three long-term wards. Fourteen (two men and 12 women) had exhibited PUBS while 12 (four men and eight women) had not. The clinical, microbiological and bacteriological backgrounds of the subjects in the two groups were compared to identify possible causes of PUBS. The findings suggest that women with urine that is alkaline and has a high bacterial yield are most likely to exhibit PUBS. There is no evidence to suggest detrimental effects on patients' health or functioning of the drainage system. However, the smell can be very distressing.

Studies which have compared leg bags and catheter valves are reviewed in Section XII.

4. SUMMARY

Taken together, published studies agree that the main factors to consider in selecting leg bags are the ease of tap operation, the comfort of suspension systems and the minimisation of leakage (Level of Evidence 2). Bags in which the tap and outlet spout are widely separated are most likely to be effective at preventing contamination of the hands with urine and cross-infection (Level of Evidence 3). There is high level evidence from studies – predominantly in acute care settings - to support the use of closed urinary drainage systems (Level of Evidence 2).

5. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

Provision of clearly presented information based on the best evidence available is needed for clinicians, carers and patients as many aspects of caring for a urinary drainage bag system are supported by scant or conflicting evidence or by custom.

There is agreement that the hands must be cleansed and clean non-sterile gloves put on prior to caring for the urinary drainage bag system and that, on completion of handling the system, the gloves must be discarded and the hands cleansed again [117], [128].

There is also mention of confusion arising for clinician, patient and carer because of the many different designs of urinary drainage bag taps, and the regularity with which such features are changed [129]. Manufacturers should ensure that the instructions and accompanying literature that they develop for their urinary drainage bag systems are clearly presented and easily understood [129] in a format which is convenient to retain and refer to.

6. RECOMMENDATIONS

- In making urinary drainage bag selections particular attention should be focused on: the ability of the user to operate the tap; comfort (especially visibility beneath clothing); freedom from leakage (especially from the welds and the tap); and discretion (especially from the welds and the tap); and discretion (especially from the welds and the tap); and discretion (especially visibility beneath clothing) (Grade of Recommendation B).
- The patient’s individual needs and personal preferences should determine the use of leg / suspension / attachments and position of where the bag is worn (Grade of Recommendation C).
- Maintain closed urinary drainage system for indwelling urinary catheterisation where the system is only broken to change the sterile bag according to manufacturer’s recommendation or in a shorter period of time if clinically indicated (Grade of recommendation A).

7. PRIORITIES FOR RESEARCH

Jones, et al [128] identify many of the issues concerning the handling of urinary drainage bag...
systems that require further research, including the issue that has already been discussed above, of how long a closed urinary drainage system can be left unbroken before the urinary drainage bag is changed. Jones et al [128] also suggest research is needed into:

- How often and how drainage bags should be emptied?
- If a closed urinary drainage bag link system is used, does the night bag that is connected to the leg bag need to be sterile or can it be a reusable one?
- If a reusable night urinary drainage bag can be used, how should it be cared for when not in use?
- What is a reasonable method to dry reusable bags after they have been washed?
- To establish whether the incidence of UTI is increased in hospital, community or residential aged care settings when urinary drainage bags in closed drainage systems are changed at different intervals (eg the time of catheter change rather than weekly).
- To determine in own home settings whether a closed catheter drainage system is more effective at preventing urinary tract infections than a reusable non-sterile urinary drainage bag washed out each day with soap and water.
- To determine in own home settings whether a closed catheter drainage system is more effective at preventing urinary tract infections than a reusable non sterile urinary drainage bag washed out each day with a diluted solution of chlorine.

3. PRIORITIES FOR RESEARCH

There is a need for leak-free, comfortable and aesthetically acceptable body-worn urine collection devices for women and improved (in these respects) products for men.

IX. BODYWORN URINALS

1. FEMALE BODYWORN URINALS

Pieper [130] has reviewed the many attempts to design bodyworn urine collection devices for women. The major challenge is in achieving a comfortable and aesthetically acceptable leak-proof seal with the body. Various designs have sought to achieve this by holding a collection device over the urethral meatus with the help of suction, straps, adhesive or close-fitting underwear. While none have found widespread success and usage, they are available commercially in some countries.

2. MALE BODYWORN URINALS AND Dribble Containers

The urine collection devices most commonly used by men are sheaths (see Section VIII) but a variety of other products such as pubic pressure urinals are available. They comprise a ring-shaped opening or cone-shaped component which is worn around the penis (and held firmly against the pubis by means of a belt and straps) and channels urine to an integral collection bag (Fig IX-1). Such devices are not widely used but they can be effective for individuals whose penis is too retracted for a sheath to be suitable. There are no published evaluations of these products.

They should be fitted by a specialist: a good fit is crucial for comfort and to avoid leakage. It is also important that the wearer / carer understands how to use the device and the importance of skin care. The wearer / carer will need good manual dexterity to manage the device. Several urinals will be needed to use in rotation, allowing each to be properly washed and dried between periods of use.

Dribble pouches are also available for light incontinence (Fig IX-2) but there are no published evaluations of these products.

3. PRIORITIES FOR RESEARCH

There is a need for leak-free, comfortable and aesthetically acceptable body-worn urine collection devices for women and improved (in these respects) products for men.

X. MECHANICAL DEVICES FOR WOMEN WITH URINARY INCONTINENCE

Female mechanical devices are designed to prevent urinary leakage in different ways and fall into three main categories: those that are applied over the urethra at the external meatus; those that are placed within the urethra (intraurethral devices) and those that are inserted into the vagina (intravaginal devices). Both designs of urethral device are intended to occlude the urethra and the intravaginal devices are intended to provide some support to the bladder neck and possibly some compression to the urethra. These devices are also known as occlusive devices and are primarily used for women with stress incontinence. There has been one Cochrane review of these devices [131].

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding mechanical devices are high levels of motivation and acceptability of the concept of use, good cognition and good manual dexterity. They should probably be avoided by those with skin sensitivity or if avoidance of urinary tract infection is a priority.

1. DEVICES THAT OCCLUDE AT THE EXTERNAL MEATUS

Urethral occlusion devices have been developed to
Figure IX-1: A variety of pubic pressure bodyworn urinals for men.

Figure IX-2: A dribble pouch.
block urinary leakage at the external urethral meatus (Fig X-1). Several devices have utilized either adhesive or mild suction to achieve occlusion. In addition to the simple barrier effect, compression of the wall of the distal urethra has been hypothesized to contribute to continence.

Miniguard (Uromed Inc., but no longer available) is an angularly shaped foam device which utilizes an adhesive hydrogel to adhere to the peri-meatal area. The device is single use, removed prior to voiding, and disposable. FemAssist (Insight™ Medical Corp., but no longer available) is a hat-shaped silicone device, which adheres by applying an adhesive gel to the edge of the device, squeezing the central dome and creating a vacuum. The device is then placed over the urethral meatus and, upon release, the meatal mucosa is drawn up into the device and the urethral lumen is occluded. It may be worn for up to four hours or until voiding, after which the device is washed in hot soapy water and reapplied. The device was reusable for one week. CapSure (CR Bard Inc., no longer available) was applied and retained by suction. A petroleum based lubricant is applied prior to device use. The device is removed for voiding and re-utilized for up to two weeks.

Miniguard: Eckford et al. [132] studied the efficacy of a single application of this device during a one hour pad test and reported that 25% of patients were continent, 50% were improved, but 25% had worse incontinence. Brubaker et al. [133] enrolled 411 women to their study; 390 used the device, and 346 completed the study. Results showed significant improvement in symptoms. The incontinence impact scores significantly decreased from a mean of 41.0 (out of 300 – high scores worse) to a mean of 10.5 at 17 weeks. Twelve hour pad test showed mean urine loss decreased significantly from 15.8 to 6.9 ml and incontinence episodes from 14.2 episodes per week to 4.9 episodes at week 17. Symptoms of vulvar irritation or lower urinary tract discomfort occurred in a small percentage of subjects but it was generally transient, and only three women discontinued using the device for this reason. There were no statistically significant differences in the proportion of subjects reporting urinary tract infection during device use compared to beforehand. The authors concluded that the device was safe and effective (Level of Evidence 3).

FemAssist: Versi et al. [134] studied 155 women with stress or mixed incontinence, of whom 133 attempted to use FemAssist and 96 enrolled in a four-week study. Their mean pad test loss fell from 27 g to 9.4 g (p< 0.001) and 49% were dry. Symptomatic cure was more likely in those with mild incontinence. Of the nine women who had a positive pad test (>2 g) without the device, five were dry (<2 g) with the device (p<0.05). VAS scores showed a significant improvement for the symptom of stress incontinence (p<0.05). QoL scores improved significantly by 38% (p<0.05) for the IIQ and 29% (p<0.0 1) for UDI (Level of Evidence 3).

Moore et al. [135] reported on 57/100 recruited women who completed a one-month trial. Reduction of incontinence was statistically significant on pad testing, which revealed that 47% of the patients became continent and 33% had more than 50% benefit compared to baseline, while 9% had worse leakage. Those with severe baseline leakage were as likely to respond as those with mild or moderate pad test loss. Women with stress, urgency or mixed incontinence appeared to respond equally well. Dropouts included 13% who were unwilling to utilize the device (Level of Evidence 3).

Tincello et al. (136) in a 3-month prospective study involving 27 women with urodynamic stress incontinence found the median (range) loss with and without the device was 4.9 (0-65) ml and 21 (1-94), respectively (p< 0.01); and 20 patients were less wet when using the device. Discomfort was greater among the women with a greater loss. The acceptability correlated negatively with discomfort (r = -0.53) and negatively with embarrassment (r =-0.39); 15 patients (56%) reported that they would use the device in the long-term (Level of Evidence 3). Tincello et al.[137] later reported on 41 women recruited to use the device over a three month period, but 10 declined to participate, six withdrew before two weeks, 10 failed to attend two week follow-up and 11 did not attend three month follow-up. Only two completed the study. There was no difference in pad test or voiding diary grades. The authors concluded that the device had low acceptability and was ineffective, and could not be recommended for non-surgical management of stress incontinence (Level of Evidence 3).
**CapSure**: Bellin et al. [138] reported on 88/100 completers after 12 weeks, with 82% elimination of leakage on pad test, 91% continent on provocative stress test (single cough assessment of leakage), and 48% dry and 40% improved on urinary diaries. Pad test leakage decreased from 6.67 g (range 0.55-25.95 g) to 0.19 g (range, 0-2.5 g) by week 12. Five patients withdrew secondary to vaginal irritation and three due to poor device fit (Level of Evidence 3).

Shinopulos et al. [139] carried out a multi-centre study enrolling 100 women with stress incontinence who wore the device for 12 weeks. Eighty-four women completed the study. Mean pad weights reduced from 6.7g at baseline to 0.19 by week 12. Complications affected seven patients, including urethral / vaginal swelling and vulval abrasion, but none of the affected patients withdrew from the study. The IQOL tool showed significant mean improvement from 62.3 to 90.4.

**b) Summary**

External urethral occlusive devices were found to be of varying efficacy, with minimal morbidity. Efficacy of the combined studies reveals a continence rate of approximately 50% dry and two-thirds of patients improved, but this data is from open studies (typically pre-test / post-test with no control group) and there have been no randomised controlled trials. Devices achieve occlusion either by blocking at the meatus or compressing the distal urethral lumen and adherence to the peri-meatal area is essential to success. However, the method and degree of adherence is also the determining factor for the type and severity of local irritation.

Patient selection based on motivation, appropriate anatomy, and manual dexterity, in combination with efficacy and morbidity will determine overall satisfaction. There is no data which compares one extra-urethral device to another, or to other categories of products. Cost comparisons for disposable versus short-term reusable devices are not available. Efficacy for different grades of incontinence has not been established.

The objective degree of continence improvement in the clinical laboratory (pad and stress tests) is greater than in community use (diaries). The devices tested in these studies are no longer available and there are no external urethral devices currently on the market.

**c) Recommendations**

Although these devices have proved effective for some women (limited mainly to those with high motivation, manual dexterity and cognitive function), it appears that they have failed to find popularity with users and clinicians. They are no longer commercially available and so no recommendation on their use can be made.

**d) Priorities for research**

Further research on the development and role of devices which block urinary leakage at the external urinary meatus, with a focus on improving patient acceptability is recommended. One half of patients utilizing these devices in monitored studies were dry and two-thirds of the patients were improved with minimal morbidity. These devices may have a future role in the algorithm of conservative treatment based on patient acceptance, availability and cost, especially in those patients with mild or moderate stress incontinence, for occasional or intermittent use and/or for those who prefer to avoid pads or surgery.

### 2. INTRAURETHRAL DEVICES

Urethral inserts are silicone cylinders that are self-inserted or removed at the patient’s discretion. They are intended for daytime use, especially during vigorous physical exercise. While some women manage exercise incontinence by limiting fluid intake before or during exercise, by choosing sports that allow frequent bathroom access, or wearing absorbent pads, 20% to 40% of women cope with leakage by ceasing exercise (140). These devices have external retainers or flanges to prevent intravesical migration and proximal balloons to hold the device in place. They act by causing occlusion either in the urethra itself or at the external urethral meatus [141]. (Fig X-2)

The FemSoft (Rochester Medical Corporation) is the only urethral insert currently distributed. It has a soft, compressible, mineral oil-filled silicone layer with an insertion probe. Before insertion, the fluid distends the proximal end of the cylinder, as the user pushes the device (guided by the insertion probe) into the urethra, fluid transfers automatically to the distal end, allowing the device to pass through the urethra. Once in place, fluid flows back to the proximal end to hold

**Figure X-2: A female intraurethral occlusive device.**
the device in place. None of these devices are recommended for reuse after removal. The FemSoft Insert is currently packaged in a box of 28 inserts and each box is priced at $49.95. The Viva [142], Reliance and other intraurethral devices mentioned in this subsection, are not currently marketed.

a) Quality of data and results

The objective efficacy measurements utilized were the one-hour pad test, voiding diary and quality of life questionnaires. There have been no randomized control trials.

Nielsen et al. [142,143] and Peschers [144] studied the Viva device. Peschers et al. screened 53 patients with USI and 21 patients accepted treatment with the two sphere device. During a four month study, the investigators analyzed subjective improvement and performed pad-weight and cough tests. The authors reported that 67% of patients had improvement in symptoms. Nielsen et al. [142] studied forty women who tested two variants of the device (with one or two spheres) each for two weeks in a cross-over study. They then continued with what they judged to be the better plug in period three (two months). Only 45% (18/40) completed this period but almost all (17/18) were reported to be subjectively and objectively continent or improved. Six women developed urinary tract infections and two of these had retained a plug in the bladder.

Staskin [145] reported on a four month study of 135 of 215 patients who utilized a disposable balloon tipped urethral insert made from thermoplastic elastomer, inflated with an applicator on insertion and deflated by pulling a string at the meatal plate for removal during voiding (Reliance, Uromed Corp., but no longer available). Eighty subjects discontinued the device prematurely, mostly because of discomfort and inability or unwillingness to use the device. Miller et al [146] and Sand et al [147] then reported on 63 of the 135 patients from the above cohort who utilized the device for one year.

The Reliance device provided 72% complete dryness with 17% improvement on diary, and 80% complete dryness and 15% improvement on pad weight testing in the study by Staskin et al. [145], and 79% complete dryness and 16% significant improvement on objective pad weight studies consistent with the improvement in subjective diaries (p<.0001) for Miller et al. [146]. In the Miller study the patients reported improved comfort and ease of use over time. Sensation of device presence decreased from 35% at week one to 7% at 12 months. The volume of urine lost during exercise decreased from a median of 20g (range 4.9-80.2g) without the insert to 2.6g (1.3-6.8g) when the insert was worn (p=0.03). On a 5-point scale, in which 1 represented very comfortable and 5 very uncomfortable, subjects rated the mean comfort for the sessions performed with the insert in place as 2.1.

Boos et al. [149] reported in an abstract, a randomized prospective parallel group trial comparing the Reliance intra-urethral insert with the FemAssist external meatal occlusive device. Assessments at baseline, one month, and three months included subjective efficacy, seven day diary, and pad test (1 hour). Fifty-three females were randomized to the FemAssist and 49 to the Reliance device. There were some initial problems with sizing the Reliance. Once this was corrected, 40.8% (20) of women were subjectively dry and the remainder improved on completing the trial. Of women using the FemAssist, 28.3% (15) were dry, 60.4% (32) were improved, 9.4% (5) were no better and only one subject was made worse with device use. Problems experienced were few and minor with no serious adverse events. The conclusion was that both devices are efficacious, the FemAssist was more comfortable, but required a greater degree of user skill to achieve control of leakage (Level of Evidence 2).

Recent studies have investigated the efficacy of the FemSoft which is the only intra-urethral device which is currently available. Dunn et al. [140] measured pad weights during four standardized aerobics sessions during which six subjects were randomly assigned to exercise twice with the insert and twice without it. The medians of the averaged pad weights for the two different types of sessions were compared. Median urine loss during standardized exercise sessions decreased from 20g (range, 4.9 to 80.2g) without the device to 2.6g (range, 1.3 to 6.8g) with the device (P=0.03). Five women used the device at home during unsupervised exercise; one subject had urinary tract infection. At the end of three months, satisfaction and comfort were rated high on a 5-point scale. The conclusion was that the FemSoft urethral device is an effective, safe, and comfortable treatment for exercise incontinence in women (Level of Evidence 3).
Results from a prospective three-year study, (FDA post-approval device safety data submitted by Rochester Medical Corporation, 2002 unpublished), for evaluation of the long term effect of the device involved 41 subjects. Of the group, nine women were 65 years or older (22%, 9/41); 80% were post-menopausal with 24 women (59%) being on hormone replacement. Thirty-eight, (93%) used absorbent products to contain urine leakage prior to enrolment. A total of 66 follow-up visits took place with an average participation period of 4.2 years. Seven patients withdrew in the third year, three due to non-study related health problems and one because of dissatisfaction due to urge symptoms. Two were lost to follow up. There was a significant difference in the rates of incontinence at the three-year follow-up between users and non-users of the device: 0.83 versus 2.64 episodes per day, according to voiding diaries. The difference in urine loss during pad weighing tests was also significant. There were 24 reported adverse events in the 41 subjects enrolled. None of these events required medical intervention except for antibiotic prescription in cases of urinary tract infection. The 24 events included: bacteriuria (11); symptomatic UTI (3); urinary symptoms (3); device performance problems (2); irritation (2); and migration (1).

In 33 women a total of 38 cystoscopies were performed at three years. Only one patient was reported to have an abnormal finding, but this was due to mucosal irritation produced by an indwelling Foley catheter during one hospitalization for a problem unrelated to the device. Patient satisfaction had not changed over the follow-up time interval. The Quality of Life questionnaire (I-QoL) scores at three years were compared to those at 12 months and there was improvement from the baseline of 60.6 to 74.0. No safety concerns concerning urethral integrity were identified after the three years of continuous use. The incidence of urinary tract infections, given the high number of insertions and removals, was considered low risk (Level of Evidence 3).

b) Summary

Intraurethral devices have demonstrated high efficacy, but have been associated with urinary tract infection, hematuria and discomfort. Bacteriuria, without symptomatic infection, was similar to extraurethral device use, which approaches screening urinalysis data [133] or may be similar to the rates seen with self catheterization. Device migration into the bladder, which requires endoscopic removal is the most serious reported problem. Long-term results are limited. Patient and clinician acceptance of this form of therapy has also been limited and there is currently only one intraurethral device on the market. High cost is also a factor that probably precludes more widespread application but 'occasional' use, for example during vigorous exercise may be helpful and affordable for some patients. Good hand dexterity is necessary to use the device (Level of Evidence 3).

c) Recommendations

Intraurethral occlusive devices may be considered for women with stress incontinence but they are invasive devices with high cost and have had limited evaluation. They may be most appropriate for intermittent and occasional use (such as during vigorous exercise) (Grade of Recommendation C).

d) Priorities for research

It is important that new devices - particularly invasive ones - are evaluated by randomized trials and comparing to control approved devices. Long-term follow-up results are needed to demonstrate the effects of such devices on the urethra and / or bladder and will determine the real value and safety of devices that initially have been adopted enthusiastically.

Further development and study of the use of intraurethral devices for the treatment of urinary incontinence is recommended. In particular assessment of their cost-effectiveness and effects on quality of life, when used intermittently or for particular activities, is recommended.

3. INTRAVAGINAL DEVICES

Support of the bladder neck to correct urinary stress incontinence has been achieved, with varying success, utilizing traditional tampons, pessaries and contraceptive diaphragms, and intravaginal devices specifically designed to support the bladder neck.

a) Quality of data and results

1. TAMPONS / PESSARIES

Nygaard [150] performed a prospective, randomized, single blind, and laboratory based study testing 18 patients (age 33-73) with three 40 minute standardized aerobics sessions, utilizing a Hodge pessary, a super tampon, or no device. Urine loss was determined by a change in the weight of the pad worn while exercising. Statistical analysis of the log of urine loss revealed that women lost significantly less urine when exercising with either the pessary or the tampon than when exercising with no device. Continence rates were 6/14 cured and 2/14 improved with tampons, 4/10 improved with a diaphragm (Level of Evidence 2).

2. DIAPHRAGMS / PESSARIES

Realini et al, [151] analyzed the benefit for one week, in 10 selected patients of a coil-type diaphragm ring, which was softer than a pessary, utilizing diaries and a two hour pad test. They also gave an overall subjective evaluation of their experience. Urodynamic findings were essentially unchanged by wearing
diaphragm rings. Four of the 10 women experienced clinically significant improvement in the amount of urine lost during pad tests, number of leaks per week, and overall assessment response (Level of Evidence 3).

Suarez et al. [152] included urodynamic testing in his evaluation of a contraceptive diaphragm in 12 patients. Complete resolution of SUI was achieved in eleven of twelve patients (91%) but two of them withdrew from the study because of associated discomfort from the diaphragm, therefore, complete resolution of SUI was achieved in 9/12 patients (75%) (Level of Evidence 3).

Bhatia et al. [153] reported on the urodynamic effects of the Hodge pessary on 30 women aged 29 to 71 with a history of UI. With the pessary, 24 of the 30 patients became continent when tested in supine position with a full bladder, three of the 24 patients lost urine with coughing in the standing position and demonstrated a positive cough profile despite the presence of the vaginal pessary. Uroflowmetry data show that the vaginal pessary did not produce any obstruction to the free flow of urine and suggested this is a modality to predict the outcome for bladder neck support surgery.

3. INTRA-VAGINAL DEVICES DESIGNED SPECIFICALLY TO SUPPORT THE BLADDER NECK

Included in this category are:

1. Removable reusable intra-vaginal ring, composed of silastic, and constructed with two prongs which are placed behind the symphysis to support the bladder neck (Introl, no current distributor).

2. Single-use disposable devices: (i) A clam-type device composed of polyurethane foam, which is folded up upon its long axis and placed into the sagittal plane in the vagina, and when moistened, its dimensions expand by 30% and create a supportive cushion under the urethrovaginal junction (originally called the Conveen Continence Guard, now known as Contrelle Activgard); (ii) A version of the expanding polyurethane design, with similarities to a tampon, (Conveen Continence Tampon, Coloplast, Denmark (no longer available) (Fig X-3); (iii) An expanding polyvinyl alcohol sponge (Ladycon, Home Care Engros, Norway); (iv) a simple surgical foam cylinder with drawstring e.g. Rocket stress incontinence device (Rocket Medical PLC)

4. REUSABLE INTRA-VAGINAL RING (INTROL)

A pilot laboratory study was carried out by Biswas [154], the developer of the device, employed a straining cystogram. Eighty-six percent of the patients were continent when tested with the device in place on cystogram. Following this study, the number of device sizes was increased from eight to 25. Evaluation studies followed examining efficacy, safety and satisfaction. Davila [155] initially demonstrated that 83% of patients were dry on pad weight test. Later [156] the researchers enrolled seventy women (53 completed) aged 24-76, 29 with stress, and 24 with mixed incontinence in a one month study. A statistically significant reduction in incontinence was noted on pad testing (stress mean 46.6-16.6; mixed, mean 31.9-6.8 g) and in bladder diary (stress, mean 28.6-7.8 losses per week; mixed, mean 30.2-15 losses per week). QoL scores (I-QoL) improved in both groups. With the device in place, urodynamic testing indicated normalization of urethral function without evidence of outflow obstruction. Subjects found the device comfortable, easy to use and convenient. Side effects included five urinary tract infections and 23 cases of vaginal soreness or mild irritation (Level of Evidence 3).

Moore et al. [157] detailed problems with both sizing and efficacy. Of the 80 recruits, four could not be fitted, and 11 did not satisfy all entry criteria. Of the 65 participants, 39 (60%) withdrew; 20 for distorted vaginal anatomy which made fitting difficult, five for lack of efficacy, four for constipation, and ten for unrelated patient events. In the remaining 26 patients, pad test weights decreased from a baseline median of 19g to 2g (p<0.001), 62% were continent, and 15% were >50% improved, and wished no further therapy. Moore et al. commented that the device was difficult to fit in women who have had multiple vaginal surgeries or were oestrogen deficient. Long-term follow-up showed that 18 of 26 (from the original 65) continued to wear the device at six months (interim dropouts being due to concurrent illness in half, the remainder had declining efficacy). Of these, 78% continued to wear the device for a minimum follow-up of two years (Level of Evidence 3).

In a separate study of patients with mixed incontinence by Moore et al.[135], five of 21 recruits never wore the device home, leaving 16 participants. A further two did
not reach week four, because of poor efficacy or inability to fit the device. In the 14 who reached week four, the median number of leaks/day declined from 4.3 to 1.0 (p = 0.002). Median pad weight loss fell from 53 to 7g. (p = 0.012). Cystometry showed an increase in maximum bladder capacity (p < 0.05) and a modest reduction in severity of detrusor overactivity, with no evidence of outflow obstruction. Three women discontinued because of poor efficacy or a poorly fitting device, leaving 11 of 16 participants (69%) at week eight, when median pad weight decreased to 2ml (Level of Evidence 3).

Kondo et al. [158] found no urinary flow obstruction with the device in place. Urine loss decreased from 20.6 to 4.8 gm. per hour (p < 0.001) on the 60-minute pad weight test. Twenty-two patients (29%), reported complete continence, and 39 (51%) had decreased severity of incontinence by more than 50%. Minor adverse effects occurred in 26% of the patients. According to the global usefulness rating which was employed, 62 patients (81%) had some or maximum benefit (Level of Evidence 3).

5. DISPOSABLE INTRA-VAGINAL DEVICES

Thyssen et al. [159] tested the Continence Guard in 26 women with stress incontinence before and after one month’s use: four women discontinued the treatment because of discomfort or difficulties in using the device 9 (41%) were subjectively cured of incontinence, 10 (45%) improved while three (14%) claimed unchanged incontinence. With the device in place all had decreased leakage at the 24-hour pad weighing test and unchanged urodynamic tests. No vaginal or urinary infections were found (Level of Evidence 3).

Thyssen et al. [160] reported on 19/22 women with stress incontinence, subjectively and objectively cured or improved in a short-term study, and who then continued the treatment with the device for one year. All 19 completed the study, 13 (68%) were subjectively dry, (26%) were improved and one (5%) reported unchanged incontinence. All but one had decreased leakage at the 24h pad test, and 67% a greater than 50% decrease. Subjectively cure was 41%, and 36% were dry on 24 hour pad test. Overall reduced leakage was statistically significant (p < 0.0005) No significant changes were found in the other urodynamic measurements, specifically, urinary flow rate.

Sander et al. [161] found subjective cure in 11/55 women (20%) and improvement in 27/55 (49%) was reported. Results of the 24-hour pad test and mean leakage and episodes in the voiding diary significantly decreased. After three months, 58% of the 55 patients desired to continue device usage. There was a highly significant improvement in QoL scores using the IIQ, as well as two additional incontinence-related quality of life questionnaires. Responses to the SF-36 general health questionnaire showed no significant changes

Hahnet al. [162] reported on 121 women, in a four week study. Patients dropped out because of vaginal irritation (25%), other product-related reasons (6%), lack of time (6%), or failure to complete a user questionnaire. Of the remaining 90 (mean age 47.5), 85 performed a 24 hour pad test, which showed that baseline leakage of 42 ml/ 24h decreased to 14 ml/ 24h (p <0.001). Of these, 39 (46%) were continent. The device was considered unpleasant by 8%, and caused some local discomfort in 62% on direct questioning: 75% of those wished to continue using the device. The authors noted that older women (age 56-65) tolerated the device and appeared more motivated to continue. Coexistent atrophic vaginitis and the use of topical oestrogen was not discussed.

Thyssen et al. [163] reported on 94 women recruited in a cross-over study, which compared two versions of the same device; the Conveen Continence Guard (CCG) and the Contrelle Continence Tampon CCT. 62 women (66%) completed the study with withdrawals mainly due to discomfort or for unknown reasons. Both devices reduced leakage significantly but the CCT was significantly better than the CCG. Few side-effects were reported. Thirty-two women continued the treatment for one year or more with 63% preferring the “tampon” type design for its ease of use.

The report on the polyvinyl sponge by Glavind [164] was an acute laboratory study of only six women utilizing a pad test measurement during 30 minutes of aerobic exercise Without the vaginal sponge the patients had a mean loss of 7g (range 2-18g) during exercise. With the vaginal sponge in situ there was no leakage.

There has been a recent report of a novel disposable intravaginal device (ConTIPI ltd. Israel) which may come to market. This device has a resin core with support ‘poles’ covered with a soft nylon mesh that stretches between the arms of the poles to act as a suburethral sling. Ziv et al. [165] recruited 60 women with severe stress incontinence to test the product. A seven day ‘control’ period was followed by a 28 device usage period.

There was no control arm or comparison product. Pre-weighed pads were used during the test period and the primary end point was the percentage of women achieving at least a 70% reduction in pad weight gain from the control period to the last 14 days of usage. Ten women withdrew from the study during the test period, four for device related reasons. Using intention to treat analysis 85% of women achieved at least 70% reduction in pad weight gain. The most common adverse events reported were mild and included genital tract discomfort, pain and spotting with blood; the only report of a moderate event was of candidiasis. The authors conclude that the device is easy to use, well-tolerated and effective. Further evaluation will be needed.
b) Summary
Support of the bladder neck resulting in improved continence is possible with intravaginal devices without evidence that they cause significant lower urinary tract obstruction or morbidity, but the evidence is limited. (Level of Evidence 3).

Studies performed in the acute setting, regardless of the device type, demonstrate better performance than diary based studies performed over time. Efficacy appears to be higher in patients with minimal to moderate urinary leakage.

Relatively high drop-out rates in monitored studies, during which patient support is provided, indicates the need for proper patient selection and patient and provider education, but may also indicate limitations in product efficacy, difficulties in application or other factors such as discomfort (Level of Evidence 3).

c) Recommendations

Vaginal support devices may be considered as a treatment option when managing women with stress urinary incontinence, dependent upon the availability of product, patient ability to manage the product (particularly manual dexterity) patient acceptance, and cost (Grade of Recommendation C).

d) Priorities for research

Long-term results are not available and studies comparing these therapies to other forms of conservative therapy or surgery are needed.

4. OVERVIEW OF MECHANICAL DEVICES WOMEN

a) Overall summary

The recent Cochrane review of mechanical devices for urinary incontinence in women [131] review found only six trials that met their criteria and concluded that the role of such devices is questionable. The authors state that there are indications that using mechanical devices might be better than no treatment but that the evidence was weak and that there was insufficient evidence to recommend any specific device or to show that mechanical devices are better than other forms of treatment.

In this section we have attempted to review all available evidence including many trials that did not meet Cochrane criteria. Most trials were open pre-test post-test trials with no comparators and the strength of this evidence is relatively weak. Although most trials showed positive effects on symptoms, this was often combined with relatively high drop-out rates and unwanted effects, such as discomfort, skin irritation or urinary tract infection.

Although many products have appeared on the commercial market, few have stood the test of time and are currently marketed – there are no external urethral devices available and there is only one intra-urethral device. There are at least two intra-vaginal devices available on the market and these may have potential to be more acceptable to women because of their similarities to familiar tampons. The relative lack of market success for these products may indicate low efficacy and unwanted effects, but may also reflect their relatively high cost compared to pads which are the main alternative.

b) Overall recommendations

It is possible that some of the mechanical devices currently marketed are effective and acceptable to a minority of women and, given that they are relatively non-invasive (with the exception of intra-urethral devices), they may be suggested to patients for consideration and testing, particularly for short-term or occasional use.

c) Overall priorities for research

The substantial withdrawal rate and the frequency of unwanted events indicates that there is a need to establish efficacy of these devices (compared to no treatment) over longer time periods (more than a year), with careful identification of unwanted effects.

There is also a need to compare devices with simple, cheap devices. The Cochrane review recommends an intravaginal tampon as a suitable comparator.

There are indications that the devices may best be used occasionally or intermittently for specific activities and there is a need for this type of use to be tested, possibly compared to the most common alternative - an absorbent pad.

As these devices aim to prevent urine leakage there is also potential for testing their efficacy compared to other treatments such as pelvic-floor exercises or surgery.

XI. MECHANICAL DEVICES FOR MEN WITH URINARY INCONTINENCE

Male mechanical devices aim to prevent urine leakage by compressing the penis. A variety of designs are available but occlusion is usually achieved with either a clamp or a peri-penile strap (Fig XI-1). Such devices have the potential advantages of low cost and simplicity compared with a sheath and drainage bag. However there is potential for tissue damage and these devices should be used with caution.

Careful assessment is necessary for use of these devices because there is potential for damage to the penis from ischaemia (restriction of blood to the penis).
Such devices should be fitted by a trained health professional and subject to regular review. Use should be limited to men who are assessed as being cognitively intact, are aware of bladder filling, have normal genital sensation and intact penile skin, have sufficient manual dexterity to open and close the device (Moore 2004) and are motivated and willing to use such a device.

1. QUALITY OF DATA

The use of penile compression devices is described only rarely in the literature (166); (167) and is usually referred to as a last resort where other forms of management have failed or been judged inappropriate. There has only been one published evaluation (168).

2. RESULTS

Moore et al. [168] evaluated three different devices (Timms C3 penile compression device; Cunningham clamp; and U-Tex male adjustable tension band) in a cross-over study in which twelve men with stress urinary incontinence following radical prostatectomy tried each device in turn. Each of the devices significantly (p<0.05) reduced mean urine loss (measured using a 4h pad tests) compared with baseline measurements. There was some objective or subjective improvement in continence for each of the 12 men with at least one of the devices, although none completely eliminated urine loss when applied at a comfortable pressure.

Ten of the 12 men rated the Cunningham clamp positively; two, the C3; and none, the U-Tex. However, the C3 and U-Tex allowed good cavernosal artery blood flow while the Cunningham clamp significantly reduced it. Overall Moore et al. concluded that, used correctly, the Cunningham clamp can be an effective method of controlling urinary incontinence (although it should be noted that complete control i.e. no leakage, was not achieved) in men with stress urinary incontinence who are cognitively intact and aware of bladder filling, and have normal genital sensation, intact penile skin and sufficient manual dexterity to open and close the device.

Expert opinion and anecdote suggest that penile clamps may be more successful when used for short periods, for example when undertaking activities such as swimming or jogging. Such activities may not only exacerbate incontinence but also preclude the use of bulky and / or absorbent products.

3. SUMMARY

Male mechanical devices can partially control urinary leakage (but not eliminate it at comfortable levels of use) but are likely to lead to reduced cavernosal artery blood flow and therefore care must be taken to ensure regular removal or release (Level of Evidence 2).

4. RECOMMENDATIONS

- Male mechanical devices may be considered for selected men with stress urinary incontinence who are cognitively intact and aware of bladder filling, and have normal genital sensation, intact penile skin and sufficient manual dexterity to open and close the device (B).
- The devices should be fitted by a trained health professional and reviewed regularly (Grade of Recommendation C).
- The devices may be considered for short-term use when undertaking sport or other activities, as an adjunct to management with other products (Grade of Recommendation C).

5. PRIORITIES FOR RESEARCH

- There is a need for mechanical devices for men which are discreet, easy to use and which prevent leakage without risk of tissue damage.

XII. CATHETERS

Urinary catheters can provide an effective way of draining the bladder in either the short-term or long-term, by intermittent or indwelling catheterisation, where alternative strategies are unsuitable or unsatisfactory. However, indwelling catheters are rarely completely trouble-free and the risk of catheter-related complications is high, with substantial detrimental impact on patients, carers and healthcare services. It is generally agreed that catheter use should be avoided wherever possible and only adopted for those in whom alternative strategies are unsuitable or unsatisfactory, after careful assessment of the patient and their particular problem [169].
This section examines the characteristics of urinary catheters, and provides a critical review of existing evidence to guide decision-making on choice of catheters, equipment and management strategies to minimise associated risks. Specific issues relating to short-term catheterisation are addressed, but the main focus of the section is on long-term management of bladder dysfunction, by intermittent catheterisation (least invasive) or indwelling catheterisation (most invasive). An overview of factors influencing choices of catheterisation strategy is provided in Table XII-1. Detailed discussion of key issues is provided under the following headings: user characteristics, catheter characteristics, associated risks / problems, catheter management.

The bulk of research evidence on catheter use relates to short-term catheterisation. In particular there are numerous trials which focus on catheter-associated urinary tract infection since this is well recognised as a major source of healthcare associated infection. The quality of data is very variable and many studies are limited by being underpowered and by other design issues, including poorly defined outcome criteria and highly selected study populations. Much less research has addressed intermittent or long-term indwelling catheter-related issues and guidance to healthcare practitioners remains largely based on expert opinion. Some of the difficulties in conducting research on use of continence products are discussed in Section III. Further discussion related specifically to catheters is provided within the following sections (Table XII-1).

1. INTERMITTENT CATHETERISATION

Intermittent catheterisation (IC) is the act of passing a catheter into the bladder to drain urine via the urethra, or a catheterisable channel such as a Mitrofanoff diversion. The urine can be drained into a toilet, urinal, plastic bag, or other reservoir. The catheter is removed immediately after drainage. This technique avoids many of the problems associated with indwelling catheters. Intermittent catheterisation may be carried out using a sterile technique in some care settings, but clean intermittent catheterisation (CIC) or clean intermittent self-catheterisation CISC [170] is widely accepted as a safe technique for people who are self-caring in their own homes. Since some studies do not distinguish between CIC and CISC, the term CIC has been adopted to cover both throughout the following section. CIC provides much greater convenience than urethral catheterisation, without unacceptable increases in infection rate, and has become a method of choice for management of bladder drainage for neurogenic and non-neurogenic bladder dysfunctions where urinary retention is a significant symptom and not easily remedied by other relatively simple means, eg TURP for prostatic obstruction. CIC can be taught to people of all ages, including the very elderly and children as young as four years old, with parental supervision [171,172] CIC can also be taught to carers, where this is an acceptable procedure to both patient and carer.

a) Quality of data

The majority of research evidence on intermittent catheterisation relates to catheter-associated urinary tract infection (CAUTI) and catheter materials and coatings. The most frequent complication of CIC is urinary tract infection (UTI) but it is unclear which catheter types, techniques or strategies, affect its incidence. There is wide variation in practice and important cost implications for using different catheters, techniques or strategies. Two relevant Cochrane reviews were identified; ‘long-term bladder management by intermittent catheters in adults and children’ [173]; and ‘urinary catheter policies for long-term bladder drainage’ [174]. The objective of the first review was to examine which intermittent catheter types, techniques or strategies, affect the incidence of UTI. Fourteen trials were included but sample sizes were small and attrition of participants was problematic. Definitions of outcome variables and follow-up periods differed, making it difficult to draw clinically useful conclusions. Several of the trials were more than 10 years old and were typically less rigorous in design and analysis. The authors concluded there is insufficient evidence to state that incidence of UTI is affected by use of sterile or clean technique, coated or uncoated catheters, single (sterile) or multiple use (clean) catheters, self-catheterisation or catheterisation by others, or by any other strategy. The objectives of the second review [174] were to determine if certain catheter policies are better than others in terms of effectiveness, complications, quality of life and economics. Comparisons included type of catheterisation (intermittent, indwelling urethral and indwelling supra-pubic) and antibiotic prophylaxis. Seven trials were included but all were small and confidence intervals were wide. There was limited evidence which indicated that prophylactic antibiotic therapy was associated with reduced episodes of bacteriuria (asymptomatic and symptomatic) in subjects using intermittent catheterisation. In both reviews, the trials which met the inclusion criteria were limited by small sample sizes and methodological weaknesses. A third review on ‘catheter policies for management of long-term voiding problems in patients with neurogenic bladder’ [175], which aimed to assess the effects of different types of urinary catheter (IC): in managing the neurogenic bladder, found there were no trials that met the inclusion criteria. Other research in this area is dominated by retrospective reviews of bladder management outcomes of patient cohorts. Long-term follow-up studies are almost exclusively of patient groups with neurogenic bladder disorders. Small scale, comparative studies of new products are common and are often industry-sponsored. Quality of life issues are vitally important for continence product users but studies are often limited by outcome
### Table XII-1. Catheter choices. Catheters should only be considered where there is no satisfactory, non-invasive alternative to manage bladder drainage.

<table>

</table>
| Intermittent catheters (IC)       | • If more than 100ml retained in bladder (C)  
• Concept of IC acceptable to user (or carer)  
• User has sufficient dexterity and cognitive ability to manage regular drainage | • In general (as with all catheters), where alternative, non-invasive management is satisfactory  
• If user lacks motivation or unable to cope with regime | • See Section XII.1  
• Greater independence for users  
• No need for urine collection bags  
• Reduced risk of catheter-associated complications  
• Greater freedom for sexual activity. |
| Long-term indwelling catheters (LTC): general | • Only for voiding problems which cannot be managed satisfactorily by other strategies (pads, other products or IC) (A)  
• User or carer able to empty drainage bag regularly | • In general (as with all catheters), where alternative, non-invasive management is satisfactory  
• Avoidance of UTI is a priority (A)  
• Cognitive impairment (danger of interfering with catheter) (C)  
• High risk of recurrent catheter encrustation & blockage (B) | • See Section XII.2  
• May be required: (i) to drain the bladder where there is urinary retention; (ii) to improve care of for those with severe incontinence who cannot manage otherwise, are terminally ill, or need secure urine drainage to heal skin lesions / wounds affected by the presence of urine |
| LTC: urethral insertion           | • Concept is acceptable                                                                                                           | • History of urethral trauma  
• Haematuria of unknown origin  
• High risk of catheter being expelled (bladder spasm) |                                                                                                                                                        |
| LTC: supra-pubic insertion        | • Concept is acceptable                                                                                                           | • Haematuria of unknown origin,  
• Bladder tumour  
• Small, contracted and fibrotic bladder  
• User is obese |                                                                                                                                                        |
| Short-term indwelling catheter    | • Post-operative controlled drainage  
• To monitor urine output  
• To irrigate the bladder  
• To instil medication  
• To relieve retention of urine | • In general (as with all catheters), where alternative, non-invasive management is satisfactory  
• Avoidance of UTI is a priority (A) |                                                                                                                                                        |
measures predominantly based on user satisfaction, in the absence of clear criteria. Few studies have directly compared CIC with other methods of bladder drainage.

**b) User characteristics:**

CIC is a commonly recommended procedure for people with incomplete bladder emptying not satisfactorily managed by other methods. CIC can be appropriate for post-void residual urine volumes of 100ml or more in:

- Patients with neurological disorders that result in urinary retention problems, including failure to empty the bladder, incomplete emptying, detrusor sphincter dyssynergia.
- Patients with difficulty emptying the bladder after surgical procedures, if outflow obstruction occurs either in the short or long-term.
- Patients who accumulate a build up of residual urine caused by detrusor overactivity and inadequate bladder emptying.
- Acute urinary retention (most commonly in men).
- Management of urethral stricture.
- Emptying the bladder following continent urinary diversions such as a Mitrofanoff diversion.

CIC may be a practical option for patients who are:

- Sufficiently motivated to manage their bladder drainage by this technique.
- Sufficiently dexterous to perform the technique. An appropriate level of manual dexterity is essential but generally if people can write and feed themselves they have sufficient dexterity [176].
- Sufficiently cognitively aware to adhere to a regime and empty the bladder at appropriate time intervals to prevent bladder over-distension and preserve upper urinary tract function.
- Unable to perform the technique themselves but willing to accept the procedure from a carer.

Most men require some form of lubrication to aid catheterisation, which can be on the catheter surface or instilled into the urethra [177] (Level of Evidence 3). For those with preserved urethral sensation, a local anaesthetic gel may be needed. Many female patients also use a catheter lubricant / anaesthetic gel although some choose not to. In developing countries, where resources are limited (or sometimes through patient choice), patients sometimes use plain water as lubricant [178] (Level of Evidence 4).

Regular bladder drainage is important to avoid potential damage to the upper urinary tract from urine reflux and raised intravesical pressure from build up of residual urine. Patients require individualised care plans to help identify appropriate catheterisation frequency, based on discussion of voiding dysfunction and impact on quality of life, frequency-volume charts, functional bladder capacity, and ultrasound bladder scans for residual urine. Some people need to catheterise several times per day, others less frequently. Catheterising frequently enough to avoid residual urine greater than 500ml is a general rule for adults but further guidance is also provided by urodynamic findings, detrusor pressures on filling, presence of reflux, and renal function. Disabilities such as blindness, lack of perineal sensation, tremor, mental disability and paraplegia do not necessarily preclude individuals from mastering the technique if they have sufficient manual dexterity [176]. Lack of motivation is the most common reason for failure, often linked to difficulty managing the technique or adhering to the required regime.

Children at school need a multi-professional assessment which may include a continence advisor, paediatric community nurse or school nurse, the child’s consultant, the child and parents. With adequate training, suitable facilities and supportive teaching staff many children are able to carry out CIC themselves either on a toilet or from a wheelchair. CIC has been shown to be a viable therapeutic option for children with a large post-void residual urine volume in the absence of any neurological abnormality [179]. Intermittent catheterisation has also been shown to be an effective technique for elderly patients with post-void residuals more than 50% of the bladder capacity, resistant to other treatment [180]. In a group of 21 patients (mean age 76.5 years), 12 mastered the technique of CIC, with the remainder catheterised by their partners or nurses. Urinary continence was restored, urgency, frequency and nocturia decreased and UTI rate diminished, resulting in improved quality of life.

Advantages of intermittent over indwelling catheterisation include:

- Greater opportunity for individuals for self-care and independence.
- Reduced risk of common indwelling catheter-associated complications.
- Better protection of the upper urinary tract from reflux.
- Reduced need for equipment and appliances e.g. drainage bags.
- Greater freedom for expression of sexuality.
- Potential for improved continence between.

**c) Catheter characteristics**

Types and characteristics of catheters used in intermittent catheterisation vary considerably so evaluation and selection of products is complex [173].
Plain uncoated catheters (typically clear plastic PVC) are packed singly in sterile packaging. As per industry standards, all disposable catheters are intended for one-time use but PVC catheters are frequently cleaned and reused by individual users because of cost or concern about environmental issues. Some healthcare professionals make a distinction between ‘single-use’ (i.e. disposed of after insertion) and ‘single patient use’ (cleaned and re-used by the same patient for a limited period of time, such as one week). Where products are used in ways which differ from manufacturers’ guidance, both patients and healthcare professionals should recognise their personal, professional/legal responsibilities. In some countries, including the US, there are very clear governmental directives that catheters identified as single-use devices should not be re-used in any setting. US patients should be provided with an adequate number of catheters to use a sterile catheter for each catheterisation, and patients and carers must be informed that catheters are identified for single use only.

Most uncoated intermittent catheters are used with separate lubricant, although this is a matter of personal choice. Cleansing for re-use (where this occurs) varies from being washed with soap and water, boiled, soaked in disinfectants, or microwaved. Cleaned catheters are air dried and then stored in a convenient container (often plastic containers/Zip loc bags or paper bags). Metal catheters made from silver or stainless steel can be sterilized by heat or chemicals and may be used repeatedly for longer periods than other reusable materials.

Coated catheters are single use only (they are not currently suitable to be cleaned and reused) and are designed to improve catheter lubrication, ease of insertion and convenience. Coated catheters may reduce urethral trauma and CAUTI although good quality research evidence remains limited. The most common coatings are hydrophilic (which require the addition of water to the catheter to form a lubricious layer) or pre-lubricated (whereby the catheter is supplied pre-packed with a coating of water soluble gel). There are also several pre-lubricated products with an integrated collection bag (all-in-one) which gives flexibility for the user and are efficient for hospital use.

Intermittent catheters range in size from 6-20 Ch, with most common sizes being 10-12 for females and 12-16 for males (Fig XII-1). Intermittent catheters are generally around 40cm long (male length) and are more rigid than indwelling catheters to aid insertion. A variety of aids to assist catheterisation are available (Fig XII-2).

Some women find a stiffer catheter easier to handle and some designs are slightly curved and made only in female length (around 18cm) to accommodate their requirements. Some manufacturers produce conveniently packaged ‘catheter-sets’ where the catheter is already attached to a urine containment pouch inside the pack and a non-touch, clean technique is facilitated by holding the catheter inside the bag and gradually advancing it from the bag during insertion. Catheter designs may include a protective tip to help reduce the transfer of bacteria from the distal region of the urethra further into the bladder. Patients should have the opportunity to try different catheters and choose which best suits their needs and lifestyle. Different catheters/packs may be appropriate at different times e.g. when added convenience for quick and efficient use and disposal is important, such as going to work or on holiday.

An effective intermittent catheter should have the following characteristics:

- Smooth for comfort, but sufficiently firm for easy insertion and maintenance of lumen patency.
- Minimal friction on insertion or removal.
• Smooth edges to catheter eyes to avoid tissue trauma on frequent catheterisation.
• Shaped for easy passage through urethral contours.
• Easy to hold and manipulate for those with limited dexterity.
• Easy to identify correct end for insertion and for drainage, for those with visual impairment.

Although there is an increasing range of intermittent catheter types on the market - including many pre-lubricated products with integrated collection bags - the quality of evidence for clinical benefit is poor. De Ridder et al [181] conducted a prospective, randomised, parallel, comparative trial of a hydrophilic coated catheter with an uncoated PVC catheter with 123 male spinal cord injured (SCI) patients. Only 57 completed the 12 month study but fewer patients with the coated catheter experienced one or more symptomatic UTIs (p=0.02). There was no difference in haematuria, leukocyturia and bacteriuria. However a recent Cochrane Review [173], concluded that overall current research evidence is weak, most studies are underpowered and conclusions are limited by serious design issues. An earlier literature review (182) also indicated the wide variety of materials and techniques used for intermittent catheterisation. It concluded that there was no one best technique or material and that choice of both depend greatly on the patient’s individual anatomic, social and economic status.

d) Associated risks / problems

Urinary tract infection is well-recognised as the most frequent complication of intermittent catheterisation [173;182]. The accumulation of urine in the bladder provides a reservoir for infection, but it has also been proposed that the increased intravesical pressure reduces the vascular supply to the bladder tissue rendering it more susceptible to bacterial invasion [183]. A post-void residual urine volume of 150ml has been demonstrated to be an independent risk factor for the development of UTI, in stroke patients [184] (Level of Evidence 2).

In Wyndaele’s review of complications of intermittent catheterisation (82 studies), prostatitis was identified as a risk in men but epididymitis and urethritis were relatively rare [182]. Trauma from catheterisation, measured by haematuria, was noted to occur regularly but lasting effects were more limited. The prevalence of urethral strictures and false passages increased with longer use of CIC but the review concluded that the most important preventative measures are good education of all involved in CIC, good patient compliance, use of an appropriate catheter material, good catheterisation technique and the avoidance of bladder over-filling. Similar findings were reported by Campbell [185] in a follow up of children with spina bifida who had used intermittent catheterisation with uncoated PVC catheters for at least five years. The incidence of urethritis, false passage, or epididymitis was very low whilst adherence to the protocol was excellent. However, Ku et al [186] found a higher incidence of epididymitis in their cohort review of 140 male, SCI patients followed over 16 years.

1. Urinary tract infection

It is difficult to know the prevalence of UTI associated with intermittent catheterisation as reports vary widely and definitions of UTI are inconsistent, sometimes based on bacteriuria alone (asymptomatic) and sometimes on symptomatic UTI (with or without clearly defined criteria). Other variations include the evaluation methods used, catheterisation techniques, frequency of urinalysis / culture, administration or not of prophylactic antibiotics, and the patient group studied (including gender, functional ability, behavioural and personal hygiene factors). In a prospective study of 128 SCI patients, where the incidence of UTI was calculated as the number of episodes per 100 person-days, the overall incidence of UTI was 0.68. The rate for males using CIC was 0.41, compared to 2.72 for those using an indwelling catheter [187]. Biering-Sorensen et al. (188) studied 77 SCI patients on CIC after five years and found that 81% had been treated for at least one UTI, 22% had two-three UTIs/year and 12% had four or more per year. The technique of intermittent catheterisation used does not seem to be a risk factor and despite different catheterisation techniques used, the number of episodes of clinically significant nosocomial urinary infections and the mean species turnover remains similar [189] (Level of Evidence 2).

In the Cochrane review cited above [173], the primary outcome measure was catheter-associated infection (definition of infection as used in the trial reports). Fourteen trials met the inclusion criteria but too little data could be entered into a metaanalysis to produce meaningful data summaries. Based on the available data, the authors concluded that there appeared to be no clear difference between various methods of catheterisation (sterile catheterisation techniques, clean catheterisation with a single-use sterile catheter, or clean catheterisation with a clean reused catheter). Whilst the outcomes of this review raise questions over efficacy and cost-effectiveness of expensive coated catheters it is clear that further robust research is needed. All sample sizes in the trials were small and only two included statistical power calculations, although they were unable to achieve their predicted sample sizes. Most studies suffered from high attrition rates and several reports were more than 10 years old.

The challenges of obtaining sound data in this clinical area continue to hinder the accumulation of evidence to help guide healthcare practitioners. A common difficulty is in the establishment of robust outcome
measures. UTI remains the most clinically important primary outcome variable but bacteriuria/positive urine culture is not clinically relevant unless accompanied by symptoms. Symptoms themselves may present in vague and imprecise ways, especially in elderly and/or SCI patients where symptoms can be masked or unclear.

A Cochrane review on urinary catheter policies for long-term bladder drainage [174] reported limited evidence that prophylactic antibiotic therapy was associated with reduced episodes of bacteriuria (asymptomatic and symptomatic) but all trials were small and confidence intervals were wide. The authors caution that possible benefits from prophylaxis must be balanced against possible adverse effects such as the development of antibiotic resistant bacteria.

In order to improve rigorous clinical evaluation of current and innovative products for CIC, more epidemiological data on user populations and characteristics of catheter use is needed. A recent Canadian national survey of intermittent catheterisation practices following SCI [190], reported on 912 responses to a 36-item self-report postal questionnaire. Fifty five per cent of respondents used intermittent catheterisation regularly, with users forming a significantly younger group than non-users (P=0.001). The majority of users (73%) used a clean technique. The remaining 27% reported using a sterile technique. Uncoated catheters were used most commonly; 74% only used uncoated catheters; 15% used hydrophilic coated catheters; and 11% reported using both types. These notable differences may be partially related to patient education, costs to patients and health insurance funding constraints. The majority of uncoated catheter users used their catheter only once (53%) but a further 30% used their catheter more than nine times. The mean frequency of self-reported CAUTIs in the past 12 months (symptomatic but not necessarily confirmed by laboratory evidence) was 2.6, with females experiences significantly more infections than males (P=0.003). Although the use of hydrophilic coated catheters was associated with a lower rate of CAUTI (2.46 v 2.62 for those using uncoated catheters), this difference was not reported as statistically significant. However UTI rates are multifactorial and are unlikely to be fully accounted for by the variables investigated. A significant relationship between number of catheterisations per day and CAUTI rates was identified, with those who catheterised only once a day having the highest rate of infections (P=0.03). This is consistent with previous suggestions that increasing the time that colonised urine is present in the bladder is associated with increased infection rates [181]. It is interesting to note that, while extra fluid intake was positively related to reduced rate of CAUTI (P<0.001), catheter re-use, catheter disinfection and antibiotic prophylaxis were not significantly associated with CAUTI rate. Clearly there are potential limitations in this study as with any which employs self-report methodology. These include self-selection of respondents, accuracy of recall and quality of information provided, but the large number of respondents and the degree of internal consistency reported by the researchers provide credibility to these results.

Several studies have sought to determine whether the antibacterial effects of cranberry extract will reduce or eliminate bacteriuria and pyuria in patients using intermittent catheterisation, particularly in SCI populations [191,192]. In a randomised, double-blind, placebo-controlled study of 48 SCI patients living in the community and using intermittent catheterisation or external urine collection device, participants ingested 2g concentrated cranberry extract in capsule form or placebo daily for 6 months [192]. There were no differences between groups with respect to number of urine specimens with bacterial counts >10^5 cfu/ml, types and numbers of different bacterial species, numbers of urinary leukocytes, urinary pH, or episodes of symptomatic infection.

2. Tissue Trauma, strictures and other complications

Long-term follow-up studies have examined other complications associated with intermittent catheterisation and found urethral trauma to be common [193,194]. Urethral bleeding is frequent in new patients and has been noted to continue to occur in up to 30% on a long-term basis [194,195], however risks of tissue trauma may be reduced with newer catheter products which are designed to reduce friction. Consequently the outcomes of older studies need to be considered with caution. The withdrawal frictional force was compared between two hydrophilic coated catheters and one uncoated catheter in a prospective, randomised, participant-blinded, crossover trial by Stensballe et al [196]. Forty participants completed the study and it was interesting to note that while one coated catheter (SpeediCath) exerted a lower mean withdrawal force than the other catheters, the second coated catheter (LoFric) exerted a significantly higher mean friction force than both the other catheters. Both hydrophilic coated catheters were associated with less microscopic haematuria than the uncoated catheter. Similarly, there was a lower incidence of microscopic haematuria reported in two of the coated catheter groups compared to uncoated catheters in trials included in the Cochrane review [173]; 0.31v0.65 [197]; 6/14 (43%) v 11/14 (78%) [198]. Trauma of the urethra, especially in men, can cause false passages. Treatment for false passages in SCI patients by six weeks indwelling catheter use and five days antibiotics, has been reported to be effective [199] (Level of Evidence 3). The false passages had disappeared on cystoscopy and CIC could be restarted.

It has been claimed that the long term risk of urethral
stricture formation may be less when hydrophilic coated catheters are used [200]. The degree of urethral inflammation, measured by urethral cytology in two groups using CIC (one using ordinary PVC catheters with lubricant; the other using hydrophilic coated catheters), showed significantly less urethral inflammation in the hydrophilic coated catheter group. Although this data suggests some benefit in using hydrophilic coated catheters to minimise stricture formation in the long-term comparative studies are limited. One recent follow-up study of 31 females with spina bifida, using CIC for a median of 15 years, examined risk of urethral lesions. There were few problems reported (only on 20 occasions in a total of 459 patient-years), despite long-treatment periods and use of non-coated PVC catheters [201].

The relative importance and cost-effectiveness of hydrophilic catheter coatings has not been adequately addressed in large scale studies to date. Hedlund et al. [202] in their review of 28 CIC studies, called for a prospective, randomized, long-term, multi-centre study to address clinical benefit and cost effectiveness. Data on patient characteristics should include age; gender; diagnosis of bladder dysfunction; reason for CIC; physical and mental disability; manual dexterity; and previous treatments. Effect parameters should include number of catheterisations; urinary tract infection (symptomatic or asymptomatic); early and long-term urethral complications; patient satisfaction, preferences; and drop-out rates. Robust studies of this nature are still awaited.

3. OTHER COMPLICATIONS

Formation of bladder stones has been found to be associated with long-term use of CIC in a number of studies [203] (Level of Evidence 2). Barroso et al. [204] reported an increased risk of developing bladder calculi in children performing CIC based on the records of 403 children. Stones were diagnosed in 28 patients. The incidence was slightly higher in those with a Mitrofanoff conduit but was not influenced by bladder augmentation (Level of Evidence 3). A retrospective study of 140 SCI patients, followed up from 1987 to 2003, identified 27.9% of patients diagnosed with epididymo-orchiditis. This problem was more common in patients using CIC compared to indwelling catheterisation (42.2% v 8.3%, P= 0.03). Multivariate analysis showed CIC to be an independent risk factor for epididymo-orchiditis, with SCI patients in this study subject to a 7-fold higher risk (OD 6.96; 95%CI, 1.26-38.53 [186].

e) Catheter management

1. Education, support and quality of life (QoL)

Good education of all involved in CIC, good patient compliance, use of an appropriate catheter material, and good catheterisation technique have been identified as the most important measures to prevent adverse complications [182]. Factors affecting adherence to self-catheterisation procedures have been explored, addressing both initial mastery of technique and both short-term adherence and long-term adherence [205,206]. Time taken to build confidence is variable and may range from days to years [206]. General determinants of adherence related to knowledge, complexity of the procedure, misconceptions, fears, shame, motivation, quality and continuity of professional care. Integration of the CIC regime into everyday life was a recognised difficulty and for younger patients, in particular, availability of materials, physical impairments and resistance to ‘sickness role’ were factors which could also compromise adherence. Qualitative research studies using a grounded theory approach have identified similar factors influencing variations in quality of life (see also Section XII.4).

These include sex; lifestyle; frequency of duration of carrying out CIC; technical difficulties; type of catheter; co-morbidities; and individual predispositions [207]. In the large scale Canadian survey above (190) 71% reported that CAUTIs had negatively impacted on their QoL score (a 10-point scale). Severeable significant variables associated with CAUTI and QoL were determined. Interestingly, time lost from social activities was more strongly associated with compromised QoL than actual number of infections or days lost from work.

2. Catheter cleaning for re-use

Where catheters are cleaned for re-use they may continue to be used many times, up to weeks or even months. However, health professionals and users need to recognise their personal responsibilities and liabilities in supporting this approach since manufacturers’ guidance will normally relate to single use only (see also Section XII.1.3). Questions over how long the same catheter may be safely reused require further examination, and may be particularly important in developing countries, where access to new supplies may be limited [208].

Methods of cleaning or re-sterilising include soaking in a variety of antiseptic solutions or boiling water or microwave sterilisation. In a study which compared three home cleaning methods used by patients performing CIC, all of the following were found to be effective: 0.6% hydrogen peroxide; bleach in a 1:4 solution with tap water; and betadine in a 1:2 solution with tap water [209]. None of the cleaned catheters showed detectable bacterial growth for 48 hours after the cleaning procedure was performed (Level of Evidence 4). Lavallee et al. [210] also compared the effectiveness of hydrogen peroxide, vinegar, dishwashing detergent, and tap water alone to clean catheters contaminated with Pseudomonas aeruginosa and Escherichia coli. They also examined the effect of immediate rinsing and drying before cleaning.
Table XII-2. Intermittent catheterisation

Patient education & support:

• Discussion of individual bladder dysfunction and reasons for CIC.
• Personal anatomy and identification of urethral orifice.
• CIC technique — comfortable position, frequency, observation of patient’s technique.
• Hygiene.
• Discussion of any psycho-sexual anxieties (body image, sexual function etc).
• Single use versus reusable catheters (cleaning, storing, re-use, disposal). NB including awareness of personal / legal issues.
• Difficulties and what to do.
• Dietary advice and avoidance of constipation.
• Obtaining supplies.
• Follow-up visits and consultations.

Guidance for common problems:

• Catheter will not go in at first attempt – relax for a while and try again a bit later; lubricate catheter (eg dipping in water or gel); if necessary seek professional guidance.
• Catheter inserted into vagina by mistake – withdraw, wash and re-insert.
• Catheter will not come out – leave for a few minutes, relax and try to ‘let go’, cough gently and withdraw catheter.
• UTI – report changes in urine (eg blood, sediment, smell). Know how to recognise signs of symptomatic infection and seek treatment and review of CIC technique.

Results indicated that rinsing and drying immediately after use was the most effective at reducing bacteria to near zero (Level of Evidence 4). Microwave sterilization has been advocated by some, but has not been adequately evaluated. A study by Sherbondy, et al. [211] showed that even where standardized instructions (both verbal and written) were provided, microwave sterilization techniques by patients performing CIC varied considerably. Many patients surveyed did not follow the study instructions recommending sterilizing used catheters on a daily basis, cleaning with soap and water and air drying before inserting into a microwave oven on a paper towel. Microwaving on a high setting for six minutes on a rotation table was recommended together with a heat sink – a cup of water in a microwave-safe container placed in the microwave to absorb extra heat. Catheter melting was reported by 63% and was significantly associated with the absence of a rotation

If microwaving is to be accepted as an appropriate sterilization method then users must be provided with a standardised, evidence-based, protocol to follow. A recent study reported the development of titanium dioxide-coated catheters for CIC which were easily sterilized under certain light sources and were shown to be safe in experimental studies [212]. Preliminary clinical analysis with 18 volunteers was also promising.

1) Comparisons between intermittent and indwelling catheterisation

A systematic review of risk factors for UTI in adults with SCI reported evidence of fewer infections in patients using intermittent catheterisation compared to indwelling catheterisation (213). Twenty two studies met the inclusion criteria for evaluation but the authors noted that many had important methodological deficiencies. Intermittent catheterisation has also been shown to be associated with fewer UTIs compared to indwelling catheterisation in elderly patients after surgical repair of hip fractures [214] and in a comparative study of patients at a hospital department of urology [215].

Patel et al.[216] examined the outcomes of different forms of urinary drainage for men with acute urinary retention. After a short period of indwelling urinary catheterisation patients were taught to use CIC (34 men). Patients who failed this were re-catheterised and taught to manage a valve or failing this a leg bag (16 men) and then discharged home. The CIC group had a higher rate of spontaneous voiding (56% v 25%) and a lower incidence of UTI (32% v 75%). At TURP 20% in the CIC group had a UTI compared to 69% in the indwelling catheter group. Patients using CIC preferred it and had fewer complications. The authors concluded that CIC was well accepted by those patients who were able to manage the technique, resulted in fewer UTIs and should be considered in patients presenting with acute retention.

In a recent 2-week prospective study of intermittent catheterisation versus indwelling urethral catheterisation in older female patients in a rehabilitation setting, 81 females >65 years with post-voiding residual volume persistently >300 ml were randomized to one of two groups[217]. Both groups demonstrated similar success in regaining bladder function and similar rates of bacteriuria. The authors concluded that intermittent catheterisation was justified in managing this patient group, particularly since indwelling catheters were deemed to hinder rehabilitation and adversely affected quality of life.

In a prospective RCT of CIC versus supra-pubic catheterisation (SPC) for post-operative bladder care following hysterectomy in 40 women there was no significant difference in the length of bladder care between the two groups[218]. Bacteriuria was higher
in the CIC group at days 3 and 5 (p=0.05 and 0.004 respectively) although it is unclear whether there was evidence of symptomatic infection. However, there was a higher incidence of symptoms / problems arising from the SPC site, of which 23% were shown to have a positive wound swab. The authors concluded that despite a higher rate of bacteriuria, the high incidence of site problems with SPC could be avoided by CIC. The technique of CIC was seen to be more acceptable to patients (p=0.009); allowing fewer disturbances at night (p=0.006); greater freedom to lead a normal life during the day (p=0.000); and less anxiety / embarrassment (p=0.005) compared to SPC.

**g) Summary**

CIC is the optimum method of urinary drainage in patients with neurogenic bladder dysfunction and others with problems of bladder emptying. It can be taught to patients of all ages who have sufficient manual dexterity and motivation to manage the technique. Urinary tract infection is the most frequent complication and the most important preventative measures for all complications are good education of all involved in CIC management, good patient compliance and support, use of an appropriate catheter material and good catheterisation technique. Difficulties in carrying out the procedure such as physical and technical difficulties, embarrassment, time involved and lack of appropriate public facilities may deter users from adhering to the regime. Hydrophilic-coated catheters confer benefits in terms of comfort and minimised tissue trauma compared to non-coated catheters (Level of Evidence 2/3) but evidence of benefit in relation to urinary tract infection is less clear.

The available data on intermittent catheterisation does not provide convincing evidence that any specific technique (sterile or clean), catheter type (coated or uncoated); method (single use or multiple use), person (self or other), or strategy is better than any other for all clinical settings. This reflects lack of reliable evidence rather than evidence of no difference. Currently clinicians will need to base decisions about which technique and type of catheter to use on clinical judgment, in conjunction with patients. Differential costs of catheters / techniques may also inform decision making.

In particular, CIC has been shown to have benefits over indwelling catheterisation in the following ways:

- Avoidance of common problems associated with LTC use such as catheter leakage and / or practical management of drainage systems
- Avoidance of complications linked to bacterial biofilm formation, including catheter encrustation and blockage. Strong evidence for reduced risk of CAUTI is less clear.
- Maintenance of some level of bladder capacity and muscle tone by allowing the bladder to fill periodically, compared to free drainage by indwelling catheter.
- Less urethral inflammation (measured by cytology) than urethral indwelling catheterisation (Level of Evidence 2/3).
- Lower incidence of bladder calculi than indwelling catheterisation (Level of Evidence 2/3).

**2. INDWELLING CATHETERISATION**

Indwelling catheters (Fig XII-3) may be used in the short-term to manage an acute need for controlled bladder drainage or as part of a long-term management strategy (Table XII-1).

Catheters may be inserted into the bladder urethrally (UC) or suprapubically (SPC) through an incision in the abdominal wall. The continued requirement for indwelling catheterization should be reviewed at regular intervals and the catheter removed promptly if no longer necessary, since catheter use is associated with a number of risks. The major complication associated with short-term, indwelling catheters used in acute care, is nosocomial (healthcare acquired) catheter-associated urinary tract infection (CAUTI), which can lead to life-threatening bacteraemia in vulnerable groups and may also contribute to reservoirs of antibiotic resistant microorganisms [169] [117] [219]. Long-term catheters (LTC) are also associated with increased risk of CAUTI and a further range of problems including: recurrent blockage due to encrustation by mineral deposits; meatal tissue damage - often caused by excessive weight from heavy drainage bags; frequent bladder spasm with potential expulsion of the catheter; formation of bladder calculi; and potential for long-term neoplastic changes.

![Figure XII-3: A Foley catheter (left) and a suprapubic catheter with a sharp trocar for introducing the catheter (right).](image-url)
in the bladder (although further long-term studies are needed to establish this risk). Although for some patients an LTC catheter can provide satisfactory management of bladder problems and greater independence, others experience pain and discomfort with a catheter in situ and / or, are distressed by the impact of a catheter on their body image and sexuality. Intermittent catheterisation (See Section XII.1) is less invasive and is generally associated with fewer risks.

**a) Quality of Data**

Seven Cochrane reviews relating to short and long-term indwelling catheter use were identified. Reviews on short-term (<14 days or other temporary short-term use as defined by triallists) catheter issues included: types of urethral catheters for management of short-term voiding problems in hospitalised adults (220); policies for bladder management [221]; the role of prophylactic antibiotics [222]; and policies for removal of short-term indwelling catheters [223]. The objective of the first review [220] was to determine the effect of type of indwelling urethral catheter on the risk of UTI. Twenty-three trials - comparing different types of standard catheters or a standard catheter with an antiseptic catheter (silver alloy or impregnated with silver oxide), or an antibiotic impregnated catheter (either minocycline and rifampicin, or nitrofurazone) - met the criteria. The reviewers concluded that currently available evidence suggests that silver alloy catheters prevent asymptomatic bacteriuria in the short-term catheterised patient, although trials are generally of poor quality (Level of Evidence 2/3).

They also recommended that further economic evaluation is required to confirm that infection compensates for the increased cost of the silver alloy catheters. Catheters impregnated with antibiotics were also beneficial in reducing bacteriuria in hospitalised adults catheterised for less than a week but data were too few for those catheterised longer. However, it is important to note that although bacteriuria is a commonly used outcome measure in CAUTI studies there is much debate over the clinical utility of this measure. Many studies fail to distinguish between asymptomatic bacteriuria and symptomatic infection. This is discussed further in Section XII.h.2.

The second review [221] included 14 trials which reported on comparisons between SPC and UC for short term (up to 14 days). Higher relative risks scores were found for UC related to more bacteriuria (RR 2.60; 95% CI 2.12 to 3.18), more frequent re-catherization (RR 4.12; 95% CI 2.94 to 7.56) and increased discomfort (RR 2.98; 95% CI 2.31 to 3.85) (Level of Evidence 1). The third review [222] included six parallel group RCTs and reported weak evidence that antibiotic prophylaxis reduced the rate of symptomatic UTI in female surgical patients, compared to antibiotics given when clinically indicated. The review of policies for catheter removal reported suggestive, but inconclusive, evidence of benefit from midnight removal of the catheter (larger volumes at first void) and shorter hospital stay after early rather than delayed removal. There was little evidence on which to judge other aspects of management such as catheter clamping, prior to removal.

Of the three Cochrane reviews relating to long-term catheter use, a review of comparative methods of using catheters for neurogenic bladder management [175] failed to find any trial that met the inclusion criteria. A second review [224] to compare types of indwelling catheter for long-term use (defined as >30 days) found only three trials which met the inclusion criteria. One trial compared antiseptic impregnated catheters with standard catheters and two compared different types of standard catheter. The authors reported ‘an astonishing lack of evidence for this clinically highly relevant problem’.

Since the included studies were very small and showed methodological weakness, the authors concluded that the available evidence was insufficient as a reliable basis for practice and catheter choice remains largely based on clinical experience. In the third Cochrane review on ‘urinary catheter policies for long-term bladder drainage’[174], seven trials met the inclusion criteria. All were small, with wide confidence intervals. No appropriate trials addressed comparisons between: indwelling UC and SPC; UC and intermittent catheterisation; or SPC and intermittent catheterisation.

Evidence pertaining to whether antibiotic prophylaxis is better than antibiotics given when clinically indicated, was insufficient as a basis for clinical practice. A Cochrane review protocol for washout policies for the management of long-term catheters in adults has been published [225] but there is little published clinical evidence to review, to date. Overall long-term catheter care practices remain poorly supported by research evidence. This is at least partially due to difficulties in conducting trials in long-term catheterised populations for a variety of reasons, many of which have been discussed in earlier sections.

The impact of long-term catheters on users’ quality of life (QoL) is a very important issue which has not been studied adequately. No Cochrane reviews have dealt with this topic directly, although several reviews have included issues with an impact on QoL such as catheter related complications and comfort. One RCT addressed education needs of catheter users. Other studies include a small number of prospective cohort studies, with the remainder being retrospective studies and case series reports, providing evidence at Level 3. Much relevant research uses qualitative research methodologies, aimed at understanding the nature of long-term catheter-related issues and patient concerns. Measures of QoL used commonly rely on a single question of quality of life or satisfaction on a 3- or 10-point scale.
Validated QoL instruments, such as SF 36 are not only infrequently used, but are likely to lack sensitivity for the specific issues which concern catheter users. There are currently no device-specific measures as advocated by ICS (226), although work in this area is continuing.

b) Prevalence of indwelling catheters use

Short-term catheterisation is common in acute care settings, with up to 25% of patients receiving a catheter during their hospital stay [169,227]. The prevalence of LTC use in home care or community care settings varies widely and can be more difficult to determine. A large scale survey of 4010 older people (>65 years) receiving home care in 11 European countries, found a mean prevalence of LTC use of 5.4%, ranging from 0% in the Netherlands to 23% in Italy [228]. In another large study of 1004 frail older women living in the community the reported LTC prevalence rate was 38.1% [229].

There is evidence that older patients aged 65 years or more are often catheterised inappropriately [230-232]. Gokula et al. [231] surveyed a 10% random sample of patient charts from 2845 elderly patients who received an indwelling catheter during hospital admission in one year. Less than half the selected charts recorded an appropriate indication for catheterisation. An explicit reason for catheter insertion was documented in only 13% of charts and there was no written order for catheterisation in 33% of the charts. Only 18% had documented care plans for catheter removal.

Expert opinion and experience suggests that even when there is an appropriate clinical reason for initial catheterisation, patients may remain catheterised unnecessarily if medical and nursing staff fail to review ongoing need (Level of Evidence 3). Problems of inappropriate catheter use may be compounded when patients are transferred from one clinical setting to another without adequate information on why the person was catheterised [233]. Wald et al [234] reported that 32% of patients catheterised during treatment for hip fracture in their study were discharged to nursing homes with the catheter still in place.

The prevalence of catheterized patients in nursing homes is generally higher than in people living at home and has been reported to be around 9% in the UK [235], but there may be considerable variation between homes [236]. In nursing homes in the US, it has been estimated that between 7-10% of the residents have an LTC [237], although figures vary from state to state. More recent data from analysis of a US National Nursing Home Survey [238] and a point prevalence study of nursing home-associated infections in the Department of Veterans Affairs nursing home care units [239] demonstrated similar prevalence. Tsan et al. [239] reported a prevalence of 10.7% for indwelling urethral catheters and 2.46% for suprapubic catheters amongst a nursing home population of 11,475 in 133 care home units. There is some evidence of decreasing rates of urinary catheterisation in some places. A retrospective cohort study of the use of urine collection devices in skilled nursing facilities (SNFs) in five US states examined the characteristics of 57,302 patients who remained in an SNF for one year in 2003 [240]. The prevalence of indwelling catheterisation was 12.6% at admission and 4.5% at annual assessment (P<0.001). Paraplegia, quadriplegia, multiple sclerosis and comatose state were strongly associated with LTC use. Male residents were more likely to use a catheter at every assessment, as were obese patients; individuals with diabetes mellitus, renal failure, skin conditions, deep vein thrombosis, aphasia or end-stage disease; and those taking multiple medications.

Duration of catheter use in home settings varies widely, with a median of 3-4 years and some individuals using them over 20 years [241-243]. Management regimes for continence problems in older people continue to demonstrate a predominance of containment strategies, using pads and catheters [244] and consequently unwarranted use of LTCs for incontinence continues in many places despite known catheter-associated risks.

c) User characteristics

Short-term catheterisation (usually defined as up to 14 days) is most commonly used:

- During surgical procedures and post-operative care.
- For accurate monitoring of urine output in acute illness.
- Instillation of medication directly into the bladder.
- For relief of acute or chronic urinary retention.

Long-term indwelling catheters - routinely changed and replaced, often over many months or years - may be required to aid those who have difficulty emptying their bladder due to obstruction or neurological disorders, where intermittent catheterisation is not a satisfactory option. LTCs may also be used to provide supportive care for those with severe incontinence who cannot manage otherwise, are terminally ill, or need treatment to heal skin lesions or surgical wounds affected by the presence of urine.

Long-term catheterisation is most commonly used to help manage:

- Bladder outlet obstruction (BOO), where patients are unsuitable for - or waiting for - surgical relief.
- Chronic retention, often as a result of neurological injury or disease (where intermittent catheterisation is not possible).
• Debilitated, paralysed or comatose patients (in presence of skin breakdown and infected pressure ulcers).

• Intractable urinary incontinence where catheterisation enhances the patient’s quality of life (as a last resort when alternative non-invasive approaches are unsatisfactory or unsuccessful).

d) Routes of catheter insertion

For some patients the insertion of an indwelling catheter suprapubically (SPC) into the bladder, through the abdominal wall, offers advantages over the urethral route (UC). SPC may be necessary following urethral or pelvic trauma but also offers advantages in acute and long-term care. In frail elderly men, and / or those prone to infection e.g. diabetes mellitus, SPC can be preferable to a urethral insertion to avoid urethritis, orchideepidymitis and prostatitis [245]. Strategies to support the SPC may be required (e.g anchoring to the abdominal wall with a BioDerm tube holder) to prevent traction and potential displacement of the catheter or balloon [246].

Advantages of SPC compared to UC are:

• Avoidance of risk of urethra trauma to men and women during catheter insertion and withdrawal.

• Avoidance of risk of urethral destruction / necrosis from pressure caused by the weight of poorly supported catheter bags, expulsion of the catheter (particularly in neurologically impaired women), or sitting on the catheter in wheelchair bound women.

• Ease of access to entry site in patients with reduced mobility, who are wheelchair bound, have restricted hip mobility, or experience urethral pain.

• Facilitation of post-surgical trial of voiding (by temporarily clamping the drainage tubing).

• Greater freedom for expression of sexuality, although this may be counteracted by perceptions of altered body image.

• Reduced risk of contamination where faecal incontinence is a problem.

SPC insertion is generally contra-indicated in patients with haematuria of unknown origin, bladder tumour, or small contracted or fibrotic bladders which may have resulted from long-term urethral catheterisation on free drainage. In obese or immobile patients the traditional SPC stoma site may become concealed by an apron of excess anterior abdominal wall fatty tissue which can lead to sub-optimal care by both patient and carer. SPC is an effective and well-tolerated method of bladder management for many SCI patients [247-249]. In Sheriff et al’s study [247] the general level of satisfaction with SPC was very high with 70 % of patients awarding a satisfaction score of 9/10 and 95% awarding 7/10 or more. It is of interest to note that in 18% of cases, an SPC was inserted following the request of the patient, having heard about this form of bladder management from others. A review of current literature on SPC in the neuropathic bladder, by Feifer & Corcos [249] identified some notable differences between early studies and more recent reports. Problems and complications of SPC identified in earlier studies of SCI patients were less common in the more recent investigations, in which patients were managed with anti-cholinergics, frequent catheter changes and volume maintenance procedures. Recent studies demonstrated similar morbidity profiles to clean intermittent catheterisation.

Although SPC has gained wide acceptance for bladder drainage and many regard SPC insertion as a simple procedure, it is not without risks. The initial insertion of the SPC requires a minor surgical procedure which presents a potential risk of injury to adjacent structures to the bladder, especially the small and large intestines with resultant peritonitis [247] [250]. Other complications of initial SPC insertion include misplacement [251-253] and incisional hernia [254,255]. There are a number of SPC techniques for insertion described in the literature and training models have been developed to facilitate teaching [256]. Some modern catheter insertion kits employ the initial introduction of a guide wire into the bladder, to facilitate accurate positioning of the catheter introducer. However, where patients are at high risk of bowel injury (eg previous abdominal surgery or small fibrotic bladders which do not expand well at cystoscopy), some authorities recommend introduction of the SPC by percutaneous technique using intraoperative ultrasonography combined with flexible cystoscopy [257,258]. In low risk patients nurse specialists may undertake first insertion of an SPC, according to agreed policy and protocols [259]. Subsequent SPC changes can be competently managed by skilled nurses [260].

e) Catheter characteristics

An effective indwelling catheter should have the following design characteristics:

• Retained in the bladder effectively, yet easily removable without trauma to tissue.

• Soft ‘tip’ within the bladder to avoid pressure damage to the mucosa.

• Effective drainage while minimising risk of bladder mucosa being ‘sucked’ into drainage channel.

• Conforms to shape of urethra.

Despite some notable efforts to improve catheter design, the original Foley design has changed very little over the years and remains the most common. However traditional drainage systems may fail to drain the bladder to completion, due to potential outflow obstruction caused by air-locks within the curled, redundant drainage tubing segments. A novel, spiral-
shaped, drainage tubing design has recently been reported which appears to optimize flow and minimize residual urine [261]. Further evidence of efficacy is awaited.

f) Catheter materials

An ideal catheter material requires the following properties:

• Soft for comfort.
• Causing minimal tissue reaction or friction.
• Sufficiently firm for easy insertion and maintenance of lumen patency in situ.
• Elastic recoil so that an inflated balloon can deflate to almost its original size.
• Resistant to colonisation by micro-organisms and to encrustation by mineral deposits.

Catheters are made of a variety of materials including polyvinyl chloride (PVC or plastic), latex rubber with or without a coating, silicone or metal. Plastic catheters are relatively cheap to manufacture, have a thin wall and relatively large lumen, and are designed for short-term use (in situ up to 14 days). Latex catheters are restricted to short-term indwelling use (and commonly avoided where possible) because of potential discomfort due to high surface friction, vulnerability to rapid encrustation by mineral deposits from the urine and the implication of latex allergic reactions in the development of urethritis and urethral stricture [262-267] or anaphylaxis [268].

Attempts to minimise friction during catheterisation and to reduce tissue reactions have led to the coating of latex catheters with tightly bonded materials designed to provide a smoother, less irritant surface which also minimizes absorption of water by the latex (and subsequent changes in internal and external catheter diameters). Polytetrafluoroethylene (PTFE or teflon) coated latex catheters are sometimes used for medium-term use (catheter can remain in situ up to 28 days) but the materials known to cause least friction and tissue reaction are silicone elastomer and hydrophilic polymer-coated catheters, or all-silicone catheters [269] (Table XII-3). These materials are therefore recommended for long-term use (i.e. expected to remain in situ for 14 days or more, and changed regularly for a new catheter as part of a long-term strategy of care). LTC materials are also less vulnerable to rapid colonisation by bacteria and encrusting by mineral deposits than short-term catheter materials. There is evidence that silver-alloy coated catheters can help to reduce risks of CAUTI in the short-term (where bacteriuria is used as the outcome measure) (See Section XII.2.h), but no currently available material or surface coating is completely immune to microbial colonisation.

Inflation of silicone catheters with water can sometimes lead to water loss from the balloon over time, with an associated risk of the catheter falling out [270]. Consequently some manufacturers recommend filling the balloon with a 10% aqueous glycerine solution.

Most catheter materials are suitable for either UC or SPC, however not all UC catheters are also licensed for SPC. Suprapubic catheter removal is sometimes associated with trauma of tracts or stoma site where overgranulation has occurred, with bleeding and patient discomfort [260;271]. This can be a particular problem with catheter materials such as all-silicone, which are prone to hysteresis, leading to balloon cuffing on deflation. This problem may also occur with hydrophilic coated catheters but is less common [272,273]. Management of this and other catheter-related problems is considered below in Section XII.2.k

The main finding of a recent Cochrane Review of types of indwelling urinary catheters for long-term bladder drainage in adults [224] was a remarkable

lack of evidence for this clinically, highly relevant problem. Despite consideration of 11,000 abstracts and 74 full papers, only three trials met the inclusion criteria. Since these were very small and showed methodological weakness, the authors concluded that there was insufficient evidence to provide a reliable basis for clinical decision-making and catheter choice remains largely based on clinical experience.

g) Catheter size – catheter gauge, length and balloon size

Indwelling catheters are formed either by building up layers through dipping and coating on a shaped ‘former’ or by a process of extrusion of a single material. Catheter size is measured in Charriere (Ch) – also called French gauge (Fr) - which refers to the circumference of the catheter shaft in millimetres. Internal diameter varies depending on the manufacturing method, with the extrusion process resulting in a catheter with relatively thinner walls and a larger lumen for the same Charriere size. A size 12Ch catheter made by dipping and coating will have an external diameter of around 4mm and an internal diameter of around 2mm or less.

Urinary flow rate is related to the internal diameter of the catheter but 12-16 Ch catheters (usual sizes for adults) easily drain normal quantities of urine, including larger volumes produced by diuresis [274]. Although larger sizes may be needed following urological procedures where blood clots and other debris are a problem, large catheters are generally associated with increased bladder irritability and spasm [108], and with potential blockage of para-urethral glands and tissue damage, including urethral strictures. Therefore large catheter sizes should be avoided wherever possible. Small balloon sizes are recommended for all patients (10ml for adults and 2.5-5ml for children) to minimise the risk of discomfort and bladder irritation. Larger balloons tend to sit higher in the bladder with potential for increased residual urine volumes to collect below the catheter eyes. Larger balloons are also associated with increased risk of mental tissue damage caused by bladder spasm and possible expulsion of the catheter with a fully inflated balloon.

The most common sizes of SPC catheters for adults are also 12-16Ch. Some SPC kits provide a specific catheter in the kit and therefore dictate the sizes available; others allow the insertion of a range of Foley catheters. Since the catheter is inserted into the bladder via an artificial stoma it is possible that slightly larger sizes may be better tolerated than for UC although there is no research evidence to support this.

The standard male length catheter (41-45cm) is available to males and females but a shorter female length (25cm) can be more comfortable and discrete for some women. The female length catheter should not be used for males as inflation of the balloon within the urethra can result in severe trauma. Paediatric catheters are usually approximately 30cm long.

h) LTC–associated risks / problems: catheter-associated urinary tract infection (CAUTI)

The urinary tract is recognised as the commonest site for nosocomial infection in hospitals and nursing homes, accounting for between 21% and 45% of all healthcare-associated infections [239,275-278]. National nosocomial infection surveillance systems monitor CAUTIs and provide guidance for benchmarking [279]. The presence of an indwelling catheter is a key risk factor in around 80% of nosocomial UTIs. The risk of bacteriuria increases by 5-8% per day of catheterisation [280-282] and all LTC patients are likely to be bacteriuric within 4 weeks. A majority of microorganisms derive from the patient’s own colonic and perineal flora or from the hands of health-care personnel during catheter insertion or management [169].

Access is gained in two ways: (1) extraluminally during catheter insertion or via the periurethral space; (2) intraluminally following breaks in the closed system or contamination of urine in the drainage bag. The comparative importance of these routes is difficult to determine, but animal models have demonstrated rapid colonisation via the intraluminal route following a break in the closed system, compared to the extraluminal route (32-48 hours v 72-168 hours respectively) [283]. However, clinical studies have shown that colonisation will occur even when strict infection control practices are adhered to [284].

Indwelling catheters rapidly become colonised by micro-organisms which form a strongly adherent biofilm on catheter and drainage equipment surfaces. Biofilm formation begins by deposition of a conditioning layer of proteins, electrolytes and other organic molecules from the urine [285] which may then mask catheter surface properties designed to inhibit colonisation. Micro-organisms attached to catheter surfaces divide to form micro-colonies, ultimately developing a complex three-dimensional structure, including fluid filled channels through which the biofilm members receive nutrients, diffuse away wastes and send chemical signals to each other [286].

Catheter biofilms commonly comprise mixed communities of micro-organisms embedded in a matrix of host proteins and microbial exopolysaccharides [287,288] (Figs XI-4, XII-5 and XII-6). Microorganisms growing as a biofilm are less susceptible to antimicrobial therapies than free-living organisms and are a major source of resistant, nosocomial pathogens [169] [219,289]. Decreased susceptibility arises from multiple factors including; physical impairment of diffusion of antimicrobial agents, reduced bacterial growth rates; and local alterations of the micro-

environment that may impair activity of the antimicrobial agent [286]. The close proximity of cells within a biofilm can facilitate plasmid exchange and the spread of antimicrobial resistance [285].

1. Prevalence of CAUTI

The majority of research on the risks of CAUTI has been conducted in acute care settings where catheters usually remain in place for less than 14 days and many patients’ health is already compromised by co-morbidities [290]. Less is known about the prevalence of CAUTI in long-term and home care settings or about the potential for reduction of CAUTI and improved cost benefits in the LTC population [282]. In the multi-national survey of 4010 older people (>65 years) receiving home care in 11 European countries, the risk of a UTI was found to be 6.5 times greater for catheterised individuals than for non-catheterised patients [228]. Prevalence of a UTI amongst 1004 frail older women living in the community was 21% in catheterized women compared to 10% in non-catheterised subjects (P>0.001) [229]. Furthermore, catheterised subjects were more likely to die within a year (RR1.44; 95% CI 1.01-2.07). Tsan et al’s point prevalence survey [239] of Nursing Home acquired infections found 13.2% of 11,475 residents had an indwelling urinary catheter. Of those, 13% of residents with a UC and 9.5% of those with a SPC had a UTI. In catheterised SCI populations the overall rate of urinary tract infection has been quoted as about 2.5 episodes per patient per year [291]. Although randomized trials are lacking there is some evidence of reduced rates of bacteriuria and CAUTI with SPC, condom catheters and intermittent catheterisation compared to UC [239;245;291].

Bacteriuria resulting from CAUTI invariably represents a serious complication which may occur in approximately 4% of catheterised patients with bacteriuria in acute care settings [290;292;293]. In their review, Saint et al. [292] statistically pooled results from several prospective studies on short-term indwelling catheterization (in which the definition of bacteriuria varied between studies, ranging from \( >=10^3 \text{ cfu/ml} \) to \( >=10^5 \text{ cfu/ml} \)) and estimated (Level of Evidence 2) that:

- 26% of patients (not receiving systemic antibiotics) with a short-term, standard non-coated indwelling catheter in situ for between two and 10 days will develop bacteriuria.
- 72% of patients developing bacteriuria will remain asymptomatic and not require treatment.
- 24% of those developing bacteriuria will develop a symptomatic UTI without bacteraemia.
- 4% with bacteriuria will develop bacteraemia.

This data is interesting since it provides supporting evidence that bacteriuria remains asymptomatic in a majority of catheterised patients. However, it can be difficult to generalize such data from acute care contexts to other practice settings. Unfortunately, few epidemiological studies or comparative catheter evaluations are conducted on long-term catheterised patients in community settings.

2. Outcome measures and criteria for CAUTI

Interpretation of the literature on CAUTI is often confused by the range of definitions and outcome measures used. In this chapter, the terms symptomatic infection and asymptomatic bacteriuria have been employed to distinguish as clearly as possible between symptomatic and asymptomatic conditions. However, many studies make little or no distinction between these states, referring to both as infection. This can be particularly confusing when attempting to interpret results in terms of the magnitude of infection-related problems, clinical importance and implications for services and individuals.

Bacteriuria is commonly used as a surrogate outcome measure for the clinically more important outcomes of symptomatic UTI. Although symptomatic infection is far less common than asymptomatic bacteriuria, the frequency of catheter use produces considerable overall morbidity for patients and high costs to healthcare services [294], often including unnecessary antibiotic drug therapy which may then become a major source of antibiotic resistant pathogens. Asymptomatic bacteriuria can lead on to symptomatic infection, but not necessarily. Questions about the significance of long-term asymptomatic bacteriuria in its own right (e.g. effects of chronic tissue inflammation) are currently unanswered.

In non-catheterised patients the criterion for ‘significant’ bacteriuria is commonly accepted to be \( >10^5 \text{ cfu/ml} \) but since growth of micro-organisms in catheterised patients is rapid, many authorities consider \( >10^2 \) or \( 10^3 \text{ cfu/ml} \) in a urine sample collected from the sampling port of the catheter, to be indicative [169]. Most definitions of symptomatic UTI (e.g. US Centres for Disease Control [295]) are based on those used for non-catheterised patients and include significant bacteriuria. For catheterised patients, these include presence of pyuria (>10,000 wbc/mm\(^3\)) plus one or more clinical signs and symptoms for which no other aetiology is apparent: fever, suprapubic or flank discomfort, bladder spasm. For SCI patients signs and symptoms may also include increasing spasticity and/or worsening autonomic dysreflexia (usually manifested by increase in blood pressure, headache, sweating above the SCI lesion, flushing below the SCI lesion) [296].

However, commonly used criteria for symptomatic urinary infection have been questioned by Tamblyah and Maki [290] in a prospective study of 1497 newly catheterised patients. No significant difference in
reported symptoms of pain, urgency, dysuria and fever was found between patients with a catheter-associated infection and those without, nor was there statistical evidence that peripheral leukocytosis was predictive of infection (p=0.14) (Level of Evidence 2). The criterion for bacteriuria (catheter-associated infection) in this study was \( \geq 10^3 \) colony forming units (cfu/ml urine). This finding raises further questions over the selection of the most appropriate outcome measures in studies of CAUTI. Indeed concerns have also been raised over current UTI criteria for non-catheterised populations, particularly for elderly groups, including nursing home residents. Consensus criteria (e.g. Loeb criteria 2001) have been found to be limited in terms of sensitivity, specificity and predictive value by Juthani-Mehta et al. [297] and these authors have called for clearer identification and evaluation of evidence-based clinical criteria associated with laboratory evidence of UTI. A further complication to difficulties in confirming ‘best criteria’ for UTI and CAUTI is the variation in the clinical and scientific definitions required for specific populations, for research purposes or to meet stipulations for reimbursement from governments and medical agencies. It is important that efforts to resolve these issues are progressed as quickly as possible to provide greater clarity in the interpretation of existing research, the design of new studies and the application of clinically important findings.

3. Reducing the Risk of CAUTI

Risk factors which are independently predictive of increased risk for CAUTI have been identified in a number of large prospective studies of short-term catheterised patients [169] (Table XII-4). There is evidence that females have a substantially higher risk than males (relative risk: RR 2.5-3.7) but the greatest risk is associated with prolonged catheterisation > six days (RR 5.1-6.8). A recent retrospective cohort study of 35,904 undergoing major surgery reported that 86% of patients had a perioperative indwelling catheter [298]. Multivariate analysis showed that postoperative catheterisation for longer than two days was associated with increased risk of UTI.

Although there is some evidence to suggest there may be a reduced risk of CAUTI when SPC is employed compared to UC, the data is limited, studies are often small and most catheterisations are for post-operative care in acute care settings. One large scale point prevalence study of nursing home acquired infections in >11,000 residents [239] reported that 9.5% of residents with a SPC had a UTI compared to 13% of those with a UC. These data just fail to demonstrate a statistically significant difference between UC and SPC (one-sided, Fisher’s exact test; \( P = 0.066 \)). A review of five published RCTs comparing SPC with urethral catheters following colorectal surgery [299] reported that sample sizes were small, catheters were used short-term and there was no apparent difference in the duration of catheterisation between the two techniques. Significant UTI was defined in different papers as bacteriuria with either \( >10^4 \) or \( 10^5 \) organisms or cfu/ml. Frequency of UTI was less in the SPC group in three of the studies, with no significant difference in the other two. The SPC groups reported less pain and discomfort than the urethral groups and SPC was preferred by those patients who experienced both. The authors concluded that the results favoured SPC over urethral catheterisation as UTIs are reduced, particularly in females, and the ability to attempt normal voiding is facilitated, particularly in males (Level of Evidence 2).

Much of the recent research on reduction of risk of CAUTI has centered on the development of catheters with antimicrobial surfaces, such as silver. Silver ions are bactericidal [300], non-toxic to humans when applied topically, and have been used successfully in other areas of infection control such as burn wounds. Silver is also purported to have broad spectrum activity against Gram-positive, Gram-negative, aerobic and anaerobic organisms. Early silver-coatings incorporated silver oxide into the external surface of the catheter material only, but efficacy against CAUTI was limited [301]. Subsequently, silver-alloy coatings were developed to provide an integral coating on both internal and external surfaces and promote a slow release of silver ions. Other developments have been directed towards impregnation of catheter materials with antibiotic or antiseptic agents such as nitro-

furazone [302-305]; minocycline and rifampicin [306]; chlorhexidine, silver sulfadiazine, triclosan [307] and others. Although a large number of studies (both laboratory models and clinical studies) have attempted to examine the potential benefits of antimicrobial catheters, most have used bacteriuria - rather than symptomatic UTI - as a surrogate end-point. Most reports were either prospective cross-over studies [308] or prospective surveillance of outcomes associated with introduction of new catheter types, in comparison with historical or baseline outcomes associated with previously used catheter types [309-311]. Almost all have examined short-term catheter use in acute care settings.

A recent Cochrane review [220], designed to determine the effect of type of indwelling urethral catheter on the risk of UTI, examined 23 trials, comparing different types of standard catheters or a standard catheter with an antiseptic catheter (silver alloy or impregnated with silver oxide); or an antibiotic impregnated catheter (either minocycline and rifampicin, or nitrofurazone). The reviewers commented that trials were generally of poor quality but concluded that current evidence suggests silver alloy catheters prevent asymptomatic bacteriuria in the short-term catheterised patient (Level of Evidence 1). They recommended that further economic evaluation is necessary to confirm the extent to which reduction of clinically important infection compensates for the increased cost of the silver alloy catheters. Catheters impregnated with antibiotics were also found to be beneficial in reducing bacteriuria in hospitalised adults catheterised for less than a week, but data were too few for patients catheterised longer.

An earlier systematic review of antimicrobial urinary catheters to prevent CAUTI in hospitalised patients [312] identified 12 randomised or quasi-randomised trials of silver-alloy coated (n=9) or nitrofurazone-coated catheters (n=3) compared to standard silicone or latex catheters. Pre-post study designs were excluded. No study addressed symptomatic UTI and therefore analysis was based on bacteriuria. Although all studies indicated some benefit in prevention or delay of onset of bacteriuria the effect size varied substantially between studies. Variations were related to catheter type, patient characteristics, control group bacteriuria rate and year of publication (i.e. prevailing clinical conditions at the time of the study).

Post enrolment exclusions, absence of intention to treat analysis, highly selected study samples and lack of data on clinically meaningful end-points, all limited the ability to draw definitive conclusions on efficacy. The authors concluded that, according to fair-quality evidence, antimicrobial catheters can prevent bacteriuria in hospitalized patients during short-term catheterisation (Level of Evidence 1), but trial results are highly context dependent. The relevance of results to other institutions or patient groups depends on the similarities between settings with respect to a range of variables, including: background bacteriuria rate, baseline catheter type, local catheter use and maintenance practices, patient groups and patterns of antimicrobial usage. The authors cautioned that older data may lack current relevance, particularly where background rates of bacteriuria have changed notably in the intervening period. Although there is evidence that antimicrobial-coated catheters prevent bacteriuria during short-term catheterisation, there is a lack of corresponding data to demonstrate clinical benefit [313]. Further well-designed and adequately powered randomised trials, with clinically relevant endpoints are needed to clarify comparative clinical utility and economic value.

In contrast to the majority of trials of silver-coated latex catheters Srinivasan et al [314] found no significant reduction in bacteriuria with silver-impregnated, silicone catheters despite similar performances in vitro. However, outcomes may have been affected by notable differences in the study groups in this prospective, cross-over study. The authors drew attention to the fact that not all silver products are the same and clinical trials of new products remain critically important. Any potential advantages of silver alloy catheters (or other antimicrobial catheters) for LTC patients remain uncertain, although clinical experience suggests some benefits for individuals with frequent symptomatic infections. It is not known whether argyria (deposition of silver in the skin) may be a potential problem for long-term care patients or whether silver-resistant mutants may be selected by repeated exposure [315, 316].

A common concern over the use of antimicrobial impregnated catheters is that elution of sub-inhibitory levels of the antimicrobial agent into the urine may induce resistance in resident organisms with prolonged catheter use [317]. Antiseptic agents are generally considered more likely to confer resistance to surface colonization than antibiotics and not to select for infection with antimicrobial drug resistant bacteria. Alternative approaches to inhibiting biofilm development include development of catheter surfaces which reduce protein absorption [318]; inflation of the balloon with a biocide solution, such triclosan, which then diffuses throughout the catheter material and into the surrounding area [319,320]; or efforts to disrupt matrix or glycocalyx components with agents such as heparin [321].

Relatively few studies have examined the cost benefits of different catheters. Those that have tend to rely heavily on assumptions that a certain proportion of patients with bacteriuria will develop the clinically important outcomes of symptomatic UTI or bacteraemia. The focus of economic studies generally falls on acute care settings and, as discussed earlier, it can be difficult to generalise results from one practice setting to another. Practitioners and/or institutions
who are considering introducing a new product (e.g. catheter type) for a majority of their patients on the basis of claims of improved cost-effectiveness from clinical research studies, are advised to look carefully at the similarities and differences between their own local practice (and patient groups) compared to that described in the research. Economic studies are frequently required to make assumptions about certain data (e.g. increased length of hospital stay for CAUTI) which is then applied to an economic model. (Cross ref to economics chapter). Such assumptions may or may not be applicable in local settings.

Numerous trials of oral antibiotics, antimicrobial bladder washes, drainage bag solutions and topical disinfectants all lead to the common conclusion that bacteriuria and UTI may be suppressed temporarily at best, but resistant organisms are highly likely to emerge [287]. The application of devices to secure catheters in place, to prevent a ‘to and fro’ pistoning effect that could favour invasion of catheter tracts by microorganisms, has been shown to reduce the incidence of catheter-related blood stream infection in central venous catheters. Only one prospective, randomised trial has examined a similar device for urinary catheters (StatLock) [296]. Although the study in 118 SCI patients failed to achieve statistically significant results the authors reported a clinically important reduction in the rate of symptomatic UTI of 45% and called for further larger scale trials. They also noted the polymicrobial nature of infections including the presence of a Candida species in more than 20% of infections.

4. Treating CAUTI - antibiotic use

Some studies have suggested that methenamine hippurate may have a beneficial effect in preventing bacteriuria in patients requiring short-term catheterisation during and post-surgery. However, a Cochrane review [304] designed to address this issue concluded there is not enough reliable evidence to conclusively support its use for urinary prophylaxis and identified a range of methodological limitations in existing studies. Caution is needed in translating research on reducing CAUTIs in short-term catheters to LTCs but treatment of asymptomatic bacteriuria is not recommended in either for either group. Urine cultures should be obtained before initiating treatment to permit selection of specific therapy for the infecting organism and the extensive use of broad spectrum therapy should be avoided [322].

Studies of LTC patients can be difficult given the relatively high proportion of disabled or elderly patients, many of whom are very frail. However, routine use of prophylactic antibiotics in LTC patients is not supported by research evidence and has been shown to favour the emergence of resistant organisms. In a double-blind, cross-over study of 34 elderly nursing home patients with urethral catheters [323] subjects were randomised to receive antibiotic prophylaxis (200mg/day norfloxacin) or placebo for three months, followed by cross-over. Urine cultures were obtained once monthly. Episodes of UTI, catheter-related complications (obstruction, encrustation, leakage, suprapubic pain, inflammation of meatus, haematuria and side effects of treatment were monitored weekly. Symptomatic UTI was defined as bacteriuria >=10^5 cfu/ml and (i) a temp>38.5°C for two days in the absence of other clinical sources of infection or (ii) flank pain or unexplained mental disturbance or abdominal discomfort.

Only 23 patients completed the study and although norfloxacin failed to reduce asymptomatic bacteriuria, there was a significant reduction in symptomatic UTIs (1 v 12, p<0.02) and a decrease in catheter-associated complications of obstruction and leakage (p<0.05). Of the 11 patients who did not complete the study, six died (of non-infectious causes), one died of septic shock and four were withdrawn. However, norfloxacin treatment was also strongly associated with the acquisition of gram-positive norfloxacin resistant flora (RR 4.66, 95% CI 2.47-8.80), and there was a rapid recolonisation by norfloxacin-sensitive, gram-negative bacteria on cessation of treatment. Overall the study concluded that norfloxacin failed to prevent bacteriuria in long-term catheterised patients and favoured the emergence of quinolone-resistant organisms, although there were some clinically observable benefits in some patients.

Similarly there is little strong evidence of benefit in prophylactic antibiotics prior to re-catheterisation. One RCT in which 70 residents in a long-term care home were allocated to a treatment group (1gm IV meropenem given 30 minutes before re-catheterisation) or control group (no antibiotics) showed no significant differences in urine cultures at 3, 7, 14 or 28 days [324].

When catheterised patients are prescribed a course of antibiotics for symptomatic infection a common question from healthcare practitioners is whether the catheter should be changed to a new one prior to starting antibiotics. There are concerns that this may allow time for a new biofilm to become established on the catheter within a few hours (and provide a source of re-infection) before the antibiotics have taken effect. There is little research to guide practice but in one RCT of 54 nursing home residents managed by long-term catheterisation, subjects were randomised to undergo catheter replacement, or no catheter replacement, before antibiotic intervention for clinical diagnosis of UTI [187].

Clinical outcomes (reduction in polymicrobial counts, time to achieve afebrile status and clinical status at 72 hours) were significantly better among subjects randomised to catheter change immediately before institution of antibiotics (Level of Evidence 2).
Replacement of the catheter, in patients suspected of having a UTI, prior to collecting a urine sample for culture and sensitivity testing has also been shown to reduce the number of pathogens identified, the number of antimicrobials prescribed and laboratory costs [325]. There is evidence that certain bacterial strains may be particularly difficult to eradicate. In a prospective study of infection in catheterised nursing home patients a single genotype of P. mirabilis was shown to persist in the urinary tract despite many changes of catheter, periods of non-catheterisation and antibiotic therapy [326].

Cranberry juice has long been advocated as a treatment for urinary tract infection and there is some evidence of decreased symptomatic infections in some study populations [327]. However current evidence to date is limited to non-catheterised patients and caution needs to be applied in extrapolating results to catheterised patients (see also Section XII.2.9).

i) LTC-associated risks and problems: recurrent catheter blockage

Recurrent catheter encrustation by mineral deposits, leading to catheter blockage occurs in up to 50% of LTC users, with resultant increased costs to services and patients [328-331]. Heavy encrustation on external surfaces of the catheter tip and balloon can also cause painful tissue trauma on catheter removal. The major components of encrustation are calcium phosphates and magnesium ammonium phosphate (struvite) (Figs XII-7 and XII-8) which precipitate from the urine, most commonly under alkaline conditions.

The precipitation of different ionic species (ie Ca++, Mg++, and phosphates) is influenced by their ionic concentrations in the urine. In addition, the urinary pH at which different ions precipitate from the urine varies, not only for different ions, but also between individuals and at different times[332,333]. These factors contribute, at least in part, to individual variability in terms of susceptibility to catheter encrustation and time to blockage. Catheterised patients can usually be classified into ‘blockers’ or ‘non-blockers’ [328,329] where ‘blockers’ are those individuals who experience recurrent catheter blockage within a few days to a few weeks.

Early recognition of recurrent ‘blockers’ facilitates proactive care through appropriate catheter change regimes [329]. Urine from recurrent blockers tends to have a very narrow ‘safety margin’ between ‘voided’ urinary pH and the pH at which crystallisation (or nucleation) occurs. This margin is much wider in non-blockers [334]. Precipitates occur most commonly under alkaline conditions caused by the presence of urea-splitting micro-organisms such as Proteus mirabilis, in the catheter biofilm [329,334-336].
using a model of the catheterised bladder, none resisted biofilm formation by a clinical strain of *P. mirabilis* [338,339]. Relative times to catheter blockage were: silver-coated latex 17.7h; hydrogel-coated latex 34h; silicone-coated latex 38h; all-silicone 47h. However, the authors note that the internal diameter of the coated latex catheters was much smaller than the silicone catheters (1.5mm compared to 2.5mm).

Although it is not possible to examine the effects of polymer surface properties on microbial adhesion and formation of catheter encrustation in detail here, recent studies have shown that strongly electron donating surfaces are less prone to adherence by *P. mirabilis* than more hydrophobic materials [340]. Some copolymer, polyurethane blends are associated with less microbial adhesion and improved resistance to encrustation in an artificial bladder model [341]. The effect of iontophoresis produced by passing an electric current through silver electrodes attached to catheters has also been shown to inhibit bacterial growth [342]. Another potentially promising innovation is the use of the antiseptic agent triclosan in the catheter balloon [319,320,343]. In laboratory models of the catheterised bladder infected with *P. mirabilis*, silicone and latex-based catheters, with balloons inflated with triclosan, drained freely for seven days compared to 24h for controls inflated with water.

Triclosan became impregnated throughout the silicone catheter material and strongly inhibited the formation of the crystalline biofilm. However, latex-based catheters required a higher concentration of triclosan (>1mg/ml) than silicone catheters to produce similar inhibitory effects on *P. mirabilis*. Diffusion through the latex balloon occurred but the latex-based catheter did not become impregnated with triclosan throughout. The potential benefits of triclosan in catheter balloons now needs to be tested in clinical trials but it is also important to note that not all microbial species responsible for CAUTIs are sensitive to this biocide and emergence of resistant strains is a common concern [320].

2. **Reducing Catheter Encrustation - Interventions**

A number of studies have employed *in vitro* models of the catheterised bladder to examine the influence of urinary composition on bacteria growth and encrustation, and the ability of acidic irrigations to reduce encrustation build up. There is good evidence from laboratory studies that increased fluid consumption (leading to lower concentration of encrustation components) increases the time to catheter blockage [344]. Increasing citrate concentration in fluid intake and urinary output (eg through drinking orange juice or other fruit juices such as lemon or lime) has also been shown to increase time to catheter blockage (see below). Cranberry juice has frequently been advocated to reduce UTIs, microbial adherence and biofilm development but an in vitro study by Morris and Stickler [345] drinking cranberry juice did not produce urine which was inhibitory to the development of *P. mirabilis* biofilms and catheter blockage, although increased fluid intake was beneficial. Although some studies have claimed drinking cranberry juice can decrease urinary pH in healthy volunteers [346], this is unlikely to be accomplished in catheterised patients, in the presence of continued ammonia production by the action of urease-producing micro-organisms [347].

Urease inhibitors, including acetohydroxamic acid (1.0mg/ml) and fluorofamide (1.0microg/ml), have been shown to restrict the increase in urinary pH of *P. mirabilis* infected urine from 9.1 to 7.6, in a simple physical model of the catheterised bladder [339]. Significant reductions in precipitation of calcium and magnesium salts were also noted but the impact of possible side-effects remains unclear, and therefore clinical potential is uncertain. Clinical studies on the prevention or management of catheter encrustation are extremely limited and only two relevant studies addressing the use of urease-inhibitors were identified. One early clinical study [348] examined oral administration of a urease inhibitor (acetohydroxamic acid) to five patients who required frequent catheter changes (>=1 every 2 weeks) due to encrustation and blockage. The dose was based on body weight (eg. 250mg three times daily for patients between 50-70kg). The degree of encrustation decreased significantly during therapy (p<0.05) and the authors reported minimal adverse side effects experienced by patients, but acknowledged the potential for more severe side effects to occur. A subsequent double-blind, RCT of acetohydroxamic acid in the palliative treatment of infection-induced urinary calculi, demonstrated lowered urinary pH in urine infected with *P. mirabilis* but the side effects were unacceptable to patients [349] (Level of Evidence 1).

An alternative approach to reducing catheter encrustation, aimed at increasing the ‘safety margin’ between urinary pH and the nucleation pH (pHn) (i.e. the pH at which crystals of calcium and magnesium are formed in the urine) warrants further clinical investigation. In laboratory studies using models of the catheterised bladder, the pHn of the urine was shown to increase when urine concentration was decreased and also by addition of citrate to the urine [350]. In models supplied with urine containing citrate at 1.5mg/ml or above, catheter drained freely for the 7 day experimental period. Drinking 500ml pure orange juice per day can achieve concentrations of citrate of up to 1.2mg/ml urine [333] and further clinical evaluation of the effects of increasing a patient’s fluid intake with citrate containing drinks is awaited. Viable cell counts of *P. mirabilis* in the model suggest that results were unlikely to be due to direct effects of citrate on the growth of metabolism of *P. mirabilis* in
the catheter biofilm, but rather on the process of mineral crystallization.

The reduction of encrustation and corresponding extension of ‘catheter life’ by regular instillation of an acidic catheter maintenance solution into the catheter has been advocated by some researchers, particularly where frequent catheter changes for recurrent blockage are difficult and / or unacceptable to patients. Solution G (Suby G) and Solution R (Table XII-5) have been shown to be effective in vitro models of the catheterised bladder [351-353] and in vitro models of struvite stone chemolysis [354]. In response to concerns over potential damage to the bladder mucosa from acidic catheter maintenance solutions, Getliffe et al. [352] advocate the use of small volumes of solution so that less enters the bladder. Under controlled laboratory conditions smaller volumes of acidic solutions (Suby G) (50ml), retained in the catheter for 15 minutes, were shown to be as effective as the commonly available commercial standard of 100ml. Getliffe et al. also showed that two sequential washouts with 50ml were more effective than a single washout.

There is relatively little clinical evidence to draw on in this area and outcomes remain to be tested in well-controlled clinical trials. Most clinical studies are small-scale and descriptive although both Getliffe[355] and Kunin et al. [328] compared groups of ‘blockers’ and non-blockers’ to identify characteristics of recurrent ‘blockers’. One small-scale, comparative trial of Suby G, Solution R and saline catheter ‘washouts’ in 14 older female patients [356] reported a higher incidence of red-cells in the retrieved washout fluid with Suby G compared to saline (mean incidence of 28% and 14%, respectively. However, increased shedding of uroepithelial cells was present in the retrieved washout from all three solutions suggesting this was at least partially related to the physical process of administration. This issue was previously raised by Elliot et al. [357] who also demonstrated increased uroepithelial shedding following washouts with up to 60ml saline 0.9%; chlorhexidine 0.02% or noxythiolin 2.5%.

A more recent RCT, which aimed to compare weekly catheter flushes with saline or an acidic solution, with no flushes, reported the mean time until catheter removal was very similar between groups. Importantly, there was no evidence of detrimental effects, such as increased risk of symptomatic infection, from breaking the closed system in order to apply catheter flushes. However the study was underpowered and subjects were only followed for a maximum of eight weeks. There were considerable difficulties with recruitment of patients and target numbers fell short within each group (Level of Evidence 2) [358]. Other clinical studies have focused on chemolysis of infection stones (principally composed of struvite). Stronger acidic solutions such as Solution R have been shown to dissolve fragments of struvite renal calculi following lithotripsy [359] but potential benefits may be outweighed by the greater risk of inflammatory tissue reactions when used as a catheter maintenance solution. Renacidin solution is approved for kidney stone disintegration in the US but although it may be

Table XII-5. Catheter maintenance solutions.

<tr>
<th>Solution</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Suby G or Solution G</td>
<td>3.23% citric acid solution, pH 4, containing magnesium oxide to minimise tissue irritation, aimed at reducing encrustation. Used where routine catheter maintenance is required to reduce build up of encrustations.</td>
</tr>
<tr>
<td>Solution R</td>
<td>6% citric acid solution, pH 2, containing magnesium carbonate, aimed at dissolving encrustations. A stronger acid than Suby G and therefore not recommended for frequent, regular use.</td>
</tr>
<tr>
<td>Renacidin</td>
<td>A citric acid solution, pH 3.5-4.2, containing glucono-delta-lactone to minimise tissue irritation and magnesium carbonate, aimed at reducing encrustation.</td>
</tr>
<tr>
<td>Mandelic acid 1%</td>
<td>An acidic solution, pH 2, aimed at inhibiting the growth of urease-producers. A stronger acid which is not commonly used to reduce catheter encrustations</td>
</tr>
<tr>
<td>Saline 0.9%</td>
<td>A neutral solution, pH 7, recommended for flushing of debris and small blood clots. Neutral pH solutions will not dissolve catheter encrustations.</td>
</tr>
<tr>
<td>Chlorhexidine 0.02%</td>
<td>An antiseptic solution aimed at preventing or reducing bacterial growth, in particular E. coli and Klebsiella species (but will not prevent biofilm formation on long-term catheters)</td>
</tr>

</table>

1 Available in the UK pre-packed in a sterile delivery devices designed for instillation into a urinary catheter.
2 Renacidin® is approved in the USA for kidney stone disintegration only. Although it may be effective in certain situations for persistent catheter blockers, there are no supporting studies.
3 Saline is widely available
effective for recurrent catheter blockers, there is no published research evidence of its use in this group.

Overall, methodological issues make it difficult to draw robust conclusions on the effectiveness of acidic solutions in managing catheter blockage. It is unlikely that any currently available strategies will completely prevent catheter encrustation and a more practical aim is to extend catheter life to a period which is acceptable to users and manageable by healthcare professionals. 

_j) LTC-associated risks and problems: urethral trauma, bladder calculi and bladder cancer_

1. **Urethral trauma**

Urethral trauma and discomfort can occur during catheterisation but may be minimised by using a sterile lubricant or anaesthetic gel [360] (see also Section XII.2.k), however clinical practice remains variable. More studies have considered the use of lubricants for male catheterisation but few have considered the procedure for women or for supra-pubic catheterisation [361]. A recent randomised, double-blind study with 62 alert, cooperative females requiring urethral catheterisation, demonstrated that the group receiving lignocaine gel had a significantly lower median procedural pain score compared to the group receiving a water-based lubricating gel [362]. Supra-pubic catheterisation can sometimes lead to urethral leakage which may require surgical closure of the urethra, especially in women.

2. **Bladder calculi**

Most long-term follow up studies of LTC use have addressed SCI populations. Indwelling catheters (UC and SPC) have been significantly associated with increased risk of bladder calculi formation in SCI patients, compared to intermittent catheterisation [203,363]. In a retrospective cohort study of 457 patients, controlled for variable follow up times by regression analysis, both UC and SPC were significantly associated with increased risk of bladder calculi formation compared to intermittent catheterisation IC (hazard ratio 10.5; p<0.0005 and 12.8: p<0.0005) respectively [364]. This increased risk was independent of age, sex, level and degree of injury but calculi were no more likely to form with SPC than UC (hazard ratio 1.2, p=0.6). Another case series of SPC in 118 patients with neurogenic bladders [365] found common complications were bladder calculi (25%), (particularly associated with high urinary pH) and urethral leakage (10%). Bladder calculi-free rates at five and 10 years were 77% and 64% respectively, falling to 50% at 20 years.

Where SPC has been compared to CIC the main difference appears to be in a lower incidence of bladder calculi in the CIC group. A prospective comparison of long-term outcomes between 34 quadriplegic patients managed by SPC (mean period 8.6 years) and 27 paraplegic patients managed with CIC (mean period 9.9 years) reported no significant difference between groups in respect of symptomatic UTI, renal stone, degree of bother and overall satisfaction [248] but there was a significantly increased incidence of bladder stones in the SPC group. However a recent review of current literature [249] (56 studies), concluded there were variations between older and more recent studies. More recent studies showed morbidity profiles to be similar for SPC and CIC, where patients were managed by anticholinergic medications, frequent catheter changes and volume maintenance procedures (Cross reference Neuro Chapter). A dedicated catheter clinic established to aid the management of patients having problems with LTC, reported the majority of patients were elderly with chronic disabilities. A significant proportion of those with catheter encrustation and blockage (45% of 147 patients) were shown to have formed bladder calculi [366].

3. **Bladder cancer**

A number of retrospective, cohort reports of SCI patients have linked bladder cancer with long-term indwelling catheterisation [367-369]. The reported incidence of squamous cell and transitional cell carcinoma associated with chronic indwelling catheterisation varies widely between studies but Groah et al. [369] in their follow-up of 3670 subjects, calculated that patients with SCI and an indwelling catheter were 25 times more likely to develop bladder cancer than the general population (Level of Evidence 3). For SCI patients without an indwelling catheter, the risk of bladder cancer was 15 times that of the general population. Since SCI patients are already at increased risk of developing bladder cancer compared to non-SCI groups, the influence of an indwelling catheter on bladder cancer requires further clarification, including the potential relationship between duration of catheterisation and cancer development. Bladder calculi have been identified as an independent risk factor for bladder cancer by some authors [367].

Most reports have grouped UC and SPC together as indwelling catheters but a small number of case study reports have drawn attention to long-term risks of carcinoma within the cystostomy tract with SPC, with or without further extension into the bladder [370-372]. However, in a retrospective analysis of screening biopsies for bladder malignancy in 36 patients with SPC for more than 12 years, Hamid et al.[373] found no tumours in the screened group although histological findings were frequently abnormal (Level of Evidence 2). These authors raise concerns over the interpretation of screening cystoscopy and biopsy in this population.
and note the importance of the distinguishing between histological changes and confirmed cancers when interpreting study results. Recently published guidance on management and prevention of catheter-associated urinary tract infection, based on an extensive survey of the literature, includes a recommendation that patients with urethral catheters in place for 10 years or more should be screened annually for bladder cancer [374] (Grade of Recommendation C).

k) Catheter management strategies

Although guidelines and protocols for catheter-care practices are abundant, relatively few practices are supported by research evidence and even fewer by evidence from randomized controlled trials. For example, in the ‘Guidelines for prevention of healthcare associated infections in primary and community care’ commissioned by the UK’s National Institute for Clinical Excellence [375], of 29 recommendations relating to urinary catheterisation only six were Grade A (directly based on Level 1 evidence); six with one each at Grades B and C. The remaining 21 were all grade D, being based on evidence from expert groups or clinical opinion.

1. Catheter change procedures and catheter comfort

Indwelling catheters can cause substantial patient discomfort but although anecdotal information on the discomfort experienced by many catheterised patients is readily available, there is a general lack of published evidence from research studies. Further investigation and guidance to practitioners is needed. Catheter-related pain or discomfort can occur as the catheter is passed, in situ and on removal. Local anaesthetic lubricant gels are commonly used to aid the insertion of indwelling catheters in males and protect the sensitive urothelium from trauma [376]. Similar use of anaesthetic gels is generally recommended for females although the procedure may be less consistent in some places and where only small amounts of lubricant are applied to the catheter tip this may be insufficient to coat the urethra adequately. There is little research evidence to underpin clinical practice in this area although the NICE guidelines on infection control [375] recommend: ‘an appropriate lubricant from a single-use container should be used during catheterisation to minimise trauma and infection’. The choice of lubricating gel is usually left to practitioners but not all gels containing anaesthetic agents (e.g. lidocaine) are suitable for both urethral and suprapubic use. One prospective, randomized, double-blind, controlled trial of plain lubricant versus lidocaine gel prior to female catheterisation in an accident and emergency department found no significant differences in pain ratings, based on lubricant type or catheter size amongst 100 women recruited to the trial [377]. Anaesthetic gels may be contraindicated in patients with damaged or bleeding urethral membranes and should be used with caution in those with cardiac conditions, hepatic insufficiency and epilepsy [378]. Lubricants which contain chlorhexidine have been reported to trigger anaphylaxis in a small number of patients during catheter insertion and consequently a careful history is required to screen for sensitivities [92;379].

Catheters can be painful when in situ. In one study at a US Veterans Affairs Medical Centre, 42% of catheterised patients reported it was uncomfortable, with 48% complaining it was painful, and 61% stated it restricted their activities of daily living[104]. If bladder spasm is the cause of pain when a catheter is in situ a low dose of an anticholinergic medication can help [380]. Other helpful approaches include treating constipation if present, ensuring that the catheter is the smallest size to provide adequate drainage, and ensuring that the drainage bag is well supported to prevent dragging on the catheter. Bladder discomfort related to an indwelling catheter can exacerbate postoperative pain by mimicking overactive bladder syndrome that is resistant to conventional opioid therapy. Sub-lingual oxybutinin has been shown to be an effective treatment for pain after radical retropubic prostatectomy, with significant reduction in other pain relief requirements [381]. Cuffing of the catheter material on balloon deflation (see below) and/or encrustation of the catheter by mineral deposits may cause pain during catheter removal. Encrustation is discussed further in Section XII-2.i and management of these problems is also discussed below.

Protocols on indwelling catheter change frequency vary widely from monthly to up to three months if the catheter is trouble-free. In the absence of clear supporting evidence this remains an area of controversy amongst clinicians with advocates of early change believing this to reduce the incidence of complications while others argue that frequent changes increase the risk of infection, trauma and long-term histological changes. SPC changes can be competently managed by skilled nurses [260], often in the patient’s own home, but the new catheter should be inserted as quickly as possible whilst the track is still easy to follow. A delay of only a few minutes can result in partial obliteration of the tract [382]. It is also possible to insert the new catheter too far through the bladder so it enters the urethra with resultant trauma when attempts to inflate the balloon are made. Careful observation of the length of catheter external to the abdomen and the angle of protrusion prior to catheter change can help to ensure correct positioning of the new catheter [383]. Dressings around the stoma site are not normally required unless there is excessive discharge, causing staining and/or sticking to clothing.

Urinary catheter ‘deflation cuff’ formation can be a problem in both SPC and UC, causing difficulty in removal and great discomfort to patients. Evidence suggests deflation cuff formation can be a particular
problem for all-silicone SPCs. A retrospective study of 113 patients cared for by community nurses showed that 30% of nurses had experienced problems changing catheters in the previous 12 months [384]. In vitro studies have confirmed increased retention force and resistance to withdrawal caused by cuff formation and although cuffs can form with other catheter materials (eg hydrogel coated-latex) the retention force is less than with all-silicone material [272]. It has been suggested that slow deflation may enhance the probability of the silicone balloon returning to its pre-inflation shape [273]. Alternatively, reinsertion of 0.5-1ml water is sufficient to fill the catheter inflation lumen and eliminate the balloon cuff. Subsequent use of lubrication with gentle removal of the catheter has been well-tolerated by patients and produced virtually no trauma.

2. PERSONAL HYGIENE AND INFECTION CONTROL

Meatal cleansing by simple washing with soap and water during routine bathing or showering is recommended (Level of Evidence 1) [385;386]. No consistent reduction in bacteriuria has been demonstrated by any other meatal cleansing regimes, using povidone-iodine solution or cream, chlorhexidine, polymicrobial creams, 1% silver sulfadiazine or antiseptic lubricating gels, compared to routine bathing or showering [117;245]. Effective handwashing by healthcare professionals, carers and patients, before and after handling catheters and drainage equipment is generally accepted to be the most important component of any infection control strategy. Healthcare professionals and formal carers should also wear gloves. Catheters and drainage equipment are commonly supported in position by tapes, Velcro and other securing devices (eg CathSecure, StatLock) but the importance of these in reducing risks of CAUTI and the mechanism involved are not well-established [296] (See also Section XII.2.h).

3. URINE COLLECTION – CATHETER VALVES

Urine may drain continuously from the bladder into a drainage bag attached to the catheter (See Section VIII) or intermittently via a catheter valve. The valve is a small device connected to the catheter outlet in place of a bag. Closure and opening the valve allows bladder filling and intermittent drainage rather than continuous drainage into a bag. Valves are available in a variety of designs (Fig XII-9) ranging from simple inexpensive types used for up to a week, to more expensive, complex, forms which last longer and which may permit one handed action. However, valves are not available or licensed in all countries.

Most valve designs can be attached to a drainage bag at night to allow free drainage while the patient sleeps. A valve can provide a discreet alternative to conventional urine drainage bags and may offer improved maintenance of bladder tone and capacity for appropriate patients. A spigot is not a suitable alternative to a valve since it must be removed from the catheter to allow drainage thereby breaking the ‘closed system’. Patients must be able to manipulate the valve mechanism and empty the bladder regularly to avoid overfilling, with accompanying risks of back pressure on the upper urinary tract. Valves are generally inappropriate for patients with poor manual dexterity, poor bladder capacity, detrusor overactivity, ureteric reflux, renal impairment or cognitive impairment. There is relatively little research-based literature on catheter valves with much of the evidence supporting beneficial effects derived from the level of expert opinion. Concerns over possible increased risk of infection associated with valves have not been realised although there is a paucity of research in this area. The flushing mechanism resulting from bladder filling and emptying may be expected to contribute to reduction in problems of encrustation and blockage but, again, clinical research evidence is lacking.

There is stronger evidence of benefits in terms of patient comfort and independence since this is a common finding in most studies. Five studies comparing a catheter valve with standard drainage (leg bag) were identified: three were cross-over designs, with 28, 16 and 18 subjects respectively [387-389] (Level of Evidence 3); two randomized their sample of 100 subjects to either catheter valve or standard drainage [390,391] (Level of Evidence 2). None of the studies identified any significant difference in urinary tract infection and a majority found a high level of preference or acceptability of catheter valves (>72%). There were no differences in reported incidence of bladder spasms or discomfort; however, there was a higher incidence of nocturnal frequency and episodes of bypassing with valves. It was suggested that a combination of a valve during the day and free drainage at night through an open valve connected to a drainage bag could be an appropriate management strategy.

Several studies have evaluated a single valve design [392,393] but only one has compared a broad range...
of valve designs [394]. Fader et al undertook a comparative evaluation of the seven catheter valves available on the UK market in 1996. Each valve type was tested for one week by between 19 and 36 subjects, followed by completion of a product evaluation questionnaire. Performance scores (and costs) varied widely between products but critical characteristics were: being easy to manipulate, leak-free, and inconspicuous. The authors concluded that prescribers need to be aware of the strengths and limitations of different valves for appropriate product selection (Level of Evidence 3). A more recent development concerns the design of a prototype, novel, automatic valve system for LTC patients [395] which may be helpful for patients who lack sufficient dexterity to manage a manual valve. In summary:

- Catheter valves provide a well-accepted system of bladder emptying for suitable patients who are able to manipulate the valve mechanism and empty the bladder regularly to avoid overfilling (Level of Evidence 2).
- There is no evidence of increased risk of urinary tract infection with valves compared to conventional drainage systems (Level of Evidence 2).
- Valves may promote maintenance of bladder tone and capacity (Level of Evidence 4).

4. MAINTAINING EFFECTIVE CATHETER DRAINAGE

Use of urinary catheters is rarely completely trouble-free. Catheter drainage can be compromised by a variety of factors from simple causes such as kinked tubing or the position of the drainage bag, to bladder spasm, pressure of a constipated bowel on the adjacent urethra, suction of bladder mucosa into the catheter eye, or blockage by blood clots, mucous or encrustations formed by deposits of mineral salts. The algorithms in Figs XII-10 to XII-12 combine current evidence-based knowledge and expert opinion to provide some guidance on trouble-shooting common problems.

5. RECURRENT CATHETER ENCRUSTATION AND BLOCKAGE

Factors affecting persistent catheter encrustation leading to recurrent blockage have been discussed earlier in Section XII.2.1. The day to day management of recurrent catheter encrustation and blockage is largely a nursing responsibility but there are few options available. Maintenance of dilute urine by a suitably high level of fluid intake has been shown to reduce encrustation in laboratory studies [344] and increased urinary citrate concentration produced by drinking orange juice or other fruit juices may also be beneficial [344] (see Section XII.2.1 above). However the amounts required may be relatively high and clinical studies are needed to assess benefits and possible detrimental side effects e.g on bowel behaviour. Use of a catheter valve in suitable patients may also help reduce build up of encrustation by facilitating periodic flushing but clinical evidence is currently unavailable. In a majority of patients a characteristic pattern of ‘catheter life’ can be identified with careful record-keeping of three or more catheter episodes [237; 329; 396]. This may allow pro-active strategies of care designed to change the catheter before likely blockage. However, very frequent catheter changes can be unsuccessful or unacceptable for some patients, as well as being costly in terms of health service resources [330].

An alternative strategy is the regular prophylactic instillation or irrigation of the catheter with an acidic ‘catheter maintenance’ solution to dissolve mineral deposits. In older literature the term ‘bladder washout’ appears but as the aim is to wash the catheter, rather than the bladder, ‘catheter maintenance solution’ is a more appropriate term. A range of commercially available catheter-maintenance solutions is indicated in Table XII-5, although these are not necessarily available in all countries. Support for irrigations is strongly divided between those claiming benefit for specific patients who experience very frequent blockage and those who consider any break to the closed system to increase risks of infection. Research evidence is primarily derived from laboratory models of the catheterised bladder, as considered above in Section XII.2.1. The few clinical studies which have addressed this issue have been limited by methodological deficits and small sample size.

1) Levels of evidence relating to catheter-associated risks and complications

- All currently available catheter materials are subject to bacterial biofilm formation (Level of Evidence 1).
- Silver alloy coated catheters are associated with a statistically significant reduction in incidence of asymptomatic bacteriuria in short-term catheterised, hospitalized adults (studies of varying quality included) (Level of Evidence 1). There is less robust data to show that silver-alloy catheters reduce symptomatic infection (Level of Evidence 4). Silver oxide coated catheters are not associated with a statistically significant reduction in bacteriuria (Level of Evidence 2).
- Antimicrobial catheters can prevent bacteriuria in hospitalized patients during short-term catheterization (<30days) (Level of Evidence 1). Trial results are highly context dependent and the effectiveness of specific antibiotic preparations may be limited to specific groups of microorganisms. Potential toxicity and/or antibiotic resistance is unknown (Level of Evidence 2).
- There is little evidence to guide the precise timing of catheter change when antibiotic cover is required for a particular patient. One study has shown that clinical outcomes (i.e. reduction in polymicrobial
Figure XII-10: Troubleshooting long-term catheter problems: urine does not drain (N = No; Y = Yes). (Always have a spare catheter available)
counts, time to achieve afebrile status and clinical status at 72 hours) are significantly better among subjects randomised to catheter change immediately before institution of antibiotics (Level of Evidence 2).

- A majority of health services have clear policies on the use of antibiotics, designed to limit unnecessary use. Current evidence does not support routine use of antibiotic cover during catheter changes unless the patient’s condition renders them particularly at risk (Level of evidence 4).

- Meatal cleansing by simple washing with soap and water (i.e. not with antimicrobial agents) during routine bathing or showering is recommended (Level of Evidence 1).

- Recurrent urinary catheter blockage caused by encrustation occurs in 40-50% of all long-term catheterised patients (Level of Evidence 2). In the majority a characteristic pattern of ‘catheter life’ can be identified (Level of Evidence 3).

- Evidence from in vitro models of the catheterised bladder indicates that i) dilute urine; ii) high urine citrate content (> 1.5mg/mL) reduce risk of blockage (Level of Evidence 2).

- Evidence from in vitro models of the catheterised bladder indicates that acidic ‘catheter maintenance’ solutions may have a role in dissolving encrustations in persistent blockers (Level of Evidence 2). There is insufficient evidence from RCTs to assign an in vivo level of evidence.
THE INFLATION BALLOON DOES NOT DEFLATE

PROBLEM ACTION

Blocked deflation channel?

- try to remove or dislodge debris blocking the deflation channel by gently 'milking' the catheter along its length
- try to remove or dislodge debris by inserting a few drops of sterile water into the inflation channel (no more than 1-2ml) with a sterile syringe

Faulty valve or syringe

- try a different syringe, withdraw water very slowly or leave syringe in place, the water may seep out over a period of time
- insert the needle of a sterile 10ml syringe into the balloon drainage channel just above the inflation valve. If the valve is faulty the water may be withdrawn gently via the syringe

? constipation, present - may cause pressure on the inflation channel

try to relieve constipation

consult local policy for further advice or seek medical help

**do not cut the catheter**
- it may recoil inside the urethra

**do not cut the inflation valve off**
- if the balloon does not deflate it will no longer be possible to try alternative simple methods

**do not attempt to burst the balloon by over-inflating it**
- a cystoscopy will be required to remove fragments!
- remaining fragments may result in formation of calculi

**do not cut the inflation valve off**

Record problem, actions and outcome.
Record catheter details, lot number etc and report to manufacturer

*Figure XII-12: Troubleshooting long-term catheter problems: the inflation balloon does not deflate.*
• Suprapubic catheterisation (SPC) is an appropriate alternative to urethral catheterization for many patients following appropriate risk assessment (Level of Evidence 1).

• There is some evidence for a reduction in catheter-associated infection in SPC use during short-term catheterisation (Level of Evidence 2), compared to urethral catheter insertion. However, there is no corresponding evidence for long-term catheterisation.

• Patient comfort, quality of life and satisfaction with SPC is generally good compared to urethral catheters (Level of Evidence 1).

• Catheter valves provide a well-accepted system of bladder emptying for suitable patients who are able to manipulate the valve mechanism and empty the bladder regularly to avoid overfilling (Level of Evidence 2).

• There is no evidence of increased risk of urinary tract infection with valves compared to conventional drainage systems (Level of Evidence 2).

m) Urinary catheters versus other care strategies

Very few studies have compared urinary catheterisation with other strategies to manage urinary incontinence, not least because of the difficulties in recruiting to and conducting robust trials. For male patients who do not have problems with retention of urine external urine collection systems are an option (See Sections VII, VIII and IX). One recent prospective, randomized, unblinded, controlled trial on men >40years in a US Veterans Affairs Medical Centre reported that the use of condom catheters was less likely to be associated with bacteriuria, symptomatic UTI or death than the use of indwelling catheters (97). Patients reported that condom catheters were more comfortable (P=0.02) and less painful (P=0.02) than indwelling catheters.

A small number of studies have attempted to examine preferences for different urinary incontinence treatments in long-term care. In a descriptive, comparative study of preferences for treatments for frail older adults, residents in long-term care facilities were interviewed and groups likely to serve as proxy decision makers were surveyed (family members of residents and nursing staff) [397]. Forced choice comparisons of continence treatments were measured. Although there was wide variation within and between groups, most preferred non-invasive strategies (diapers and prompted voiding) to invasive strategies including indwelling catheterisation. Older adults stated they would choose a treatment based, in part, on feeling dry, being natural, not causing embarrassment, being easy, and not resulting in dependence. Similar results, showing urinary catheterisation as the least favoured choice, were found in a study of 117 medical inpatients aged 80 years or over, their physicians, nurses and family members [398].

3. CATHETER-RELATED QUALITY OF LIFE

Use of a LTC is often a last choice for bladder management when other options such as CIC, for males a sheath (condom) catheter, or other voiding treatments like Crede procedure, are either unsatisfactory or no longer practical. Catheter users must deal with a variety of problems that disrupt their daily activities and negatively affect QoL, such as CAUTI, blockage, leakage and catheter dislodgment. In addition, the visibility of a catheter or drainage bag can contribute to shame or stigma, and urine odour can be embarrassing. A catheter can also be a reminder of vulnerability associated with illness / mortality and a symbol of a loss in control of bodily function. Yet catheter users also acknowledge catheter-associated benefits of freedom from wetness, convenience, and utility in promoting urine drainage. While this section focuses on long-term catheter use, even short-term catheters can have a detrimental impact on QoL. For instance in a study of short term catheter use prior to surgery for acute urinary retention, leaking, blocking, urgency, and pain at the penis or during erection were all reported [399].

Studies of QoL issues commonly utilise qualitative research methodologies, such as phenomenology or grounded theory approaches (see also Section XII.1.e). In-depth interviews with catheter-users and carers provide important insights into aspects of ‘living with a catheter’ and contribute research based evidence to support development of effective care strategies. Measurement of QoL and the impact of factors which may affect it is complex. Most validated QoL instruments fall into one of two groups: i) generic measures designed to encompass domains including physical, mental and social wellbeing; ii) disease specific measures designed to measure change in QoL resulting from treatment (Cross reference QoL chapter). For those people whose urinary symptoms are managed by products or devices, including catheter users, it is particularly difficult to assess the impact of the product on QoL (see earlier in this Chap). This is partially because changes are more likely to be related to improved management of ongoing symptoms rather than actual change in symptoms, and partially because QoL is also dependent on the underlying disease process.

Much of the literature on LTC use involves people with neurogenic bladder, particularly those with spinal cord injury (SCI) or multiple sclerosis (MS). Thus, QoL in catheter users must be considered from a perspective of how the disease and the device affect the individual's life. For instance, in one postal survey of 230 people with SCI, the factors which had most impact on QoL were social activities and accom-
plishments, including employment, attending school, and other activities. There was no association between QoL and different bladder drainage methods [400]. A particular problem for people with spinal cord injury or disease is autonomic dysreflexia (AD), an autonomic nervous system syndrome causing symptoms which include severe hypertension, headache and sweating. A blocked urinary catheter can be a common cause. AD can be a serious problem requiring emergency medical attention, but lack of knowledge and awareness of the risks by some health care providers can cause high levels of anxiety for SCI patients [241;401] (Level of Evidence 3).

There are currently no validated instruments measuring quality of life in people with urinary catheters, though these are being developed in the US [243] and in the UK (Level of Evidence 3).

The published literature addressing QoL in catheter-users is small, and is commonly limited to reports addressing levels of satisfaction with a device. Studies which include a broader perspective of QoL are discussed below under the following headings: changes in bladder management, embarrassment, sexuality, catheter-related pain, catheter adjustment, and self-management.

a) Changes in Bladder Management

Changes in bladder management are often made to promote QoL but there are trade-offs that require weighing up the pros and cons of various methods. People sometimes switch from CIC to an indwelling catheter - despite the inherent problems with an indwelling catheter - because quality of life might be improved. In particular, women with cervical spinal cord injury (SCI) may need an indwelling catheter because of difficulties in transferring to the toilet, limited hand dexterity, or dependence on caregivers [402]. Moreover, many people have used different bladder drainage methods over time. In one study, of 30 long-term catheter users, 80% of the sample had used another form, and 33% had used two or three different types [242]. In another small study with a sample of 11, 100% had used another method, and 27% had used two or three other types [243]. Reasons for non-compliance with CIC in relation to QoL or satisfaction have been addressed in Section XII.1.e and in some studies comparing drainage methods (Level of Evidence 3).

Two studies provided additional evidence of how changes in bladder drainage methods are made to improve their quality of life. In a retrospective study assessing compliance with bladder management, 50 new spinal cord injury (SCI) patient records were reviewed after admission, discharge, and follow up from 1994-1997 [402]. Of 38 patients on IC at hospital discharge, 20 (52%) were back to UC at follow up. Six of 10 females on IC had resumed UC. Reasons for not continuing with IC were: the need to depend on caregivers, poor hand functioning, spasticity, incontinence (despite anticholinergic drugs), and for females with cervical injury, toileting inconvenience (Level of Evidence 3). In contrast, a retrospective chart review and follow up questionnaire was used with 236 SCI injured people (at least 10 years post injury) between 1956-1990 [403]. An 85% response rate was achieved in the sample, with 82% males who had tetraplegia (47%) or paraplegia (53%). Although 46% changed their bladder management method over time and 28% considered the method a problem, in 58% of those who had tetraplegia, the use of CIC went up from 11% at discharge to 36%. Suprapubic tapping decreased from 57% to 31% and Crede increased from 5% to 19%. CIC alone, or with other methods, was the most common method (Level of Evidence 2).

b) Embarrassment

Embarrassment and a sense of lack of bladder control are two major catheter-related issues that are ongoing problems for many people. In one study at a US Veterans Affairs Medical Centre, 30% of catheterised patients surveyed found the indwelling catheter embarrassing, and 61% stated it restricted their activities of daily living [104]. The catheter is placed in a position in the body normally considered ‘private’, yet health care providers frequently need access to the site to provide care. Also, the force of urine flow is something that catheter users must deal with on a daily basis. In a qualitative phenomenological study of 14 people with long-term catheters, people told stories of how getting wet in public was embarrassing and how the force of the urine was like water that had built up pressure [404]. They used the metaphor of “flowing water” to describe the force of urine flow, the weight of the drainage bag, and the sound of urine sloshing around in the bag.

Living with the catheter was described in one qualitative study [241] as a swing back and forth between stigma, when it contributed to embarrassment or shame, and acceptance when it was working right and did not cause problems. The catheter became a source of embarrassment during catheter changes, bag emptying, and when it leaked or spilled in public. Individuals used planning and great care when going out (e.g. mapping out the toilets) to prevent urine accidents. They were bothered also by their lack of bodily control, the monotonous care, and how it was a reminder of their condition and mortality (Level of Evidence 3).

Catheter related embarrassment is a common experience stemming from exposure to the opposite sex, the visibility of the urine bag, and unpredictability of urine accidents [(405,406] [241]. Breeches in privacy were identified in two qualitative studies of the lived experience of catheter use [407] [241;408;409]. To
care providers, catheters may seem commonplace, but male / female sensitivities may occur during catheter care, particularly catheter changes, including men who are embarrassed by a female care provider [405]. Embarrassment can be minimized by providing privacy during catheter changes and same sex care providers when possible [241] [407,408]. Acknowledging the embarrassment that exists if the nurse is of the opposite sex paradoxically may diminish the vulnerability [241]. Humour is often used by care providers, catheter users, and caregivers, and a professional approach by the health care provider may help the catheter user accept the situation [241] [407,408][Level of Evidence 3].

A few studies have examined QoL issues related to practical aspects of living with the catheter, such as managing the drainage bag (See Section VIII). While most people who are self-caring cope with the management of their catheter drainage system, many find them restrictive and report a negative impact on QoL. In a small pilot study based on a postal questionnaire to LTC catheter users (n=59) [410], almost 25% of respondents stated that wearing a bag had a major negative affect on everyday living. Concealment of the bag was one of the most important concerns raised (89%). Keeping the urine drainage bag covered and its visibility minimized can help reduce embarrassment and the stigma related to using a catheter. The visibility of the bag can be considered demeaning and it exemplifies a loss of bladder control; [241,408]. Moreover, if a bag is unreliable, and springs a leak for instance, it contributes to vulnerability. Even using a catheter for a short time can be an assault to one’s dignity. In a study in post-operative short-term catheter use, people complained about feeling “on display” and objectified [407] (Level of Evidence 3).

c) Sexuality
In a study of experiences of 25 men with prostate cancer, many of whom were treated with a urinary catheter, subjects reported the catheter contributed to feelings of shame, excess hospital visits for complications, and with other treatments for cancer, an end to sexual activity [411]. Men viewed healthcare professionals as having responsibility for medical decisions and they alone felt responsible for the catheter, mictunition, and sexual life (Level of Evidence 3).

Issues related to sexuality were dominant in several other studies. Using a catheter compounded changes in sexual life caused by illness or injury [406,409]. In one study, catheter users complained that care providers did not provide enough information about sexuality and how to adapt to a catheter [409]. Despite some care provider’s reluctance to address these issues, sexual health should be a part of assessments [412], and information about sexual activity should be provided proactively, while recognizing that some catheter users will wish to engage in sexual intercourse and others will not (Level of Evidence 3-4).

The underlying disease may also impact on sexuality. For instance, a urinary catheter complicates sexual activity in people with spinal cord injury (SCI). Moreover, men may have changes in sexual performance related to ejaculation, erectile function, and arousal [413]. For females with SCI, experimenting with positions, lubrication, and preventing spasticity may be helpful in sexual activity [414] (Level of Evidence 2). For people with SCI, sex-related autonomic dysreflexia (AD) occurs most often in people who suffer from AD during bladder or bowel care (415) (Level of Evidence 2). Autonomic dysreflexia is an autonomic nervous system syndrome that occurs in people with spinal cord injury or disease. Symptoms include severe hypertension and excruciating headache as well as sweating and goosebumps. It can be a serious problem—even life-threatening—requiring emergency medical attention, yet it is sometimes ignored or disregarded by health care providers [401]. A blocked catheter is also a frequent cause of AD. In a qualitative study (409), several people complained that care providers did not know much about AD and often dismissed their anxiety and concerns (Level of Evidence 3).

d) Catheter-related Pain
Pain related to catheter use is not always recognized although anecdotal information suggests that many people find a urethral catheter uncomfortable (see also Section XII.2.k on catheter comfort and catheter change procedures). In Saint et al’s study [104] 90% of catheterised patients surveyed reported they found the indwelling catheter uncomfortable or painful. Sometimes women complained about the pain because of sitting on the catheter or sores in the vaginal area [401], however it is unclear whether sores or skin irritation are related to latex sensitivity, friction, or wetness or a combination. Bladder spasms, CAUTIs, blockage, and dislodgement can all contribute to catheter-associated pain, as well as insertion and removal procedures[401,408,418] (Level of Evidence 3). Pain arising from AD in SCI patients can result from catheter blockage and has been discussed above.

e) Adjustment to a Catheter
Adjusting to living with a catheter may take a considerable time. In Roe’s study [417] participants reported it had taken them up to a year. Similar lengths of time are commonly reported in anecdotal evidence. An educational booklet for catheter wearers has been shown to significantly improve knowledge and acceptance of the catheter [418]. Though the implications for this type of intervention are positive (Level of Evidence 1-2), the sample was small (n=45)
and the study has not been replicated. The core category identified in a study using a grounded theory approach to examine older people’s experiences of living with a LTC was ‘all about acceptance’. Two further categories defined as ‘at ease’ and ‘unease’ reflected the extremes of their experience and these were mediated by ‘interaction with others’[419]. The presence of a catheter can affect the individual’s view of their own body and such shifts in body image can cause some people to exclude themselves socially. New catheter users (both urethral and suprapubic) may resist the "intrusion of the catheter" prior to acknowledging the need for it [420]. Qualitative studies have shown that although some people felt ill prepared for a catheter, and even viewed it as distasteful, most learned to accept the device over time [408,420]. Catheter-users have described their changed perceptions of the body and of how they learned to pay attention to urine flow to prevent catheter related problems. Though most acknowledged feeling vulnerable because of disruptions caused by the catheter, they noted also that keeping urine flowing was critical to their well being [404] (Level of Evidence 3). 

Health care providers need to provide proactive support and education about the catheter and its care, particularly since some catheter users are uncomfortable in asking for help or support. Male / female sensitivities can interfere, for example, a woman might be disinclined to talk about her catheter with her son [408,420] (Level of Evidence 3).

Guiding and supporting an individual’s adjustment to living with a catheter involves promoting dignity, supporting the changed body image so that the catheter becomes a part of self (and almost not noticed), and learning self-management and self-care, and in planning for active life in the community. It is essential that catheter users know how to select suitable equipment. Simple advice such as not using a coloured catheter in the summer when white clothing would allow it to show can be very helpful. Knowing where toilets are and planning for outings (rehearsing) can prevent urine accidents [401] (Level of Evidence 3). Ambulatory females who use a belly bag need to face the toilet when emptying the bag. Since this position is associated with male toileting rather than female it can sometimes cause embarrassment. Some women may prefer to use a unisex toilet where possible.

While adjustment takes time, emotional distress with the catheter can swing back into the picture at any time if problems develop. Depending on whether the device is working well or not, people can move back and forth between acceptance and estrangement from the catheter [241] when the problem in the background emerges and brings the issue once again to the foreground [421] (Level of Evidence 3). Learning to live with a catheter involves recognizing that the benefits can outweigh the problems (409), watching for signs of problems, and adjusting to the interpersonal and sexual changes [420] (Level of Evidence 3).

f) Self-management

Self-monitoring, a component of self-management, involves awareness of what to notice and related measurements or observations [422]. Self-monitoring urine flow was found to be helpful in preventing or minimizing catheter-related problems in a pilot study with 11 community-based individuals over a six months’ time[243]. In this study, a 3-day urinary diary of intake and output was combined with an educational program, individualized to the interests of participants. Most participants said they learned to pay attention to urine flow, through observing continuous drainage into the drainage bag, increased awareness of the urine colour, position of the catheter, and by monitoring the consistency of their fluid intake [243]. Health care providers can help catheter users to learn to manage their catheter themselves, (i.e., self-care) by identifying where they are in the process of learning self-care and by working with them [420] (Level of Evidence 3).

g) Summary

Most published studies of patients with indwelling catheters have focussed on short-term catheters (< 14 days) in hospitalised patients and relatively few have compared different modes of catheterisation (urethral, suprapubic, intermittent). The main subject of research on catheter use has been the risk of catheter-associated infection and the surrogate outcome measure of bacteruria (asymptomatic) is commonly employed. However, there are important questions over the appropriateness of this as an outcome measure. Although there is clear evidence to support a small proportion of catheter care procedures (indicated below) the majority of procedures are based on clinical experience and expert opinion. Long-term studies are difficult to carry out for a variety of reasons (not least the frailty of many long-term catheterised patients) and there are relatively fewer studies based on community dwelling patients. RCTs may not be the most appropriate or pragmatic design for these groups. Although there are now a number of Cochrane reviews relating to long-term catheter use it is clear that the quality of studies available frequently precludes drawing robust conclusions.

The published literature on SPC use is still relatively small, with much of it based on single centre cohort or case studies, or on short-term post-operative care following surgical procedures (not necessarily related to lower urinary tract symptoms). The majority of reports on SPC for long-term bladder drainage focus on the management of neurogenic bladder. Robust conclusions are often difficult to reach given the relatively short follow-up time frame of many studies.
and the lack of precise definitions of key outcome measures such as measurement of infection. Overall the risks associated with short and long-term use of indwelling catheters are common to both urethral and SPC insertions, including CAUTI, tissue trauma, catheter encrustation leading to blockage, formation of bladder calculi and histological changes.

Quality of life measures, including evaluation of psychometrics, need to be developed further and tested in this population, which may have different needs than others with incontinence. Studies of incontinent people that include catheter users should present data in ways that give the reader information about this sub-population. Sensitivity and a proactive stance from care providers could prevent or minimize some of the stigmatizing effects of the catheter, including those related to privacy needs, dignity, and sexuality. Further product development may help catheter users attain a higher quality of life. Additional research on the effects of self-management/self-care may provide direction for teaching that could contribute to a higher quality of life for catheter users.

4. OVERALL RECOMMENDATIONS RELATING TO CATHETERS

a) Intermittent catheters

• Clean intermittent catheterisation (CIC) is a treatment of choice for those with ongoing bladder emptying problems and residual urine > 100ml who are able to manage the technique (Grade of Recommendation A).
• CIC technique can be taught to all ages of people with appropriate motivation and manual dexterity (or to a carer where this is acceptable to both parties). Appropriate education and ongoing support is needed (Grade of Recommendation C/D).
• Frequency of catheterisation needs to be based on individual need, to prevent over-filling of bladder (Grade of Recommendation C).
• An external lubricant or lubricant-coated catheter is recommended to minimise urethral trauma (Grade of Recommendation C).
• CIC users may benefit from access to different catheters or catheter-packs for different purposes (eg ease of use may be particular important when at work or in public) (Grade of Recommendation C).

b) Indwelling catheters

• Indwelling catheters should only be used after alternative management strategies have been considered and rejected as unsatisfactory (Grade of Recommendation A).
• Duration of catheterisation should be minimal (Grade of Recommendation A).

• A closed drainage system should be maintained to reduce risk of catheter-associated infection (Grade of Recommendation A).
• Asymptomatic bacteriuria should NOT be treated with antibiotics (unless urological instrumentation is planned) (Grade of Recommendation B).
• Routine urine culture in an asymptomatic patient is not recommended (Grade of Recommendation C).
• Silver-alloy catheters should be considered for short-term catheterised patients to reduce the risk of catheter-associated infection (Grade of Recommendation A) but further economic evaluations are required to determine cost-benefit to institutions.
• Catheter materials designed for long-term use (all-silicone, silicone or hydrogel-coating) should be used where a catheter is expected to be used long-term (i.e. >14days) (Grade of Recommendation B).
• Meatal cleansing with plain soap and water (not with antimicrobial agents) is recommended (Grade of Recommendation A).
• Addition of disinfectants to drainage bags, bladder irrigation and antibiotic prophylaxis are NOT recommended as routine infection-control measure (Grade of Recommendation A).
• If an indwelling catheter is being considered, SPC should be considered alongside UC, following appropriate risk assessment (Grade of Recommendation B).
• SPC insertion should be carried out only by appropriately trained and skilled practitioners (Grade of Recommendation C).
• UC and SPC catheters and drainage bags should be adequately supported to prevent meatal or cystostomy damage from traction (Grade of Recommendation C).
• In patients with recurrent catheter encrustation and blockage, careful monitoring should be undertaken to identify of a characteristic pattern of ‘catheter life’ and instigate pre-emptive catheter changes prior to likely blockage (Grade of Recommendation C).

c) Catheter valves

• A catheter valve can provide an effective means of catheter drainage following appropriate patient assessment (Grade of Recommendation B).
• A combination of a valve during the day and free drainage at night through an open valve connected to a drainage bag could be an appropriate management strategy (Grade of Recommendation D).
5. PRIORITIES FOR RESEARCH

a) General

- Despite much published research (primarily on short-term catheter use in acute care settings), catheter studies have been hampered by methodological weaknesses. There is a need for agreement on key criteria to permit robust comparisons between studies: (i) criteria for symptomatic UTI, (ii) significant bacteriuria in a catheterised patient and its clinical/research usefulness (iii) standardised time frames for following patients in studies of catheter-associated infection eg 48h, 5 days, 7 days, 14 days 21 days etc (iv) documentation of the use of antibiotics prior to and during a study eg preoperatively in surgery or commencement of antibiotics for other conditions during the study, (v) patient follow-up to include post catheter removal.

- A standardised definition of UTI should be adopted as the primary outcome variable. At present the most recent CDC/NHSN surveillance definition of health care-associated UTI is recommended [295]. Although criteria for both symptomatic UTI and asymptomatic bacteriuria are defined by the CDC, it should be recognised that definitions are applicable to non-catheterised populations and specific to acute care settings.

- Better adherence to CONSORT guidelines [423]eg double blind randomization with appropriate power calculations, intention to treat analysis with inclusion of study drop-outs

- Need for clinical studies which are adequately powered to detect differences in clinically and economically important endpoints in preference to (or in addition to) more easily measured surrogate endpoints such as bacteriuria.

- Comparative studies of different patient groups eg. males and females, different age groups, patients at home and those in institutional care, including patients’ comfort, satisfaction and quality of life measures.

- Further research on the development of biomaterials that resist microbial adherence and biofilm formation and/or prevent catheter-associated bacteriuria in both long-term and short-term catheter users.

- Further efforts aimed at reduction of LTC use, particularly in nursing home populations. Targeted areas to include evaluation and management of skin problems, and alternative measures for people with diabetes mellitus, obesity and communication problems.

b) Intermittent catheters

There is lack of evidence demonstrating the effectiveness of any particular catheter type, technique or strategy. Variations in clinical practice and growth in the use of single-use catheters (particularly coated catheters) with associated increased costs mean that large, well-designed, parallel group RCTs are needed. RCTs are difficult to conduct in this area and must focus on the most important pragmatic questions, for both clinical and cost-effective reasons. Key issues are identified below.

- What evidence is there that coated (single-use) catheters are superior to uncoated (multi-use) catheters and in what ways (eg infection, comfort, convenience)? Further studies are needed on the risks / benefits of single use catheterisation (new catheter used at each insertion) versus single patient use (patient cleans, stores and re-uses the same catheter for several days) for patients whose long-term bladder management is by CIC.

- To assist assessment of cost-effectiveness, it is recommended that patient acceptability / satisfaction with procedure and a measure of health state utility are measured for different situations (eg. at home and when away from home) as a secondary outcome variable.

c) Indwelling catheters

- Epidemiological studies of CAUTI in LTC use in community care settings.

- Better prospective data on long-term sequelae of indwelling catheter use, eg ongoing symptoms, strictures, calculi, bladder cancer.

- Studies comparing catheterisation techniques eg CIC, suprapubic and urethral catheters, on CAUTI and other risks or potential benefits

- Studies to determine whether the frequency of regular re-catheterisation make a difference to CAUTI and other complications

- Studies to ascertain if there are detrimental effects on bladder tissue from persistent asymptomatic bacteriuria in long-term catheterised patients.

- Clinical evaluation of strategies to reduce recurrent catheter encrustation and blockage, including maintaining a dilute urine, increased level of urinary citrate, role of acidic ‘catheter maintenance’ solutions.

- Further development of catheter materials resistant to microbial biofilm formation, new approaches to disruption of the biofilm, or alternatives to catheterisation.

d) Catheter valves

- Clinical investigation of effect of catheter valves on incidence and frequency of catheter encrustation and blockage.
• Cost-effectiveness studies of disposable versus re-useable valves.
• Studies designed to demonstrate if catheter valves promote maintenance of bladder tone and capacity.
• Further examination of combination management strategies such as valve during the day and free drainage overnight.

**e) Quality of life**

• Identification of appropriate quality of life indicators/criteria and measures for catheterised patients.
• Development of a quality of life measurement instrument including both subjective measures and objective measures, including factors such as: frequency of catheter blockage, catheter-associated infection, hospitalization, unplanned catheter changes, adequacy of equipment, knowledge about self care, interaction with caregivers in catheter management.
• Case study analyses to maximise evidence gained through clinical experience and expert opinion, particularly where opportunities for formal research are likely to be unrealistic.

### XIII. PRODUCTS FOR PREVENTING OR CONTAINING Faecal INCONTINENCE

The broader issues of conservative management of faecal incontinence are dealt with comprehensively in chapter 16 while this chapter deals with products for preventing or managing faecal incontinence. They fall into three main categories:

• Products that aim either to prevent or contain leaked stool.
• Products that seek to prevent or mask the offensive odour that occurs from leaked stool or flatus.
• Products for preventing or treating perianal skin damage associated with faecal incontinence (one of the primary complications of faecal incontinence and an important part of care).

Products dealing with skin health and odour are covered in Sections XIV and XV, respectively, while products for preventing or containing faecal incontinence are covered in this section (apart from absorbent pads, which are included in Section VI).

#### 1. PRODUCTS TO PREVENT OR CONTAIN LEAKED STOOL

Products fall into three groups:

• Plugs to prevent leakage of faeces.
• Devices to channel faeces from the rectum into a storage container.
• Absorbent pads to contain leaked faeces (see Section VI).

An anal plug (Fig XIII-1) consists of a foam, cup-shaped plug that is collapsed and held by a film for insertion; the plug opens when the film comes in contact with the moist rectal mucosa [424,425]. It is inserted like a suppository using a lubricant gel. It has a string for removal or it can be expelled by raising intra-abdominal pressure and pushing like during normal defaecation. The anal plug has been used mainly by community living people, both adults and children, who are independent in managing faecal incontinence and toileting. Another type of experimental anal plug consists of a balloon at the end of a catheter connected to a notification device. The catheter is intended to be inserted into the rectum by the user and the inflated balloon acts as the anal plug; there are also vent holes on the distal tip of the catheter (Fig XIII-2). The disposable, double lumen, balloon-cuffed rubber catheter has an infra-red photo-interrupter sensor that is connected to a pager [426]. When faeces enter the rectum, a photosensor signal is sent to the pager which then notifies the person to inflate the balloon. Before a bowel movement, the balloon is deflated and the catheter is withdrawn. To prevent ischemic bowel damage, patients are advised to deflate the balloon for 10-15 min every 3-4 hours.

By contrast, devices for channelling faeces from the rectum to a storage container are used primarily by people who are acutely ill, critically ill, confined to bed, or in long-term care institutions and receive assistance in incontinence management and toileting by caregivers [427-431]. These devices do not prevent faecal incontinence and are used primarily for preventing or treating skin damage associated with faecal incontinence. They include rectal tubes, catheters, trumpets, and pouches.

Rectal tubes and catheters are inserted into the rectum and drain faeces through openings at their proximal end into a collection bag (Fig XIII-3). Sometimes a balloon slightly distal to the proximal tip is inflated with the aim of preventing leakage of faeces around the catheter and to retard inadvertent expulsion of the tube during defaecation [428]. This arrangement works best with liquid stool which is most likely to be able to flow without blocking the drainage lumen [431,432]. Bowel management programs often include daily saline irrigations through the rectal catheter to maintain liquid consistency of stool and catheter patency. Differing amounts and frequency of irrigation have been reported (300 to 900 ml). Cutting the tip of the catheter off at an angle to facilitate drainage of stool of thicker consistency has been reported [433]. A rectal tube / catheter is contraindicated in patients who have intestinal mucosal disease, immuno-
Figure XIII-1: Anal plugs.

- a: infrared photo-interrupter sensor and flatus vent holes incorporated into the catheter
- b: 20 cc air cuff (similar to a regular bladder catheter)
- c: flatus venting charcoal filter
- d: cuff fill valve
- e: monitor connector
- f: monitor that resembles a “beeper” or pager

Figure XIII-3: Rectal catheters; Flexiseal Fecal Management System, Convatec (Nordic Capital Fund VII and Avista Capital Partners); Princeton, NJ (top); and Zassi Bowel Management System, Hollister, Inc. Libertyville, IL (bottom).
suppression, gastrointestinal bleeding or bleeding tendencies, recent myocardial infarction or prostate surgery [433,434]. Use of a rectal tube with or without inflating the balloon is controversial because of concerns of perforating the rectum, damaging the anal sphincter or rectal mucosa, stimulating intestinal secretion worsening diarrhoea and thus incontinence [432,433,435]. Critically ill patients, who often receive a rectal tube, may be at greater risk for intestinal ischemia and rectal damage because they experience shunting of blood from the gastrointestinal tract during shock or low perfusion states.

A rectal trumpet is a nasopharyngeal airway that is inserted into the rectum and connected to a collection bag at its distal end. The flange end of the trumpet is inserted into the rectum [436] (Fig XIII-4). A possible advantage of the rectal trumpet over a rectal tube is that it is shorter and has less contact with the rectal mucosa, so limiting the area of possible damage. Other limitations are similar to those for the rectal tube / catheter regarding risk of expulsion from forceful valsalva movements and dislodging during linen changes or from tugging on the collection bag [436]. Nasopharyngeal airways that can be used as a rectal trumpet are produced by several manufacturers.

An external anal pouch consists of a pliable wafer, which has an opening at its centre, an adhesive on the body side, and a collection bag on the other. The wafer adheres to the perianal skin (Fig XIII-5). The bag has a resealable port at its distal end through which faeces can be drained without the need to remove the wafer from the skin. The port can also be connected to a larger, gravity drainage bag. Some pouches have a small folded flap that allows flatus to escape so that it doesn’t inflate and rupture the bag. The pouch avoids the risks of rectal or sphincter damage associated with the rectal tube or trumpet. If used without the additional drainage bag, it can collect leaked stool of any consistency without clogging. A limitation of the rectal pouch is difficulty in applying it on people who have a small space or severe oedema between the anus and vagina or scrotum. Other reported disadvantages include difficulties in maintaining the seal (especially when the perianal skin is already damaged); break of the seal when repositioning the patient; and skin tears by traumatic removal of the adhesive [436,430].

An intra-anal stool bag is composed of a latex bag (20 cm non-extended, to 26 cm extended) that is inserted into the anus and an adhesive attachment (10 cm in diameter) applied perianally [437] (Fig XIII-6). There is a cut-out on the ventral urinary side of the adhesive wafer.

Aspects of patient assessment that are relevant to products to prevent or contain leaked stool include the following: a) physical characteristics (e.g., some anal plugs may be too large to fit smaller sized children),

Figure XIII-4: A rectal trumpet.

Figure XIII-5: An anal pouch.

Figure XIII-6: Interanal stool bag (left) and Outer attachment wafer of Interanal stool bag (right). (Reproduced with the permission of Wiley-Blackwell Publishing)
b) dexterity (e.g., some degree is needed to insert or remove an anal plug), c) mobility (e.g., rectal catheters are mainly used for patients who are in bed vs. ambulatory), d) nature of incontinence (e.g., bowel catheters will require irrigation when stool consistency is not loose or liquid in order to remain patent; and e) personal priority and lifestyle (e.g., some persons will wear an anal plug on certain occasions such as when swimming, despite discomfort).

2. QUALITY OF DATA

There have been eight published evaluations of anal plugs for controlling faecal incontinence and one of the anal catheter plug (Procon, AnaTech, El Paso, TX). Five reports included children of which two studied children exclusively [438,439]. The study designs were one randomized clinical trial, four repeated measures (cross-over), one pre-post design, one cross-sectional survey, one case series, and one case report. All of the studies of anal plugs except one evaluated products from the same manufacturer (Coloplast, Denmark). One study in children [438] compared the Coloplast device with one by Med.SSE-System, Germany. There has also been one published evaluation of a rectal trumpet using a case series design [436] and one each of an external anal pouch and an intra-anal stool bag in which no comparison group or pre-post measures were included.

3. RESULTS: ANAL PLUGS

Most evaluations of anal plugs have involved relatively small cohorts of ambulatory subjects. The largest sample had 48 subjects and 26 of 31 persons in the intervention group who wore the anal plug completed the study [440]. The aetiologies of faecal incontinence varied across studies and included spina bifida, imperforate anus, spinal injury, post-surgical incontinence, sphincteric injury, and obstetric trauma. Faecal incontinence was measured by self-report using a daily stool diary in six studies [424-426,439-441]. A questionnaire /survey was used in one descriptive study [442] and one repeated measures study [438]. The main reported outcome measures were: the number of episodes of faecal incontinence per number of anal plug uses overall. Faecal incontinence occurred in 10% to 12% of times one of the three anal plugs used due to self removal or need for defecation. Two of seven child respondents stopped using an anal plug because of pain [439]. Two or fewer soiling accidents occurred in 74% using the polyurethane plug, and in 65% using the polyvinyl alcohol plug [438].

A survey of adults and children showed that a higher percentage of children tolerated using an anal plug over a longer period of time [442]. Five of eight (63%) adult survey respondents who had faecal incontinence of various aetiologies stopped using an anal plug immediately while three used it periodically for 12 to 20 months. Two of seven child respondents stopped using an anal plug immediately while five (71%) used it weekly for an average of 2.5 years. The most common reported problems associated with wearing an anal plug included discomfort and failure to retain the plug. Despite efficacy, approximately two-thirds of the subjects in two studies [425,441] said they would not continue to wear the plug due to discomfort. Discomfort occurred in 10% to 12% of times one of the three anal plugs were worn in another study [424]. In more recent studies, three of 23 subjects (13%) reported discomfort [440], and 25% of 16 withdrew from another study because of pain [439]. Two of the children who
withdrew from the paediatric study had complained of discomfort [438]. There was no association between comfort of the plug and anorectal sensitivity during anal-rectal physiology tests in adults [425]. Approximately 20% of children reported that insertion of the polyvinyl alcohol plug was painful while 17% found removal of the polyurethane plug to be painful; one child experienced bleeding on removal of this second plug. Rectal bleeding also occurred in adults but infrequently [424]. Failure to retain the anal plug was reported by 13% of subjects in two studies [439,440] and was noted by one child in the paediatric study as a reason for withdrawal [438]. The size of any plug tested was too large for six children in one study [438]. Other tolerance problems were fairly uncommon. In one study, adults rated all three anal plugs that were evaluated as relatively easy to insert. Two plugs were difficult to remove in only 5% and 6% of uses, respectively, while the third was difficult to remove in 23% of uses [424]. Other reported problems were feeling a need to defecate [425], inconvenience or difficulty in managing [425,426], and local irritation [442].

4. RESULTS: RECTAL TRUMPET

One case series study evaluated the use of a rectal trumpet in 22 acutely or critically ill patients with faecal incontinence and perineal skin damage (436). For 90% of the subjects, the skin damage had been caused by wearing a rectal pouch immediately prior to the study. Subjects used the trumpet for periods varying between 36 hours and 16 days (mean 6.5 days; sd 4.4 days). The reasons for any discontinuation of use were reported. Outcome was determined using a daily questionnaire completed by patients' nurses and the health of the perianal skin was noted by subjective assessment. No standardised definitions or criteria for restoration of skin integrity or healing of skin damage were reported. Two subjects were lost to follow up. Faeces were successfully diverted to and contained by the collection bag in all patients. Recovery from skin damage was reported in 7 (39%) patients and partial healing of skin in the remaining 11 (61%). Discomfort on insertion was noted for 41% of subjects (Level of Evidence 3).

5. RESULTS: RECTAL CATHETER SYSTEMS

Closed rectal catheter and collection bag systems specifically designed for extended use and diversion of faeces are commercially available primarily for acutely-ill or bed-ridden patients (Flexi-Seal® Fecal Management System, Convatec A Bristol Myers Squibb Company; Princeton, NJ; Zassi® Bowel Management System, Hollister, Inc., Libertyville, IL). The catheters of these systems typically contain a retention cuff that collapses to assist with insertion (US FDA approved for up to 29 days) and a port for irrigation. In one system (Zassi) there is also a collapsible zone below the cuff that resides in the anus to allow normal anal sphincter function during use and a second port for sampling intestinal fluid. A third catheter has an inner balloon that can be inflated to serve as an anal plug to promote retention of an enema, for instance (Kim, US Patent 5 689 216, apparently not currently commercially available).

Six studies evaluated use of a rectal catheter system. Three studies used one type of catheter while the other three studies used three different types of systems. One study was of children [443]. The designs included a prospective single cohort in four studies [427;428;443, 444], a pre-post descriptive design [445], and a retrospective case-matched pre-post design [446]. The largest sample size was 106 in the retrospective chart review whereas sample sizes in the prospective studies were relatively small, ranging from 20 to 42 subjects. In the studies of adults, subjects were acutely or critically-ill patients in three studies [427;428;445]. In three studies, irrigation of the catheter with saline, a combination of lactulose and saline irrigation or use of an enema was used to keep the stool liquid and the rectal catheter patent [428;444;446]. In only two studies was the effectiveness of the rectal catheter system in reducing faecal incontinence reported (Level of Evidence 3). In the one paediatric study, 31 children (11 females) participated. Eight families refused to stop using the rectal catheter to complete an incontinence diary without use of a catheter. Two children had balloon extrusions and three were noncompliant resulting in their study withdrawal. The mean number of daily faecal incontinence episodes as reported on a daily diary decreased from 3 to 1.5 in males and from 1.6 to 1.1 in females (p<.05 for both) [443]. Three children experienced no improvement of faecal incontinence. In the one adult study, 39 of 42 subjects (62% female) with diarrhoea in intensive care units in seven hospitals completed the study. There was up to 29 days of follow-up. Varying degrees and types of leakage around the rectal catheter were reported in 71% of 198 assessments; 35% of these leakages extended to pads on the bed or beyond [427]. Seven (17%) of subjects had difficulty retaining the rectal catheter. Section VI.k discusses use of a small gauze dressing for absorbing small amounts of stool leakage and a moisture barrier as skin protective strategies that might also help prevent damage from stool leakage around a rectal catheter. Skin damage from the tape holding the catheter in place and rectal bleeding are other reported but uncommon complications [427;444].

The effect of a rectal catheter on various outcomes associated with stool leakage has also been studied. One study reported that the number of bed linen changes in burn patients with diarrhoea decreased eight-fold and dressing changes in hospitalized or burn patients decreased in half after a bowel system was introduced [444].
Other outcome measures of rectal catheter use included urinary tract infections, incidence of skin/soft tissue damage or infections, prevalence of pressure ulcers, and number of liner changes (Level of Evidence 3/4). In a retrospective review of medical records, approximately twice as many burn patients had skin/soft tissue or urinary tract infections before a bowel catheter system was introduced than after (p<.01) [446]. A prospective study of acutely and critically-ill patients showed that 41% who had normal skin in the perineum or buttocks at baseline maintained normal skin during use of the bowel catheter, 44% with some degree of skin damage improved, and 8% had worsened skin condition [427]. The percentage of intensive care unit patients with a stage II or greater pressure ulcer was observed to be less at nine months after use of a bowel catheter was introduced. The total number of patients observed was not reported. The length of time during which the prevalence of pressure ulcers was determined prior to catheter use was also not reported [445].

The condition of the rectal mucosa was observed endoscopically in 40 patients total across three studies; the evaluations were not blinded or independent and did not use a rating scale [427,428;444]. All endoscopic observations were reported as being normal after rectal catheter use. Few complications associated with use of the rectal catheter system were reported. Leakage around the rectal catheter seemed to be the most frequent problem. Catheter expulsion occurred in a small number of patients and skin damage from trying to secure the tube occurred only in one patient. Altered rectal sphincter function occurred using one of the catheters [428] (Level of Evidence 3).

6. RESULTS: ANAL POUCH

One case series study evaluated the use of an external anal pouch (Technoline, Concordia, Moderna, Italy) in 120 nursing home or hospitalized patients (65 men, 55 women, ages 45-96 years) [447]. The nursing home residents (n = 92) were bedridden and had faecal and urinary incontinence or were treated for constipation for rectal enemas that drained into the pouch. Ten had a pressure ulcer. They used the pouch for four weeks or more. Acute care patients (n = 28, of which 10 were in the intensive care unit) had diarrhoea and were temporarily bedridden. Forty-five patients who had surgery of the perineal area received a pouch to collect post-surgical drainage for up to three days. In the nursing home residents free of pressure ulcers, no new ulcers developed. In those with a pressure ulcer, healing occurred in five residents, ulcer diameter was reduced by 50% in three residents, and there was less than 50% reduction in two residents. Of the nursing home and acute care participants, 77% found the pouch comfortable and 75% thought it was better than a sanitary napkin. Seventy-seven percent of the nurses thought the anal pouch was easy to apply and 78% thought is easy to remove. Reported complications included moderate pain on removal in 18 (15%) patients in the nursing home or acute care (Level of Evidence 3).

An internal anal stool bag (Terumo Corp., Tokyo, Japan) was applied to five bedridden patients (3 female, 2 male) aged 68-90 years [437]. Persons were administered a bisacodyl suppository prior to insertion of the stool bag into the anus to control excretion of faeces. The bag was successful in collecting stool 50% of the time (Level of Evidence 3). The bag was removed after each stool was collected.

7. SUMMARY

- An anal plug can successfully prevent faecal incontinence but it is associated with high levels of discomfort, especially in adults (Level of Evidence 3).
- A rectal catheter system diverts faeces to a collection bag and promotes healing of damaged perineal skin but requires liquid stool consistency to remain patent. Some catheter systems enable irrigation of the rectum to maintain liquid stool consistency. Non-blinded and non-independent endoscopic observations suggest the catheter does not cause rectal mucosal damage during the recommended length of use (≤ 29 d in the US) (Level of Evidence 3).
- A rectal trumpet can successfully channel faeces to a collection bag and there is some evidence that it can thereby enable damaged perianal skin to recover but it has been associated with discomfort and its safety has not been determined (Level of Evidence 3).
- An external anal pouch and an internal anal bag can be used to collect stool (Level of Evidence 3) but the adhesive wafers used to adhere them can cause skin damage upon removal. The internal anal bag has been primarily used when a bowel movement is induced using a suppository.

8. RECOMMENDATIONS

- Anal plugs may be tried but many patients are likely to use them on a limited basis or reject them due to discomfort (Grade of Recommendation C).
- The use of a rectal trumpet (i.e. a nasopharyngeal tube inserted into the rectum) in patients with loose/liquid stool consistency offers an alternative to the rectal pouch when pouch adherence is a problem and may preserve perianal skin integrity or facilitate healing (Grade of Recommendation C). The safety of the rectal trumpet has not been determined, but it suggests a lower risk due to its shorter length than a standard, longer rectal tube (Grade of Recommendation C).
9. PRIORITIES FOR RESEARCH

- Development of an anal plug that is more comfortable and tolerable.
- More rigorous evaluation of anal plugs using larger subject cohorts and more objective outcome measures over longer periods of use.
- More rigorous evaluation of rectal tubes / catheters and trumpets using larger subject cohorts and more objective outcome measures (e.g., for assessing health of the rectal mucosa) over longer periods of use.
- Development and evaluation of an external anal pouch that is easy to apply and remove, adheres to skin better and, perhaps, even promotes healing of damaged skin to which it would be applied. Further evaluation of an internal stool bag with similar adherent properties (as recommended for the external anal pouch) is needed.

XIV. SKIN HEALTH AND CONTINENCE PRODUCTS

1. BACKGROUND

The skin of an incontinent individual will be regularly exposed to contact with urine and / or faeces and damage to the skin is the main physical health consequence of urinary and faecal incontinence. The majority of current knowledge about the effects of urine and faeces on skin has been obtained from studies with pads or pad materials on animals, healthy infants, and on body areas such as the forearm or back of adults. Where clinical trials have been conducted, they have usually been on infants and rarely on adults using pads. Skin irritation within the pad occlusion area is usually termed diaper dermatitis in infants. In adults the term perineal dermatitis (PD) has commonly been used, but more recently it has been proposed that incontinence-associated dermatitis (IAD) is a better term because affected skin areas are not confined to the perineum [448]. The more inclusive label ‘Incontinence-associated skin damage’ has also been applied [449] and may be preferable when describing skin problems on the buttocks, hips and sacrum where erythema or skin surface damage may also be caused by pressure, shear or friction.

a) The role of urine and faeces in skin irritation

Prolonged exposure to water alone has been shown to cause hydration dermatitis [450;451] and prolonged occlusion of the skin (as within a continence product) has been demonstrated to reduce skin barrier function [452] and significantly raise microbial counts and pH [453,454]. Repeated wetting and drying makes the skin more vulnerable to substances that are usually innocuous, e.g., bile salts [455;456]. A product that simply maintains wet and occluded skin (even without the additional constituents of urine and faeces) is therefore likely to cause skin irritation and increase skin permeability to other irritants.

Using a hairless mouse model Buckingham and Berg [457] examined the role of faeces in the aetiology of diaper dermatitis. They identified proteases and lipases as the major irritants and noted that these faecal enzymes not only irritated the skin directly but also increased the susceptibility of the skin to other irritants such as bile salts. The irritant effect of faeces was virtually eliminated by heating, which destroys enzymes, and was restored by the replacement of specific enzymes (e.g. lipase and protease). Skin damage appeared dependent on the concentration and length of exposure to enzymes in faeces [458].

A similar mouse model was used by the same researchers to examine the role of urine in the aetiology of diaper dermatitis [456]. They found that the irritant potential of urine by itself was minimal over short periods (48 hours) but after continuous exposure (10 days), skin damage became apparent. The researchers also measured skin permeability and found that continuous exposure to urine greatly increased skin permeability (more than 15 fold) compared to occluded skin or skin exposed only to water.

However, the combination of urine and faeces caused significantly higher levels of irritation than urine or faeces alone. The authors concluded that the presence of faecal urease results in the break down of urinary urea causing an increase in pH, which increases the activities of faecal proteases and lipases leading to skin irritation. The role of microorganisms - which comprise approximately 50% of the solid component of faeces - in skin damage is unresolved. Microorganisms on the skin of infants with and without diaper dermatitis were similar [459]. Zimmerer [460] sampled the microflora of the skin after pre-loading with pre-wetted patches containing urine and found that the microbial counts were significantly higher for wet patches relative to the dry patch controls. It was nearly
impossible to establish infection with the opportunistic organism, Candida albicans, on normal skin without complete occlusion of the site [461]. Therefore, it is thought that bacterial or fungal infection is secondary to alterations in the skin barrier that allow penetration of the microorganisms [462].

Zimmerer et al. [460] examined the role of skin wetness in the development of diaper dermatitis by using the volar forearms of adult volunteers. They aimed to determine the effects of wet and dry diaper materials on skin health with respect to friction, abrasion damage, permeability and microbial growth. Pre-wetted patches of baby diapers were placed on the volar forearms of adults for two hours and then the skin was subjected to friction and abrasion. The coefficient of friction for the 'wet' skin was significantly higher than for 'dry' skin although increased fluid loading of wet patches did not further increase skin friction. Similarly, skin hydrated with a wet patch showed a significant increase in skin abrasion damage relative to a dry patch. Again, variations in the fluid loading of the patch did not produce significant changes in abrasion damage.

Although the volar forearm is most commonly used for skin experimentation, it has not been shown to be a valid model for the skin exposed to an incontinence pad, i.e., buttocks and groins. Schnetz and colleagues [463] demonstrated that trans-epidermal water loss (TEWL) measurements (used to measure both skin barrier function and excess water in the skin) from the volar forearm did not correlate with those taken from the face, although the left and right side of the face showed good correlation. The researchers concluded that TEWL measurements for the study of facial cosmetics should be taken from the face rather than the forearm. Similarly, studies using the volar forearm may not be valid for the buttocks and groin. Skin in the perianal area was shown to be more sensitive to faecal irritation than that on the inner arm [464].

Berg [465] analysed the aetiological factors contributing to infant diaper dermatitis and developed a model (Fig XIV-1) to show its development and resolution. However, the applicability of this model to adults with incontinence has not been tested, and other factors such as low mobility and prolonged pressure - which are common in frail, older adults - are not accounted for in this model. In addition, this model assumes the presence of urinary and faecal incontinence, which is much less common in adult populations than urinary incontinence alone.

b) Prevalence of perineal dermatitis

Perineal dermatitis (PD) is an inflammation of the skin characterized by redness, tissue breakdown or denudement, vesiculation, oozing, soreness, itching, and in its more severe form, pain and fungal patches [466;467] within the pad area. In the largest study of assessment records of more than 59,000 residents in 510 nursing homes located in 31 US states, Bliss et al. [449] reported a prevalence of perineal dermatitis of nearly 6%. In studies with smaller sample sizes and other populations, perineal dermatitis (Table XIV-1) has been shown to affect about a quarter to a half of patients.

There is no widely accepted, valid or reliable tool for the assessment of PD / IAD although three instruments have been published [475-477]. One of these tools, the Perineal Assessment Tool, despite its name, appears to be an instrument primarily for assessing the risk of PD (versus assessing skin health) and it has been described and used by its developer as such [478]. Most researchers have reported ratings of colour changes (degree of erythema) based on visual inspection, which may be confounded by the

presence of reactive hyperaemia on areas subject to pressure (particularly the buttocks, hips and sacrum). In some studies (mainly those finding higher proportions of PD) trained staff or researchers have been utilised to carry out skin inspections at pre-specified times and in others (mainly those finding lower proportions of PD) the usual care staff have been asked to report skin problems or written records have been used; this may explain the wide range of prevalence reported.

Bliss et al. [479] prospectively investigated the development of PD using assessment data of 1,850 elders who were free of PD at admission to a nursing home. The preliminary report showed that at three months after admission, faecal incontinence alone and double incontinence were significant predictors of PD, but urinary incontinence alone was not a significant risk. The prevalence of PD appears to be influenced not only by the type of patient (nursing home versus hospitalized) but also by the type of incontinence and whether or not a skin damage prevention program is followed.

Few studies report the severity of PD. In a prospective surveillance study of 981 nursing home residents with incontinence of urine and/or stool over six weeks, the most common anatomical locations of PD were the buttocks (73% of those with PD) and perianal area (70%) followed by the genitalia, scrotum and groin (36%) and thighs (24%) with the smallest percentage near the sacrum (9%). Approximately one-third of residents had PD in more than one location. Mild PD was by far the most common (69% of residents); severe PD affected only 8% of residents [472].

**c) Pressure ulcers and incontinence**

The role of urinary and faecal incontinence in the development of pressure ulcers is uncertain. Studies aiming to identify risk factors for the development of pressure ulcers have generally found that the presence of both urinary and faecal incontinence was a risk [480,481-483], but some studies have only found faecal rather than urinary incontinence to be a risk factor [484,485]. Pressure ulcer risk assessment scales all have a sub-scale of incontinence or moisture-level, and the main mechanism for the development of pressure ulcers has been thought to be the increased friction and increased vulnerability to abrasion of wet skin.

Some researchers have used pressure ulcer classification systems, such as those published by the National Pressure Ulcer Advisory Panel (NPUAP) or the European Pressure Ulcer Advisory Panel (EPUAP), to measure skin health. The validity and reliability of most of these tools have not been established. Doughty et al [486] and Bethell [487] described numerous other limitations of pressure ulcer staging systems and despite recent revisions of the NPUAP and EPUAP staging systems, many of the shortcomings still apply. The reliability of the EPUAP staging score (which is a modified version of the NPUAP score) has been tested recently in three studies using photographs of pressure ulcers. These photographs included ‘moisture lesions’ (defined as lesions resulting from prolonged exposure of the skin to excessive fluid because of urinary or faecal incontinence, profuse sweating or wound exudate). A high degree of reliability for classification of moisture lesions was found amongst 44 pressure ulcer experts.

![Figure XIV-1: Berg’s model of diaper dermatitis (1987).](image-url)
2. CLINICAL STUDIES OF THE IMPACT OF pressures.

formation of pressure ulcers by raising interface pressures. It is therefore possible that pad folding and compression may contribute to pad / mattress. Peak pressures were frequently found pressures recorded between the buttocks and the and substantially (around 20%) increased the peak pressures. Using an articulated model or “phantom” as the subject and found that the presence of a pad significantly prevention relieving devices / measures. Fader et al. [491], examined the effects of absorbent continence pads on mattress interface pressures using an articulated model or “phantom” as the subject and found that the presence of a pad significantly and substantially (around 20%) increased the peak pressures recorded between the buttocks and the pad / mattress. Peak pressures were frequently found at the locations of pad creases and it was considered that pad folding and compression may contribute to raised interface pressures. It is therefore possible that continence product use contributes to the formation of pressure ulcers by raising interface pressures.

2. CLINICAL STUDIES OF THE IMPACT OF PRODUCTS AND PRODUCT MATERIALS ON SKIN HEALTH

In the 1980s, product manufacturers introduced diapers with super-absorbent polymers (SAP), which were designed to reduce skin wetness, buffer pH and reduce urine / faecal contact in order to help prevent diaper dermatitis. This led to clinical and laboratory studies to evaluate the efficacy of diapers with different materials, in particular, super-absorbent polymers (SAP) compared to those without, and compared to conventional washable diapers.

a) Quality of data

There are three types of studies testing the effects of different products or product materials on skin health: (i) clinical trials of normal infants wearing diapers; (ii) laboratory wet patch testing of adult forearms with diaper or continence pad patches; and (iii) clinical trials of adult absorbent pads containing different materials. The infant diaper studies were randomised controlled trials with large samples and blind measurement of outcomes. It should be noted that these studies were carried out by industry-employed staff. The infant and laboratory studies used a probe comprising two hygrosensors and thermistors (an evaporimeter) placed on the ‘wet’ skin to measure trans-epidermal water loss (TEWL), an indicator of skin hydration level. However, there is uncertainty about the optimum procedures for measuring TEWL, and different procedures and outcomes were used in the studies, making it difficult to compare results. Probably the most important threat to the validity of these studies is the selection of products or materials used in the study. None of the studies adequately described the products used - in particular, regarding their total absorbency. Thus it is possible that an alternative explanation for the fairly consistent findings that disposable pads with SAP perform better on skin outcome measures may be that those with SAP simply had greater absorbency than those without.

b) Results

1. CLINICAL STUDIES OF INFANT DIAPERS

Campbell and colleagues[492] conducted four clinical studies involving 1,614 infants randomly assigned to either disposable diapers with SAP, disposable diapers without SAP or washable cloth diapers. Disposable diapers with SAP were associated with significantly reduced skin wetness as measured by TEWL, lower pH and lower ratings of diaper dermatitis when compared to the two other diaper products (Level of Evidence 2).

Lane et al., [493] randomised disposable diapers without SAP and disposable diapers with SAP to 149 newborn infants and assessed their skin condition seven times over a 14 week period. Skin rash ratings were significantly lower for infants wearing diapers with SAP at only one time period (14 weeks) (Level of Evidence 2).

Davis and colleagues [494] assessed 150 infants over 15 weeks in a cross-over study involving four different disposable diaper types, two with different levels of

(Kappa =0.80) [488]. However, inter-rater reliability was found to be much worse (Kappa = 0.37) when photographs were viewed by 473 non-expert nurses (489) and subsequently in a European study of 1,452 non-expert nurses from five European countries (Kappa = 0.36). The authors concluded that better descriptors needed to be incorporated into the EPUAP system and more education was needed.

To investigate the validity of classifying moisture lesions, Houwing et al. [490] examined the histology of 14 biopsy samples of damaged patient skin. Skin damage was classified using the EPUAP system: 12 were moisture lesions, one was a grade 4 pressure ulcer (extensive tissue destruction / necrosis) and one was a combination of a moisture lesion and a grade 1 pressure lesion (non-blanchable erythema). Both pressure ulcers had a histological pattern suggesting ischemic pathology; the histology of the moisture lesions, however, was either of an ischemic or irritation pattern. Because of the overlap in histology patterns of some of the moisture lesions and the pressure ulcers, the authors concluded that there is no justification for classifying moisture lesions separately from pressure ulcer lesions. This finding requires further study as there are several limitations of their study. First, the true aetiology of the skin damage and the veracity of the EPUAP classification were not determined; some moisture lesions seem to be partially over a bony prominence so that a mix of pressure and moisture damage cannot be ruled out, which might explain the mixed histology patterns. Secondly, the moisture lesions and the pressure ulcer were both described as having blanchable erythema. Identification of moisture lesions as distinct from pressure ulcers is sought as a way to solve the tension between inadequate prevention / treatment of a pressure ulcer and inappropriate use of costly prevention relieving devices / measures.
SAP and two with different levels of fluff pulp only. Both diapers containing SAP were associated with significantly less skin wetness and significantly lower pH. Clinical skin ratings showed significantly lower ratings for the SAP-containing pads compared to the lower weight fluff pulp pad, but not compared to the higher weight fluff pad (Level of Evidence 2).

2. LABORATORY STUDIES OF DIAPER PATCHES

Wilson and Dallas [495] used the adult normal volar forearm skin model to compare patches taken from 16 different infant diapers. They found that disposable diapers containing SAP left the skin significantly drier than washable diapers and disposable without SAP (p < 0.01). Disposable diapers without SAP did not differ significantly from reusable diapers and there were no significant differences between products within any of the three groupings (Level of Evidence 2).

However, in a subsequent study involving 20 disposable and washable adult incontinence pads incorporating a similar range of materials to the baby diaper study Dallas and Wilson [496] found significant differences between products within each of the three product groupings but not between groupings (Level of Evidence 2). Grove et al. [497] used a similar approach to compare three infant diapers and found a significant difference in skin wetness between two that contained similar quantities of SAP (p < 0.001). The one in which the SAP was in a layer near the water-proof backing kept the skin dryer than that in which it was near the coverstock. The third diaper – which had a microporous (breathable) backing kept the skin significantly dryer than each of the other two (p < 0.001) (Level of Evidence 2).

3. CLINICAL STUDIES OF SKIN-CARE PRODUCTS AND NURSING PRACTICES TO MAINTAIN OR IMPROVE SKIN HEALTH

The skin of incontinent people requires frequent cleansing to remove urine and/or faeces. Soap and water is in common use [498] but it is known that repeated exposure to anionic surfactants (common in soaps) results in skin irritation [499:500]. In addition, the action of washing is also considered likely to contribute to mechanical damage of the stratum corneum.

Cleansing of skin soiled with urine and/or faeces should occur immediately if possible or promptly after episodes of incontinence [448;501-504]. In addition, an individualized schedule for cleansing the perineum according to patients' needs or preferences [505;506] or at routine intervals, such as daily or at bath time [448;501,507;508] has been recommended (Level of Evidence 3).

The practice of cleansing or wiping the perineum front to back is recommended as standard practice in the literature - particularly for women [509-513]; this recommendation is based on the physiological rationale of lowering presumed risk of contaminating the urethra with fecal bacteria and subsequent urinary tract infection [513]. One retrospective study of pregnant women found a significantly higher association of urinary tract infections in women who self-reported they wiped back to front (25.8%) than among those who wiped front to back (18.5%) [514](Level of Evidence 2).

To minimize friction damage of the skin during the perineal cleansing process, gentle cleansing and patting dry the skin [515,516] rather than rubbing or using a soft cloth is recommended by clinical experts [472,517,448,503,504;518] (Level of Evidence 4).

However there is some evidence that drying the skin
by patting may be less effective than gentle towel-drying or drying with a hair dryer [519]. Damp skin is more vulnerable to friction damage and special care may therefore be needed to ensure that the skin is dry. For already damaged skin, there are clinical anecdotes of using a small hand-held hair-dryer set on a low and cool setting rather than drying with a cloth. Further research into cleaning and drying techniques and products is encouraged.

Alternative cleansers are available which have been formulated with the intention of overcoming some of the limitations of soap and water. Although overhydration of skin is detrimental, an excessively dry stratum corneum develops cracks and fissures and can be as ineffective a barrier as an over hydrated one [520].

The use of topical products aiming to prevent or treat skin irritation is common but there is a lack of standardisation in definitions and descriptions of products, which makes comparisons difficult. Products such as ‘moisturisers’ or ‘barriers’ may be applied to the skin after cleansing, and some cleansers also incorporate moisturisers. The aim of moisturisers (also known as emollients) is to hydrate the skin by reducing trans-epidermal water loss through occlusion (e.g. petrolatum), by drawing water into the stratum corneum by the addition of a humectant (a hygroscopic substance, e.g. glycerol) or by adding water in the applied water-miscible product. These modes of action are often combined in the same product, but there are exceptions - such as petrolatum - which only work by occlusion [521]. Some products are designed specifically to prevent penetration of water into the stratum corneum (‘barrier’ products) such as liquid skin sealants containing polymers, and may allow trans-epidermal water loss whilst preventing external water penetration. Simple occlusive products such as petrolatum may also act as barrier products to water but also occlude trans-epidermal water loss.

The application of skin barriers is recommended on areas that would come in contact with leaked urine and / or faeces. In general these areas include the buttocks and perianal area, groin, and inner thighs. Community-living persons report leaking small amounts of faeces that remain between the buttocks. Clinically, nursing staff have observed seepage of faeces around a rectal catheter in hospitalized patients. In both groups, perianal skin protection is important, and skin barriers are recommended (Level of evidence 4).

Topical creams are commonly used to prevent and treat dermatitis but controlled experiments to assess efficacy on human and animal skin have produced equivocal results. Ghadially et al. [521] showed that barrier recovery (measured by TEWL) on experimentally irritated skin was accelerated by the application of petrolatum and De Paepe K et al. [522] showed similar results using a different moisturising cream. Hannuksela and Kinnunen [523] showed that treatment with moisturisers prevented the development of irritation in an experiment involving frequent skin washing with liquid detergent. However, Gabard [524] was unable to demonstrate significant acceleration of barrier recovery to chronically irritated skin following application of different moisturisers using a chronic irritation model and also found that some creams enhanced irritation.

The efficacy of barrier products in preventing water penetration of the skin has been tested in laboratory settings. Vinson and Proch [525] applied wet patches with a water-soluble marker to skin coated with three different barrier products and measured dye extracted from the skin by absorbance spectrophotometry. One multiple barrier product performed significantly better than a petrolatum-based and an allantoin-based protectant. Waring and Hoggarth [526] used a Chromameter to measure skin colour change after staining skin with a water-soluble dye, covering it with a barrier product and washing the skin. Petrolatum products were found to be more effective barriers than dimethicone-based products. In a later study, Hoggarth et al. [527] investigated the barrier function and skin hydration properties of six skin protectants when applied to the volar forearms of 18 healthy volunteers. The researchers found that each had different performance properties with the water-in-oil products containing petrolatum performing better than the oil-in-water products containing dimethicone for protection against irritation or maceration. However the dimethicone products had higher hydration properties compared to the petrolatum products. Overall the water-in-oil petrolatum-based product was the only product to be efficacious for all performance variables. A limitation of some petrolatum-based moisture barriers compared to a non-alcohol barrier film for individuals wearing absorbent pads or briefs is that the petrolatum-based products have been shown to transfer from the skin onto the absorbent product and reduce fluid update by 54% to 90%. [471]. However this has not been tested in clinical trials and the effects of different topical products on the leakage performance of absorbent pads is unknown.

Other practices that may affect skin health include frequency of pad changing. Increasing pad changing may reduce skin wetness by application of a dry pad and may therefore benefit skin health. Increased pad changing is commonly recommended to prevent or treat dermatitis particularly in infants [465] Level of Evidence 4.

a) Quality of data

Several studies of skin cleansing and / or moisturising / barrier products to prevent perineal dermatitis have been limited by being uncontrolled [528-531] and of small size and lacking adequate power calculations [532,533; 468], or not including any clinical outcome
results of barrier products use. In addition there was one randomised crossover trial of pad changing frequency.

b) Results

1. Skin cleansing / moisturising products to prevent dermatitis

Byers et al. [532] compared four different cleansing / moisturising regimes including soap and water using a multiple cross-over design. Despite having a very small sample size (n = 12 elderly women) they found statistically significant differences in TEWL, pH and erythema between some of the regimes, and soap and water was found to be the least effective product for skin health. No clinical outcomes were measured and differences in outcomes were small (Level of Evidence 2).

i) Cleansing products

Cooper and Gray [534] randomised 93 long-term elderly subjects to skin cleansing with soap and water or with a foam cleanser over a 14 day period and blindly assessed perineal skin photographs at zero, seven and 14 days. The skin of 37% of subjects using soap and water remained ‘healthy’ compared to 66% of subjects using the foam cleanser. However, statistical analysis was not carried out (Level of Evidence 3).

Lewis-Byers et al. [518] randomised 32 nursing home residents with incontinence to a soap and water or no-rinse cleanser regime over a period of three weeks. No significant differences in skin condition were found but no power calculations were included (Level of Evidence 3).

Although these studies did not demonstrate robust differences in skin outcomes when using different cleansing regimes, they do indicate other benefits - in particular, that savings in nursing time and care costs may be made [478,518,532,533] and that staff opinion was favourable towards cleansers rather than soap and water.

ii) Costs of barrier products to prevent dermatitis

Zehrer et al. [471] compared the cost and efficacy of three incontinence skin barrier products in 250 nursing home residents from four facilities. A polymer-based barrier film was used either once daily or three times weekly, and one of two petrolatum ointments was used after each episode of incontinence. Residents were monitored for skin damage for six months. There were no significant differences in effectiveness among the various barrier film and ointment protocols of care.

Time and motion measures were used to determine the costs of the products and associated nursing labour. Daily cost of barrier product ranged from $0.17 for the barrier film applied three times per week to $0.76 for a petrolatum ointment applied after each incontinent episode. When nursing staff labour to apply the barrier products was included in the cost analysis, costs increased from $0.26 per day for the less frequently applied barrier film to $1.40 per day for the more frequently applied petrolatum ointments (Level of Evidence 3).

Bliss et al. [472] randomly selected 16 nursing homes to compare the cost and effectiveness of four skin damage prevention regimens. In three of the four skin prevention regimens, a moisture barrier ointment or cream of different compositions (43% petrolatum; 98% petrolatum; and 12% zinc oxide + 1% dimethicone) was applied after each episode of incontinence, while in the fourth, a polymer-based alcohol-free barrier film was applied three times per week. All regimens used a pH-balanced, moisturizing cleanser of the same manufacturer as the barrier. Time and motion measures were documented for the amount of skin care products used, the number, type, and time of caregivers performing IAD prevention care, and the number and type of supplies used. Compared to the three regimens in which a barrier was applied after each episode of incontinence, the use of a regimen in which a barrier film was applied three times weekly had significantly lower costs for the barrier product, labour associated with barrier application, and total cost which included products, labour, and supplies. There were also savings in total product (cleaner and barrier) and total labour costs. The total cost was lowest for the regimen using the barrier film compared to the other regimens in which a barrier needed to be applied after each episode of incontinence. The total cost savings ranged from $0.40 to $0.85 per episode of incontinence (Level of Evidence 2).

Although both these studies demonstrated cost savings when using barrier-film products such savings are dependent on relatively infrequent application of the barrier-film product. This may be achieved by assigning product application to care staff on particular shifts but uncontrolled use of such products may be expensive.

2. Skin products to treat dermatitis

In a double blind controlled trial of 64 subjects, Anthony et al. [535] compared the efficacy of cream formulated to treat dermatitis (Sudocrem) with zinc cream BP. Thirty subjects showed inflammatory lesions of the buttocks and a significantly greater proportion of subjects allocated to Sudocrem showed reduction in skin redness at both seven days and 14 days. No differences were found in the prevention of inflammatory lesions between the two groups. Skin
measurements were made over the ischial tuberosities but the effect of reactive hyperaemia was not accounted for. There was no control group receiving no skin treatment and therefore it was not possible to establish the efficacy of using cream as treatment per se (Level of Evidence 2).

Baatenburg de Jong & Admiraal (536) determined the cost of treating moderate to severe IAD in 39 nursing home patients in the Netherlands randomly assigned to treatment with a non-stinging barrier film or zinc oxide oil. The barrier film was applied every 48 - 72 hours for less severe skin damage and 24 - 48 hours for more severe damage. Zinc oxide oil was applied twice per day and after each episode of incontinence. Both barriers reduced IAD but the non-stinging barrier film was significantly associated with reduced severity of skin redness and skin loss, although skin assessments were not blinded. The cost per day of the nursing staff labour in the regimen using the barrier film was €68.58 (sd = € 23.61) compared to €88.20 (sd = €22.88) in the regimen using the zinc oxide oil. The total cost (including barrier, labor and supplies) per day of the regimen using the barrier film (€76.13, sd = €25.48) was also less than for the regimen using the zinc oxide oil (€102.96, sd = €23.25) (Level of Evidence 2).

3. Pad changing frequency

Fader et al. [491] investigated the effect of different frequency of night-time pad changing on 81 incontinent nursing / residential home subjects from 20 homes. Following a two week baseline period, subjects were randomised by home to pad changing at 22.00 and 06.00 for four weeks followed by 22.00, 02.00 and 06.00 for four weeks, or vice versa. Blinded skin measurements of instrumental erythema (using an erythema meter), visual rating, trans-epidermal water loss and pH were made at baseline and during the last two weeks of each regime with instrumental erythema measurements used as the primary outcome variable. Trans-epidermal water loss measurements were significantly higher when pads were changed less frequently (22.00 and 06.00) indicating that skin was wetter.

No other significant differences were found. However, five subjects developed stage II pressure ulcers in the less frequent pad changing regime compared to none in the frequent pad changing regime. Although more frequent pad changing did not demonstrate less dermatitis / erythema, the pressure ulcer findings - though non-significant - make it unwise to conclude that less frequent pad changing does not damage skin health (Level of Evidence 2).

4. SUMMARY

- Perineal dermatitis is a common problem amongst absorbent product users (Level of Evidence 2).
- Skin wetness overhydrates skin and potentiates the effects of other irritants (Level of Evidence 2).
- Faecal incontinence is more irritating than urinary incontinence, but the combined effects of urine and faeces are particularly damaging to skin (Level of Evidence 2).
- Absorbent pads containing super absorbent polymers are associated with reduced skin wetness (Level of Evidence 3).
- Wet skin is more vulnerable to friction and abrasion injury (Level of Evidence 2).
- Pressure ulcers are associated with urinary and faecal incontinence (Level of Evidence 2).
- Bodyworn absorbent products may raise interface pressures measured under the buttocks (Level of Evidence 3).
- There are indications that skin cleansers may be more cost-effective than soap and water (Level of Evidence 3) and may be better for skin health (Level of Evidence 2).
- Barrier skin products may prevent water penetration into the stratum corneum (Level of Evidence 3).
- A regular and structured skin care regimen using topical preparations such as moisturisers or barrier creams is associated with a low incidence of perineal dermatitis (Level of Evidence 4).
- More frequent pad changing has not been shown to prevent dermatitis, but less frequent pad changes may be associated with pressure ulcers (Level of Evidence 3).
5. RECOMMENDATIONS

- Absorbent pads with SAP should be selected in preference to those without (Grade of Recommendation B).
- Absorbent pads should be changed regularly to minimise skin wetness (Grade of Recommendation C).
- Patients with faecal or double incontinence should be changed as soon as possible after incontinence has occurred to prevent the development of dermatitis from protease and lipase activity (Grade of Recommendation B).
- Patients should be washed gently at times of pad change with either soap and water or cleansers. Cleanser may be less time-consuming than soap and water (Grade of Recommendation C).
- Skin barrier products should be applied to areas that potentially come in contact with leaked urine and/or faeces (Grade of Recommendation D).
- Barrier products may be applied to skin within the pad area to reduce water penetration of the skin (Grade of Recommendation C).
- Buttock and sacral areas should be protected using topical skin barrier products, containment products or diversion devices in patients vulnerable to perineal dermatitis or pressure ulcers (Grade of Recommendation C).
- Cost effective approaches such as those that save nursing time and labour costs are recommended (Grade of Recommendation B).

6. PRIORITIES FOR RESEARCH

Controlled randomized trials that investigate the effectiveness of skin care products to prevent or treat perineal skin damage due to urinary and faecal incontinence are recommended. The studies should determine appropriate sample sizes using power analyses. Analyses need to be powered to distinguish effects on participants with faecal or double incontinence. Objective measures from instruments, standardized clinical assessments, and patient symptom ratings can be included. Comparisons among products of various compositions are encouraged.

XV. ODOUR CONTROL PRODUCTS

Fear of smelling is a major concern that preoccupies many people suffering from incontinence and it is an issue that has been raised in several qualitative studies that have explored the subjective opinion of the patient (eg [537, 538]) (5). Accordingly, there is a demand for products which will mask odour or, preferably, prevent it.

1. PRODUCTS FOR URINARY INCONTINENCE

Fresh, infection-free urine smells only slightly but bacterial action on urea over time yields pungent smelling ammonia.

A variety of anti-microbial solutions are available for washing such products as hand-held urinals or for treating urine spillage onto soft furnishings such as carpets. They aim to prevent smell by destroying the bacteria responsible for break down of urea. There are no robust published studies that have sought to evaluate such products. Another approach is to mask the smell of stale urine using a strong but (hopefully) pleasant smelling liquid. There are no robust published studies on such products either but anecdotal evidence suggests that, in time, the masking smell comes to be associated with the incontinence that it is intended to disguise. Several companies supply products (washable bedpads, carpets, chairs, clothing and bed linen) made with fabrics that have been treated with anti-microbial agents intended to reduce the smell of any urine on or in them. However, again, there have been no robust published studies to investigate efficacy.

One of the 12 disposable bodyworn pads for lightly incontinent women evaluated by Clarke-O’Neill et al. (19) was treated with a lavender scent but it was not found to perform significantly better than the other products in terms of preventing smell. However, the scent was appreciated by 18% of the 50 test subjects, who commented favourably on it.

2. PRODUCTS FOR FAECAL INCONTINENCE

Odour associated with faecal incontinence may occur from involuntarily leaked stool or flatus. In a study with subjects eating a self selected diet, Moore et al. [539] identified the volatile chemicals primarily responsible for faecal odours as the methyl sulphides: methanethiol, dimethyl disulphide, and dimethyl trisulphide. Hydrogen sulphide was thought to make a smaller contribution. In a subsequent study with persons consuming a bolus of pinto beans and lactulose (a non-absorbable carbohydrate) Suarez et al. [540] attributed the odour of flatus to the sulphur compounds, hydrogen sulphide, methanethiol, and dimethyl sulphide. The intensity of the odour in flatus was related to the concentration of the sulphur-containing compounds: the ability of the human nose to recognise malodorous odour appears to be related to the amount of gas expelled [540]. Different states of health and gastrointestinal function, diet composition, relative concentrations of sulphide gases and, possibly, short chain fatty acids or ammonia are expected to contribute to the odour of faeces and flatus [539] and [540].
There are several commercially available devices that are designed to absorb the odour of flatus. One such product originally called the “Toot Trapper” and renamed the “Flatulence Filter” (UltraTech products, Inc., Houston, TX, USA) is a cushion or pad (which can be placed directly against the anus) that is lined with activated charcoal. Both the cushion and pad are encased in either a washable or a disposable cover. There are similar products by other manufacturers (e.g., Flat-D by Flat-D Innovations, Inc., Iowa, USA and GasMedic and GasBGon by Dairiair and manufactured by ECVC, Greenville, NC, USA). Pads comprising fabric covered activated charcoal that can be worn next to the anus or attached to a brief (GasMedic underair pad by Dairiair and Flat-D, Flat-D Innovations, Inc., Cedar Rapids, IA). There is also underwear (briefs) entirely made of covered activated carbon cloth (Underease protective underwear (UltraTech Products, Inc., Houston, TX). Ohge at el. [541] compared the effectiveness of 11 devices containing activated carbon in six normal adults (50% female) under controlled conditions in absorbing odoriferous rectal gases. Five types of seat cushions, four types of pads, and two types of briefs (one that held a pad next to the anus and one made of activated carbon fiber fabric) were tested. A mixture gas comprising 100 ml of nitrogen with traces of hydrogen sulphide (40 ppm), methylmercaptan (40 ppm) and hydrogen (5,000 ppm) was instilled into the rectum of the subjects via a rectal tube. Since hydrogen does not react with charcoal, the amount of unabsorbed sulphide was determined from the ratio of sulphide to hydrogen collected from the pantaloons relative to the ratio in the instilled gas. The subjects wore mylar pantaloons that were sealed at the thighs and waist with elastic bandages to reduce convection to the air. The subjects’ clothing, apart from any device, absorbed approximately 22% of sulphide gas. The cushions absorbed an amount comparable to usual clothing, 20%. The various pads and the brief with an attached pad held near the anus absorbed 55-77% of the rectal gas. The underwear made of charcoal fabric was the most effective and removed nearly all (95-99%) of the sulphide gas. The charcoal fabric briefs are reusable and the charcoal is allegedly regenerable with heat. There are no reports of any odour absorbing devices being evaluated in persons with faecal incontinence. In vitro studies showed that each device had the capability of absorbing the rectal gases and that their performance efficiency depended on contact between the charcoal element and gas. Briefs entirely made of activated charcoal fabric appear to provide the greatest surface area for contact with malodorous rectal gas. The absorption of odorous gas by clothing suggests that washing outer clothing as well as underwear is important to reduce odour.

Some products aim to reduce the amount of malodorous flatus that is produced. Administration of the probiotic, Lactobacillus plantarum, (5 x 10^7 cfu/ml) in a randomized trial of 60 patients with IBS significantly reduced flatulence (by half in 44% of patients). Only 18% of the placebo group reported reductions of flatulence [542]. Although administration of charcoal, yucca and zinc acetate reduced the percentage of episodes of malodorous gas [543], there are inconsistent findings about reductions in flatulence from ingesting activated charcoal in humans [544,545]. Two clinical trials involving small sample sizes (19 and eight persons, respectively ) showed that the over-the-counter product, Beano, which contains α-galactosidase, reduced flatus frequency in normal persons following the ingestion of beans (546;547). A significant reduction in cumulative breath hydrogen excretion over an 8-hour period after α-galactosidase vs. placebo suggests α-galactosidase reduces flatus production [547]. Although Ganiatas et al., 1994 reported a significant decrease in flatus using 240 galactosidic units (GalU), Di Stefano reported that effects of 1200 GalU but not 300 GalU were significantly different from placebo. One GalU is the amount of galactosidase that releases 1 µmol of galactose from its substrate in one minute [547]. Differences in the test diet or lack of adequate statistical power may explain these differences since neither study reported a power analysis. Although a reduction in the amount of intestinal gas produced may decrease the volume of odour, it may not decrease its potency or perceived odour.

A few products are available that aim to prevent, absorb, or control odour associated with involuntarily leaked stool or flatus associated with faecal incontinence. These include cushions and pads that absorb odour as well as probiotics and enzymes, which aim to reduce production of malodorous gas.
3. RECOMMENDATIONS

- Briefs made of activated charcoal fabric are recommended over pads or cushions containing activated charcoal for absorbing odoriferous rectal gas (Grade of Recommendation C).
- Since some pads absorb up to 75% of gas, there may be value in offering patients who have smaller amounts of gas the opportunity to compare pads and briefs for themselves. (Grade of Recommendation D).
- For those persons experiencing stool leakage due to flatus, over-the-counter -galactosidase containing products, which reduce flatus frequency, can be tried in an attempt to reduce FI frequency (Grade of Recommendation B).
- Washing of outer as well as under clothing after flatus is recommended to reduce odour due to absorption of gas by clothing (Grade of recommendation of C).

4. PRIORITIES FOR RESEARCH

- Investigation of whether probiotics or changes in dietary intake can modulate or reduce the odour of flatulence or leaked faeces.
- Development of an absorbent product that can reduce the odour of leaked faeces while protecting the skin.
- Investigation of the efficacy of anti-microbial agents in textile products (soft furnishings and bedding) for reducing odour associated with urinary and faecal incontinence.

APPENDIX 1 – DIRECTORY OF CONTINENCE ORGANIZATIONS
I. INTRODUCTION

Continence promotion, education and primary prevention involves informing and educating the public and health care professionals that urinary incontinence and faecal incontinence are not inevitable, but are treatable or at least manageable. In addition, other bladder disorders such as bladder pain syndrome/painful bladder syndrome/interstitial cystitis and pelvic organ prolapse can be treated successfully. Taboos on mentioning disorders of the bladder and bowel are gradually lifting in most cultures. Two decades ago it was almost impossible to have urinary incontinence discussed in the media. Today, in most countries, consensus panels, government funding of continence initiatives and practice guidelines have been developed in the area of urinary and faecal incontinence, and many are referenced in this chapter. Around the world, expert panels have suggested that urinary and faecal incontinence be combined through a multidisciplinary approach to further research priorities.

Thus, there have been advances in promoting awareness of both urinary and faecal incontinence. Popular magazines, local and national papers, radio, and television, regularly cover topics on urinary incontinence in most developed countries. Many countries have run national or local public awareness campaigns, usually spearheaded by a national continence organisation. Many also have confidential help lines, which can be accessed anonymously. The World Wide Web provides a convenient source of health information for a growing number of consumers. Some experts believe that persons with incontinence might get valuable advice and comfort by using interactive services such as the chat rooms on the internet. However, in developing countries, public information and campaigns through these mediums is limited or non-existent.

This chapter updates previous International Consultation on Incontinence (ICI) chapters on three areas: continence promotion, education and primary prevention.

The majority of information available in these areas is on urinary and faecal incontinence which are the primary focus of this chapter. The first section reviews continence awareness by discussing health promotion and care-seeking behaviours for these conditions. It is evident that progress has been made in the promotion of continence on a worldwide basis but not much has changed in help-seeking behaviour for these disorders.

There is a lack of evidence on translating awareness into behavioural change and on what triggers help-seeking behaviour. Information is provided on continence promotion programs and advocacy through service delivery, models of care and worldwide organizations. Although there is a great deal of published information on building public and health care professional awareness of incontinence, there is minimal information on the effectiveness of changing public and professional attitudes and knowledge about it. Documentation of the success of campaigns is lacking and should be measured by behavioural changes and ultimately by improved patient outcomes.

A second topic reviewed in this chapter is the education of professionals in the areas of urinary incontinence, faecal incontinence, pelvic organ prolapse and bladder pain syndrome. The use of medical guidelines and care pathways will be discussed. Finally, as these conditions are prevalent but often ignored by sufferers and professional, the third topic addressed is primary prevention with identification of modifiable risk factors. There is a need for further research to substantiate the benefits of primary preventative strategies, including long term follow-up.
II. CONTINENCE AWARENESS

LITERATURE SEARCH

The online databases Medline, Embase, Biosis, Cinahl, Psychinfo, ERIC and Cochrane were searched, with focus on literatures published in and after 2003. The following search terms were used: awareness, consumer, education, urinary incontinence (UI), faecal incontinence (FI), incontinence, continence, continence awareness, continence promotion, health education, public education, public awareness, pelvic organ prolapse (POP), interstitial cystitis (IC), bladder pain syndrome (BPS), painful bladder syndrome (PBS) and outcome measures. Non-English language papers were noted but excluded from the review unless they contained English-language abstract providing sufficient information.

1. BACKGROUND

For a health-related issue like incontinence, the altruistic reason to educate consumers – referring mainly those with incontinence and their family members or informal caregivers, as well as individuals at risk – must be to increase awareness of incontinence and the benefits of prevention and management, with the noble goals of eliminating stigma, promoting disclosure and care-seeking, and reducing suffering [1]. Much of the health promotion efforts related to continence issues are undertaken by the many non-governmental continence organisations, professional and advocacy groups listed in Appendix I. Although in some countries, there is also strong governmental support, including a national advocacy on achieving an effective health literacy system. Components of such a system involving many levels of educational, health-care, and community service providers have been identified and include: (a) an information dissemination system providing materials that are readable, comprehensible, trustworthy, and culturally sensitive; (b) a coordinated health literacy learning system; (c) a measurement and assessment system; (d) a formal and informal health advice system, including a hotline, handbook, and online support; and (e) a health care professional educational system [2].

Consumer education in terms of having access to information about incontinence in this age of digital technology is a non-issue, especially for those internet users who tend to have a higher literacy level [2]. In light of the reluctance of those affected by stigmatized illnesses such as incontinence to seek treatment or to ask health care professionals for information, the internet may prove to be a useful tool for patient education and public health outreach. [3, 4].

The internet is widely accessible and frequently searched for health information. Recent estimates indicate that around 20% of U.S.A. adults use the internet for health information [5]. Among those who do not use the internet, 60% are aware of publicly available internet access points within their community [6]. Also, the internet can be searched anonymously and informally. People with low levels of education and low socioeconomic status are less likely to use the internet [7]. Health care professionals can assist consumers to find reliable information sources by providing details of reputable web sites [8].

In a national survey of internet users in the U.S.A., [9] Berger 2005, found a trend among people with a stigmatized illness such as UI to more likely report that using the internet increased their health care utilization and communication with a health care provider.

A Google search for “urinary incontinence (UI)” and “faecal incontinence (FI)” yielded about 1.7 million and 62,800 websites respectively; “interstitial cystitis (IC)” - 828,000 sites, “painful bladder syndrome (PBS)” - 38,000 sites and “pelvic organ prolapse (POP)” – 120,000 sites. Many were repetitions. For “continence promotion”, the yield was about 6,450 sites, and for “continence awareness (CA)”, it was about 2,840. There was reference to 114 sites for “continence awareness” and “UI” or “FI”; 35 sites for “continence awareness” and “IC”, and 40 sites for “continence awareness” and “POP”. Many of the sites were related to non-governmental organisations such as the International Continence Society (ICS), the National Association for Continence (NAFC) and the Interstitial Cystitis Association (ICA), and the International Foundation for Functional Gastro-intestinal Disorders (IFFGD).

a) Health promotion

Efforts to promote continence may be enhanced by adopting evidence based theories and methods from the field of health promotion. Health promotion was defined by the Ottawa Charter for Health Promotion in 1986 as “the process of enabling people to increase control over and to improve their health” [10]. Hence, health promotion is an important factor in primary, secondary and tertiary prevention efforts directed at individuals, communities and populations with or at risk of developing incontinence.

Health promotion frameworks can be used to plan and evaluate the effectiveness of strategies and programs used to promote continence. When planning health promotion interventions consideration needs to be given to the demographic features of target groups including age, gender, culture, language and socioeconomic background. Health promotion strategies need to address issues such as accessibility, availability of transport and the cost of health promotion programs [11]. Other considerations include communication strategies. As noted above, there is an increasing trend for consumers to search and obtain information from the internet.
Palmer and Newman [12] reported on a U.S.A. health promotion project conducted in 2000 to determine the needs of senior citizens concerning bladder control issues. Focus groups of older adults attending health seminars in urban, community and church settings were conducted. The primary objective of the project was to determine the understanding of older adults in the areas of general health and their beliefs surrounding the problem of UI. The 82 participants were predominantly African-American women representing all socio-economic levels. Seniors expressed confusion when asked if “overactive bladder, bladder control issues and urinary incontinence” were the same condition. Most seniors said they felt comfortable about discussing bladder control issues, but most admitted that their physician had never asked them, nor had they raised the issue. However, they did discuss UI with family members and friends and they were aware that many persons with whom they socialize might have a problem with UI. The majority of seniors answered “no cure” when asked if treatments were successful.

b) Care-seeking (help-seeking) behaviour

Despite the considerable impact of incontinence on quality of life (QoL), many people never seek help for their incontinence and are thus uncounted [13]. Current research in the area of care-seeking (also referred to as “help-seeking” or health-seeking) behaviour (seeking help from a health care provider or professional) in women with UI has determined that fewer than 38% sought help for their condition, and they waited more than a year to do so [14]. A European survey reported that patients wait from 2 to 11 or more years before seeking treatment [15]. Huang et. al. [16] reported that fewer than 50% of women in the U.S.A. with clinically significant UI reported seeking treatment. This was despite the fact that all women in this study had heath insurance that would pay for services and had continuous access to a primary care provider. Women with stress UI are more likely to seek help when there is severe leakage that is having a significant impact on their QoL [17]. Shaw and colleagues [18] surveyed adult women attending primary care practices in UK and of those who noted UI symptoms (n=3273), only a total of 15.8% of women with stress UI, 32.3% of those with urge UI and 33.7% with mixed UI had sought help for urinary symptoms during the preceding 12 months. This study also found that when women sought help for UI, only one-third will receive appropriate treatment [17].

Men tend to be less proactive in health seeking behaviour. Gender specific strategies to address this should be considered [19]. Men with lower urinary tract symptoms (LUTS) have been found to seek help less frequently than women [20]. Conversely, a study into the prevalence of UI in men in the U.S.A. found that whilst only 50% of men with continence issues sought help, these men consulted their doctor within 12 months of the onset of symptoms [21]. This time period is much shorter than the length of time taken by women to seek help [21]. Men are more likely to seek help for LUTS if they have had advice from others or received information in the media, than seeking help as a result of their symptoms [22].

In a population-based study in Sweden (a supplement to a comprehensive survey of public health and general living conditions), a postal questionnaire comprising 12 questions on UI received a response rate of 64.5% from 15,360 randomly selected residents (aged 18–79 years) [23]. The prevalence of UI was 19% (when defined as “any leakage”) and most considered their problems to be minor. Only 18% of those with UI desired treatment. Of the 17% who had reported severe problems that interfered with daily life, 42% did not want treatment. The authors suspect that lack of knowledge, worries about different procedures and negative expectations may be important factors. They concluded that UI may not be an unrecognised major problem except for a limited group, and suggested that healthcare resources should be optimized to identify and meet the needs of those who are most afflicted.

Muller [24] reported on several epidemiologic surveys conducted over a 5 year period by the U.S.A. continence advocacy group, the NAFC. These surveys indicated that UI and overactive bladder (OAB) are prevalent problems and that most people do not understand these conditions. In one survey, conducted in 2000, only 26% of respondents (18% of men and 33% of women) reporting bladder control symptoms had discussed them with a doctor. This survey attempted to examine bathroom-related attitudes and behaviours and found that most feel the bathroom is a “haven” for refuge while others feel it represents a symbol of incarceration because of the preoccupation with the need to be near one frequently.

Bathroom privacy, cleanliness and ease of accessibility were voiced as concerns with only 20% of respondents noting that they are comfortable using a bathroom outside their home. A second survey by this group was conducted online (over the internet) and includes 1,025 interviews of U.S.A. adults (ages 30 to 70). This survey showed that women wait longer (average 6.5 years) than men (4.2 years) to seek out a diagnosis for their symptoms.

Barriers to seeking help for continence issues have been frequently identified in the literature and include embarrassment, social stigma and the mistaken belief that incontinence is either inevitable, untreatable and a normal part of aging [25]. Women with POP have also reported that fear and embarrassment are barriers to seeking help. Other barriers include the perception that incontinence and LUTS are not serious [26]. However symptoms such as nocturia have been linked with serious consequences such as falls and associated morbidity in older adults.
Bladder and bowel continence is an adjustment to the social norm, especially in Western cultures, which have developed acceptable rules and behaviour for bladder and bowel emptying. [27, 28] If incontinence occurs in adulthood, persons revive those childhood beliefs and begin to internalize their condition causing a decrease in self-esteem and feelings of not being “normal” [29]. These barriers are shared by the public as well as by many health care providers [30]. Unfortunately, factors that promote health seeking behaviour for continence issues remain less well researched and the triggers for help-seeking behaviour are complex and multifactorial. With chronic problems like UI, FI, POP and BPS/IC/PBS, it is important to understand what triggers the patient to consult a health care provider [28]. Older people may be keen to seek help if they are concerned that a health issue such as incontinence impacts on their ability to remain independent and living in the community [31].

In certain parts of the world, the gender of the person with UI may be a factor in help-seeking behaviour and the gender of the health care provider may be a barrier. Doshani and colleagues [32] explored views and experiences of South Asian Indian women with UI and found that feelings of embarrassment were present, especially with male health care providers.

Rizk [33] identified reasons why women in the United Arab Emirates (UAE) were not seeking medical help for UI. Data from questionnaires was collected on 400 women (mean age 54.2) out of 448 enrolled subjects and noted that, 81 (20.3%) admitted UI and only 25 of these (30.9%) had sought medical advice. The reasons were embarrassment (38.2%), choice of self-treatment because of low expectations from medical care (38.2%), preferring to discuss the matter with friends, and assuming that UI is normal (23.3%). Women with UI were troubled by their inability to pray (90%) and to have sexual intercourse (33.3%). Saleh [34] found similar results when surveying women in Qatar who reported that UI interfered with their ability to pray (64%) because of lack of cleanliness and need to void and 47% reported that UI interfered with marital relationships.

Rizk and colleagues [35] also investigated the prevalence and help-seeking behaviour of women (n = 400, mean age 37.9) with FI using the same method. Fifty-one participants (11.3%) admitted FI; 26 (5.8%) were incontinent to liquid stool and 25 (5.5%) to solid stool. Thirty-eight patients (8.4%) had double (urinary and fecal) incontinence. Sixty-five patients (14.4%) were incontinent to flatus only but not to stools. Only 21 (4.2%) admitted FI; 26 (5.8%) were incontinent to liquid stool and 25 (5.5%) to solid stool. Thirty-eight patients (8.4%) had double (urinary and fecal) incontinence. Sixty-five patients (14.4%) were incontinent to flatus only but not to stools. Only 21 (4.1%) had sought medical advice. Women did not seek medical advice because they were embarrassed to consult their physician (64.7%), they preferred to discuss the difficulty with friends, assuming that FI would resolve spontaneously (47.1%) or was normal (31.3%), and they chose self-treatment as a result of low expectations for medical care (23.5%). Women with FI were bothered by the inability to pray (92.2%) and to have sexual intercourse (43.1%). These studies note that both UI and FI are common yet underreported by UAE women because of cultural attitudes and inadequate public knowledge. These authors felt that male provider gender may also be a barrier to seeking health care in Middle Eastern women with UI. They were also surprised to find that women perceive their problem to be a neurological or “senile” disorder rather than related to childbirth or menopause.

There are several strategies that can be used to promote help-seeking behaviours and they need to include those that are culturally appropriate [36, 37]. Minority and disadvantaged groups have lower rates of health seeking behaviour for UI that may relate to a number of factors such as access to care and socioeconomic factors [38]. Understanding the reasons why people do or do not seek treatment for incontinence is hampered by the ethnic homogeneity of the existing data as most is derived primarily from white Caucasian populations and there is a lack of comparisons with ethnic minority populations.

Factors that enhance or enable people to change health behaviours include advice given by physicians [39]. Opportunities to promote continence can present themselves during other health screening activities such as cervical cancer screening [40]. Whilst health care professionals may enable people to seek help, those who have a lack of interest in incontinence can negatively affect health seeking behaviour in consumers [41, 12]. Other initiatives to promote health seeking behavior can include providing written information [42]. Continence health promotion information provided in a brochure [43] and in a computer based program [44] were found to improve health seeking behaviour.

Language, level of education and cultural factors may also be barriers to seeking help [45]. Consideration should be given to health literacy in target populations. Health literacy affects the ability to read and understand health information in written formats. Poor health literacy results in lower rates of health seeking behavior [46].

One of the most supportive government sponsored initiatives is from Australia. The National Continence Management Strategy (NCMS) was established in 1998 by the Australian Government Department of Health and Ageing. Funding of over $33 million AUD has been allocated for the period from 1998 – 2010. More than 120 projects have received funding for research, public awareness activities, continence education, resource development and continence service development. The Strategy is now in its third phase of activity. A final evaluation report on Phase 1 and 2 of the NCMS was released in September 2006 [47, 48]. In the area of continence awareness,
the report noted that recognition of the barriers to help-seeking behaviour and identification of the most appropriate terminology and key messages would strengthen awareness raising strategies. The provision of an incontinence specific helpline (the National Continence Helpline) has been an important awareness raising initiative. Table 1 reviews the specific programs developed and implemented by the NCMS.

2. CONTINENCE PROMOTION PROGRAMS

Continence promotion programs vary across countries and cultures, but the singular aim of creating awareness is similar. There is no standard model, nor is there a standard outcome measure to determine the effectiveness of the program. While the current level of evidence for effectiveness of continence promotion program in raising awareness generally is level 4, there is a need for research to provide a higher level of evidence to affirm its effectiveness to generate higher interest and support.

Efforts to raise awareness of continence issues need to consider the following:

- **Target population** - Continence promotion programs need to consider age, gender and culture of target populations. It is necessary to consult with target groups when planning programs in order to meet the needs of these groups and to enhance help-seeking behaviour [49].

- **Target issues** - A continence promotion program needs to address risk factors and management options in different target groups.

- **Promotional material** – Newman [50] reported on a mail survey of 1,500 women, noting that most of the 422 respondents wanted more information regarding UI, and while they may not be equipped to fully understand the problem, they expect doctors, nurses, medical professionals, retail outlets, medical supply companies, and mail order houses to provide the information, including information through consumer advertising.

- **Channels of communication** – Health care professionals may launch campaigns or seminars to increase practice revenues. Commercial companies often fund public campaigns in order to sell their products. Continence organizations may be driven by missionary zeal or organizational growth. Regardless of motivation, care should be taken to avoid raising public expectations beyond what the services or products can deliver. Individualised “coaching” of the affected is one key channel that continence nurses use in the promotion of continence [51].

  a) **Creating public awareness**

In the area of UI, building awareness among the general public is usually attempted via the media.

Using the media to disseminate information in the form of Public Service Announcements (called PSAs) has been practised extensively in the U.S.A. to promote AIDS awareness and as anti-smoking campaigns. The U.S.A. National Institutes of Health, in partnership with the American Uro-Gynecologic Association, American Urological Association, American Foundation for Urologic Disease, National Association For Continence, Society of Urologic Nurses and Associates and the Simon Foundation for Continence, launched a national awareness campaign in 1997. The Let’s Talk About Bladder Control for Women awareness campaign (http://kidney.niddk.nih.gov/ kudiseases/ pubs/bcw_ez/index.htm) offers easy-to-read booklets explaining the symptoms, types and causes of poor bladder control, as well as treatment options. The materials are designed to encourage and enhance communication between and among women and their health care providers. Free consumer and health care provider kits are available through a toll-free phone number. In 2001, the NAFC in the U.S.A. produced and disseminated continence awareness PSAs to 380 television media markets, including Hispanic outlets.

In many cultures, one of the best vehicles to reaching the public is through an informed journalist. Journalists often use a “media hook,” an interesting story that will take priority over other news on the television, radio or newspaper. Having a spokesperson with the problem or finding a celebrity who is willing to speak for the cause can help [27]. These individuals can act as “influence leaders.”

The Japan Continence Action Society held a “Toll Free Telephone Clinic” and callers were asked how they heard about the line. The responses in 2006 were: 30% from television, 16% from the web, 11% from a newspaper, 9% from a book, 6% from a friend, 5% from a brochure, 3% from a magazine and 20% others and/or unknown. In a UK campaign, Norton [52] found that newspapers were by far the most common source of information, followed by radio.

A media campaign should use multiple channels to ensure the broadest coverage [53]. An initial channel should include print media, television and radio. The Internet, phones, and other mobile devices are also effective outreach channels [54]. A second channel could be specialised age and health publications. A third channel could be the use of posters and brochures placed in medical offices, hospitals, senior’s centre, pharmacies and churches. A final channel could be direct presentations to the public, such as at senior’s centres [55].

Roe [56] suggested that local initiatives on the availability of services and how to access them, as well as health education information on UI, may be more effective in raising public awareness and should supplement national campaigns. Awareness raising materials include pamphlets, self-care instructions, visual aids, pictographs, posters, banners, decals and advertisements in newspapers, magazines, newsletters, CD and films. Muller [57] believed that the change related to increased public awareness and help-seeking behaviour for continence care is likely to fuel the demand for innovation in technology and products. The Simon Foundation for Continence developed an innovative community education initiative The Bladder Health Mobil. This initiative provides education, increase public awareness, and promote early diagnosis and proper treatment of UI and other bladder control problems. It also facilitates dialogue between consumers and their health care professionals [58].

Terminology used when discussing urinary and bowel incontinence is important. The words “continence” or “incontinence”, “interstitial cystitis” or “painful bladder syndrome” and “pelvic organ prolapse” are poorly understood and simpler terms may achieve greater public recognition in many languages and cultures. The use of “overactive bladder” in advertising has increased reporting of the condition to primary care professionals in the U.S.A. In the area of bowel disorders such as FI, it is felt that people find it difficult to find the right words to discuss their symptoms [27]. The International Foundation for Functional Gastrointestinal Disorder (IFFGD) in the U.S.A. has found that people will often report having diarrhea to their physician. If the physician or nurse does not question the patient any further regarding the ability to control gas, liquid or solid stool, the incontinence may not be discovered.

**b) Program evaluation**

Evaluation methods need to be established prior to developing the continence promotion program. Evaluation should include quantitative measurements and qualitative measures. Open-ended questions may be more sensitive than “direct satisfaction” questions [59, 60].

Health promotion evaluation methods include process evaluation, impact evaluation and outcome evaluation. Evaluation measures can include the number of media responses to a media release, or numbers of people who sought help.

In the evaluation report of the Australian NCMS, a total of 16 projects were undertaken for raising continence awareness, with focus on the development and distribution of information resources for use by the general community and specific target groups [47, 48, 61]. As of June 2006, a market survey found that 9 of the completed projects with measurable outcomes had generally shown favorable outcome.

Evaluation of the effectiveness of leaflets or brochures is gathering better evidence. An Australian study found that provision of a continence education package, which included a Continence Educational Brochure...
helped to improve the health-seeking behaviours of participants who were bothered by UI symptoms [62]. Within 3 months following the education, of the 111 participants who were bothered by UI symptoms, 49 participants (44.1%) indicated that they had discussed the issue of bladder or bowel problems with someone directly because of the study or the information contained in the brochure. More than 94% of participants who remembered the brochure indicated that they believed it would be helpful if given to other people. In a study of 1175 participants, Wagg et al [63] reported that a self-help standard treatment leaflet is as effective as structured help from a continence nurse in reducing bothersome urinary symptoms in women. Similarly, a Swedish population-based study found that the distribution of a brochure on UI to the general public was well received and can be an efficient method to spread knowledge and encourage self-management [64].

The interventions that are most effective in reaching the public and triggering the desired behaviour seem to vary between countries and cultures. Television and newspapers work best in Singapore, with a “cured” patient bearing testimony to former suffering and its alleviation having the most impact. In the U.S.A., television advertising targeting OAB, funded primarily by pharmaceutical companies, has yielded a significant response. Nationwide television reaches more people than the circulation of any single newspaper or the distribution of a booklet through physician offices. In March 2008, Japanese National Television broadcast a program about UI during “golden time” (2000 to 2045 hours). The audience rating was 15.6%, the highest in a year (usual rating 12%), and more than 500 calls were received in one night, requesting repeat broadcast and more details about treatment. There are also cultural differences in the online health information is used, as well as the types of sites users prefer to surf [54].

In France, the effect of health education was evaluated in a randomized study in sheltered accommodations for the elderly [65]. Twenty centers were randomized to either a single one-hour health information meeting or control group. During a 30-minute talk, a nurse encouraged people to visit a physician if they had urinary problems. A questionnaire three months later found that the experimental group was much more likely to have had treatment if they were incontinent (41% vs. 13% controls) and 82% said that they had received some information about UI in the previous 3 months (compared to 22% controls).

A health promotion project called ‘Dry Expectations’ was developed and implemented in six ethnically diverse, predominantly minority, and inner city senior centres in the U.S.A. in 1996 [55]. The program was designed to address an older population. The project consisted of three phases: orientation and training of key staff members/peer educators at the centres (train-the-trainer model); educating seniors through four one-hour weekly sessions involving visual aids and completion of bladder records and quizzes; and follow up sessions with senior staff/peer educators to reinforce the previous training. The program was very well received by the participants, and approximately 80% felt they had more control over their bladder by the end of the last session.

The impact and success of any continence promotion program must surely be its sustained effectiveness many years down the road, be it for primary prevention or treatment. A randomized controlled study of 359 community-dwelling older women showed that group instruction supplemented with brief individual instruction as needed is an effective teaching method for the acquisition of knowledge and motor skill in bladder training (BT) and pelvic floor muscle training (PFMT). The 1 year adherence following a behavioural modification program ranged from 63 to 82% for PFMT and 58 to 67% for BT [66]. Adherence is reduced over time and the marked benefit of intensive PFMT seen short-term may not be maintained and the long-term adherence to training can be low [67].

c) Recommendations for Continence Awareness and Promotion

Based on the literature reviewed in this section, the following recommendations can be made:

- Continence awareness should be included in any national advocacy program that is working towards an effective health literacy system, as it is consistent with and requires the involvement of many levels of educational, health-care, and community service providers, namely a(n):
  - Information dissemination system providing materials that are readable, comprehensible, trustworthy, and culturally sensitive;
  - Coordinated health literacy learning system;
  - Measurement and assessment system; and
  - Professional health care provider learning system. (Grade D)

- Continence awareness should be part of the main stream and on-going health education and advocacy programs with emphasis on eliminating stigma, promoting disclosure and help-seeking behaviour and improving quality of life. (Grade D)

- There is a need for research to provide higher level of evidence on the effectiveness of continence promotion programs to increase awareness, be it for primary prevention, treatment or management. (Grade D)
There is a need for research on the most effective means to educate the public and professional groups on continence issues. Specifically, there is need for research on:
- Identification and understanding of barriers to health-seeking behaviours
- Translation of research into improved clinical practice and identification of methods by which this happens.
- Effectiveness and impact of consumer education initiatives.

(Grade D)

3. CONTINENCE ADVOCACY

Advocacy is defined as act or process of defending or maintaining a cause or proposal. Advocacy, as it pertains to incontinence, involves assisting individuals in finding necessary health care and treatment. Organisations consisting of professional and public members promote continence advocacy as a core mission.

a) Service delivery

The provision of continence care and services in each country will depend on the organisation and infrastructure of its health services. It is difficult to make recommendations that will apply in such a variety of contexts. In addition, UI is so widespread and affects so many different types of people that they can present for help to literally any health care professional. This means that there will seldom be one portal of entry to a continence service.

When new services are created, there is a temptation to focus on the high technology investigation and medical treatment elements without considering the infrastructure needed to support that service [68]. However, there has never been a comprehensive examination of an optimal service. It is not known whether academic, specialist-led centres will achieve better and more cost-effective results than primary care clinics, domiciliary services or any other model. However, most experts believe that female UI is initially most effectively diagnosed and managed by primary care providers compared to specialist services.

In 2000, the UK’s Department of Health issued guidance on continence services that outlined a good practice model to achieve more responsive, equitable, effective continence services [69]. In the U.S.A., the primary sources of care for the majority of Medicare patients (primarily an elderly population) are family physicians and primary care physicians [70]. Less than 1 person in 1000 is admitted to an academic, medical centre hospital [71]. Thus, in the U.S.A., elderly persons with UI and FI will probably be seen by primary care physicians for initial assessment. This is unlikely to address the needs of developing countries (such as the Asia Pacific area or in Africa) where dissemination of expertise to rural communities and isolated community health care workers is more logical. They are being implemented in several countries using shared teaching and educational resources through co-operative arrangements of the respective Continence Foundations. Thus, the general practitioner or family physician plays an important role in the first line treatment of UI that may be treated successfully with conservative treatments in the majority of patients [72, 73].

In some health systems, both UI and FI have traditionally been seen solely as a nursing problem, with little interest or input from other members of a multidisciplinary medical team. Except for a few isolated areas, the main intervention has been trying to help the individual and caregivers cope with symptoms rather than attempting to treat the underlying cause of the UI. For example, in the UK, it is common for an elderly person presenting with UI to be referred directly to the district nurse “for assessment for pads and pants,” with no physical examination or further investigation considered.

In fact, UI is often a complex and multi-faceted problem, particularly in frail or dependent individuals, and it may require input from a wide variety of disciplines to tackle it effectively. Symptoms typically associated with incontinence may also be indicative of other conditions as evidenced by the urgency and frequency symptoms of BPS, also referred to as IC and PBS, a chronic inflammatory condition of the bladder [74, 75]. The ICI Committee 19, addresses bladder pain syndrome. While it may not be practical for all specialties to work in close proximity, there is a need to consider carefully who does what, with protocols to guide appropriate referral and ensure good liaison. It is important that there are neither gaps, nor overlaps, in the service.

In countries such as Australia, New Zealand and the UK, where there is a national network of Continence Nurse Advisors (CNAs) or Continence Nurses. These nurses liaise, integrate services, and guide individuals through the referral route most appropriate to their individual needs.

The efficacy of Continence Nurse Practitioners (CNPs) in the UK was reported by Matharu and associates [76] who studied four hundred and fifty (450) women over 40 years of age who underwent urodynamic studies in the UK after seeing a trained CNP. In patients diagnosed with detrusor overactivity, the CNP had prescribed 79% to have drug therapy and 64.8% to have PFMT. In those with urodynamic stress UI, 88% had appropriately been assigned to have PFMT. Nursing assessment has the potential to assign patients to the correct conservative treatment thereby shortening waiting times for urodynamics and specialist assessment.
Shaw, Williams, and Assassa [77] conducted a postal survey of people in the UK receiving services for UI by CNPs. Participants expressed satisfaction with nurse-led services because of the interpersonal skills, technical skills, and communication and information-giving abilities of the nurses. There is more evidence that treatment of incontinent community-dwelling individuals by a “continence nurse” is beneficial in terms of clinical outcomes [78]. Although some might see multidisciplinary working as the ideal, the reality is not always smooth. In some situations, rivalries and competition between disciplines and medical specialities is evident. This may be because of competition for patients and revenue, or because of disputes over the demarcation of the scope of different disciplines (such as the boundary between urology and gynaecology, or between nursing and physiotherapy).

There are no studies directly comparing the effectiveness of specific delivery systems for continence care. In certain cases, enthusiasts have conducted research and results may not generalize to the wider setting. Others have combined the expertise of multidisciplinary teams to maximize service delivery. The level of evidence on service delivery models is 4.

i) The need for service

As discussed at the beginning of this chapter, the majority of people (60-70%) who admit to UI in prevalence surveys do not seek professional help [13, 71, 79]. Not all incontinent people want or need help, and this may vary considerably between different cultures. For example, a postal questionnaire asking about urinary symptoms found that nocturnal problems caused the most bother (69% were bothered by nocturnal enuresis, 63% by nocturia). Only 50% found stress UI a bother and only 56% were bothered by urge UI [80]. A community based study found that only 15% of severely incontinent women (daily incontinence requiring protective pads most of the time) were worried about it, 15% felt that their activities were restricted and the majority seemed able to cope [81]. Overall, 78% were not worried by their incontinence and the authors suggested that services should be targeted towards the minority who do find it a problem. In Japan, it has been found that 55% of elderly incontinent people do not consider incontinence a bother, but 15% did not leave home, 10% found it difficult to leave home, and 10% felt that they caused bother to family and neighbours [82]. However it is pertinent to note that, there is significant underreporting by patients of UI and the severity of symptoms [83]. It is also evident from this data that the burden of incontinence, is responsible for 20% of healthy life lost for 75 year olds and older [84] and has the third highest impact on QoL of major chronic conditions [85].

A Japanese survey of over 1,000 caregivers of elderly incontinent people in the community found that more than 80% of caregivers are female and over half were more than 60 years old [82]. The caregivers felt that incontinence caused problems with the home getting dirty (10%), extra laundry (9%), need to wake at night (7%), and not being able to go out because of incontinence (9%). When asked what kind of government service they wanted, caregivers replied “health training” (10%), “knowledge about incontinence” (10%), and “supply of a portable toilet” (3%). Only 6% wanted the government to send them professional caregivers and only 4% desired referral to a specialist physician.

Incontinence is responsible for up to 30 - 50% of admissions into nursing homes, often precipitated by the burden of care on caregivers who spend half of their care-giving time providing personal care such as toileting assistance [86]. Some people seem to cope better than others with symptoms, and some had coping strategies, which were easily undermined by any suggestion that professional help was required [87]. Few people seem prepared to take action to prevent UI.

This can create a dilemma and raises many questions. Should health care professionals attempt to persuade or educate people who do not see UI as a problem that it is an abnormal condition? Should a patient who is “not bothered” by symptoms be treated because the partner or caregiver requests the physician’s assistance? This may be of concern, as Rodriguez, et al. [88] found that physicians underestimated the degree to which patients were bothered by their symptoms 25% to 37% of the time. Is lack of bother genuine or simply a defense against having to tackle an unpleasant problem? Does early intervention prevent later deterioration in symptoms? Does delay in treatment mean that success rates are lowered? There is scant evidence on any of these issues, or on the most acceptable way of providing help.

It is the impression of all members of this committee that, specifically for the field of UI, due to the high percentage of people not seeking help (for all the above mentioned reasons), that health care professionals must develop a concept of a “reaching-out” service and to actively provide service for incontinence care, meaning promoting awareness, openly discussing and actively detecting UI and providing simple and efficient therapy.

b) Models of continence care

Continence care was defined by the Canadian Continence Foundation as “all measures directed toward the prevention, improvement and or management of urinary incontinence” [89]. In this chapter, anal and faecal incontinence will be included within the concept of continence care.
As noted above, continence care is well suited to management in the primary care setting. A range of models are described below.

1. **Single Specialist Model** - This is a service led by a consultant or specialist physician (urologist, gynaecologist or urogynaecologist), often focused around an “urodynamic unit” providing medical or surgical treatment. This is the most common model in developed countries; the best of them have a nurse continence advisor or continence nurse specialist as an integrated part of the service.

   In some countries, physiotherapists (PTs) have also developed a specialized practice with incontinent patients. In France, all women, after childbirth, are entitled to a maximum of 10 sessions of pelvic floor muscle physiotherapy, paid for by the government. In Australia, Scandinavia and the UK, research on PFMT has been led by PTs. However, there is a lack of consensus as to best practices for UI. In a postal survey of British PTs, many were providing specialized service. Gynaecologists were the most common source of referral. The majority said physiotherapy was the first line of treatment. Pelvic floor muscle exercises and electrical stimulation were the most used modalities. However, there was little consensus about optimum treatment regimes amidst a wide variety in the details of therapies used [90].

2. **Nurse Continence Advisor Model** - The nurse continence advisor (NCA) may be independent but is usually associated with community/area health centres, where they may have variable professional support from general practitioners (GP) and family physicians. Continence nurses often work in both hospital and community, and the service is focused on primary care, particularly district nurses. Key roles include patient assessment and implementation of conservative management strategies where appropriate and facilitating patient access to incontinence product subsidies or schemes.

   The Department of Health in the UK has commissioned an evaluation of different models of nursing services, with and without specialist NCAs. It was found that where there is a continence nurse, incontinent people are more likely to receive targeted referral to specialists such as an urologist, and are more likely to have had investigations such as urodynamic testing and to receive more appropriate treatment and care for their UI. These patients were also more likely to report satisfaction with the service. In contrast there is still concerns that general nurses continue to “contain the problem” instead of promoting continence despite acknowledging its importance [91].

   In a series of studies performed in Leicestershire UK, the short and long-term outcomes of a new CNP-led service for urinary symptoms (3 and 6 months after implementing the program) were examined and evaluated [87, 92, 93]. Williams, et al. [93] reported on a randomized, controlled study of 3,746 community-dwelling individuals greater than 40 years of age (61% women) who had incontinence, frequency, urgency, and nocturia all impacting QoL. The experimental group was comprised of 2,958 patients. The standard care was the control group (n=788) who accessed GP services and existing continence services in the area. The experimental group received an 8-week primary intervention package by the CNP (21 generalist nurses who trained as CNPs), delivered evidence-based behavioural interventions using predetermined care pathways in four visits over an 8-week period. Interventions included advice on diet, fluids, BT, pelvic floor muscle awareness and healthy eating. Individuals whose symptoms persisted after primary intervention were offered urodynamic testing. The CNP led service had a 10% higher cure rate than standard care with statistically and clinically significant reductions in urgency, frequency, nocturia and UI. In addition, QoL improvements were greater in users of the CNP led service and higher levels of patient satisfaction were achieved. This is the first study to show the effectiveness of nursing services on urinary storage symptoms (rather than simply incontinence) and associated QoL. The authors noted that the public health value of a 10% reduction in symptoms is substantial when applied to such a common problem.

   A similar RCT in Australia compared outcomes in 145 women presenting with stress UI, with or without urge UI, randomly allocated to a standardised regimen with the NCA or treatment by an urogynaecologist [94]. After 12 weeks, 110 women were evaluated. Sixty-four percent (n=58) of the NCA group and 52% (n=52) of the urogynaecologist group were asymptomatic with a dry pad test. There were no significant differences between the groups for incontinence scores, pad test changes, voids/day or scores on Urogenital Distress Inventory or Incontinence Impact Questionnaire. The treatment by the NCA took a median of 160 minutes, but cost AUD59.20 compared with 90 minutes of gynaecologist time at a cost of AUD189.70. At 2.5 years, 29% of the NCA group and 41% of the other group were dry. The authors concluded that similar results were achieved at lower cost using the NCA.

   An additional number of studies support the efficacy of specialist NCA in the delivery of community continence care [72, 95, 96]. In the U.S.A., urology nurses have been trained as “teachers” to successfully implement behavior modification program to groups [97].

   In the U.S.A., there has also been an increase in nurses who specialize in dealing with patients with pelvic floor disorders including UI, FI, POP, and BPS/IC/PBS, although there are no academic or clinical proficiency requirements in order to be considered a CNP or “continence nurse specialist.” Those nurses who do specialize in continence care have obtained their knowledge and skills through self-
motivated activities [98]. Masters prepared or educated “advanced practice nurses” (APNs) have become increasingly interested in and knowledgeable about the assessment, diagnosis, and treatment of people suffering with UI. These nurses are developing a nursing subspecialty in the care of individuals with UI and related pelvic floor dysfunction and provide comprehensive assessment and treatment (drug and conservative therapy) and act as educators and researchers [25].

A 2000 study in the U.S.A. demonstrated significantly improved outcomes for three clinical problems: UI, depression, and pressure ulcers when advanced practice gerontological nurses (APNs) worked with nursing home (NH) staff to implement scientifically based protocols [99]. In addition to working with NHs to provide resident evaluation as physician extenders, this research indicates that this service model using an APN can be an effective link between current research based knowledge about clinical problems and NH staff. This study also showed that consistent educational efforts with staff and NH residents demonstrated that interventions could improve or stabilize the level of UI in these individuals.

In some countries the NCA is attached to a district nursing service providing expert advice and support for non-specialist nurses with patients who have continence problems.

3. MULTIDISCIPLINARY RESOURCE AND REFERRAL CENTRE MODEL - Multidisciplinary clinics, as service models, have been shown to provide comprehensive continence care. In multidisciplinary clinics, such as a “Pelvic Floor Clinic”, gynaecologist, urologist, colorectal surgeon, and continence nurse work together [100]. Some pelvic floor clinic staffing models also include physical therapists and registered dieticians.

An Australian study took all community referrals of those who had been incontinent for at least two months and had at least one episode in the preceding 2 weeks to a continence clinic. [101]. Patients were randomised to conservative treatment or control, with a crossover design. Patients were asked subjective questions about embarrassment, odour, depression, family relationships, isolation and laundry on a 4-point scale ranging from no effect to major effect upon life. The questionnaire was completed at the start, and at 2, 4, 8, and 12 months. Seventy-eight patients entered the study: 87% improved with treatment (vs. 41% controls). Fifty-two percent were moderately or severely embarrassed at the start of the study period, but at 4 months, only 17% were. Depression decreased from 49% to 22% and isolation from 28% to 12%. Odour and the use of extra laundry also decreased. All benefits were maintained at 12 months. Controls did not improve on these items until crossed over to active treatment, despite feeling better. The authors conclude that conservative treatment in a multidisciplinary community clinic improves continence and well being.

The Continence Foundation of Australia is funded by the Australian Government to employ continence nurse advisors in the National Continence Helpline to provide advice to consumers and health professionals, including referral advice. Evaluation of the helpline by Deakin University showed the majority of callers took action to improve the incontinence issues they enquired about and, the most common course of action following the phone call was to change how they dealt with incontinence [48].

An expansion of this service provision is exemplified by the National Centre for Continence in Israel, which aimed to provide an integrated service [102]. The Center’s professional team not only treats incontinent patients but also educates GPs and nurses who come from pre-selected peripheral/outlying clinics, and provides ongoing support and advice as well as a pathway for tertiary referral. A local team (GP and nurse) are also selected to be in charge of promotion, detection and treatment of incontinence at the clinic. They later become “in charge” of incontinence in their region. This model allows national distribution of continence services with support from the resource centre and provides interdisciplinary exchange, as well as, maximum co-operation between Medical Centres and community health services. The national centre is funded by government and industry to provide a “Hotline” for the public, to promote education programmes in nursing and medical schools, hospitals and nursing homes, and to develop guidelines for diagnosis and management of incontinence by primary healthcare staff.

A report on continence care services worldwide noted that services were scattered, inconsistent and considerable discrepancies exist in their funding. It was concluded that there is a need for accessible (and affordable) continence care and multidisciplinary teamwork [103].

4. PRIMARY CARE MODEL - There are many factors that can persuade health care planners about the importance of adequate investment in community continence services: the prevalence and the number of incontinent people is likely to increase with an aging and increasingly dependent population and many frail, disabled or elderly people are incontinent for reasons extraneous to the urinary system (such as poor mobility, an inappropriate physical environment or lack of an individualised care regime). It is often best to provide an initial assessment for such individuals in their usual surroundings and to reserve hospital or clinic (specialist or academic) referral for those who do not respond to simple measures such as treatment of constipation, modifying a diuretic medication, or provision of accessible toilet facilities. A number of guidelines have suggested an algorithmic, step-wise
approach to assessment and treatment of urinary incontinent patients and many conservative treatments have a good success rate in primary care [104, 105, 106, 107, 108].

A New Zealand study of 600 family physicians found that most respondents provided continence care and 2.6% offered special clinics for continence promotion [109]. Fewer than half felt confident to diagnose the causes of incontinence. Confidence in managing incontinence in children was consistently lower than for other childhood problems. There was no difference by sex in confidence, although female respondents were more likely to consider management of continence care as part of a practice nurse’s role and to routinely ask women about UI during a ‘well’ visit. Most respondents (71.9%) could not remember having had any formal training in the management of incontinence either at the undergraduate or postgraduate level. Recall of postgraduate education was associated with greater levels of confidence in management of incontinence problems.

Family physicians have been shown to be successful in treating UI. A UK study examined assessment and treatment of 65 women, who were treated according to their type of UI [110]. Those with stress UI were treated by PFMT, those with urge UI by BT and medication, and those with mixed UI by both. Patients with stress UI or urge UI, but not mixed, improved compared to controls at 12 weeks. A Dutch study of 110 women reporting UI to a family physician was randomly assigned to the treatment or control group. Treatment was PFMT for stress UI and bladder training for urge UI [81]. Patients were interviewed at 3 and 12 months, with crossover at 3 months for controls. At 3 months, 60% were dry or only slightly continent. Mean wet episodes were down from 27 to 5 per week. Seventy-four percent felt improved or cured and there was further slight improvement at 1 year.

A study in a community clinic in Israel showed that after training, family physicians detected 98 patients with UI during a period of 19 months [111]. Mean age of the 94 females and 4 males was 71 years (range 56-89). Most patients (53) were detected by the physicians on direct questioning, some by nurses (29) and only 18 by self-referral. After a mean follow up of 10 months, 35 were dry and 32 significantly improved. Cure or improvement was achieved at the clinic with no discharge destination was altered by the presence or absence of UI – 57% vs. 82% being discharged home, respectively, and 29% vs. 12% being discharged to a nursing home or other health care venue. In addition, the time in rehabilitation was 185.6 days with UI compared with 156.8 days without UI, and geriatric costs in evaluation and management were higher in the UI group. The level of functional independence and motor function also impacted outcome.

Elder services (e.g long term care or nursing homes) There is growth worldwide in the use of APN “continence” specialists practicing in home care and LTC settings, providing expert consultation in UI and related disorders [25, 98]. Many have developed innovative approaches to management of UI in nursing homes. Bucci [114] developed the CHAMMP (Continence, History, Assessment, Medications, Mobility, Plan) tool to educate nursing home staff in the U.S.A. on a comprehensive continence assessment and to assist in implementation of individualized plans of care. The CHAMMP program improved one facility’s Quality Measure Indicator Report. ICI Committee 11 discusses services for frail elders.

Services in developing nations - The potential demand for UI services in developing nations far outstrips the resources that are available. The provision of services will depend on dedicated healthcare professionals with support by government or industry and by a local continence organisation to educate a new generation of service providers who will carry the services to remote communities. In some instances, consideration will have to be given to cultural, social mores and taboos.

For example Ethiopia’s Health Minister has stressed the need to develop rural health services to reduce the incidence of fistula and to have first time mothers examined by Traditional Birth Attendants (TBAs). The ICI Committee 18, Vesico vaginal fistula in the developing world addresses service for this specific condition. It is planned that TBAs will be trained to identify high-risk women, and thereby divert expenditure from high cost physicians and urban health services to training community health workers and health education. Attitudes on female circumcision, contraception and women’s health, which are often decided by their husbands, obviously have much wider implications than just continence care.

Continence services are a relative luxury, to which countries with a low per capita income are unlikely to devote scarce resources whilst other population health issues have precedence. For example, in Brazil, priorities for their health budget are childhood immunizations, AIDS/STDs, basic sanitation, healthy environment and literacy to help with the problem of street children.
c) Worldwide organisations

The stigma associated with incontinence is similar to other conditions and is associated with public ignorance and lack of awareness [114]. Despite all this, it is important to understand how attitudes and stigma have changed for these conditions. An important component is breaking the cycle of public and personal ignorance through education and public awareness programs. Patient advocacy organisations for UI have been formed worldwide to promote awareness. But for any advocacy group to be successful, there needs to be a partnership between health care professionals, governments, and industry groups with a vested interest to work together to break the cycle of ignorance and negative attitude.

Professionals (e.g. urologists, urogynaecologists, gynaecologists, primary care practitioners, physiotherapists, nurses) and professional organizations have been instrumental in promoting awareness of incontinence in all care settings. The International Continence Society (ICS) established the Continence Promotion Committee (CPC) to promote education, services and public awareness about incontinence throughout the world, and to facilitate communication, exchange of information and partnerships between continence organizations, health care professionals, governments, and industry. The CPC’s multinational and multidisciplinary representation aims to identify broad issues through an international forum that can facilitate translation at the local and national level. Each year at the ICS’s annual meeting, the CPC has held workshops around various themes that have a broad national focus such as prevention; general practitioner education; and promotional strategies. Its relevance, as is the case with each of the national organizations, is to recognize the interface between continence management and continence awareness and promotion. The CPC is increasing continence awareness through the hosting of Public Forums in conjunction with the ICS annual meeting. In 2009, it will sponsor World Continence Week.

Although it may not be practical to develop global and uniform strategies for continence promotion and public awareness, much can be learned from the positive and negative experiences of other organisations in other countries.

Continence promotion is a most challenging endeavour. Although the ratio between affected patient populations and continence organisations funding has not been formally studied, anecdotal information suggests that fund-raising for continence programmes is among the most difficult of medical problems for which to obtain funding. In view of all these challenges, the proliferation of new continence organisations, especially in the Far East and in South America, is a validation of both the need for continence promotion and the dedication of those who have recognized and are addressing this need.

1. **Continenice organisations** In the past fifteen years, several national organizations have been formed under various auspices to tackle issues to do with incontinence awareness, education and promotion. Organizations which promote continence are as diverse as the cultures they serve. They represent a wide diversity of models, including consumer-led, company sponsored, patient-only, professionals only, and organizations which have deliberately set about trying to bring together all relevant stakeholders in a relatively democratic model. In every part of the world, these organizations play a dynamic role in building both public and professional awareness of this underserved and underreported condition.

Most continence organizations are poorly capitalized, being either under- or unfunded (i.e. run by volunteers) and are held together initially by either a dedicated patient advocate or an energized healthcare professional. In most cases, this professional is an urologist or nurse whose patient population includes persons with UI.

As of 2008, there are 47 Continence Organisations in 34 countries world wide with an additional 2 international patient-based organisations. Appendix 1 is a directory and provides the contact details of various national continence organisations. Most of them function as multi-disciplinary bodies. The previous ICI chapter published results of a survey conducted on these organizations [117] Findings include:

- More than 50% of these organizations have been in existence for more than 10 years and that membership includes both professionals and the public.
- Organizations have oversight from advisory boards consisting of consumers (lay public) and health care professional members.
- Most have developed medical guidelines for continence care which represent solo efforts by the organization or in collaboration with the medical community and the government.
- Funding is an ongoing challenge for most of these organizations. Very few receive government funds, and most rely on support from industry or manufacturers of drugs and products for specific projects.
- Continence awareness is being provided generally to a public that has ‘very little’ to ‘no understanding’ of incontinence.
- There is now an increase in media interest in continence.

Education about incontinence has been identified as the most important method to decrease the perceived stigma associated with the disease. A successful method to educate has been through public awareness campaigns, health promotion projects, or health fairs.
Information is provided on the internet through websites developed by each continence organization. These websites provide useful information on incontinence, what it is, and how it can be managed, treated, and cured. They provide frequently asked questions (FAQs) as well as useful links to other continence related websites.

A needed service identified by several organizations concerns the management or containment of urine leakage through the use of products and devices. A guide to continence products has been developed by many organizations and is available to the members as well as health care professionals. This is aimed at providing useful information about the range of different products available.

Most have developed a directory of health care professionals who have expertise in the area of incontinence and its management. Certain organizations have this directory available through their website.

Organisations that primarily target the general public typically do not participate in educating professionals. Those countries where a consumer-based organisation does not exist do engage in educating professionals as well as raising the awareness of incontinence to the population in general. In those countries that have consumer-based continence organisations, there are national public awareness campaigns (e.g. the U.S.A. has a designated Bladder Health Week every fall and November is Bladder Health Awareness Month). It is generally felt that media coverage is inadequate. However, in a recent article, the NAFC (U.S.A.) strongly advocates enlisting the help of the media as one of the 3 main strategies that will help to improve the quality of life for many incontinence sufferers in future [57].

There is a paucity of published work on the formation of national organisations that target consumers or the general public. The level of evidence on the impact of national organisations increasing continence awareness is Level 3.

2. Networking of Continence Organisations

While there is little data on the outcomes of the use of organisations to change consumers’ views and awareness of incontinence, sharing of experience and collaboration amongst countries could lead to more efficient use of resources. For instance, in 1998, the Asia Pacific Continence Advisory Board (APCAB) was established with a mission to develop Continence Promotion programmes that work together with health care professionals and the general public to develop strategies to increase awareness and reduce the social burden of UI in the Asia Pacific Rim.

The APCAB member countries are Thailand, Korea, China, Hong Kong, Taiwan, Malaysia, Indonesia, India, Philippines, Singapore and Pakistan.

d) Recommendations for Continence Advocacy

Based on the literature reviewed in this section, the following recommendations can be made:

- Government support and co-operation are needed to develop services, and responsibility for this should be identified at a high level in each Health Ministry. Incontinence should be identified as a separate issue on the health care agenda. There is a need for funding as a discrete item and for funding, not to be linked to any one patient group (e.g. elderly or disabled), and should be mandatory. (Grade D)

- No single model for Continence services can be recommended. In all health care systems, much will depend on the local health care structure. Because of the magnitude of UI, prevalence, detection and basic assessment will need to be performed by primary care providers. Specialist consultation should generally be reserved for those patients where appropriate conservative treatments have failed, or for specified indications. (Grade D)

- There is a need for research on outcomes, not just the process of service delivery. This research should have patient-focused outcomes, evaluate the outcomes for all sufferers who present for care, use validated audit tools/outcome measures and longitudinal studies of the outcomes of services provided. (Grade D)

- There is a need for cost-effectiveness studies of services currently being provided. (Grade D)

III. PROFESSIONAL EDUCATION

LITERATURE SEARCH

The online databases Medline, Embase, Biosis, Science Citation index, Web of science and Cinahl were used to obtain the literature, additional databases of ERIC (an education database) and psycheit were also searched. The focuses of the searches were between 2004-2008, although literature from the preceding 10 years was also scanned to ensure thorough coverage. The objective was to obtain relevant literature relating to incontinence education. The following search terms were used: incontinence, overactive bladder, health education, education, allied health care professionals, doctors, nurses, consumer, and public education. There was significant overlap between the searches made on different databases as would be expected. The search largely identified the literature already used for the chapter in 2002/2004. Additional references from the preceding 4 years were included and references found which had not been previously identified were also incorporated.
1. BACKGROUND

With the continued advances in health care, increasing public pressure to provide high quality evidence-based care, limited time for health professionals to update their knowledge and the recognised ineffectiveness of passive ‘lecture style’ education provision, the need for new models to change health care providers’ behaviour is essential. Nowhere is this more relevant than in the provision of care for those with UI and FI where traditionally educational provision has been inconsistent at best.

Professional education is a key component in the provision and care of individuals with UI and FI. In their state-of-the-science statement on the prevention of faecal and urinary incontinence, Landfeld et al [1] identified that education of health care providers alone is insufficient to improve detection and treatment of UI and FI. However they recognise that in order to appropriately detect and evaluate incontinence, professional education is required along with outreach and practice-based resources. To date, the education and training of those involved in the provision of continence care has been poor.

It is well recognised internationally, that continence care provision in the area of UI has developed at different rates within differing care models, resulting in scattered and inconsistent services [103]. There are wide variations in health care professional input and a lack of continuity of care between primary and secondary care providers [117]. Central to the provision of high quality continence care is the education of the individuals providing care, including physicians, nurses, and allied health care professionals. There is limited literature on the educational preparation and ongoing training of those health care professionals engaged in continence promotion, care, and referral and even less on the evaluation of education programmes in terms of educational or practice outcomes. It has long been recognised that professional education with reference to UI and FI remains only a small part of the basic training of physicians, nurses, or allied health professionals and on-going training is largely ‘ad-hoc’ with huge variations in the types, content and quality of such training. An early survey in the UK found minimal attention given to incontinence in both medical and nurse training, and a key recommendation for improving continence care was an increase in quality and quantity of professional education [117]. This has clearly not occurred. While educational initiatives have been undertaken, they remain fragmented and inconsistent internationally. Most notable is the absence of evidence demonstrating an impact of professional or public education on the burden of suffering posed by OAB and UI. The ICS has established an Education Committee to promote, organise and co-ordinate all educational advances undertaken under the auspices of the ICS. This promises to be a step forward in defining core competencies and educational goals and objectives for trainers and trainee alike. Subcommittees in medical student and resident education, nurse education, physiotherapy education have been established. Though to date, educational initiatives are broadly medical. Details are available on the ICS website (www.icsoffice.org).

There is a paucity of published work on professional education on UI or FI. Similarly, there are few studies addressing the effectiveness of education in improving the knowledge of learners, or on whether improved knowledge impacts on patient outcomes. Since the publication of the ICI chapter in 2005 [116], the evidence has been building but the level of evidence on the effectiveness of professional education remains poor.

This section will examine the available evidence on the effectiveness of professional education on incontinence for different groups of health care professionals.

2. PHYSICIANS (FAMILY PHYSICIANS/GENE-RAL PRACTITIONERS/PRIMARY CARE PHYSICIANS)

Physicians (general, primary care, and family physicians) often have a gate-keeping role in continence provision as they are often the most likely first point of contact when patients seek formal help for their incontinence [118]. They may refer their patients to other health care professionals in primary care, such as a continence advisor (nurse or other allied health care provider), or, to a specialist in secondary care. Physicians provide this service without having undergone essential training in the management of patients with urinary symptoms, as this is largely unavailable.

a) Medical education

Most physicians have received little education about incontinence, fail to screen for it, and view the likelihood of successful treatment as low [119]. At the same time, there are no data confirming the benefits of screening as a method to reduce the burden of suffering from UI. A postal survey noted that only 18% of respondents said providers asked them to complete a questionnaire about bladder control during routine office visits and a majority (69%) felt it would be very helpful in prompting discussion if their physician or health care professional provided a form for them to check off symptoms of incontinence [50].

Traditionally, UI and FI have formed only a very small part of the undergraduate medical curriculum. Education on UI has usually been fragmented across different organ systems, with training scattered between gynaecology, urology, and geriatric medicine. Bladder and pelvic floor anatomy is poorly covered in preclinical training and relevant physiology is rarely
mentioned. A survey of urology residency directors, medical student educators in urology, and urology applicants identified UI as one of the 8 most commonly cited topics to be included in a core urology curriculum [120]. Co-ordination between the disciplines is rare, although there are some international examples of joint seminars/modules on urinary and faecal incontinence (University of New South Wales) and inter-disciplinary input into curriculum (University of Newcastle). Minimal training is provided on paediatric continence issues.

There is a clear history of inadequacies in continence care which have been acknowledged for some time. In 1983, the Incontinence Action Group published a report [121] which identified 'the huge gap which exists between available knowledge of the causes and methods of management and that which is actually known to practising nurse and doctors.' In their review of the evaluation and treatment of women with UI in the primary care setting, Walters and Realini [122] found that UI can be diagnosed accurately by family physicians using basic tests.

A later study found that outpatient geriatric assessment units were better than physicians in community based practices at identifying patients with both mild and severe incontinence [123]. There is clear evidence that there is a need for further education of health care professionals. Brocklehurst [118] found that less than 25% of patients with UI were given a full examination by their GPs. Deficits in the knowledge of GPs about UI were found by Jolley and Wilson [124] in a survey of 1284 GPs. They also found that GPs lacked confidence in their abilities to diagnose and manage UI, although this lack of confidence was not related to length of practice as a GP. In an analysis of incontinence in the community, the action taken by many GPs was found to be suboptimal, with considerable geographical variation [125]. Fewer than 5% of those who consulted a doctor in this survey were referred to a nurse or incontinence clinic. It also suggested that medication was often prescribed without clinical examination and probably without a diagnosis being made. In a study by Briggs and Williams [126], 42 of 101 general practitioners surveyed never used the service of a continence advisor for older patients although the service was available to them.

There have been efforts to educate family physicians in Australia; in 1989, the New South Wales state government gave AUD 25000 to the Continence Foundation of Australia to develop an educational package (15000 copies) on incontinence to be distributed to all family physicians in the country [127]. An evaluation of the package was undertaken to determine whether the package significantly improved knowledge of incontinence. There was no difference in initial knowledge between the intervention and control groups, but there was a significant difference in post-pack scores between the groups with no difference in scores on questions not in the pack. Sixty-three percent continued to use components of the package later in clinical practice. However, response rate from the 510 family physicians contacted was only 16%.

Two studies have reported that family physicians can be effective in treating UI by using conservative treatments when educated and motivated [95,128] with cure or improvement rates reported at 60 - 70%. Education can also increase referral rates to specialist practitioners [129]. However, the best format for education initiatives to all professionals needs further delineation. The use of road shows (e.g. continuing medical education [CME] seminars), teleconferences, guidelines, booklets and face-to-face teaching are commonly used but rarely evaluated.

There is very little available literature on knowledge amongst family doctors on faecal incontinence. A study has recently been undertaken to explore GPs awareness of surgical treatment options for FI. [130]. A postal questionnaire was mailed to 1,100 GP's in Yorkshire region in the UK, a response rate of 48.5% was achieved. The questionnaire assessed basic knowledge of FI and treatment options. Overall knowledge was poor, with the majority unaware of available investigations, treatments and specialist centres. The authors recommend better communication between specialist centres and GPs, as well as CME programme implementation.

There is growing evidence to suggest that traditional ‘lecture style’ medical education is ineffective in changing physician behaviour and ultimately patient outcomes [131]. More innovative teaching methods are clearly required. Levine and colleagues [132] used a train-the –trainer model to evaluate the management of a number of common geriatric conditions including incontinence. This model involved training, by an expert faculty, a team of non-expert peer educators. These peer educators used a toolkit, to conduct small group learning sessions.

These sessions were evaluated immediately after and 6 months after the education sessions. The model used principles of knowledge translation and active teaching using tool kits based on guidelines to train geriatricians. Results showed statistically significant improvements in self reported knowledge, attitudes and office based practices. The study concluded that modest changes in practice in relation to geriatric conditions were achieved using this peer led approach. Whilst such evaluations are promising, such models are difficult to sustain and costly. Perhaps most importantly they point to the need to use innovative teaching methods to ensure that educational efforts actually make a difference.
b) Medical specialists

There is little new published evidence on medical specialist training in the form of effective training interventions. Specialist training in incontinence is not always adequate. A survey of urological trainees between 1988 and 1994 in Australia showed many felt their training in the management of incontinence had not been adequate [133]. The Colleges of Obstetrics and Gynaecology in the United Kingdom and Australia and the American Board of Obstetrics and Gynaecology have developed courses and credentialing of specially trained urogynaecologists with separate examinations. Similarly, both the American Urologic Association and the European Board of Urology conduct courses, CME programmes and set standards in UI management. However, both UI and FI still may be perceived as exclusive to “super-specialists,” potentially alienating colleagues.

A survey of 163 urodynamic services in the UK found that half the respondents felt their training in urodynamics was inadequate [134]. This led Ellis-Jones and colleagues [135] to explore whether a recognised education and training programme for urodynamics led to changes in urodynamic practice. They asked programme delegates to complete a questionnaire (n=84) pre and post education programme and found that 79% reported a change in practice following completion of the course. This type of evaluation of an education programme is essential to determine the value of such courses, however the evaluation of programmes are often undertaken by those delivering the programme and the need for independent evaluation should not be underestimated.

Committee 7, Dynamic Testing, of the ICI recommends that invasive urodynamic studies should be performed in accredited urodynamic laboratories, by trained and certified staff, with formal control of the quality of the results. This committee highly recommends the establishment of national accreditation, training, certification and quality-control programmes.

3. NURSING PROFESSIONALS

Nurses have a significant role to play in the area of incontinence as they are the largest single group of health care professionals around the world and are often the first to become aware that the patient is experiencing incontinence. Cheater and colleagues [136] found that in the UK, an average community nurse case load will comprise approximately one-third of patients with UI. There have been a number of recent studies which explore the use of new innovative methods of education provision for nurses. Rogalski [137] reports persistence in the lack of educational emphasis on common symptoms like UI and recommends a curriculum model based on existing guidelines and the best available evidence which could address this shortfall and would increase the quality of continence service provision.

A common theme that runs through the international nursing literature over the past two decades is that nursing staff recognise a lack of knowledge of UI and indicate that they would like further training [138, 139, 140]. There are significant gaps in knowledge and clinical practice adoption related to both UI and FI although nurses worldwide have played a major role in developing new information and testing interventions [141]. Although nurses can provide effective interventions in the area of UI, there is limited research on effective interventions for FI.

Innovative methods of improving knowledge amongst nurses have undergone recent evaluation. An important study undertaken by Cheater and colleagues [142] adds to the debate by examining the value of audit and feedback and educational outreach which in the past has often focused on doctors’ behaviours rather than nurses. In this study, the researchers undertook a cluster randomised trial to evaluate 194 nurses in 157 family practices with 1078 patients with a diagnosis of UI. They found that when compared to educational materials alone, there were no improvements in care for either educational outreach or audit and feedback (all groups did improve but differences between groups were not significant). McConnell et al [41] describes how advanced practice nurses learned evidence based approaches to managing complex cases including incontinence in nursing home residents. Advanced practice skills included assessment and diagnosis appraisal of evidence for management. The authors suggest that such practices can enhance both student and facility outcomes, although no systematic evaluation was undertaken.

Ostaszkiewski [143] describes a nursing leadership model to enhance continence care in older adults. Evaluation of the programme suggests improved management and assessment of incontinence for individuals sustained after a two year period. Leadership programmes have proved effective in a number of areas in nursing provision.

Within these more recent studies, the use of innovative methods of knowledge transfer and education are beginning to be adopted, such methods, used in other areas of professional education may be well suited to UI and FI.

Some self-study materials have been developed which link issues on continence care with other regulatory and policy content such as recognition and reporting of elder abuse and neglect [144].

a) Specialist nurses

Educational courses on incontinence are available for nurses in the UK, U.S.A., Europe and Australia and are beginning to appear in Asia, notably Hong Kong and Singapore. These courses vary from 2 to 4 weeks of face to face didactic courses to distance learning.
courses lasting 4 to 6 months that lead to a post-basic nursing certificate.

In the UK, education programmes are documented at the Association for Continence advice website (http://www.aca.uk.com/education_modules.php) and comprise information on 1 day courses as well as diploma courses, degree modules and masters level study. Such databases of courses offer an excellent overview for students and providers.

Williams et al [145] conducted a small study in the UK that showed improvements in both knowledge and attitudes of nurses who undertook a specially designed full time, 3 month programme that included a continence module.

Internationally, there is inconsistency in the provision of specialist education to prepare nurses to practice as experts in the field of incontinence. Programmes of study are developed, but rarely fully evaluated. The need for innovative web-based learning programmes incorporating modern information and communication technology (e-learning) may offer one way of providing standardised programmes of study to practitioners.

Beitz and Snarponis [146] describe their innovative online learning programme which includes continence nursing. They feel that such teaching strategies are acceptable to nurses.

As with physicians, it is unlikely that improving nursing knowledge alone will translate into improved clinical practice, or into the ultimate goal of improved patient outcomes. A review of hospital policies and community nursing practice in an area with a well-established continence service and education program demonstrated very little evidence that improved education had a tangible effect on practice [147]. The authors concluded that nurse specialists are most usefully employed providing a clinical service to individual patients rather than spending their time educating other nurses.

There is a lack of consensus on what should be taught to different nursing groups at each educational level. It is not clear how educational needs can be met or who will pay for the time and expertise required to provide educational initiatives. Governments, as primary payer of nursing home care, have a vested interest in promoting continence in order to minimise costs. It is likely that the continence nursing home resident requires less nursing time than an incontinent resident. It therefore falls to the payer to underwrite the education that is needed to promote continence.

In the U.S.A., the Centers for Medicare and Medicaid Services has developed a “guidance” for UI care in nursing homes and provided web-based education to staff. (www.cms.internetstreaming.com)

More emphasis on incontinence care and the nurses’ role in continence promotion should be encompassed in basic nurse training courses. Specialist continence nurse practitioners and nurse continence advisors are likely to be the best instructors to provide this education.

Standard Setting, care pathways and level of continence knowledge - Standard setting has been one method by which general nurses can acquire skills to meet set standards of practice. But a more effective method may be care pathways which map out a timed process of patient-focused care which specifies key events, tests and assessments to produce the best-prescribed outcomes, within the limits of the resources available, for an appropriate episode of care [148].

The use of Continence Care Pathways has been evaluated amongst generalist nurses. It was found that the use of such pathways has aided in the identification of reversible causes of incontinence (e.g., UTI, medication, fluid intake, constipation, dexterity and mobility issues), and addressed poor quality of life and bothersomeness issues [149]. In a recent audit of 144 continence care providers in the UK, this group found that nearly half of them were using the guidelines and found them to be effective in helping with assessment and management of patients [150]. By using care pathways, patients could be referred to specialist nursing care more appropriately for specific treatment beyond the scope of the generalist nurse, or when they failed to respond to first line therapy. The care pathway identified the needs of the patient, directed simple investigation and primary therapy, but also identified the resources needed by the nurses (e.g., urine testing dipsticks, lists of drugs, frequency/volume charts). The pathway could be modified according to the equipment and expertise locally available. Educating large numbers of general nurses to follow a simple pathway with basic continence-care competencies [151] may allow better use of specialist nursing time and specialized skills [152].

Jha, Moran, Blackwell, and Greenham [153] conducted a small study of women attending gynaecology outpatient departments with incontinence problems. Thirty-five percent (7/20) patients did not need to see a doctor as they were symptom free following treatment recommendations by continence nurses using an integrated care pathway. The authors felt this process facilitated earlier diagnosis, improved access to specialist services and discharge from secondary care.

The level of knowledge about UI within the general nursing community appears to be less than ideal in both the U.S.A. [151, 154] and Sweden [139]. Many non-specialist nurses (referred to as general nurses) desire, and have a need for, more education about what they can do to better manage incontinent patients. Moreover, the quality of life of the incontinent nursing home resident is often more dependent upon the skill,
education, and attitudes of the nursing aide than of the qualified nursing staff.

In an older UK study of learner and qualified nurses’ knowledge, only 12% of qualified nurses had received any education on incontinence in the previous 12 months, and for those who had, most was on products [155]. Forty-four percent of charge nurses and 81% of staff nurses had received no additional training on incontinence since qualifying. Further work on attitudes via a questionnaire to qualified nurses on hospital wards found predominantly therapeutic, rehabilitative attitudes, but also a number of misconceptions. Twenty one percent thought their primary role with incontinent patients should be supplying products and 11% saw incontinence as an inevitable part of aging. Sixteen percent agreed that incontinence was often due to laziness and 28% thought that incontinence was more distressing for a younger than for an older adult [156]. In a further survey of trained nurses, the author found that nurses still focus primarily on palliative rather than therapeutic care and lacked knowledge on which to base care [157]. However, nurses with a post-basic qualification or in-service education were more likely to have positive attitudes, although it was not clear whether this was as a result of the education, or whether these nurses already had a positive attitude and had therefore self-selected to receive further education.

More recently, Rigby [158] explored whether increased continence knowledge amongst general nurses resulted in changes in clinical practice using an opportunistic sample of 130 general nurses achieving a 54% response rate to all stages of the study. The results demonstrated a significant change in knowledge score for nurses following a continence study day, but showed that application in clinical practice of this knowledge posed significant problems. This study had a number of limitations using a small opportunistic sample with poor response, however the real challenge remains of not simply increasing knowledge, but translating that knowledge into improvements in clinical practice.

In the U.S.A., although there are a growing number of nurses who are developing expertise caring for incontinent patients, there are no academic or clinical proficiency requirements to be considered a “continence nurse practitioner or specialist.” In 1993, the Wound, Ostomy, and Continence Nurses Society developed the first certification program for continence care nurses in the U.S.A. The Society of Urologic Nurses and Associates certifies different levels of nurses in the area of urology and in urodynamic testing. The norm is that most “continence” nurses in the U.S.A. obtain their knowledge and skill through self-motivated activities. A survey of nurses attending a national nursing conference on UI asked about educational preparation related to this condition [159].

Respondents reported that less than half (40%) received academic education including course work in accredited post-baccalaureate or graduate programmes related to UI. However, most nurses (76%) obtained instruction at professional conferences, continence clinics supervised by nurse practitioners or physicians, “on-the-job” training, self-study, or in-service programmes.

In another UK study of general nurses’ knowledge of UI, a clinical handbook was evaluated using a pre- and post-test design with an experimental and control group [112]. This study showed that the use of the handbook, which consisted of a decanted, user-friendly, research-based resource on continence care, improved nurses’ knowledge of incontinence. A significant improvement in reported clinical practice was found for 86% of variables in the experimental group compared to a 59% improvement in controls. However, only 54% of those approached agreed to enter the study, suggesting a general lack of interest and motivation.

4. PHYSIOTHERAPY AND OTHER ALLIED HEALTH PROFESSIONALS

Physiotherapists or physical therapists (PT) have long played a part in continence care and the management of UI. In some countries, patient self-referral to specializing physiotherapists has become commonplace. Physiotherapists’ involvement in UI appears to be either on the basis of individual interest or through association with women’s hospitals or obstetric departments, rather than as part of a general physiotherapy practice [160]. As such, they tend to be highly motivated and enthusiastic.

Pharmacists have a variety of roles to play in continence care. In Australia, they have been avid consumers of continence education programmes. In 2004, the Pharmacy Guild launched an educational and promotional program for their members with appropriate outcome evaluation measures. The public sees pharmacists as important and approachable sources of health information, especially information on medicines that may cause or exacerbate UI and FI. Many retail pharmacies display health promotion literature on a range of subjects including UI. Pharmacists may also advise the consumer on appropriate continence products. Educational seminars for pharmacists are generally well received. There are a growing number of CME programmes for pharmacists on the Internet either through new products or through sites such as www.worldwidelearn.com which aims for on-line CME for pharmacists and technicians.

There is also a need to address the training needs of nursing assistants and aides, particularly in the nursing home setting. In the U.S.A. and many other countries, one concern is the high turnover rate among first-line
caregivers in institutional and home care settings, making it difficult to maintain desired training levels. Nursing assistants are often the people providing ‘hands-on’ incontinence care and yet, often with the least training. Certainly, in terms of published evidence there are few reports of efforts to train nursing assistants.

Regulatory issues are often linked not only to quality of care, but also to reimbursement for clinical care and services. Reimbursement policies for services often determine which professionals are able to provide continence care. In the Netherlands, for example, the government pays for up to 14 visits to a physiotherapist for incontinence therapy. In the U.S.A., patient’s visits to a physiotherapist are restricted.

5. IMPACT OF UI GUIDELINES

The development of guidelines, primarily on UI and more recently FI, has increased significantly in recent years throughout the world [104,161,162,163,164,165,166,167,168]. In 1992 and 1996 (revised), the U.S.A. Agency for Healthcare Research and Quality (AHRQ) (formerly known as the Agency for Health Care Policy Research (AHCPR)), sponsored the development of clinical practice guidelines that were produced to help standardize the assessment and management of urinary incontinence in adults [104, 161]. Aimed at health care professionals, the guidelines are widely quoted, but they have failed to impact the practice of physicians or trainees [169]. A more recent study in North Carolina, U.S.A. used a multifaceted educational intervention based on the 1996 AHCPR guideline in 20 of 41 primary care practices and failed to show an effect in increasing screening or management of UI by PCPs [170]. They concluded the guidelines may not be the best approach to treating UI in this setting. Similar disappointing results have been reported in Europe [107]. However, nurses have used the AHCPR recommendations more effectively than physicians, incorporating them into curricula, evidence-based clinical practice, and care pathways [171, 172, 173].

More recently, Penning-van Beest et al [174] report on the impact of the Dutch College of General Practitioners, treatment guidelines for incontinence. They identified a cohort of women with newly identified incontinence (n=1663), they found that the majority of women did not receive active treatment within 1 year of identification, many received no active treatment and use of pads was high. They recommend that this lack of active treatment could be addressed through better physician education.

Many of the published guidelines focus on younger, healthy, community dwelling adults. Guidelines for evaluation and treatment of UI and FI in children and the elderly population or those with significant comorbidity need to be developed. These will need to take into account issues such as cognitive impairment which can influence continence status in older adults [175].

Fung [176], in a small study in a large academic Veterans Affairs medical centre in the U.S.A., used guidelines to develop condition-specific computerized templates to serve as guides for clinicians to ask questions and perform elements of a physical examination for two specific medical conditions UI and falls. This study demonstrated that a set of templates can be developed within an existing electronic health record system and can be used to prompt a clinician to obtain elements of a history and to perform physical exam elements in relation to falls and UI.

Changing the current patterns of medical care with respect to detection and management of incontinence through education is a difficult task [177]. Guidelines for medical practice can contribute to improved care only if they succeed in moving practice closer to the guideline recommendations [178]. Unless there are other incentives or the removal of disincentives, guidelines are unlikely to effect rapid changes in actual practice. It is recognized that other tools or strategies are needed to augment and build on educational endeavours [179]. Strategies that aid in implementation of a guideline include reminder systems to remember when to implement guidelines, tracking systems to identify patients who need follow-up and continuous quality improvement monitoring and regulations. Educational programmes alone may change knowledge and attitude, but rarely change behaviours. Guidelines combined with continuing medical education programmes may be more successful [105].

Even evidence-derived guidelines may not always result in better practice or outcomes. The implementation and evaluation of such a guideline in one primary care practice in the UK from which 1503 patients were randomly selected has been reported [171]. Thirty-five percent of women and 9.9% of men suffered from incontinence in the previous two months, but 61% had never sought help. Of those who did, 63% were referred to specialists, 53% had a urine test, 1 in 4 women had a vaginal examination, and 4 of 206 persons with UI were asked to complete a frequency/volume chart. After implementing the guideline, two abdominal examinations and one new rectal examination were performed, but no new vaginal examinations were performed. Frequency/volume charts were given to three people. Two patients used fewer drugs. The severity of incontinence was unchanged following the intervention. Family physicians did not effectively implement the guideline. It remains to be tested whether, properly used, guidelines can improve incontinence in practice.

In 2006, a national UK guideline was produced on UI in women [165]. Within the document the area of
surgeons competence is discussed however there is no mention of other care providers education and training (including GPs, nurses, physiotherapists etc). In order for services to be delivered effectively, primacy needs to be given to practitioners education and training in such documents.

In a 1999 repeat of a 1996 survey, among 6481 patients older than 50 years, it was found that after numerous UI awareness and education campaigns, German physicians were even less likely to address incontinence than 3 years earlier [180]. The “don’t ask, don’t tell” attitude between physicians and patients, has significant fiscal implications for health care. The consequence of not treating the condition may increase the annual cost of care by an estimated USD 3941 per individual [181]. Funding for conservative management of UI, or better-informed public demand, may stimulate more interest and improved performance among this important group. It remains critically important that PCPs have an understanding of how to manage UI effectively [182].

They used a questionnaire in a convenience sample of 558 staff attending workshops. The authors report striking deficiencies in knowledge amongst staff, and identified managerial structures as barriers to guideline implementation. They suggest such barriers need to be overcome in order to improve the quality of care.

A number of CME programmes for PCPs on UI are now available through Internet sites. One by the American Geriatrics Society covers screening for UI, history taking, ruling out other factors, urinalysis, behavioural therapy and challenges in impaired people. Pharmacy Times site offers a free Temple University program with 2 CME credits on medical management of UI.

It covers differentiation between transient and established incontinence, identification of medications which can contribute to UI and agents which can be used to manage the various types of UI, how to assess, choose appropriate pharmacotherapy and identifying which agents should not be used.

In 1998 the Japan Continence Action Society compiled a Continence Educational set (CE-set) for professionals to use in the community. The CE-set comprised text books, lantern slides, and a CD-ROM based on current evidence. Fifty five CE-sets were distributed to Health Education centres in each prefecture. In 2008, only 11 of the CE-sets had been used, whilst 44(80%) remained unused. The single factor that encouraged use was whether a continence course had been provided in the region or not.

Realistically the likelihood of obtaining adequate independent funding for effective professional education on UI and FI is unlikely in the current economic climate.

6. RECOMMENDATIONS FOR PROFESSIONAL EDUCATION

Based on the literature reviewed in this section, the following recommendations can be made:

- There remains a need for rigorously evaluated continence education programmes which adhere to defined minimum standards for continence specialists and, generalists, utilizing web-based and distance learning techniques alongside audit and feedback, train-the trainer models and leadership models as well as traditional methods. The following should be considered:
  - Compulsory inclusion of a specified number of hours of incontinence education in the basic curriculum (physicians, nurses, physiotherapists and other allied health professionals). Ideally incontinence should be identified, planned and taught as a separate topic.
  - Specific education programmes adhering to approved standards should be reported to a recognized central body linked to appropriate evidence and guidance.
  - Where possible, education programmes should be independently evaluated using appropriate research methods. (Grade D)

- There is a need for research on the most effective means to educate professional groups on continence issues. Specifically, there is need for research on:
  - The effectiveness of innovative teaching methods in improving knowledge and practice
  - Translation of research into improved clinical practice and identification of methods by which this happens.
  - Mechanisms for increasing professional motivation to acquire education and improve performance. (Grade D)
IV. PRIMARY PREVENTION

LITERATURE SEARCH

1. BACKGROUND

Urinary incontinence is a highly prevalent and chronic condition that can be prevented by addressing modifiable risk factors through primary prevention. Although the evidence base for FI and POP is more limited than that for UI, the conditions share many similarities with respect to risk and treatment, suggesting that similar benefits may derive from population-based strategies [116]. These strategies may also be relevant to people with bladder pain syndrome (also referred to as interstitial cystitis, painful bladder syndrome and urologic chronic pelvic pain), although there is no research on primary prevention for this condition.

In the past few years, substantive work has examined the evidence base for preventative strategies for incontinence. This work included a Cochrane Review of conservative management for post prostatectomy urinary incontinence [184], an extensive Evidence Report conducted for the U.S.A. AHRQ on prevention of urinary and fecal incontinence in adults, [167], and a state of the science conference also on the prevention of urinary and fecal incontinence in adults, sponsored by the National Institutes of Health in the U.S.A. [166].

Primary prevention refers to efforts directed at a community or population level to promote protective health behaviors [185] in order to reduce the incidence of UI, FI and POP. Other preventative measures include secondary prevention (where screening of asymptomatic people occurs in order to detect symptoms early and provide treatment) and tertiary prevention (where efforts are directed at curing, rehabilitating, restoring function and preventing future relapse of symptoms) [186]. This section will focus on primary prevention of UI and POP. Additional and more in-depth information is presented by the ICI Committee 4, Pathophysiology of Urinary Incontinence, Fecal Incontinence and Pelvic Organ Prolapse; Committee 12, Conservative management of urinary incontinence (men and women), and pelvic organ prolapse. Primary prevention of FI is addressed by Committee 16, Conservative and Pharmacological Management of Faecal Incontinence in Adults. There is no evidence concerning addressing secondary and tertiary prevention of bladder pain syndrome.

2. POPULATION-BASED PREVENTION

Prevention should include education about behavioural changes that increase the probability of incontinence, the normal functioning of the urogenital and gastrointestinal tracts, expected age related and developmental changes, and how to find the appropriate treatment providers. Raising awareness of health problems and providing information on terms used to describe symptoms assists in promoting help-seeking behaviour [187].

The 3rd ICI stressed the importance of all healthcare professionals promoting primary prevention of incontinence [116]. It was acknowledged that this would require raising the level of community awareness, providing public education as well as addressing healthcare professionals' education. Whilst some advances have been made, these strategies remain a priority. The challenges of dealing with an ageing population are likely to result in urological symptoms including incontinence being as prevalent as cardiovascular disease in the U.S.A. by 2025 [188, 189] and is likely to result in an increased demand for hospital and long term care [190]. As noted above, incontinence is responsible for up to 30 - 50% of admissions into nursing homes, often precipitated by the burden of care on care givers who spend half of
their care-giving time providing personal care such as toileting assistance [84]. Caregivers of people with dementia living in the community have been shown to benefit from learning strategies to assist in preventing and managing FI [191]. This study highlights the need to include carers in primary and secondary prevention strategies.

Programs developed to raise awareness of continence issues should consider targeting a range of groups including people of different ages and genders [47]. Consideration should be given to the setting in which the health promotion program is to be delivered such as schools, work places, community groups and health care institutions [192]. It is acknowledged that whilst some nations are successfully implementing primary prevention strategies, others are yet to effectively implement secondary prevention measures such as assessment and management of continence conditions [193]. In Australia, the UK and the U.S.A, continence organizations have received additional support from national governmental departments and agencies resulting in greater resources being applied to preventative and continence promotion programs.

The evidence for population-based prevention strategies remains at Level 4, Grade C.

3. RISK FACTORS

There is an increasing body of evidence linking incontinence with other conditions. These links provide opportunities to benefit from cooperative efforts with other health promotion initiatives. Identification of individuals who have the potential for becoming incontinent is an important primary prevention activity.

Level 3 Grade B evidence exists for general risk factors of age, pregnancy, parity, [194, 195, 196]. Earlier studies reported Level 3 evidence regarding the risk of overweight and obesity in women [92, 197]. More recently a systematic review has found Level 2 and Level 3 evidence that establishes overweight and obesity as independent risk factors for the development of UI in women [198]. Women with obesity and diabetes have a greater risk of developing pelvic floor disorders, including UI, FI and pelvic organ prolapse [199]. There is a 91% prevalence of these pelvic floor disorders in morbidly obese women [200].

Higher body mass index (BMI) and greater weight are independent risk factors for stress and mixed UI in middle-aged and menopausal women [198, 201]. There is Level 3 evidence to recommend that women with a BMI over 30 should be advised to lose weight to reduce their UI [165]. Randomised control trials have found that women who are overweight or obese can reduce the frequency of urine loss by losing between 3 - 5% of body weight [202] and 7% of body weight [203]. Bariatric surgery for morbidly obese women has resulted in “significant improvement” of UI and has reduced the prevalence of FI from 19% to 9% [204]. A weight reduction program focusing on avoiding weight gain and maintaining a waist circumference within a normal range may lower the risk of UI in women [205].

Diabetes - Lower urinary tract symptoms and changes in bladder function occur in over 50% of men and women with diabetes [206; 207]. In middle-aged women, diabetes is the strongest risk associated with the development of UI [197] and the increase in severity of UI [208, 209]. The risk of pathological bladder changes and incontinence may be reversed if diabetes can be prevented by lifestyle interventions including weight loss [206; 209] and physical activity [206]. Providing this information to patients may be a strategy to motivate people to take positive action to improve their health.

Fluid intake - Urinary symptoms may be adversely affected by extremes of fluid intake. Amending high or low fluid intake improves UI and OAB [165]. Patients who decrease an excessive fluid intake experience decreased urinary frequency and urgency to statistically significant levels [165; 210]

Diet - The effect of diet on urinary function is not well studied, however it has been reported that eating a diet containing vitamin D, potassium, chicken, vegetables, bread and protein may lead to a reduction in the risk of stress UI and OAB [165]. Diets containing carbonated drinks, high fat levels, cholesterol, vitamin B12, zinc [166] and spicy foods and artificial sweeteners were associated with an increased risk of UI or an increase in the severity of OAB. There are mixed results on the effects of caffeine upon nocturia and OAB, with one study of normal volunteers reporting no change in nocturia [211] and others that showed an association with caffeine ingestion and nocturia but not urinary urgency [212, 213]. A recent study with normal volunteers found that artificial sweeteners had a significant effect upon increasing urinary frequency and urgency [212].

Diet is also implicated in the exacerbation of urinary symptoms in BPS/IC/PBS. The types of food and drink reported to aggravate these symptoms include chocolate, citrus fruits, and tomatoes, carbonated drinks, [214], alcohol, coffee, and tea, [214, 215, 216].

Physical activity - Low impact physical activity in younger women appears to assist in promoting continence [217]. Conversely high impact, strenuous physical activity can aggravate symptoms of PBS [218]. Older women who engage in regular physical activity such as walking have significantly lower levels of UI [219] and are less likely to have urgency if they exercise at least weekly. It is not clear if commencing exercise could reduce urgency [165]. Severity of UI in women is related to the perception of UI being a barrier to exercise, and women with severe UI are less likely to achieve recommended amounts of
physical activity required for good health. Women with less severe incontinence are more likely to wear a pad or restrict their fluid intake in an attempt to minimize UI when exercising [220].

**Depression and mental health** - Incontinence has been linked with mental health issues, including depression and self-harm. This may be due to a common underlying causality rather than incontinence causing depression or risk of self-harm [218]. Severity of incontinence is strongly associated with major depression in women [222] and screening for depression should be considered when a women presents with severe UI. The World Health Organization (WHO) predicts that by 2020 depression will be the second highest cause of disability for all ages and genders [223]. It is likely that the prevalence of incontinence will rise as a consequence of this. IC is also associated with a higher risk of depression [218, 224]. Symptoms are exacerbated by psychological stress [215]. This syndrome is frequently associated with fibromyalgia and irritable bowel syndrome [215, 224]. A recent study however has found that women with fibromyalgia have a pattern of urinary symptoms that are distinct from those experienced by women with PBS/IC [225].

**Cigarette smoking** Whilst cigarette smoking has previously been shown to exacerbate OAB and has been linked with UI and FI [167], research has not yet demonstrated that smoking cessation results in changes to UI or FI [164, 165].

**Occupational risk factors** Increasing voiding intervals have been reported in workers who have limited access to toilet facilities (such as teachers, nurses and production workers). This is thought to result in reducing bladder sensation and lead to UI [167]. An earlier study found that women in the military and the occupations described above deliberately restricted their fluid intake in order to control their UI [226]. A recent study however has found that women with fibromyalgia have a pattern of urinary symptoms that are distinct from those experienced by women with PBS/IC [225].

Management of the second stage of labour may also affect continence. Pelvic floor muscle trauma may be reduced by allowing the woman to bear down when she has an urge to push and avoiding instrumental delivery when possible [235].

When clinical guidelines have provided an indication for the use of an episiotomy, debate has ensued as to whether a midline or mediolateral episiotomy will provide the best protection to the perineum. A case-control study found that a mediolateral incision reduced the risk of third degree tearing of the perineum. The angle of the episiotomy resulted in a 50% relative reduction of sustaining a third degree perineal tear for each 6° away from the midline [43].

Previously Level 2 and Level 3 evidence suggested that elective caesarean delivery could be considered as a UI prevention strategy. Women who had a caesarean section have less UI at three months post partum [233], however the risk of UI is not completely eliminated as 14% of women still report UI [236]. More research is required into UI occurring before and during pregnancy due to the strong link to UI occurring postpartum [237]. In addition, antenatal UI has been found to be an independent risk for postpartum FI [167; 229].

Despite a significant body of evidence that advocates PFMT before, during and after pregnancy to prevent and treat UI during pregnancy and in the postnatal period, [204]; [167], the actual number of women performing regular PFMT during pregnancy varies from 17% in Norway, 69 % in the UK and 54.5 % in Australia [238]. Poor adherence to PFMT is also an issue [239]. The effectiveness of PFMT in preventing
childbirth related UI, in conjunction with the non-invasive nature of this self-care strategy, makes it a logical focus for UI prevention efforts among women during the period of childbearing. [240]. Due to the lack of research, there is only Level 4 evidence to support the use of PFMT to prevent incontinence during pregnancy and in the post natal period.

5. PREVENTION OF PROSTATECTOMY-RELATED URINARY INCONTINENCE

Prostatectomy remains an established risk factor for UI in men [241], resulting in postoperative pad use [242] and decreased quality of life [243]. Despite advances in surgical techniques that have reduced the risk of UI, it remains a distressing post-operative complication for many men [244]. It is of concern that over 40% of men in one study claimed not to have received preoperative information that they may develop UI following prostate surgery [245].

Pre-operative UI is a significant risk for UI following a radical prostatectomy [246].

A Cochrane Review published in 2008 found few studies on the effect of PFMT undertaken prior to radical prostatectomy on the development of UI post-operatively [247].

One RCT compared subjects given biofeedback and daily home exercise to controls given usual post-operative instruction to cut off the flow of urine when urinating [285]. The intervention group achieved continence faster and suffered less severe UI than controls.

Secondary prevention of UI with men undergoing PFMT following radical prostatectomy also shows conflicting results, with some showing no change on UI [249] and others showing improvement in men who underwent PFMT compared to men who did not [250]. The Cochrane Review concluded that the evidence was inconclusive and that there was a paucity of quality research in this area, [247].

Whilst there is a focus on UI and erectile dysfunction after radical prostatectomy, a number of men experience fecal urgency and FI post-operatively, with a small percentage of men developing FI two years post-operatively. It is suggested that there may be a higher number of men with FI post-operatively than currently reported [245].

Researchers are urged to investigate preventative strategies for FI and faecal urgency following radical prostatectomy [166] as currently there appears to be no research into this area.

In regards to prostatectomy, there remains mixed Level 2 evidence to support the use of PFMT pre and post-operatively for UI. There is no evidence to either support or refute the use of PFMT pre and post-operatively to prevent FI.

6. PREVENTION OF URINARY INCONTINENCE IN OLDER ADULTS

It is predicted that the number of people aged over 60 will increase from 650 million in 2005 to over 2 billion in 2050 [223]. Whilst ageing does not cause incontinence it is acknowledged that the risk of incontinence increases with advancing age and is associated with a concomitant increase in a range of co-morbid conditions.

Older adults are a heterogeneous group, and therefore preventative strategies for older adults need to take into consideration the well aged as well as the frail aged. It is important to involve older people and upcoming generations in health promotion research and health promotion intervention programs targeted at older people [251].

Due to the association of diabetes and UI, gerontologists have an important role to play in screening older women with diabetes for UI so that they can receive treatment [206].

Well older adults - There is Level 2 evidence to support the use of preventative strategies in well older adults. These strategies include promoting self-efficacy such that the individual has a belief that they have the capacity and skills to improve their own health. In addition, self-efficacy improves the ability to cope better with symptoms and is linked to motivation, knowledge of the benefits of making changes, and adherence to behavior change [252; 253]. Self-efficacy over UI may be enhanced if women are taught self monitoring techniques such as adjusting fluid and caffeine intake, resolving constipation, pelvic floor muscle training in “Quick Kegel” contractions and monitoring voiding intervals [254]. These self-monitoring techniques resulted in decreased volumes of urine loss and improved quality of life [254]. Promoting self-efficacy results in good adherence to PFMT in older, well educated women [255]. Self-efficacy measures such as the Geriatric Self-Efficacy Index for Urinary Incontinence can be used to determine adherence to behavioural programs developed for the prevention and management of UI [253].

A behavioural modification program delivered to women aged over 55 years reported the preventative effects of increasing pelvic floor muscle strength and increasing time between voids upon continence status, suggesting that preventative strategies are effective in older women [66, 256; ]. A recent systematic review concluded that there was “moderate evidence” to support the use of PFMT and bladder training in resolving UI in women [257]. An older study reported that these interventions were “very successful” in treating UI in elderly community dwelling people [258].

Frail older people Correlations have been found between poor general health and severe urinary and/or
fetal incontinence in frail older people [259]. Incontinence is the second main reason for frail aged people to seek admission into nursing homes in the UK and the U.S.A., and is the third main reason in Australia [88]. Incontinence in nursing home residents has negative effects upon the morale of residents, families and staff. Conversely the time and effort spent in promoting continence through toileting programs and other strategies is labour intensive and also places strain upon staff [129].

A recent study has found that there is a greater risk of functional disabilities in men and women who are obese, specifically those with higher waist circumference measurements [260]. These disabilities are associated with a range of chronic health conditions, including incontinence. Prevention of obesity may prevent the development of functional disabilities, chronic health problems and incontinence in the frail aged [260].

Treatment of poor mobility and communication difficulties [259], UTI, environmental barriers and removing physical restraints [261], could reverse or ameliorate urinary and/or fecal incontinence. Despite this, a UK survey of continence practices in care homes there were few mobility programs in place to promote continence [88].

Falls have been associated with a range of factors, including UI and taking medicines such as diuretics [262, 263]. Falls have also been associated with OAB, urge UI and nocturia [264]. Opportunities exist to link with other health promotion programs targeted at older adults such as falls prevention programs [262]. However opportunities to promote continence are not currently being adopted in these programs, despite incontinence being a known risk for falls [264]. A number of factors have been identified linking the risk of incontinence to chronic health conditions in the frail aged. Screening is recommended to identify risk factors for incontinence in the early stages when it may be easier to adopt preventative strategies [167].

Whilst strategies to address these factors have been recommended there is a lack of studies to show the efficacy of these interventions. Due to the paucity of research in this area there is Level 4 evidence to recommend the use of preventative strategies described above to prevent incontinence and promote continence in frail aged adults.

7. PREVENTION OF PELVIC ORGAN PROLAPSE

Some degree of POP is reported in 51% of women aged over 50 years who have had children [265]. Whilst clinical assessment of POP has revealed higher prevalence, mild degrees of prolapse may be asymptomatic. There is mixed evidence related to risk factors associated with developing POP. Smoking, increased waist circumference and higher BMI were not associated with POP in one study [266]. Another study reported that grand multiparity (defined as five or more vaginal deliveries) and raised BMI are risk factors for POP [267]. It was also found that in older women that POP worsened and resolved over time [267]. Irritable bowel syndrome was found to be associated with POP [268].

A systematic review of POP conducted in 2007 concluded that whilst there is currently no research to demonstrate effective prevention, conservative strategies such as weight loss, avoiding heavy lifting, resolving constipation, pelvic floor physiotherapy and addressing obstetric risk factors should be considered [269]. One report presents Level II-3 evidence that symptoms of POP are relieved by the use of a vaginal pessary. This is of relevance to women who choose or are not able to have surgery and those who are awaiting surgery [265].

Pelvic organ prolapse in women may be decreased following the long term use of a vaginal pessary [265]. The use of a pessary may also assist in improving bladder, bowel and sexual functioning but there is mixed evidence for improvement of stress urinary incontinence and urge urinary incontinence [265].

A Cochrane Review of pessary use in 2004 was unable to find any randomised control trials assessing the efficacy of pessary use [269]. These authors also note that despite this lack of evidence, pessaries have been used for centuries and are currently used in clinical practice by the vast majority of gynaecologists, urogynaecologists and nurse specialists.

8. PREVENTION OF FAECAL INCONTINENCE

Whilst it appears that people are seeking help more readily for UI, the problem of FI remains under-reported [130] especially in older people [270] and few physicians ask patients about it [271]. Analysis of studies on FI is hampered by a lack of standardised terminology with regards to stool consistency, gas leakage and frequency of incontinent episodes [166, 272, 273]. Whilst acknowledging that prevention of FI is important, it is recognized that more research is needed to determine the risk factors and interventions to prevent FI [274]. An extensive systematic review of risk factors associated with FI is reported by Committee 4, Pathophysiology of Urinary Incontinence, Fecal Incontinence and Pelvic Organ Prolapse and hence only a brief summary is provided below. Risk factors for developing FI include diarrhoea [274], irritable bowel syndrome (IBS), UI [271], [272], and obesity, particularly for people with a BMI more than 40 [272, 274]. Morbidly obese women may have rates of FI as high as 63% [271]. Chronic obstructive pulmonary disease, diabetes, colectomy and cholecystectomy are also associated with an increased risk of FI [275]. An association with FI has been found in postmenopausal women [275]. Conversely it was also found that the use of hormone replacement therapy in women increased the risk of FI [275].
9. RECOMMENDATIONS FOR PRIMARY PREVENTION

Health promotion strategies aimed at individual, interpersonal, community and population levels are needed in order to promote urinary and fecal continence [192]. Educating people about continence issues and ways in which they can improve their bladder and bowel health will also assist in removing some of the stigma that surrounds continence issues [167]. Conversely, care needs to be taken to ensure that incontinence is not “normalised” as this can have the unintended consequence of people not seeking help for a condition deemed to be “normal” [276]. For moderately overweight women, the Third International Consultation on Incontinence recommended programs such as Weight Watchers® to encourage moderate weight loss as first line therapy in overweight women. There is little evidence at this stage to demonstrate that these recommendations have been followed. The acceptance of public health programs to reduce obesity, increase physical activity and promote eating fruits and vegetables can be built upon to improve their bladder and bowel health will also assist in removing some of the stigma that surrounds continence issues [167].

Based on the literature reviewed in this section, the following recommendations can be made:

- Primary prevention studies should not be limited to individual interventions, but also test the impact of population-based public health strategies (Grade C).
- PFMT should be a standard component of prenatal and postpartum care. Due to the number of women who experience incontinence prior to pregnancy, measures need to be taken to instruct women in PFMT prior to pregnancy (Grade C).
- Randomised controlled trials (RCTs) should be conducted to test the preventative effect of PFMT for men post-prostatectomy surgery (Grade B).
- Further investigation is warranted to assess the efficacy of PFMT and BT for primary prevention of UI in well older adults (Grade B).

Primary prevention efforts should be aimed at interventions to promote a healthy body weight to assist in the prevention of incontinence (Grade A).

VAS: Visual Analog Scale
Since the first publication of the ICI, which included a basic review of the economics of urinary incontinence, our knowledge about this subject has increased substantially. Initially, many publications in this field comprised simple Cost of Illness (COI) studies, in which the cost of managing incontinence conditions were tabulated, without measurement of the benefit of treatment outcomes. Since that time, continence clinicians have become increasingly aware that we need to balance the cost of the illness against the cost of a range of treatments, to yield the net benefit for the money spent. Also economic analysis should not just consider the objective reduction in leakage severity, but also consider the improvement in overall quality of life.

In the last decade, we have become increasingly aware that economic analysis of incontinence is somewhat dependent upon the condition to be studied. For example, stress incontinence can be readily cured by a range of surgical options, but the benefit may decay over time. Stress incontinence can also be cured by more time-consuming physical therapies but these depend upon patient compliance with treatment over time.

On the other hand, pharmaceutical companies have provided an increasing array of anticholinergic treatments for the overactive bladder, but these may require prolonged administration with longstanding drug costs. Such pharmacotherapy needs to be accompanied by bladder training, which also requires patient compliance to achieve success. The benefit of surgery for Botox injections is well known to decline with time. Because of these individual characteristics of the subtype of incontinence, the blanket term of “the economics of incontinence” is less applicable, one should drill down into the relevant treatments of these aetiological subgroups. The present chapter takes account of these considerations, and is arranged according to incontinence subtype.

More recently, clinicians have become aware that uterovaginal prolapse treatments require economic analysis, which have received little attention to date. As the population becomes increasingly elderly, prolapse will become more common. Resources allocated to this condition need to be spent prudently. Finally, the last taboo of faecal incontinence has come into the spotlight. As a wider range of conservative, surgical and neurostimulation treatments become available for this condition, our scientific community has realised that economic analysis of these treatments is becoming feasible and increasingly important. Thus for the first time a part of this chapter is dedicated to the economics of faecal incontinence.

In the first three monographs produced by the ICI, the broad context and some of the statistical methods of economic analyses were included. However, the range of mathematical treatments of these conditions has expanded so that a brief summary of newer methods is now included.

II. BACKGROUND

1. PLACING ECONOMIC ANALYSIS OF CONTINENCE CONDITIONS INTO PERSPECTIVE

When a patient with urinary or faecal incontinence (and to some extent prolapse) walks into a doctor’s office in any country, they will have already incurred some personal costs in managing the condition at home, such as pads or laundry expenses. He or she will then have a basic consultation, tests will probably be ordered, a range of outpatient conservative (including pharmacological) treatments may be prescribed, or a surgical procedure that may involve day-only stay or an inpatient stay may be recommended. At some stage, particularly in the elderly, the patient may suffer a urinary infection which may be associated with the incontinence/cystocele, or may slip in their urine on the way to the toilet and have a fall. These are known as the direct personal and treatment costs of the condition, which are included in Cost of Illness (COI) studies.
The patient may have lost time off work, stopped heavy lifting, or had to retire early because of the condition. These are known as Indirect Costs, which are often included in COI studies. Finally, the patient is likely to have undergone pain (from urine excoriation on the perineum) or suffering (e.g. inability to go out of the house due to constant leakage and foul smell rendering them socially unacceptable) which are known as the Intangible Costs. These are seldom included in simple COI studies, but are considered if Quality of Life tests are included in the study.

The way in which these various costs can be measured varies a great deal from country to country. Although all countries regulate health care to some degree, they do so in very different ways (e.g., the regulatory environment within which health care is provided, insurance, limitations on the building of hospitals, and control over health care costs such as drug prices [1]. Health care systems, as a nation, province, or health plan, can limit the treatments for which they will pay or set limits on the prices. This has implications for estimating costs, and places an even greater burden on researchers to describe explicitly where, when and how the costs were calculated.

Patients often observe very different "costs" for health care goods and services. Cost is the amount to produce the good, whereas a charge represents the amount on a bill, which often includes profit for the manufacturer. Therefore, different accounting systems can yield very different cost estimates.

Most of the hospital accounting systems in the U.S. focus on billing and payments. The charges listed on the bill usually overstate costs and are rarely paid in full by the payer. For example, in a recent study of the costs of surgery for female fecal incontinence (FI) in the US [2], hospital “charges” were defined as the amount that the hospital actually billed to the payer for the surgery etc, but the hospital “costs” were defined as the amount that the hospital actually received in payment! Only after understanding this definition can one make sense of the fact that hospital “charges” for FI surgery rose from $48 million to $57 million over 3 years, but the hospital “costs” increased only slightly from $23 to $24.5 million over the same 3 years (Figure 1).

In the U.S., researchers have developed imperfect methods for adjusting the charges with a hospital-specific ratio of costs to charges to better estimate costs [3]. Charges, however, are not always available. Integrated health care systems, including Canada and the U.K, do not routinely generate bills. For these systems, researchers have developed methods for generating pseudo-bills and cost estimates [4-6].

Many cost determination methods are used. Most analyses include a combination of “gross costing” and “micro costing” [7]. These terms are similar to the phrases “top-down” and “bottom-up”. Accounting and billing systems use micro-costing methods, whereby detailed estimates of time and products (inputs) are combined with unit costs to estimate total costs. Micro-costing (or “bottom-up”) is challenging to perform because a single inpatient stay or outpatient procedure might have hundreds or thousands of inputs. Even when there is just a single input, such as a tablet, the cost can vary by location or the time of purchase if prices fluctuate. At the other end of the spectrum, gross cost methods (“top-down”) identify a limited number of important characteristics such as the Health Care Resource Group (HRGs) in the U.K., Diagnosis Related Groups (DRGs) in the U.S or Australia, and length of stay. These characteristics can then be combined using different techniques to estimate total costs.

Accounting systems are limited in that they always report the health care payer’s costs or charges. Since societal costs are of most interest [7, 8], one must distinguish between and include both provider-incurred costs and patient-incurred costs. This distinction is important for urinary incontinence, since most providers do not pay for routine care (e.g., pads and protection). These costs are usually incurred by individuals, and in 1995 the routine care costs in the U.S. represented at least 50% of the total cost of urinary incontinence [9, 10].

Thus the conclusion drawn by a researcher may be heavily dependent upon the completeness of their methodology. For example, a recent study from the USA [11] analysed Medicare claims for the treatment of urinary incontinence among women aged 65 or older for 3 years (1992, 1995, 1998) including outpatient, inpatient and emergency department visits.
Such Medicare claims nearly doubled over the time frame, from $128 million to $234 million, largely due to increased numbers of women treated by office visits and ambulatory (day only) surgery for items such as collagen injections. When the per capita changes were analysed, and inflation was considered, costs had actually declined by 15%. However, the editorial comment following this article points out that Medicare claims do not quantify pad usage, and cannot record pharmacotherapy for urge incontinence. Since we know that overactive bladder is more common as age increases, such pharmacotherapy is likely to be increasingly important in the over 65 age group, so that the conclusion of a 15% drop in per capita Medicare expenditure are not likely to be valid in general. The editors pointed out that the article was mainly representative of patients with stress incontinence as a result. Such methodology issues are important.

In the example described above, the “perspective” that the researchers used was that of Medicare claims. In other words, Medicare was the “payer”, not the patient. This highlights the fact that costs can be evaluated from several different perspectives. The four most commonly used perspectives are (1) overall society costs, that include all aspects of care and treatment, (2) the payer, such as Medicare, (3) the provider, such as a hospital or managed care plan and (4) the patient.

In general, health economists prefer that a societal perspective (include all costs) is used [7,8]. This facilitates comparison of the cost of illness across different countries. The problem is that different countries use different frameworks for reimbursing some or all of the costs of various conditions, so that international comparison remains controversial.

2. COUNTRY SPECIFIC ECONOMIC ISSUES

From the perspective of a patient, large costs are often incurred when paying for routine care products, treatments, lost wages, and long-term care. These patient costs vary by country. For example, in Sweden and Spain, the government (tax based) health insurance does cover routine care products. In the UK, age-dependant patient subsidies are available for pads. In Germany and Spain, pad costs are reimbursed if prescribed by a doctor [12]. In Australia, low-income patients can apply for a subsidy to reimburse most of their routine care products, but more wealthy patients must pay all costs. In the USA, such products are not covered at all and can be very expensive.

From the patient’s perspective, out of pocket expenses for outpatient physiotherapy (pelvic floor muscle training) also varies considerably between countries. For example, a set number of physiotherapy visits (4-6) are free of charge in the UK and Spain, but patients in other European countries must give a co-payment that represents about one third to one tenth of the real cost (Table 1 below).

The degree of government subsidy to the patient varies greatly by country. In the UK, most patients use the National Health Service (NHS) so that all office visits, tests, outpatient visits and surgical treatments are free to the patient. Pharmacotherapy does attract a small out of pocket payment for each drug. In Italy and Sweden pads are reimbursed, but not in Germany. Pads are not routinely subsidized, only at the discretion of the local Care Trust. In Australia, about 70% of patients only have government insurance, similar to the UK NHS, but 30% of patients

also have private insurance so that inpatient treatments attract a rebate from their health fund. In the USA, adults over age 65 and those with a disability are covered by the Medicare program. This provides coverage for inpatient, outpatient and pharmacotherapy, although patients are generally responsible for sizable co-payments and nursing home care is capped. Those not covered by Medicare often have private insurance or Medicaid (a program for people with low incomes); nonetheless about 48 million Americans lack any insurance.

In the Netherlands, all legal residents are obliged to purchase a basic health policy (the purchase of a complementary policy covering extra health services remains voluntary). The choice of health insurer and type of health plan is free. The government establishes what is in the basic package and under what conditions people are entitled to care.

As regards long term care benefits for those in residential care, considerable variation occurs. In the USA, Medicare and Medicaid benefits are time limited for re-imbursements to nursing homes and other assisted living facilities. Usually after several months benefits stop and payment must come from private insurance or the patient’s pocket. In Australia, low income patients who have no private superannuation (pension fund) can receive the “old age pension” which covers fully funded long term care, albeit in lower-calibre facilities than would be chosen by those who could afford better (similar to the Netherlands system). In Japan, generous long term benefits are provided to long term institutional residents, so that out of pocket payments are reduced.

3. OTHER “FRAMEWORK” ISSUES

Another methodological issue that must be incorporated into any study is the context of time framework. As mentioned in the Introduction, many continence treatments are time dependant, ie their effect extinguishes over time. However, from an economic view, a standard methodology exists. First the author of any study must identify the year for which the costs were calculated. Some economic studies collect costs over many years and also make projections about the future. In this case, the costs should be adjusted so that they reflect a single year. Future costs should be discounted to represent the present value. Controversy exists about the appropriate discount rate [13-15] but most international studies use a discount rate of 3% per annum. See Adang et al. [16] for example.

Second, costs borne in past years should be expressed in the current year’s dollars. In many countries, past and future costs can be adjusted by the Consumer Price Index or other appropriate indices for all urban consumers (e.g., www.stats.bls.gov). In the UK, the Health Service Cost Index or the Retail Price Index, published by the NHS Executive, Leeds, UK, can be used to adjust the costs of health care services; other indices would be used to adjust other items, such as wages (www.statistics.uk.gov). Most countries track inflation using relatively standardized methods, thereby providing a method for inflating past costs.

Caution is needed because general inflation relates to the cost of a consistent set of goods over time, eg the goods must be of the same quality over time, and thus the costs observed five years ago can be observed today. If so, then the inflation index is informative. However, medical goods change rapidly. For example re-usable laparoscopic equipment has been replaced by disposable equipment which is usually more expensive, and the newer drugs for OAB are generally more expensive. This makes it difficult to determine whether any changes in price is due to inflation or due to improved quality. Thus, just inflating costs from many years ago can be misleading.

In summary, defining and measuring costs in health care can be difficult. Often there is large variability in costs. Given this uncertainty, researchers should use sensitivity analysis to investigate how different cost estimates can influence the results. By this we mean re-running the analysis with different input parameters. As we describe in the next section, explicitly describing these contextual issues is crucial for interpreting results.

III. TYPES OF ECONOMIC ANALYSIS

1. OVERVIEW

A typology of economic analysis for health and medicine has emerged over the past few decades. This section reviews these studies.

a) Cost of illness (COI)

As already described, COI studies summate the costs related to a condition for a given population. The costs are annualized for a given year (ie 2008). A COI is a descriptive analysis and is only as good as its assumptions and only as complete as current knowledge allows. However, COI studies provide little information to decision makers about how to allocate scarce resources for treating conditions, because there is no attempt to measure the “value” of the relevant treatments or health interventions.

b) Cost minimization analysis (CMA)

CMA compares the costs of alternative health care strategies, assuming that the benefits of the alternatives are equivalent. When the two treatments are truly equivalent in their risks, outcome, and an individual’s preference for them, then a cost minimization analysis is sufficient; the cheapest intervention is to be preferred.
c) Cost consequence analysis (CCA)

CCA is a variation on cost-minimization analysis, which involves assessing whether a new treatment results in a greater decrease in health care utilization than another treatment. Thus costs of the intervention are compared to health care utilization, such as the cost per hospitalization averted. There is a naturally appealing rationale for conducting this analysis. Unfortunately, when examined in detail, this rationale boils down to an analysis of whether the new treatment saves money in comparison to the alternative treatment. Accordingly, a cost-utility or cost-benefit analysis provides many advantages over a cost consequence analysis.

d) Cost-effectiveness analysis (CEA)

CEA refers to the broad class of calculations where the effectiveness measure is a general health outcome. CEAs with narrowly focused health outcomes (e.g., incontinence episodes) have well-accepted limitations. Most notably, the use of narrowly focused health outcomes will miss other important effects. For this reason, there has been widespread agreement on the use of quality adjusted life years (QALYs) as the preferred health outcome in cost-effectiveness analysis.

e) Cost-utility analysis (CUA)

CUA refers to a CEA when QALYs are used as the outcome measure. Gold et al [7] and Drummond et al. [8] have published texts that discuss standard techniques for conducting a CUA. In health and medicine, the CUA is considered to be the gold standard. Utilities capture all potential benefits of an intervention and allow comparisons with other health conditions, making cost-utility analysis a powerful research tool.

Compared to other medical fields, we have minimal data on utilities in incontinence or on the effect of treatment or change in incontinence severity upon preferences, to date.

Data in a CEA and CUA are represented by an incremental cost-effectiveness ratio (ICER). The ICER represents the average cost of the intervention group minus the average cost of the control group. This amount is then divided by the average utility of the intervention group minus the average utility of the control group (see Section IV.2).

f) Cost benefit analysis (CBA)

Involves measuring the benefits in dollars. When everything is measured in dollars, optimal choice can be easily found by addition and subtraction. However, it is difficult to measure benefits in dollars, and many researchers, policymakers and clinicians are averse to placing a dollar value on life. CBA is rarely used in health.

g) Summary

COI and cost-minimization analyses are simple, yet limited economic tools. Most new treatments offer additional benefits at an additional cost. The CBA, CUA and CEA were designed to determine how much money it costs to obtain another unit of effectiveness. Although the CUA is the preferred method, there are many challenges with calculating a QALY. We will discuss these issues in more depth because different methods for calculating QALYs can have a very profound effect on the interpretation of the CEA.

2. DETAILS OF DECISION ANALYSIS

Decision analysis is a tool that can be used to summarize effectiveness data, costs data, or combine both cost and effectiveness data in a CUA. The value of decision analysis is highlighted by a recent multi-site clinical trial by Albo and colleagues [17] that compared Burch colposuspension to fascial sling for stress incontinence. They concluded that the fascial sling yielded a higher rate of successful treatment, measured as a composite outcome, but also resulted in greater morbidity. Even in well-designed multi-site clinical trials, the results may be ambiguous. Decision analysis may be used to overcome this ambiguity. Decision analysis is a quantitative probabilistic tool for resolving problems when there is uncertainty with regards to treatment options.

There are two primary decision analytic methods (see below); each has its strengths and weaknesses. The starting point with any decision analysis is the delineation of a clinical question, such as how to treat women with stress urinary incontinence. The question should fully and fairly address the clinical question or questions. One might develop add on questions, such as how to treat women who had surgical failure, but it is often best to address these more specific questions as part of the broader decision analysis.

A benefit of decision analysis is that researchers can combine data from multiple clinical trials and marry that data to observational information (e.g., long-term follow-up data). Decision analytic tools are flexible and can be used to identify the treatment that maximizes quality of life. One can also use the same model to address issues of cost-effectiveness. Hence, one of the first tasks in the decision analysis is to identify the primary outcome. Outcomes such as quality adjusted life years (QALYs), that can reflect treatment and disease, are recommended. By using QALYs, one can overcome conflicting data—for example, the finding that vaginal slings have higher success rates but also greater morbidity. As is discussed elsewhere in this chapter, QALYs value all aspects of quality of life and combine that information with mortality. Next, the researcher must determine whether the model will include cost information or not. Some decision analytical models focus only on
outcomes, while others add cost data to address resource allocation questions.

By combining data from multiple sources, decision analysis can be used to model lifetime costs and benefits. Researchers are often tasked with identifying the treatment(s) that maximizes lifetime benefits or lifetime cost-effectiveness. Randomized trials, while the gold standard for assessing causation, are time limited, often following participants for less than five years. Decision analysis can extend such data to consider future events, such as surgical failure rates, nursing home admission or life expectancy. Decision analysis can also be used to understand if the analysis differs by perspective. Payers, providers and patients all have different perspectives, and decision analysis makes it relatively easy to consider each of these perspectives and whether they differ from a society perspective. Frequently it is helpful to understand where the perspectives diverge as this can highlight conflicting incentives. Aligning incentives, when possible, is often seen as socially optimal for governmental regulations and programs.

a) Steps in a decision analysis

Decision analysis can be boiled down into five steps. The first step involves identifying the structure of the problem and this requires the listing of all decision alternatives, all clinical outcomes, and a sequence of events. Once step one is complete, then step two involves assigning probabilities to all chance events (e.g., death). Step three involves assigning outcome (e.g., QALYs) to all outcomes. The fourth step involves the mathematical calculation of expected utility for each strategy. Step four will often identify the preferred strategy. The final step involves identifying the robustness of the model and this is achieved by conducting sensitivity analysis.

Every decision model involves some assumptions. Frequently assumptions are needed to incorporate clinical trial data in the model. For example, a common assumption is that the effect shown in a clinical trial is generalizable to the broader population—treating women with Burch colposuspension will result in effects like those seen in Albo and colleague’s [17] paper. Some assumptions may seem trivial, but it is best to delineate each assumption along the way. Published decision analysis should include a table of assumptions along with other data inputs; frequently this is the first table in the decision analysis.

The clinical question and the structure of the problem (step 1) should provide guidance on the decision model. Frequently decision trees are used because they address the question at hand. Decision trees are so named because they look like a tree with a trunk, branches and leaves.

While decision trees are easy to describe and conduct, it is hard to include time in the analysis. Diseases often change over time and people may transition into and out of different health states. A strength of Markov models is their ability to include these time-related transitions. We will discuss decision trees first and then Markov models in more detail afterwards.

b) Decision Tree

In the decision tree, there is a distinction between a decision node and a chance node. A decision node is a point where a choice is made by the decision maker (typically a physician or patient). For example, for a woman with stress incontinence, the choice to operate (yes or no) would be represented with a decision node. A choice must have at least two options and more than two choices are permitted. However, each choice must be mutually exclusive. A patient cannot choose both operation and no operation. A chance node is a point where chance determines fate. For example, the decision maker chooses to operate or not operate, and hopefully the treatment is successful, but treatment success or failure is a chance node. Not only must chance nodes be mutually exclusive, but they must also be collectively exhaustive (one of the changes must happen and the sum of probabilities for all of the chances must add to 100%).

In addition to chance and decision nodes, there are terminal nodes. These nodes are the final outcome for the pathway taken. Sometimes understanding the nodes makes more sense when looking at the pictorial representation. Figure 2 shows a hypothetical decision tree for treating a patient with stress incontinence. In this hypothetical situation, we structure the model to have two options: surgery or drugs. It is overly simplistic in that we do not differentiate between drugs. Also, the model is completely hypothetical in that a surgical death rate of 10% and a 10% cure rate are not realistic.

The main choice is surgery versus medical management. Surgery carries some risks—a small probability of operative death. The decision nodes are represented by squares while chance nodes are represented by circles. The terminal nodes are cure, no cure, operative death or non-adherence, which is the same as no cure. This is a hypothetical decision model, and most decision models are much more complex. Clearly this model could be expanded to include behavioral treatment and each decision node could be expanded to consider all relevant alternatives (sling, Burch colposuspension, tension-free vaginal tape) (Figure 2).

For the next step in the decision model, one must include probabilities at each chance node. We must identify the probability the disease is cured after operation. Researchers should review the published literature to find this probability and ideally some information about the distribution around this probability (e.g., probability= 58% with a 95% CI 51-68%).

After including probabilities, one must place values next
to the terminal nodes. These values must be a single outcome and QALYS are preferred, although life years are used for some diseases. With outcome and probabilities, one can then “run” the decision tree. Because there is one decision node with two options, we will be computing expected values for the two options. Running the model involves starting at each endnode and working left or backwards. The expected value for the surgical survival node is 3.8 QALYS (Figure 3).

The expected value for the surgical operative death node is 0. When we combined a 10% chance of operative death (0 QALYS) and a 90% chance of survival (3.8 QALYS), we find the expected value of surgery is 3.42 (Figure 4). If we do the math for the lower branch, we get the expected value for drug therapy is 3.76 QALYS. Because 3.76 >3.42, we would recommend surgery over drugs if the sensitivity analysis shows this result to be robust. The decision tree in the example focuses on QALYS for UI treatment and it ignores and cost differences, but it could be easily modified to include cost information.

c) Markov Model

The decision tree, as shown above, assumes the chance of events is stable over time. Our knowledge about urinary incontinence suggests otherwise. A person, for example, could get surgery for stress incontinence, but over time we need to include the potential for surgical failure. Markov models are good for incorporating changes in health states over time. At their core, Markov models are mathematical techniques, derived from matrix algebra, that describe the transitions a cohort of patients make among a number of mutually exclusive health states over time. The model works by cycling to make new calculations for each period of time.

The pictorial depiction of a Markov model is typically shown as a decision state. Figure 5 shows a very basic three-state Markov model. At each period in time, a person has to be in one and only one of the states. But with each change in time (cycle), the person can move to another state, shown with arrows, depending on the possible states and a probability. If the person dies, they are shown to enter the death state. The person cannot leave this state.

Some aspects of the Markov model construction are similar to a decision tree and some are different. Setting up the model is quite similar. One must identify the health states and the transition probabilities. What is quite different is that one must determine the cycle length—the rate at which you allow people to change states. The cycle length should be a clinically meaningful period of time and this choice is also frequently affected by the availability of data. There may be publications showing annual failure rates for surgery and so one could choose an annual cycle or choose a monthly cycle, making a correction to the probabilities so that the sum of twelve months is equivalent to the annual data.

For a Markov model, one needs to know the value for each state. Again, QALYS is the preferred metric. When the model runs, the program keeps track of the amount of time each person spends in each state.
Transitions to other states are handled by transition probabilities, and decisions, such as the decision to get treatment, can affect transition probability. Models can use cohort simulations where a large hypothetical cohort of patients is run through the model. This does not provide information on the distribution of expected values. Monte Carlo simulations run each patient through the model a large number of times (e.g., $10^4$). In doing so, this provides a distribution and variance information on patients.

With Markov models, sensitivity analyses remain a crucial step to test the robustness of the model. Recent advances in sensitivity analyses and in the graphical presentation of data general require the use of specific software. Although some people program Markov models into a spreadsheet, such as Excel, both Tree Age and Decision Maker software are well known for their ability to streamline decision analysis and provide many advanced features that would be very difficult in Excel.

### 3. STATISTICAL ANALYSIS

One of the tasks of data analysis is to provide answers to the research questions being studied. When a study examines the relationship or association between two variables, such as the frequency of incontinence and the cost of incontinence care, then a bivariate correlation is useful. The **correlation coefficient** measures a linear relationship between these two variables to show the degree of association ranging from 0 (no relationship) to 1.0 (a perfect positive relationship) or -1.0 (a perfect negative relationship). When there is more than one factor that can explain the variation of the cost of treating incontinence, such as the age of the patient, other illness conditions, and employment status, a **multivariate regression** analysis is required. For instance, in a study by Birnbaum and others [18] to examine the costs of stress urinary incontinence, their **log-linear regression** model indicated that patients with surgery would cost more than those without surgery, and patients with other co-morbidities would cost more than those without. To test the statistical significance of these covariates, a **standard error of the coefficient** of these variables is needed, for which a t-test can be used. The predicted log-linear dependent variable can be transformed into a nominal value.

Another useful application of multivariate regression model using a **dummy variable** may occur when a cost-effectiveness analysis of a particular intervention (clinical trial), is desired. For instance, in a randomized clinical trial of a behavioral therapy to reduce urinary incontinence in nursing homes Hu et al. [19] used a Dummy Variable (a value of 1 for treatment group and zero for the control group) that the treatment group’s wet episodes have been reduced by 26% over the baseline while the control group remained the same after the 22-week follow-up period. When comparing cost differences between two conditions or two programs, (e.g. [18]), the study used the dummy variable (stress incontinence equals 1 and non-stress incontinence is ‘0’) in the regression model to show that the added cost (incremental cost) for stress incontinence patients was 30% higher than non-stress incontinence costs, after controlling for other covariates.

When incontinence episodes have a **discrete probability distribution**, the probability of either having an incontinent episode or not having one episode is random, these events can be analyzed by a negative binomial distribution. Under this distribution, a mean of a given time period (such as the weekly number of episodes of urinary incontinence), and variance of the incontinence can be estimated. For example Hughes and Dubois [20] used such a **negative binomial distribution** to compare the cost-effectiveness of extended-release formulations of oxybutynin and Tolterodine for treatment of OAB.

With discrete value and skewed distribution, negative binomial distributions can also be used for the regression model, instead of using a linear regression model. In the statistical literature, the **Poisson distribution** is a special case of binomial distribution. In this case, the variable takes a value of 0, 1, 2, 3,..., $n$. Poisson regression is an extension of the negative binomial regression.

### 4. BUDGET IMPACT ANALYSIS (BIA)

Providers and payers often have priorities that are not directly addressed by a cost-effectiveness analysis from a societal perspective. The budget impact analysis (BIA) was developed to inform a decision maker on how alternative technology will affect their budget. A BIA will often focus on the decision maker’s costs and over a short time frame (e.g., 1-3 years). Other parameters in the model, such as patient characteristics or input costs, can also be tailored specifically for the decision maker. Making decision based solely on a BIA can lead to suboptimal social
results. Hence, scientists advocate that a BIA be done in conjunction with a CEA so that decision makers are informed about the broader social implications of their decision. The International Society for Pharmacoeconomics and Outcomes Research (www.ispor.org) has created guidelines for conducting a BIA and these can be found on their website.

IV. PRACTICAL ASPECTS OF ECONOMIC ANALYSIS IN THE CONTINENCE FIELD

1. HEALTH OUTCOME MEASURES SUITABLE FOR USE IN ECONOMIC ANALYSES

There are a number of health outcomes that are used in economic evaluations of incontinence. These include disease-specific outcomes, health status and health value (e.g., QALY). Each is discussed in turn.

a) Incontinence specific outcomes

Cost-Effectiveness in Health and Medicine [7] recommends using QALYs as the effectiveness measure in the CEA. However, the panel also notes that analysts can use a clinical outcome measure. For incontinence, clinical outcome measures include 24-hour pad test, a voiding diary, or urodynamics. These outcomes are attractive for clinicians because they often use these measures in clinical practice.

Clinical outcomes can be very valuable in identifying when a treatment is efficacious. However, using clinical outcomes in a CEA yields results that are limited in scope. A treatment might have improved a person’s quality of life, but had little effect on the clinical outcome measure. In this case, the results would be biased. In addition, a CEA with a clinical outcome measure might not be comparable to another CEA with a different clinical outcome measure. A clear advantage of cost utility analysis is that QALYs can be generalized beyond incontinence. For this reason, QALYs and CUAs are the gold standard.

b) Health Status and Quality of Life Measures

There are a number of frequently used and highly regarded general health status measures, such as the SF-36, the Sickness Impact Profile and the Nottingham Health Profile, which describe a person’s current health state. Instruments that assess how a person perceives or feels about their health state are called quality of life (QOL) measures.

Chapter 5 in this book reviews generic and disease – specific quality of life measures, which are useful for understanding the effects of a treatment. However, because they cannot be used to create QALYs they are of limited value in economic analysis. The exception is the SF-36 for which Brazier et al. [21] have created a rudimentary utility scoring system.

c) Health value

Although there are several ways of measuring the value of a health state, the most common are willingness to pay (WTP, [22]) and the quality-adjusted life year (QALY). We focus on QALYs as they represent the current standard for measuring health value.

QALYs denote the relationship between the value of a given health state and the length of time a person lives in that health state. The value of a given health state is measured in ‘utilities’, where ‘utilities’ represent preferences for a given health state.

To understand utilities, consider the following. Most people would prefer to be healthy over a given time rather than suffer constant urinary or fecal incontinence. Utility measurement refers to valuing these preferences on a life-death scale with endpoints of 1.00 and 0.00, where 1.00 is perfect quality of life (best imaginable) and 0.00 is death equivalent quality of life. For example, the measured utility for urinary incontinence may be 0.60. If treatment improves this to 0.70, then the value of the treatment is 0.70 – 0.60 = 0.10. If this utility gain is maintained over time, say for 10 years, then the gain is 0.10 x 10 = 1.00 QALY. Because utilities fall on the life-death scale, they are (in theory) common across all health states and therefore can be used to compare the effect of interventions in different health fields, or different interventions within the same field. For example, the QALYs gained from treatment for incontinence could be compared with those gained from treatment for depression. Where treatment costs (including costs to the patient) are known, the treatment providing the lowest cost-per-QALY gained is preferred as this ensures society gains the greatest benefit from the health care dollar.

Direct and indirect methods have been used to elicit utilities [23]. The most common direct elicitation methods for valuation include time trade off (TTO), standard gamble (SG), and the visual analog scale (VAS). For description of these methods, see our previous chapter in this ICI Monograph series [24].

1. INSTRUMENTS MEASURING UTILITIES SUITABLE FOR QALY CALCULATION

Multi-attribute utility (MAU) instruments can be used instead of the direct elicitation methods. Simply, a MAU-instrument decomposes HRQoL into health domains (e.g., mobility and emotions). Respondents provide estimates for each of the parts, which are then ‘valued’ and recomposed back into a utility. The three most commonly used MAU instruments are QWB, HUI and EQ5D (as reviewed by Hawthorne & Richardson [25]).

2. QUALITY OF WELL-BEING INDEX (QWB)

The QWB has three dimensions (Mobility, Physical Activity, and Social Activity), with 3–5 levels each,
and 27 illness symptoms. [26]. The QWB requires trained interview administration (15–35 minutes), although a shorter version is available; a self-report version is under development. The upper boundary is 1.00, lower boundary is 0.00

3. Health Utilities Index (HUI)

The HUI uses 12 items that measure 8 domains (Vision, Hearing, Speech, Ambulation, Dexterity, Emotion, Cognition and Pain). The upper boundary is 1.00, lower boundary is –0.36.

4. EQ5D

The EQ5D was developed by the Euroqol team from 7 European countries [27, 28]. It has 5 items measuring Mobility, Self-care, Usual Activities, Pain/Discomfort and Anxiety/Depression. The upper boundary is 1.00, lower boundary is –0.59.

5. SF6D

Although two different algorithms have been published for deriving preference-based values from the SF-36, only the second is described here [21]. Whenever SF-36 raw scores are available, SF6D utilities can be computed. The SF6D measures physical functioning, bodily pain, mental health, physical role, emotional role, social functioning, and vitality. The endpoints for the SF6D are 1.00, and 0.30 for the worst possible health.

6. Other MAU instruments

The Assessment of Quality of Life (AQoL) includes five dimensions: Illness (not used in utility computation), Independent Living, Social Relationships, Physical Senses and Psychological Well-being [29]. The upper boundary is 1.00, lower boundary is –0.04. The Rosser Index has two dimensions measuring disability and distress, and measured 29 health states. Values (magnitude estimation) were from a convenience sample of 70 respondents [30]. A revised version in the early 1990s included discomfort as an additional dimension [30]. Administration requires a trained interviewer. The upper boundary is 1.00, and the lower boundary –1.49, which means that health states worse than death are permitted. The 15D was created in Finland. It has 15 items, measuring Mobility, Vision, Hearing, Breathing, Sleeping, Eating, Speech, Elimination, Usual Activities, Mental Function, Discomfort & Symptoms, Depression, Distress, Vitality and Sexual Function [27]. The upper boundary is 1.00, lower boundary is +0.11.

For a full review of cost utility analysis up to 2004, see our previous chapter [24]. For subsequent studies, see Section V of this chapter.

One final note about collecting utilities is warranted. Many people with incontinence are not cognitively able to complete a MAU or go through a standard utility elicitation process. Some of the MAUs, such as the HUI 3, have been validated for use with proxies. Although not always possible, if proxies are expected then proxies should be gathered for all cases, even those patients who complete the utility measure themselves, so that the method is applied in a standard fashion.

2. “DO IT YOURSELF” - HOW TO CONDUCT A COST UTILITY ANALYSIS: THE COMMITTEE’S RECOMMENDATIONS

The cost utility analysis (CUA) now represents the gold standard for medical decision making. Therefore, the remainder of this section highlights ten key issues that must be addressed in a CUA. These ten principles, summarized below, comprise an appropriate minimum standard for performing and reporting cost utility analyses. The principles were identified from guidelines established by the Panel on Cost-Effectiveness in Health and Medicine convened by the United States Public Health Service [7] Each principle should be explicitly addressed in every study.

1. The Research Question must be clearly stated. All CUAs must compare at least two different treatments or interventions. One of these should include the current standard practices. For example when comparing surgeries for stress incontinence, one of the comparators should be a longstanding method; avoid comparing two new methods side by side.

2. The Time Frame over which costs and benefits are measured should be long enough to capture the economic impact of an intervention and future health outcomes. Pharmacology studies of 12 weeks duration give very little real economic information, and surgical complications/ failures seldom emerge in less than 1-2 years.

3. Perspective: The choice of perspective should be clear. Total society perspective (all payers) is the gold standard. Other perspectives, such as the payer or patient perspective, may be useful but must be stated clearly.

4. Probabilities are needed for each “chance” event, such as chance of cure or chance of an adverse event. The best sources of probabilities come from meta-analyses of randomized clinical trials, or if not available use data from individual clinical trials.

5. Costs: Units of expense and unit costs should be described in detail. Information on the source (e.g., charges, payments) and year of the cost data should be presented. If the costs were inflated and/or converted from another currency, then this must be described.

6. Outcome Measure: Measures of effectiveness depend on the type and objectives of analysis. Quality adjusted life years are the gold standard, as described previously in this chapter.

7. Analytic Model: Each intervention being assessed
must be described and possible courses of events identified, including the expected course of disease, treatments, complications, and outcomes. This may be performed using a spreadsheet/clinical trial path, or Decision Tree, or Markov Model.

8. **Discounting:** Since the value of both costs and benefits may decrease over time, discounting is used to calculate the present value of money and health states that will occur in the future. Future costs and utilities should be discounted to present value; 3 % per year is a recommended starting point.

9. **Incremental Analysis:** The purpose of a CUA is to describe the relative value of one health care strategy compared to another. An incremental cost-effectiveness ratio (ICER) is the incremental cost divided by the incremental effectiveness of intervention a compared to intervention b, and is calculated as follows.

\[
\text{ICER} = \frac{\text{Average Cost}}{\text{Average Utility}}_{\text{intervention A}} - \frac{\text{Average Cost}}{\text{Average Utility}}_{\text{intervention B}}
\]

Averages should be used rather than other measures of central tendency, such as medians, because it is important to include the effect of outliers. The leverage of the outliers should be tested in a sensitivity analysis.

10. **Sensitivity Analysis:** A sensitivity analysis should allow the reader to understand whether the conclusion of the analysis would hold true if either the Costs or the Probabilities (of cure or complications) were to vary substantially. For example if one treatment costs 5,000 Euro and has a cure rate of 90%, and the second treatment costs 2,000 Euro with a cure rate of 80%, then the ICER will assess whether the resultant benefit in QALY/Quality of Life makes the first treatment worthwhile.

Having reached this conclusion, the researcher should then vary the costs and the cure rates in the model, to see how much variation in real life would be allowed yet still maintain a valid conclusion.

Documenting these boundaries helps define the conditions under which a treatment is preferred. Researchers are developing innovative methods for conducting sensitivity analyses.

Probabilistic models that use simulations are becoming more common, although they can be computationally complex.

---

**V. SUMMARY OF RECENT ECONOMIC ANALYSES**

*Note:* the Committee strongly recommends that all studies of economic analyses should publish the timeframe in which the study was actually performed (because the date of publication is often months to years later), and that the currency employed be stated for that year/timeframe. This is essential for accurate discounting of costs over time, and for comparing economic analyses of treatments performed in different years.

1. **SURGICAL TREATMENT COST EFFECTIVENESS STUDIES**

   **a) Is treating incontinence cost-effective?**

Since the last ICI meeting in 2004, several cost-effectiveness analyses of surgical interventions for stress incontinence have been published. These analyses systematically compare costs and outcomes of surgical treatments for stress urinary incontinence. The largest number of cost-effectiveness analyses were done comparing less to more invasive procedures – tension-free vaginal tape (TVT) vs. alternative surgeries for stress incontinence and laparoscopic vs. open procedures. These are inherently appropriate for CEA since the less invasive approach is more likely to be less costly (both direct costs of surgery, hospitalization and indirect costs of shorter recovery time) yet may be less effective, be associated with more adverse events and/or result in lower health-related quality of life.

   **b) TVT vs. Other procedures**

Several studies compared the cost and cost-effectiveness of incontinence surgeries, supporting the finding that tension free vaginal tape (TVT) is more likely to be cost-effective compared with the other surgical procedures. However, there is a need for longer-term follow-up data from methodologically rigorous randomized trials to provide a better data to estimate the relative benefits and cost implications.

Cody and colleagues [31] evaluated the effectiveness and cost-effectiveness of tension-free vaginal tape (TVT) compared to standard surgical interventions for stress incontinence [31, 32]. Effectiveness and cost (2001 pounds Sterling £) estimates came from a systematic review of studies published from 1966 to 2002 that compared TVT with any alternative surgical or injectable agent therapy and utilities were estimated using the EQ5D in a surgical trial [33]. A Markov model was developed to estimate costs and quality-adjusted life-years for up to 10 years following surgery. They found that open colposuspension, laparoscopic colposuspension and traditional slings have similar cure rates to TVT, whereas injectable...
agents have lower cure rates. In economic modeling, TVT dominated open colposuspension (lower cost and same QALYs) within 5 years after surgery. The range of outcome measures used to define ‘cure’ were not described, which may affect the accuracy of these conclusions.

However, there were no randomized controlled trial (RCT) data beyond 2 years post-surgery, and long-term effects could not be ascertained. TVT was more likely to be cost-effective compared with the other surgical procedures. Increasing the absolute probability of cure following TVT increased the likelihood that TVT would be considered cost-effective. The likelihood of TVT being cost-effective was 86% if decision-makers are willing to pay up to £30,000 per additional QALYs. In sensitivity analyses, TVT’s dominance depended on the assumption that retreatment open colposuspension has lower cure rates than a first colposuspension and the rate of retreatment. In the short- to medium-term the effectiveness of the TVT is similar to alternative procedures and TVT is less costly. Yet, they concluded that the long-term performance of TVT for effectiveness and adverse effects is unknown.

Wu and colleagues [34] performed a methodologically excellent cost-effectiveness analysis of Burch colposuspension compared with TVT for stress incontinence. They developed a Markov decision model to compare costs ($2005 US dollars) and QALY’s (on Health Utilities Index) over 10 years from a health care system perspective. Probabilities, costs and utilities were estimated by literature review and used generalizable measures. After surgery, outcomes included cure, persistent stress incontinence followed by second surgery, and persistent stress incontinence and mesh erosion after tension-free vaginal tape. In their base-case, the Burch strategy cost more than TVT ($9320 vs $8081) but was slightly more effective (7.260 vs 7.248 QALY’s), with an incremental cost-effectiveness ratio of $98,755 per QALY. The model was most sensitive to cost difference between the strategies, utility, probability of mesh erosion and the relative risk of a cure. The incremental cost-effectiveness ratio was less than $50,000 per QALY when the relative risk of cure after Burch vs. TVT was greater than 1.09. In this well done study using state-of-the-art methods, Burch colposuspension was not cost-effective compared with TVT. However, if the tension-free vaginal tape failure rate was to increase over time, Burch may become cost-effective, reinforcing the need for long-term follow-up in surgical trials and cohorts.

Manca et al. [33] assessed the cost-effectiveness at 6 months of TVT compared with open Burch colposuspension as a primary treatment for urodynamic stress incontinence in 344 women in a multicentre RCT at 14 centres in the UK and Ireland. Resource use included length of hospital stay, time in theatre and management of complications and was based on UK unit costs at 1999-2000 prices. They collected primary data on QALYs with the EQ-5D health questionnaire. At 6 months TVT dominated colposuspension: TVT had lower mean costs and higher mean QALY’s. TVT resulted in a mean cost saving of £243 (95% CI £341, £201) compared with colposuspension and differential mean QALYs per patient (TVT - colposuspension) of 0.01 (95% CI -0.01 to 0.03). In sensitivity analyses, the probability of tension-free vaginal tape being, on average, less costly than colposuspension, was 100%, and the probability of tension-free vaginal tape being more cost-effective was 95% if the decision-maker was willing to pay £30,000 per additional QALY. Over six months, TVT was a cost effective alternative to colposuspension. The study was limited, however, by short follow-up.

Moreno et al. [35] performed a cost-minimization analysis of ambulatory surgery compared with inpatient surgery for TVT in a public hospital in Spain. They used activity-based (micro) costing of surgery, emergency service and admissions to hospital immediately following surgery. They observed that the mean cost for patients in the ambulatory group was 42% lower than that for the hospitalized patients and that ambulatory surgery had equal efficacy to the surgical intervention.

c) Open vs. laparoscopic colposuspension

A methodologically excellent study by Dumville et al. [36] compared the cost-utility of laparoscopic versus open colposuspension to treat female urinary stress incontinence at 6 months. Cost utility analysis was performed alongside a RCT at 6 centres within the UK. Data on costs (£) and generic health-related quality of life (EQ-5D) were collected and patient-specific quality-adjusted life years (QALYs) calculated. Healthcare costs over 6-month follow up were higher for the laparoscopic arm than for the open arm (£1805 vs. £1433; differential mean cost £372; 95% CI 274, 471) due to increased theater costs. QALYs were slightly higher in the laparoscopic arm relative to the open arm (0.005; 95% CI -0.012, 0.023).

The ICER was £74,400 at 6 months. At 24 months, higher mean QALY’s persisted in the laparoscopic arm and modeling showed the ICER was reduced to £9300 (see Figure 6 below). Limitations include few longer-term data on efficacy of the laparoscopic approach. While laparoscopic colposuspension was not cost effective compared with open colposuspension during the first 6 months following surgery, it may be cost effective over 24 months.

d) Injectable agent therapy

A cost- effectiveness and cost-consequence analysis found that urethral injection therapy is likely cost-effective compared to surgery to treat recurrent stress
urinary incontinence. However, the study was limited by lack of long-term data and choice of outcome measures. Oremus et al. [37] performed a cost-effectiveness analysis to compare each of three surgeries (retropubic suspension, transvaginal suspension, sling procedures) with collagen injection therapy to treat female stress urinary incontinence after the failure of initial surgical treatment. The analysis used decision-modeling from the Canadian health care system perspectives using probabilities from a literature review and generalizable Canadian cost data. While the treatment with the lowest average cost was collagen (2718 Canadian dollars), the surgeries had higher probabilities of success (defined as ‘cure’). The ICERs for all treatment comparisons indicated that the cost to cure an additional patient with surgery could range from 1824 - 6814 Canadian dollars in Ontario and 1388 - 3008 Canadian dollars in Quebec. These ratios were sensitive to changes in the mean number of injections for collagen patients and to a reduction in the length of hospital stay for surgery to 1 day. Each of the surgeries has a relatively small additional cost per cure for stress incontinence compared to collagen injections. Collagen injection may be cost-effective as a follow-up treatment to initial surgical failure when the number of injections is kept to a minimum and hospital stays after surgery are relatively lengthy.

Tierney et al. [38] performed a “bottom up” study of the costs of performing TVT, open colposuspension and collagen injections in Scotland but only short term hospital costs were considered.

Kobelt and Fianu-Jonasson [39] performed a cost-consequence analysis including resource utilization and utility of a urethral injection therapy (the Zuidex system of prefilled syringes of non-animal stabilised hyaluronic acid/dextranomer (NASHA/Dx) gel) compared to TVT for stress incontinence. Utility was measured using the EQ-5D in 82 patients undergoing injections, and cost data were collected prospectively in a 12-month efficacy study of injections and retrospectively for TVT (n = 77). Injection therapy provided utility benefits that were similar to those previously reported for TVT(0.05 at 3 months and 0.01 at 12 months) and was associated with similar or lower overall costs in the short-term (€ 2200 at 3 months and € 3100 at 12 months for injection vis. € 4200 at 6 months for TVT). From an economic perspective, NASHA/Dx gel could be considered at least as favourable as TVT, pending the availability of long-term effectiveness data.

Kalsi et al. [40] performed a cost-consequence analysis of resource utilization and health benefits of intradetrusor injections of botulinum neurotoxin-A at 16 weeks in 101 patients with intractable overactive bladder (OAB) enrolled in a research protocol in the UK. The cost of therapy was quantified based on NHS resources used from the perspective of the UK NHS. After 16 weeks, 65% of patients showed > 25% improvement and 53% at least a 50% improvement in > two out of five OAB parameters (Figure 7). Therapy cost pounds 826 per patient, with a cost-effectiveness ratio of £ 617 per patient-year with > 25% clinical improvement. The investigators concluded that there is a role for botulinum toxin injection. However, the study was severely limited by using an outcome measure that is not generalizable and has minimal value (>25% clinical improvement), by short term follow-up and by having no comparison with a standard alternative therapy.

e) Conclusions

Current data on the cost-effectiveness of surgical treatment for stress incontinence show minimally invasive surgery (TVT, injectable therapy) vs. more invasive surgeries like the Burch colposuspension are likely cost-effective. However, the studies are limited by poor longer-term data on the effectiveness of less invasive procedures. In addition, these cost-effectiveness and cost-utility analyses are limited by lack of primary and/or generalizable data on costs,

Figure 6 : Changes in the ICER from 6 months to 24 months when comparing laparoscopic versus open colposuspension (reproduced with permission from BJOG).
clinical outcomes and utilities and not using a accepted and generalizable outcome (cost per QALY or cost per “cure”). Further, few have primary data to perform analyses over a longer timeframe. Further research suggestions include unbiased assessments of longer term performance from follow-up of controlled trials or population-based registries, more data from methodologically sound RCTs using standard outcome measures, use of accepted standards for selecting outcome measures and for decision modeling, and a surveillance system to detect longer term complications.

2. OUTPATIENT CONSERVATIVE THERAPIES

a) Prospective studies of conservative therapy costs

Neuman et al. [41] calculated the physiotherapy treatment costs for 274 women with stress incontinence in Australia. A median of 5 (IQR 4-6) treatments were given, for a median cost of 250$ (IQR 206-295). When cost of a GP visit was added, with MSU total cost of 302 AuD (in 2000). In the 208 women who completed therapy, weekly leakage episodes declined from 5 (IQR 3 -11) to 0 (IQR 0-2 leaks). Using intention to treat analysis, 64% of patients were dry on a stress test (or 84% of those who actually completed therapy). Improvement was observed using the Kings Health Questionnaire, but utilities were collected. This appears to be the first prospective study of physiotherapy costs for stress incontinence.

Williams et al. [42] of the Leicestershire UK MRC Incontinence Study Team undertook a large RCT of conservative therapy. Personal and treatment costs were measured (year 2001). Of the 29,039 men and women who leaked several times per month and had frequency, urgency and nocturia, 6,207 agreed to participate in a home interview, of whom 3,746 were randomised. They were allocated in a 4:1 ratio to either treatment by a specialist nurse continence advisor (who provided conservative treatments and urodynamic testing) or access to routine continence care by their GP and local continence nurse. Cure at 6 months occurred in 28% versus 19% [95%CI5-13, p < 0.001].

The intervention costs at 6 months (252 £, IQR 234-268) were greater than the routine costs (73 £, IQR 53-93). Cost effectiveness was calculated by dividing the between-group differences in the costs by the mean difference in outcome i.e. number of symptoms resolved. The incremental cost per additional symptom alleviated was 488 £ at 6 months: although of interest this is not a standard calculation in economic analyses.

Female participants in this study then were offered a more detailed treatment program [43]. A RCT of the effectiveness of three treatments for women age >40 with urodynamic stress or mixed incontinence was undertaken. Of the 238 women randomised between 1998 and 2001, 79 were allocated to control therapy (a brochure about pelvic floor muscle training (PFMT) followed by fortnightly visits to a continence nurse for 3 months), 79 were randomised to detailed personal PFMT by a continence nurse for 3 months, and 80 were randomised to vaginal cone weight therapy for three months.

The costs of the intervention were gathered by an interviewer-administered questionnaire (no further details), and from local and national cost data [44]. These comprised 287 £ for controls, 338 £ for PFMT, and 305 £ for vaginal cone weight therapy. There were no statistically significant differences between intervention groups (6%, 4% and 85% were cured, with 34%, 30% and 30% satisfied).

Subak et al. [45] prospectively ascertained the personal “routine care” costs of incontinence in 293 women age over 40 who had stress or urge leak more than 3 times per week, wanted help, but had not been treated in the previous 3 months. A self-report questionnaire asked about pad and laundry usage was given, quality of life was tested by Health Utilities Index Mark 3 and Willingness to Pay for incontinence was determined.

The mean annual cost (in 2005 dollars) of routine care was 492 US$ (SD 898), which increased with the severity of incontinence. The costs for those with urge leak and mixed leak were greater than those with stress leak. For the first time, it was found that the costs were 2.4 fold higher for African Americans than for white women. There was no association between household income and incontinence costs. The quality of life (on HUI) was poorer as the frequency of incontinence increased, but not as the severity increased. Women were willing to pay $70 per month for 100% reduction in the frequency of incontinence. Willingness to pay increased 2.3 fold in the highest income bracket compared to the lowest. Because
willingness to pay for improvement exceeded the routine care costs by 3-7 fold, effective continence treatment is likely to be economically feasible.

Ho et al. [46] performed a “bottom up” study of the short and long-term direct costs of conservative and surgical management of childbirth-related stress and mixed urinary incontinence (UI). A cohort of 150 women, who presented with post-childbirth incontinence during an eight-year period (1992-1999) were evaluated. Costs for treatment episodes during conservative and surgical management were calculated and related to cure. At 6-13 years follow up, personal and treatment expenditure was measured using a postal questionnaire.

During active treatment in the Unit, patients with stress UI treated conservatively incurred a median cost of AU$658 per capita (IQR 476 – 1191 AU$) compared to a median cost of $6,870 per capita for surgical treatment (IQR 6,320 – 7508 AU$). Similar cost difference was seen for the two treatment options in patients with mixed incontinence. Of regular clinic attendees, 39% of conservatively treated and 78% of surgically treated patients were cured.

At 6-13 years follow up, there were 82 women with a known address, of these, 43 (52%) responded to the survey, of whom 46% remained cured. The median treatment cost for the total group of postnatal incontinence (irrespective of continence status) was 885.80 per capita per annum (IQR 338- 2,589).

Foote and Moore [47] studied an RCT of Nurse Continence Advisor (NCA) therapy (N = 73) versus Urogynaecologist therapy (N = 72.) Both had significant improvements in leaks per week and incontinence score. QOL improvement was also similar (1.5% vs 1.2%). The economic data found a similar improvement in pad usage costs ($A2.90 vs $A3.52). The clinician costs were significantly lower for the NCA group ($A60.00 vs $A105.00, P < 0.0001). The cost per QALY was significantly lower for the NCA group ($A28,009 vs $A35,312, P = 0.03). Both groups had significant improvements in pad testing and leaks per week. The cure/improvement rates were also similar at three months (100% vs 89%).]

b) Retrospective studies of conservative and surgical therapy costs

Kinchen et al. [48] from Eli Lilly Research Laboratories (USA) undertook a retrospective analysis of private insurance and Medicare claims for stress incontinence in 8,126 women who had at least 12 months of claims data. Patients who were in “capacitated insurance cover” (i.e. managed care) were excluded because charges for their services were often “negotiated down”. Of the remaining 6,672 women, a mean of 0.4 inpatient care days and 1.6 incontinence related outpatient service days occurred, and 3.5 incontinence-related prescriptions were given. The mean (SD) annual incontinence related expenditures per person, including inpatient and outpatient services (with pharmaceutical costs) was a total of 1,382 US$. Patients who had surgery had a mean total expenditure of $3620 (SD 3958) which was about ten fold greater than those who had non-surgical services ($350, SD 724). Only 10% of patients in the study group were age over 65, so the sample was not representative of the total population but only of those with private insurance.

A more detailed study of 3 different costing methodologies, also using health care claims data, was performed by Birnbaum et al. [49], also from the Eli Lilly Company (see also Statistical Analysis section). They used individual claims data from over 100,000 women aged 18- 64 who were in a managed health care plan. A sample of 1006 women with stress urinary incontinence (SUI) were compared to 6475 continent women. The three economic analyses were as follows:

1. Costs of Treatment of stress incontinence
were summated from the all claims data for this condition. Of the continent women, 14% had surgery, 23% had medical claims, the average costs was 606$ per patient per annum (in 1998 dollars).

2. The Incremental Cost of an SUI patient was calculated by summating the total costs of patients with SUI versus the total costs of patients without SUI. The average direct medical costs of SUI was 134% greater than that for a non-SUI patient. The indirect costs were 163% higher.

3. The Incremental Cost of SUI Illness were calculated by measuring the costs of SUI and the costs of treating conditions that may be causally related to SUI, such as obesity, chronic cough, diabetes and menopause. The average direct medical cost of SUI was $5,642 per person per annum. The indirect workplace cost of SUI was calculated to be $4,208 (but little methodology was provided). For patients who underwent surgery, the average direct medical costs were $9,985 versus $5,024 for those treated without surgery.

Kinchen et al. [49] also from Eli Lilly published an analysis of the direct costs of SUI among women enrolled in Medicaid. The authors pointed out that because of the “predominantly female population served by Medicaid”, it was important to undertake this particular analysis. Claims were recorded from Jan 1999 to Dec 2002, converted to 2002 dollars, in 4 states of the USA. The use of services one year before and after diagnosis of SUI or mixed incontinence was compared. Surgical procedures and a large list of surgical complications were examined. Co-existent prolapse, and prescriptions for anticholinergic drugs, were also tabulated. Comorbidities such as hyper-

tension, irritable bowel syndrome, cancer, diabetes and depression were noted. In the 4 year period, there were 48,160 Medicaid claims for urinary incontinence in general, of whom 28% had a SUI diagnosis, 5% were mixed incontinence, 6% were urge incontinence and 61% were unspecified incontinence (suggesting general practitioner claims without a precise diagnosis). Of those with SUI diagnosis, 36% were also Medicare eligible.

About half of the claimants in all the states were aged less than 40 years. In the SUI group, about 30% received anticholinergic drugs. Surgery was performed in 13%, of these about 8% had prolapse surgery as well. Looking at the pre-diagnosis 12 months versus the post SUI diagnosis year, in those who underwent surgery the total health care costs increased by 53% (from $8,400 to $12,900). In those who did not have surgery, the total costs increased by 3% (from $11,100 to $11,600). After analysing incontinence specific costs, the surgical expenditure ($3,200) was almost tenfold greater than the nonsurgical expenses ($420). For the 4 states included in the analysis, approximately 1% of females had a diagnosis of SUI during 2002. Average total spending accounted for by incontinence related care for the SUI patients was less than 0.1% of total Medicaid spending.

More recently, Turner and colleagues [50] estimated the cost of clinically significant stress and urge incontinence for the UK to be £536 million for the NHS and a further £207 million paid for by individuals incontinence for the UK to be £536 million for the NHS and a further £207 million paid for by individuals. In the UK, however, the National Institute for Health and Clinical Excellence (NICE) requires economic review. They have denied approvals for new drugs that have an incremental cost effectiveness ratio greater than 30,000 pounds per QALY.

In response to the regulatory requirements, drug developers routinely conduct economic evaluations. In the UK, such efforts are done as part of the NICE review. In the US, developers present economic data to purchasers for post approval marketing. Many purchasers have formularies, or lists of medications that they are willing to pay for, and the economic evaluation is frequently part of the request to place the new drug on the formulary.

In the next sections, we review the existing literature on the economics of drugs for incontinence and overactive bladder. We then outline drugs that are under development, and suggest methods to enhance their economic evaluations.

1. APPROVED MEDICAL TREATMENTS

There are five commonly used medical treatments for incontinence and overactive bladder: tolterodine (Detrol), darifenacin (Enablex), trospium (Sanctura), solifenacin (Vesicare), and oxybutynin (Ditropan). These drugs are predominantly used for urge incontinence or overactive bladder and work as antimuscarinic targeting M2 and M3 receptors. There are currently no commonly used medications for fecal incontinence, although there are some medications to treat its side effects. Surgical and behavioral treatments are common for stress incontinence, although there is some recent research on duloxetine, (widely used as an antidepressant), for stress incontinence.

Many economic evaluations are funded by drug developers and compare the investigational drug to placebo or to an older compound that has known problems with side effects (e.g., immediate release oxybutynin). With independent funding, Ko et al. [51] conducted an economic evaluation of five antimuscarinic drugs in eight treatment formats for the treatment of overactive bladder. They compared immediate-release oxybutynin, extended-release oxybutynin, transdermal oxybutynin, immediate-release tolterodine, extended-release tolterodine, trospium, solifenacin, and darifenacin. Their analysis concluded that solifenacin had the lowest costs and highest effectiveness in the treatment of OAB. However, their analysis faced many limitations. It did not meet common standards set forth for cost-effectiveness analysis [7, 8]. It focused on the payer’s perspective (rather than a societal perspective), had a very limited time frame of 3 months (rather than lifetime costs and benefits), and used complete continence as the main effectiveness measure (rather than QALYs). Given these limitations, these results must be interpreted cautiously. We believe that additional studies using standard methods would be beneficial.

Most of the economic work in this area compares oxybutynin to tolterodine. Guest et al. [52] compared the cost-effectiveness of oxybutynin immediate release, oxybutynin extended release and tolterodine. They created a 6-month decision model from the payer’s perspective and used short-term clinical endpoints (daily incontinence episodes and daily micturations). They concluded that extended release oxybutynin appears to be the most cost-effective of the three treatments. Getsios and colleagues [53, 54]
conducted two economic evaluations comparing oxybutynin extended release to tolterodine, and found that evidence suggesting that oxybutynin extended release may be cost-effective to tolterodine. Hughes and Dubois [55] created a CEA model but were very cautious in their interpretation, given the data limitations.

O’Brien and colleagues [56] conducted a cost effectiveness analysis using a 1 year Markov model. They attempted to determine the cost-effectiveness of tolterodine for patients who discontinued oxybutynin, using the payer perspective. They concluded that, “The incremental cost per QALY was Can $9,982 [year of costs not stated] and appeared to be robust to alternative model parameter assumptions.”

In 2005, Getsios and colleagues [57] published a review of the economic studies for overactive bladder, highlighting many of the limitations including a lack of comparisons of drugs to behavioral training. The UTIN group, which published a paper describing its trial design [58], is currently conducting a clinical trial comparing behavioral treatments to medications for urge incontinence. This high-quality study will measure costs and utilities, and through a NIH-funded substudy, separate researchers will conduct the economic evaluation of this trial.

There have been a handful of studies involving secondary data. Nitz et al. [59] analyzed secondary data from a large US health plan to assess the association between types of OAB treatment and health care costs in 2001 and 2002. They found that differences in health care costs were associated with type of treatment. Their analysis, while interesting, had a number of limitations including relatively old data (old in terms of OAB) and use of data from a single health plan. They also do not control for some economic issues and it is unclear how they handle people who change their medications. A cleaner analysis would have been to identify new claims for OAB treatment and then followed these patients, using an intent-to-treat analysis plan.

Darkow et al. [60] conducted a statistical analysis of secondary data to assess the additional cost of having OAB. They found that people with OAB had higher medical care costs, controlling for age and many comorbid medical conditions. Their results may be confounded by a number of issues because people with OAB are different from people without OAB in many ways that are not observable to researchers. Grocela and colleagues [61], reviewed the literature to determine how the introduction of pharmacy benefits for Medicare beneficiaries would affect the OAB market.

1. **Darifenacin Hydrobromide (Enablex)**

Darifenacin was approved by the FDA in 2004, based on Phase II and III controlled clinical trials with over 8,800 patients. Short term efficacy (12 week) as well as longer term effects (24 and 52 week) were evaluated [62]. Few patients discontinued taking the drug in either the darifenacin arm (3.3%) or the placebo arm (2.6%). Patients assigned to darifenacin experienced decreased incontinence and voids/day, increased bladder capacity, and decreased urgency. Results were evident at 2 weeks and were sustained through the year endpoints.

Abrams and colleagues [63] found that darifenacin was associated with significant improvements in quality of life as measured by the King’s Health Questionnaire at 12 weeks relative to placebo. Chancellor et al. [62] found that darifenacin and darifenacin combined with a behavioral modification plan both resulted in improvements in symptoms and quality of life, as measured by the Overactive Bladder Questionnaire (OAB-q), but there were no differences between the two groups. Unfortunately, neither the Abrams nor the Chancellor study measured utilities, so it is hard to gauge the magnitude of these quality of life effects. Besides the Ko [51] article discussed above, there is little data on the cost-effectiveness of darifenacin.

2. **Trospium Chloride (Sanctura)**

Approval was based on two Phase III double-blind, placebo-controlled trials comparing the reduction in the frequency of urination and the reduction in urge urinary incontinence episodes at 12 weeks with over 600 patients. The trials selectively identify high risk patients (e.g., those who had 10 or more toilet voids per day) to increase the power of detecting a significant result. This, however, makes it hard to generalize the findings to other patients. Patients treated with trospium chloride experienced significant improvement in number of voids per day and number of incontinent events at the end of the 12-week trial, compared to patients on placebo. Besides the Ko [51] article discussed above, there is little published data on the cost-effectiveness of trospium chloride.

3. **Solifenacin Succinate (Vesicare)**

Solifenacin succinate was evaluated in 12-week, randomized, placebo-controlled phase III clinical trials with more than 3000 OAB patients. US and European studies found solifenacin succinate was statistically superior to placebo in terms of micturition frequency, nocturia, volume voided, pad use, urgency episodes and incontinence episodes. Long term data suggest that the effects are maintained at 1 year. Besides the Ko [51] article discussed above, there is little published data on the cost-effectiveness of solifenacin succinate.

4. **Tolterodine (Detrol)**

Tolterodine has been extensively tested in controlled clinical studies against placebo. Newer clinical trials have combined tolterodine with tamsulosin (Flomax) and found that the combination of drugs providers
greater benefits than tolterodine alone in terms of lower urinary tract symptoms [64]. Tolterodine has also been tested against oxybutynin, with results favoring tolterodine in terms of tolerability (e.g., dry mouth, constipation). A number of studies have assessed the cost-effectiveness of tolterodine and in comparison to oxybutynin and we reviewed these results above.

5. EXTENDED RELEASE OXYBUTYNIN:

Patients treated with extended release oxybutynin showed significant improvements with total continence and improvements in OAB symptoms. Extended release oxybutynin was well tolerated by most patients, with more than 90 percent of patients reporting satisfaction with therapy, yet moderate-to-severe dry mouth was reported by a quarter of the patients.

6. OTHER MEDICATIONS

Brunenberg [65] conducted a Markov model to assess the cost-effectiveness of duloxetine, a serotonin and norepinephrine reuptake inhibitor, for stress incontinence. The model was designed to compare two strategies: duloxetine alone and duloxetine after inadequate response to pelvic floor muscle training [PFMT] compared with PFMT or no treatment for women 50 years of age or older.

The results showed the incremental cost per incontinence episode, but a major challenge with interpreting this paper is that it is narrowly focused on a pharmacotherapy +/- PFMT and does not include other treatments for stress incontinence (e.g., surgery).

Das Gupta and colleagues [66] developed a cost effectiveness model to assess the cost-effectiveness of duloxetine for moderate to severe SUI. Their model, however, was limited in that they assumed that drug treatment was fully effective. Even so, their results were highly sensitive to the time frame of the analysis.

7. THE RESEARCH AND DEVELOPMENT PIPELINE

Although governments vary in their desire to see economic analyses with an investigational new drug application, we believe that gathering evidence in clinical trials is the best way to conduct high a high quality economic evaluation. Therefore, we searched the World Health Organization and the National Institute of Health’s clinical trial registry (www.clinicaltrials.gov) to learn about completed and ongoing studies for urinary incontinence and overactive bladder (search date 1/30/2008).

We found 64 drug trials and Table 2 summarizes the results. Each trial is listed once and there were four trials in which one drug was compared to another. In these cases, we listed the trial under the first drug listed in the registry. The greatest number of trials was on tolterodine (22 of 64)[51]. The drug with the most active number of trials was solifenacin, with 10 ongoing trials or trials that are about to start recruiting.

Of all the trials, 89% were industry funded with others being funded by US, UK and Israeli governments. The clinical trial registry includes information on the phase of the trial and the primary and secondary outcomes. Outcomes are “text fields” and there was considerable variability in how people entered data for the trials. Some trials provided the specific outcome measures, while other trials just mentioned urinary incontinence frequency and urgency. Quality of life was mentioned 18 times (28%); discussion of utilities or quality adjusted life years (QALYs) or economic outcomes (e.g., lost productivity or costs) was extremely rare (Table 2).

In 2007, the Cochrane Collaboration reviewed anticholinergics for the treatment of overactive bladder and urge incontinence [67]. The Cochrane authors reviewed twelve clinical trials and found “inadequate evidence to assess whether or not available alternative drugs are better or worse than anticholinergics in the management of people with symptoms of overactive bladder syndrome.” In their recommendation section, they conclude that “larger randomised controlled trials versus anticholinergics and conducted in clinical settings are required to further establish the role of these other medications in the management of overactive bladder.”

We agree with this statement and believe that better economic evaluations start with collecting the right information in high-quality clinical trials. We applaud the use of disease specific quality of life measures in clinical trials, but would also like to see the addition of utility measures, such as the Health Utilities Index that is being used in the UTIN network BE-DRI trial [68].

In addition, we believe that clinical trials need to include resource use questions to identify medical care use as well as routine care at home (e.g., use of pads or additional laundry). Dowell et al. [69] and Subak [45] created questionnaires for such data collection. Finally, we believe that it is easy to bias a cost-effectiveness analysis by focusing on a few treatment options, on a specific perspective, or with a limited time horizon. Therefore, while the clinical trials are the building blocks for the economic analysis, the economic analysis needs to embrace the societal perspective and lifetime costs and benefits.

4. COST IMPLICATIONS OF INCONTINENCE IN NURSING HOME SETTING

Two key aspects of cost of care for nursing homes are (1) cost of nursing home admissions attributable to urinary incontinence, and (2) the direct treatment cost of urinary incontinence.

Additional nursing home admissions cost is often a major component in the total cost of urinary incon-
In a 2001 study [70] the cost estimate was $2.4 billion in 1995 dollars. In a 2004 study [71], the cost estimate was $4.0 billion in 2000 dollars. In a recent update by Morrison and Levy [72], the attributable fraction (AF) statistics from published data was shown to be $6.0 billion in 2004 dollars. The Attributable Fraction (AF) statistics are obtained by using incontinence prevalence rates for those admitted to nursing homes, as compared to those who were not admitted to nursing homes. It shows that reimbursement for treatment of UI in the community might help or delay institutionalization and offset some costs of staying in nursing homes. The AF method has been used in the economic cost of mental illness, smoking, and cancer diseases. The new estimated magnitude shows that reimbursement for treatment of UI in the community might help or delay institutionalization and offset some costs of staying in nursing homes.

Holroyd-Leduc, et al. [73] used a population-based prospective cohort study from 1993-1995 to determine whether UI is an independent prediction of death, nursing home admission, and decline in activities of daily living (ADLs). Over 6,500 elderly (>age70) were included in the study. It was found that after adjusting for confounders, UI was not an independent predictor for death, nursing home admission, or functional decline.

Within nursing homes, labor costs are a major component of caring for incontinent patients. These costs are studied via time/motion observation, correlated with severity and type of incontinence. In 49 long-term care facilities in North Carolina, USA, it was found that the incremental labor costs (per shift) were $3.31 for patients with occasional UI and $5.61 for patients with frequent UI [74].

Bliss et al. [75] addressed the cost/effectiveness of incontinence-related treatment of skin condition in 16 US nursing homes. Care of perineal skin is crucial to incontinent persons in nursing homes. Four regiments of different moisture barriers were applied. Time and motion measurements included skin products and time spent. It was found that using acrylic barrier film spray achieved cost savings of between $854 to $1,862 per resident, with better skin protection than the use of an ointment or cream.

Bates-Jensen et al. [76] examined the effect of an exercise and incontinence intervention upon skin health outcomes in nursing home residents. However, no cost data was actually provided. A review [77] on perineal skin care protocols and skin barrier product use has been reported, but no cost data was mentioned.

In contrast to the nursing home/long care facility, Morris, et al. [78] undertook a "bottom-up" costing of both urinary (UI) and faecal incontinence (FI) in the Sub-Acute Care setting, which provides short term rehabilitation of acute physiological insults in the elderly. They costing 3,621 occasions of care in 29 incontinent patients for up to 3 weeks. Pure UI occurred in 97%, with pure FI in 62%. The median per capita incremental cost of these conditions was 49 AUD (IQR 36-59) per 24 hours (in 2003). On average, 2 hours per 24 hours were dedicated to

| Table 2. Registered Clinical Trials for Urinary Incontinence and Overactive Bladder |
|---------------------------------|------------|---------|---------|---------|---------|------|
|                                | tolterodine | darifenacin | trospium | solifenacine | oxybutinin | Total |
| Number of trials               | 22         | 10       | 2       | 16       | 14       | 64   |
| Completed                      | 12         | 8        | 0       | 6        | 10       | 36   |
| Recruiting                     | 8          | 2        | 2       | 7        | 3        | 22   |
| terminated                     | 1          | 0        | 0       | 0        | 0        | 1    |
| Not yet recruiting             | 1          | 0        | 0       | 3        | 1        | 5    |
| Industry funded                | 19         | 10       | 2       | 14       | 12       | 57   |
|                                | 86%        | 100%     | 100%    | 88%      | 86%      | 89%  |
| Phase                          |            |          |         |          |          |      |
| Phase IV                       | 12         | 6        | 2       | 8        | 6        | 34   |
| Phase III                      | 5          | 2        | 0       | 5        | 6        | 18   |
| Phase II                       | 4          | 1        | 0       | 3        | 1        | 9    |
| Phase I                        | 1          | 1        | 0       | 0        | 1        | 3    |
| QOL Outcome                    | 9          | 4        | 0       | 2        | 3        | 18   |
| QALY Outcome                   | 0          | 0        | 0       | 0        | 1        | 1    |
| economic outcome               | 0          | 0        | 0       | 0        | 1        | 1    |

(86% 100% 100% 88% 86% 89%)
continence management. The incontinence costs on the "night shift" were almost as great as those for the day shift. Hence because of reduced night staffing, continence management comprised a heavy load at night.

5. LONGITUDINAL BURDEN OF DISEASE STUDIES

For the first time in this ICI report, we find a number of studies that attempt to measure the cost of incontinence over the long-term time frame. As pointed out by Birnbaum et al. [79] the study of "the lifetime cost of illness" is a rather recent area of research. These authors combined case-control methods (to calculate annual medical costs of stress incontinence, cardiac disease and diabetes) with knowledge of the incidence of the conditions, assuming "steady state conditions" of the costs, to project the lifetime costs of each disorder. Using a dataset of medical claims covering 1996-1998 for 931 women with stress incontinence who were under 65 at that time, they extrapolated the lifetime costs base on "published government statistics". The prevalence rate for women >65 was assumed to be the same for women < age 65, which is probably an incorrect assumption. The authors calculated an annual treatment cost for stress incontinence of 15,000$USD per woman, and gave a lifetime cost of 58,000$. Treatment methods and lifetime expectancies were not given, so that the study was largely a hypothetical model with insufficient characterization of the model parameters. Nevertheless such attempts at modeling the lifetime costs do need to be performed in greater detail in the future.

As regard the Overactive Bladder (OAB) a study that reported "longitudinal" costs of medication actually reported data of 275 patients in North Carolina age >65 years receiving antimuscarinic drugs for 1-3 years [80]. The study calculated that a 10% increase in adherence to the prescribed OAB medication was associated with a decline in overall health costs of 5.6%.

As regard the impact of incontinence upon employed women, Fultz et al. [81] sent a postal questionnaire to 5130 American households, yielding 3364 female replies (age 18-60). Of the 2326 employed women, 37% had leaked urine in the past month, severity was judged by Sandvik index. Severity was slight 52%, moderate 40%, severe 8%. The impact of incontinence upon ability to concentrate, performance of physical activities, self confidence, and ability to complete tasks without interruption increased with the severity of the leak and affected nearly 75% of all those with severe leak status.

Similarly, Wu et al. [82] focused upon the work loss burden of women with OAB. The number of days absent was 15% higher among 3077 OAB employees compared to 6154 controls. Multivariate analysis showed that OAB subjects had 4.4 more days off work than non-OAB subjects, yielding an annual excess cost of $1220 per OAB employee.

Finally, Reeves et al. [83] employed a theoretical model based upon a large prevalence study of OAB [84] to derive the future cost burden for OAB in five European countries (Figure 8). They calculated an annual per capita expense of Euro 269-706 per annum.

A more detailed analysis of OAB costs in Germany [85] that included psychiatric costs of OAB-related depression, and nursing care, indicated an annual per capita expense of €609-1170 per annum.

6. PROLAPSE TREATMENTS, COST IMPLICATIONS

Despite the high prevalence of pelvic organ prolapse and frequency of surgery for prolapse, there are minimal data on costs or cost-effectiveness of medical care for this condition. One COI study estimated the annual direct cost of surgery for pelvic organ prolapse in the U.S. using national data. [86]. Direct costs of
pelvic organ prolapse surgery were US$1,012 million (1997 dollars; 95% CI US$775, US$1,251 million), including US$499 million (49%) for vaginal hysterectomy, US$279 million (28%) cystocele and rectocele repair, and US$135 million (13%) abdominal hysterectomy. Hospitalization accounted for a majority of the total cost (71%) with the remainder being physician services (29%). Twenty-one percent of pelvic organ prolapse operations included urinary incontinence procedures (US$218 million). The annual direct costs of operations for pelvic organ prolapse are substantial and similar to other surgical interventions for women (breast cancer, gynecologic cancer, urinary incontinence).

A recent Cochrane review of surgeries for the management of pelvic organ prolapse (Maher et al) emphasized the importance of CEA and CUA [87]. They observed that abdominal sacrocolpopexy is associated with a lower rate of recurrent vault prolapse and dyspareunia than the vaginal sacrospinous colpopexy yet these benefits must be balanced against a longer operating time, longer time to return to activities of daily living and increased cost of the abdominal approach. Similarly, the use of mesh or graft inlays at the time of prolapse repair may reduce the risk of recurrence and the addition of a continence procedure to a prolapse repair operation may reduce the incidence of postoperative urinary incontinence. Yet, these benefits need to be balanced against possible differences in costs and adverse effects, which have not been assessed and, like surgical treatment for stress incontinence, are inherently appropriate for CEA since there may be differences between procedures in costs, clinical outcome and health-related quality of life.

Maher et al performed a randomized trial of abdominal sacral colpopexy vs. vaginal sacrospinous colpopexy to treat vaginal vault prolapse among 95 women [88]. Secondary outcomes included the impact on cost (measured as Australian bed and operating theater costs) and general- and incontinence-specific quality of life. Two years after the operation, the subjective and objective success rates were similar between groups. The abdominal approach was associated with a longer operating time, a slower return to activities of daily living, and a greater cost than the sacrospinous colpopexy (P<.01). Both surgeries significantly improved the patient’s quality of life (P<.05). These data suggest that formal cost-utility analysis would be beneficial if further compare these two common procedures for pelvic organ prolapse. Additional data with generalizable costs and utility measures and long-term efficacy outcomes are needed.

Weber and Walters [89] compared the cost-effectiveness of preoperative urodynamic testing vs. basic office evaluation in women with prolapse and stress incontinence, using a theoretical decision-analytical model. Costs were obtained from US government data and effectiveness of urinary incontinence surgery was based on published literature (in 2000). The strategies of basic office evaluation and urodynamic testing had the same cure rate of urinary incontinence (96%) after initial and secondary treatment. The incremental cost-effectiveness of urodynamic testing was $328,601 for single extra cure of urinary incontinence. In sensitivity analyses, basic office evaluation was more cost-effective than urodynamic testing when the prevalence of pure detrusor instability was <8% or when the cost of urodynamic testing was >$103. Urodynamic testing was not cost-effective before surgery for prolapse and stress urinary incontinence symptoms. However, the current routine use of sling procedures for stress incontinence limit the broad applicability of the study.

Segal et al. [90] compared the feasibility and cost of local anesthesia with IV sedation versus general anesthesia for vaginal correction of pelvic organ prolapse (N=40). “Costs” were recorded as hospital charges. Mean operating room, anesthesia, and surgical time, use of postoperative medication, postoperative verbal numerical pain scores and length of hospital stay were similar between the two groups. However, mean recovery room and total hospital charges were significantly lower in the local anesthetic group. These data suggest that local anesthesia with IV may be less costly for vaginal surgery to correct pelvic organ prolapse. Data on effectiveness are needed.

7. ECONOMIC CONSEQUENCES OF FECAL INCONTINENCE

a) Cost of illness

A prevalence study [91] in a long-term care hospital (457 patients) showed a prevalence of fecal incontinence of 46% (defined as at least one incontinent episode per week). The prevalence rate of urinary incontinence was 62% and combined incontinence 44%. The total annual cost of incontinence (urine plus fecal) per patient was $9771. Of the total costs, 83% was associated with nursing time, and 13% with laundry.

A study in the Netherlands published in 2005 calculated the costs of fecal incontinence in outpatients [92]. Total costs were estimated to be €2169 per fecal incontinent patient per year. Production losses in paid and unpaid work accounted for more than half of the total costs and costs of health-care visits accounted for almost a fifth of total costs. Costs associated with protective material (partially reimbursable and not reimbursable) formed only one-tenth of total costs, while incontinence medication was responsible for only 5% of total costs.

b) Prevention

To date it is not completely clear what the causes are
of fecal incontinence, therefore primary prevention is difficult. Pelvic floor exercises before and after vaginal delivery could help to prevent incontinence. One study investigated in a decision analysis the effect of elective cesarean section for macrosomic infants to prevent maternal fecal incontinence [93]. It appeared that for every 100,000 deliveries, the policy of elective C-section resulted in 185.7 fewer cases of fecal incontinence, and cost savings of $3,211,000. According to the authors, this policy would prevent one case of fecal incontinence for every 539 elective C-sections performed.

c) Hospital costs

Treatment and follow-up costs for fecal incontinence are identifiable. However, economic assessment is difficult because of the lack of uniform study populations, variation in techniques, reimbursements systems and regional costs. There is a limited number of studies that systematically compare costs and outcomes of fecal incontinence treatments.

Mellgren et al followed up 63 patients with FI and estimated that the average lifetime cost associated with treatment and follow-up was $17,166 per patient in 1996, with average facility charges associated with sphincteroplasty to be $8555 per procedure [94]. Sung et al. [2] showed that in the US total charges associated with surgical treatment for fecal incontinence increased from $34 million in 1998 to $57.5 million in 2003, translating to a total cost of $24.5 million in 2003. Variables associated with increased costs included number of procedures per admission, length of stay, patient age, and race.

Different surgical options are available. In a study by Adang and colleagues performed in 1998, the costs of dynamic graciloplasty were compared with costs of colostomy and conservative treatment [16]. The costs of all activities were calculated, inside and outside the hospital, for all three alternatives. Costs were based on real prices, not on charges. A distinction was made between direct and indirect costs. For conventional therapy, direct costs outside the hospital were counted, such as diapers, enemas, tissues, and diets [16]. Hetzer et al. [95] compared the costs of Sacral Nerve Stimulation (SNS) and sphincter repair. The SNS cost analysis was performed on an intention-to treat basis. The analysis was performed from a hospital perspective; therefore only direct medical costs were assessed. These authors also transformed the results of the Adang study to 2005 Euro’s to be able to compare both studies. In figure 9 the estimated long-term costs per patient for each treatment are shown.

In a Markov model, Tan et al. [96] compared the cost-effectiveness of artificial bowel sphincter (ABS), dynamic graciloplasty (DG) and permanent end stoma (ES) for the treatment of fecal incontinence. It appeared that over the 5-year time horizon, ES gave a QALY gain of 3.45 for 16,280 £, giving an ICER of 4719 £/QALY. The ABS produced a gain of 4.38 QALYs for 23,569 £, giving an ICER of 5387 £/QALY. The DG produced a gain of 4.00 QALYs for 25,035 £, giving an ICER of 6257 £/QALY. The authors concluded that all three procedures were cost-effective. The ES was most cost-effective over 5 years, while the ABS was most cost-effective in excess of 10 years.

Finally, the direct and indirect costs of transanal irrigation for neurogenic faecal incontinence +/- obstructed defecation were compared with routine conservative management. Using micro costing over a very short time frame, transanal irrigation was more efficacious and slightly less expensive, but no QALYs were employed [97].

d) Consequences of Incontinence

The most frequently cited and most costly consequences of incontinence include admission to a nursing home or long-term care facility, and dermatitis. No study was found focusing solely on the effects of fecal incontinence, but many on the costs for urine incontinence and/or fecal incontinence. These results are described earlier.

VI. SUMMARY AND FUTURE RESEARCH PRIORITIES

In the four years since the last ICI consensus conference, several high quality economic analyses of stress incontinence treatments have been published. The Committee notes that evidence regarding cost

![Figure 9](image-url)
utility of outpatient therapies for stress incontinence remains very limited. However the economic analysis of therapy for overactive bladder syndrome requires greater effort, to encompass longer time frames and wider use of QALYs that can yield cost utility analysis (CUA). The Committee was disappointed to find that only 2 of the 64 currently registered clinical trials for OAB drug therapy included QALYs as an outcome measure.

In our previous Committee report, we provided a table giving international comparisons of the per annum expenditure from European countries, the USA and Australia, so as to provide a “global summary” of the costs of urinary incontinence. Similar data are here provided for OAB in our Table 8b [83], ranging from 200 – 1400 Billion Euros per annum. The data from Birnbaum et al [79] allow estimates to be made for per annum stress incontinence costs in the USA. However, no recent comparative studies have been published to allow us to give a global summary of all urinary incontinence costs at the present time. Indeed, with our increasing awareness of the human suffering costs arising from urinary fistulae in the developing nations, the Committee felt that it would be inappropriate to construct such a table that would include only patchy data from developed countries.

In the field of prolapse, it is not yet known whether any currently available QALYs are sensitive to treatment benefit, so that CUA may still not be feasible in this area. As regards faecal incontinence, research into Cost of Illness remains rather preliminary, so that broader more long term studies are needed. More data about Cost Utility in Faecal Incontinence is urgently needed.

The Committee commends the recent emergence of studies into the Burden of Disease for all continence conditions. The impact of both faecal and urinary incontinence upon costs in the nursing home or subacute care are becoming more fully understood but still require greater study.

As regards methodology, researchers need to consider carefully how they construct the model parameters for Decision Tree Analysis and Markov Models, so that “real life” assumptions are made. The gold standard remains Cost Utility Analysis in parallel with Randomized Controlled Trials, and we urge all clinicians to consider costs as an important outcome measure.

VII. APPENDIX – SEARCH STRATEGIES

We performed a comprehensive computerized medical literature search (PubMed) for the years 1966 through 2008 to identify all economic, health-related quality of life and cost-effectiveness analyses published on urinary incontinence, fecal incontinence or pelvic organ prolapse.

Our initial search strategy was very broad and meant to be very sensitive but not specific. We performed a search for the following Medical Subject Headings (MeSH) and keywords: cost-effectiveness analysis, health care costs, quality-adjusted life years, costs and cost analysis, sickness impact profile, or utilities and urinary incontinence, overactive bladder, fecal incontinence, anal incontinence, uterine prolapse or pelvic and prolapse. The initial searches were reviewed to identify articles appropriate for more detailed evaluation.

The literature was reviewed for studies describing costs associated with fecal incontinence. The costs for FI can be differentiated to costs for the disease of FI itself and for costs associated with the treatment of FI. Systematic searches of electronic databases were conducted, including National Library of Medicine (Medline), Cochrane economic evaluation database, Embase. The years included in the searches were 1970 – April 2008.

We combined the search terms (incontinen* AND (fecal or faec* or anus* or anal*)) or fecal incontinence [MeSH] with cost-effectiveness OR Health Care Costs [MeSH] OR “Costs and Cost Analysis [MeSH].

Inclusion criteria were: fecal incontinence as primary disease, data on costs available. Studies were excluded when they were a review, case-report or focused solely on urinary incontinence. 159 manuscripts were retrieved (Medline: n=70; Cochrane economic evaluation: n=82; Embase: n=7), of which 19 were duplicates.

The remaining 140 manuscripts were assessed for eligibility by reading title and abstract. This resulted in 24 potentially eligible citations. When full citations were obtained 19 studies could not be included. Two cost of illness studies, null on prevention studies, three on hospital cost studies and null on the consequences of incontinence

The International Consultation process focuses on exploring the current knowledge base in order to guide the clinical care of patients by using the highest possible degree of evidence. The assignment for this committee is slightly different. The charge is to define research methodology that will guide today's investigators in producing exceptional work—the kind of data that provides the convincing evidence needed to direct clinical practice, stimulates other investigators and generates new research ideas, and leads to a better understanding of physiology and pathophysiology of the disease(s) studied.

Urinary incontinence and lower urinary tract dysfunction comprise a group of common diseases, and far more knowledge of their origin, diagnosis, treatment and prevention is needed. Clinical research is a pre-condition for any progress in these areas. In this chapter the committee provides general recommendations for good research practice, including principles of clinical trial design and statistical methodology. In addition, specific recommendations applicable to types of treatments and studies of different groups of patients are presented. Other ICI committees report on the etiology, epidemiology, pathophysiology, prevention, and economic impact of lower urinary tract dysfunction. This chapter covers these areas only when appropriate and in minimal depth.

The Oxford Centre for Evidence-based Medicine Levels of Evidence and Grades of Recommendation (http://www.cebm.net/levels_of_evidence.asp) are difficult to apply to this section. This work differs from the clinical committees in that the findings are not based on clinical trials but rather on the statistical and mathematical science as well as expert opinion. In many cases the quality of the “evidence” is very high, even when based on expert opinion. Therefore, in order to comply with the spirit of the Consultation the recommendations in this report are graded as follows:

- **High**: Supported by strong evidence (multiple strong publications)
- **Medium**: Supported by moderate evidence (limited/moderate level publications)
- **Low**: Expert/Panel opinion

The report endorses published guidelines produced by the International Continence Society (ICS) [1-14, 193] and Society for Female Urology and Urodynamics (SUFU) [15-17]. Consistent use of the methodology and approved terminology endorsed by these groups will not only facilitate incontinence research by producing high quality studies but also facilitate communication about research.

The aim of clinical research is to evaluate potentially effective treatments that will significantly reduce symptoms of lower urinary tract dysfunction, and/or prevent them from occurring. The need for high quality research is similarly evident. The prevalence and impact of genitourinary disease coupled with an aging population observed in many countries will result in an increased demand for effective incontinence therapies.

At the same time, evidence about the etiology and risk factors for developing incontinence, the optimal treatment strategies, and effective prevention is deficient. The quality of research is of the utmost importance. While there is ample evidence that urinary incontinence is a troublesome disease resulting in reduced quality of life, investigators must compete for research funding against projects studying with heart disease, cancer, and many other life-threatening diseases. Only the highest quality work will be successful in today's competitive environment.

There are many goals of research—foremost to improve care of patients, but also to promote understanding of the disease process. We need a broad spectrum of information if we are to not only understand which treatments work but also why they work (or don't). The ultimate goal is to produce credible research. When research is inherently credible due to strong study design the impact is maximized. The clinical application of the research will be hastened and other investigators will be energized to use the information in their own quest for knowledge.
II. GENERAL RECOMMENDATIONS

1. THE PLANNING PHASE OF A CLINICAL STUDY ON INCONTINENCE

The planning stage of both prospective and retrospective studies requires the same deliberate approach. Having formulated a general research question, the investigator reviews previous and, if possible, ongoing work in the field to determine how the research question fits within the current body of knowledge in that area. A thorough knowledge of related clinical research is the cornerstone of protocol development. Care should be taken to identify studies that are well designed and clinically relevant. The research reviews provided by the Cochrane Incontinence Group (http://healthsci.otago.ac.nz/dsm/wch/obstetrics/cure) provide an excellent starting point for most major incontinence topics. This collection of carefully scrutinized data allows researchers to focus their research on key questions. Following the recommendations made by the Cochrane Group will help to ensure that future studies will be interpretable in the context of past work.

Based on a thorough literature review, the investigator clearly describes the primary research question(s), summarizes the background information, and formulates the rationale, objectives and hypotheses for the study.

A rule of thumb for all research is that one should ascertain the simplest study design which will provide the greatest likelihood of answering a given hypothesis or question. The study must attempt to provide a convincing answer to the question in a cost and time-efficient manner. In addition, it is ideal that clinical research be performed in concert with more basic investigations with the aim of discovering how a treatment works, not just whether it works. In terms of designing the study, this may be thought of a balance between breadth and depth [18]. Although the number of questions in a single study should be limited, it is still relevant to record as many as observations as is possible without jeopardizing recruitment or retention with onerous demands.

Once the concept of the study has been clearly defined, the search for an appropriate funding agency commences. The chance of a successful application increases when the investigator ensures that the application meets the mandate of the funding agency.

2. STUDY DESIGN

The type of study and other aspects of study design are the framework within which the study objectives are met. An initial decision must be made as to whether the study will be observational or experimental. Experimental studies are where the investigators control the process by which it is decided which treatment a participant should receive, while in observational studies the treatment decisions are not in any way influenced by the investigators and the research study. The strength of the scientific evidence arising from various experimental study designs are ranked as follows:

Strength of study design (ranked in descending order of strength)

a) Randomized controlled clinical trial(s)

1. DOUBLE-BLINDED: Neither the participants nor the investigators (in particular, those responsible for outcome assessment) know which subjects are receiving the active treatment while the study is in progress.

The randomized controlled trial (RCT) is the gold standard study design. The participants are assigned to a particular treatment group by a mechanism designed by the investigators and based on a chance allocation to the various treatments. Provided that adequate concealment is maintained, neither the patient nor the investigator can influence which group any particular participant will be assigned. This provides protection from allocation bias by the investigator and/or subjects. RCTs are expensive to conduct and can occasionally be ethically problematic. However, the central importance of the RCT in terms of influencing decisions about patient care should and will continue.

b) Non-randomized controlled clinical trial(s)

This category includes trials in which the basis for treatment allocation is known to the investigator prior to obtaining informed consent (for example, day of clinic appointment). A major shortcoming of this study design is that baseline characteristics of the treatment groups may be significantly different.

c) Case series

Case series are studies that describe the outcome when all subjects receive the treatment being investigated. This is the weakest study design, but researchers may have to resort to using this approach because it is the only practical approach, e.g., when they study rare diseases or when therapy becomes so established in the medical community that conducting a randomized clinical trial is not feasible. Because of an absence of an internal comparison or control group, a group external to the study must be used for comparison, raising questions about patient selection and comparability with other populations.

Properly planned and executed, the RCT is the optimal approach to limiting allocation bias [19]. RCTs compare outcomes in groups of subjects for whom treatment was allocated by chance. Using this approach,
treatment groups should not vary at time of randomization in any meaningful way thus minimizing potential bias in the characteristics of the treatment groups [20]. Subject assignment must be concealed during enrollment (for example, by separating allocation from the process of recruiting subjects, and by using remote randomization such as by telephone or web-based procedures), and wherever possible treatment allocation must be concealed during the trial (for example, using blinding with or without placebo). In some studies, blinding of subjects and health care providers may not be possible, for example in trials of some surgical procedures or health care delivery methods. In almost all cases, however, the personnel collecting outcome data should be blinded to the subjects' treatment allocation.

Observational studies include a variety of designs, from cross-sectional descriptive studies in which the primary purpose is estimation of the prevalence of incontinence in a defined population, to case-control studies and long-term prospective or retrospective cohort studies useful in studying rare diseases and identifying risk factors. Observational studies may be purely descriptive (case series), or they may be analytic when designed with a control or comparison group. Observational studies can contribute useful information on many aspects of health care [21], and may be necessary precursors to a randomized trial. Also, they may be the only source of information about the effect of natural events such as lifestyle changes in whole populations (for example the obesity epidemic). However, all comparisons based on observational data have a common limitation – the inability to ensure that one is comparing like with like. In particular, it is not possible, even with advanced statistical methods, to eliminate the bias resulting from the effects of the selection process, whether induced by the patient or clinician. Normally, RCTs are not subject to bias when comparing groups. However, external validity may be threatened through selection of participants for RCTs.

Although the classical RCT involves the study of parallel groups, other options are possible and may overcome some of the limitations of the classical approach [22]:

d) Parallel Trials

These designs offer one group of subjects the treatment under study, and a parallel group assigned to a placebo or some alternative treatment. In clinical trials of drug treatment the dose of the drug may be either held constant or varied to maximize clinical benefit and/or minimize side-effects. More complex study designs can in some circum-stances be worth considering – for example, factorial trials where two or more interventions can be investigated simultaneously [23, 24], and cluster randomized trials whereby groups of participants rather than individuals are randomly allocated to the trial arms [25]. This strategy might be employed when studying an intervention requiring policy changes in an institution, with a hospital, clinic, or health care system being the unit of randomization.

e) Crossover Trials

Subjects receive both the treatment being studied and the placebo/alternative treatment, with the order in which the treatments are received being randomly assigned. The benefit of crossover studies is that they eliminate the effect of variation between groups of participants seen in parallel trials, that is each subject serves as his/her own control. Crossover studies are particularly well suited for small studies, where the course of the disease under study is believed to be stable, and where the primary objective is to measure a short-term change in symptoms in response to treatment. The duration of treatment effect is critical in determining whether the crossover study design is appropriate – too long an effect, and the disease state may become unstable before the patient has completed all arms of the study; too short, and it may not be possible to detect the effect during the period of data collection. Carryover effects may occur, in which the results of the first treatment are prolonged and affect the results of the second treatment. To avoid this, a washout period should be planned, in which participants receive either placebo or no treatment. A run-in period in which signs and symptoms are monitored may be necessary before treatment commences to ensure that only those whose disease state is stable are included. Given these features and limitations, this design is unlikely to be widely applicable in studies of interventions for incontinence.

f) Equivalence/non-inferiority trials

The primary objective of an equivalence trial is to demonstrate that two treatments are similar in outcome or that there is no difference between treatment and controls. This design may be appropriate when one treatment is considerably more cost-effective, offers a better quality of life, or is less toxic or time consuming for the patient while producing a similar clinical outcome. The observed difference in outcome between two treatments should be clinically unimportant and be accompanied by a narrow confidence interval in order to state that two treatments actually are equivalent. For example, if separate studies indicated similar effects of pelvic floor exercises and a new drug in the treatment of stress incontinence, one might set up a study to demonstrate that no important difference in clinical effect was present between the two treatments by direct comparison. The study must have the statistical power to convince readers that there is no risk of type II error (which means that a study erroneously concludes that there is no difference between two groups). Such power depends heavily on the number of subjects in a study and must be calculated in the designing process, preferably by
help of statisticians. Clinically unimportant differences may be quite small, necessitating large sample sizes [26, 27]. The number needed in a particular study will depend on the outcome measure. An equivalence trial can be a powerful design when appropriately employed, and is not the same as failing to find a difference between two groups. Particular caution is required in applying these trials in the context of (especially pragmatic) trials where non-trivial proportions of participants switch from one intervention to another.

g) Drug trials are categorized according to the following definitions [26] [28].

- **Phase I studies**: The first studies of a drug in humans, often open label and uncontrolled, concentrating on safety and frequently but not exclusively carried out in healthy volunteers. Pharmacokinetic and tolerance information is obtained from Phase I trials.

- **Phase II studies**: The first attempts to investigate treatment efficacy, often the first use of the drug in subjects and focusing on short-term outcomes. A common objective of Phase II studies is dose finding in terms of efficacy. Two sub-types may usefully be distinguished: Phase IIA studies where single treatments are considered in relation to a minimum response prior to further investigation; Phase IIB where direct comparisons are made between interventions, albeit on a small scale and not necessarily involving randomization [29].

- **Phase III studies**: Large-scale, authoritative randomized studies performed once the most likely effective and tolerated treatment regimens have been established. The objective is often to establish that the intervention is suitable for registration/approval with the appropriate regulatory authority. Trials are conducted after submission of a new drug application (NDA), but before the product’s approval for market launch. Phase IIIB trials (between submission for approval and receipt of marketing authorization) may supplement or complete earlier trials, or seek different kinds of information (for example, quality of life or marketing). Phase III trials are also used to investigate the effectiveness and cost-effectiveness of various interventions – that is, non-drug including organizational issues – and not necessarily with reference to regulatory authorities. All Phase III trials should be subject to a formal sample size calculation – for instance to obtain sufficiently precise estimates of the comparisons between treatments or to have a reasonable chance (power) of detecting a difference if one exists (see section II C 7 below).

- **Phase IV studies**: These investigations are usually carried out after registration/approval, to investigate the drug’s safety and efficacy in different populations. Such post-marketing surveillance studies are typically larger and simpler than regulatory studies; they may lack a control group and are often conducted using surveys.

Precisely which study design to choose to answer a given primary research question depends on a number of factors, including the ability to recruit sufficient participants for a particular design (see Statistical Considerations, below), the natural history of the disease, the treatment itself, and patient outcomes. Patient-related outcomes may be short-term, such as changes in signs or symptoms, or longer-term, such as survival.

Once the sample size required to answer the primary research question has been calculated, it is usually obvious whether the study can be performed at a single institution, or whether a multicenter study will be required. Single institution studies have the benefit of being less complicated from a logistical perspective.

While multicenter trials are more complex to manage and are usually more expensive, they provide larger numbers of participants in a shorter period of time, and increase the generalizability of research findings.

Common mistakes that can occur during the planning and conduct of a study are described in Table 1.

3. STUDY CONDUCT AND STATISTICAL CONSIDERATIONS

The planning for a research study must begin early. All issues should be addressed at the start of the planning process, and many will need to be revisited at suitable times throughout the project. Many of these issues are statistical; indeed, the major statistical input to a study should be at the design stage, including planning the data analysis in advance to follow the design of the study.

The issues covered here relate to: study design; sampling strategies; randomization and stratification; primary and secondary outcomes; inclusion and exclusion criteria; blinding and effects on validity; control of bias; sample size considerations; pragmatic and explanatory trials; data analysis; and reporting of randomized controlled trials (RCTs). Only the principal features of study design and analysis will be covered here; extensive coverage is available elsewhere [27, 28, 29, 30, 31].

Regarding presentation, as part of the "Enhancing the QUALity and Transparency Of health Research" (EQUATOR) Network project a website was developed at www.equator-network.org. On the website, the Consolidated Standards of Reporting Trials (CONSORT) statement provides guidelines for reporting the design, detailed methods, and results of RCTs. Many of the points discussed here relate to those guidelines, which should be closely followed throughout the design, conduct, analysis and presentation of RCTs as is required by most leading medical journals [34]. Of note, prior to participant enrollment, the International Committee of Medical
**Table 1. Common pitfalls in preparing and writing protocols (from Spilker 1984)**

<table>
<thead>
<tr>
<th>Category</th>
<th>Pitfalls</th>
</tr>

</table>
| **A. Study objectives**            | 1. Expressed too generally to allow a specific study design to be constituted  
2. Ambiguous or vague  
3. Not achievable with the current study design. The study may be too complex or there may be inadequate resources to conduct the study |
| **B. Study design**                | 1. Insufficient statistical planning—the design will not adequately address study objectives  
2. The design chosen is beyond current state of the art  
3. Inadequate validation of outcome measures  
4. Inadequate statistical power. The chosen sample size is too small to detect clinically meaningful differences  
5. Inappropriate use of active or inactive controls  
6. Lack of placebo or double blind when one or both should be incorporated  
7. Dose regimen too restrictive (e.g., range of allowed doses, alterations of dosing for adverse reactions)  
8. Failure to consult with statistician regarding randomization process |
| **C. Inclusion/exclusion criteria**| 1. Too stringent to allow adequate numbers of subjects to be enrolled. Overly stringent criteria also reduce the generalizability and thus the impact of research  
2. Too broad to create homogenous groups. |
| **D. Screen/baseline/treatment**   | 1. Time periods for data collection are either too long or too short for optimal conduct of the study  
2. Too few or too many measurements are requested  
3. Subjects may be inappropriately entered into the study before complete screening  
4. Excessive blood volume removed for testing or an excessive period of fasting is required. This is especially common in pharmacokinetic studies |
| **E. Drug packaging/dispensing**   | 1. Drug packaging that does not permit all options allowed by protocol to be followed |
| **F. Study blind**                 | 1. Study blind easily broken because of "obvious" characteristics (e.g., adverse reactions, changes in laboratory parameters, drug odor) that are difficult or impossible to adequately mask  
2. Study blind easily broken by observation of drug interactions or other situations by the investigator (e.g., marked improvement in study group or changes in blood levels of concomitant drugs)  
3. Study blind inappropriate |
| **G. Data collection and analysis**| 1. Poorly designed data collection forms  
2. Incorrect statistical methods used to analyze data, including baseline comparisons  
3. Failure to make the primary research question the main focus of the analysis  
4. Reliance on within group rather than between group comparisons in parallel group trials  
5. Overreliance on p-values without presenting confidence intervals |
| **H. Overall**                     | 1. Ambiguous language that allows different interpretations  
2. Too many comparisons requested. Five of every 100 independent comparisons will be statistically significant by chance alone, when alpha is 5% and there are no true differences between the comparison groups.  
3. Lack of internal consistency in the protocol  
4. Discretionary judgments allowed by the investigator. This may seriously affect the quality and quantity of data obtained  
5. Presentation/reporting fails to accord with CONSORT guidelines |
Journal Editors (ICMJE) recommends information about trial design be placed into an accepted clinical trials registry [35]. For studies of diagnostic tests the Standards for Reporting of Diagnostic Accuracy (STARD) [36] statement fills the same role and information is also included on the EQUATOR website. Guidelines for reporting meta-analyses are described by the Quality of Reporting of Meta-analyses (QUORUM-37) and Epidemiologic research reporting guidelines are contained in STROBE, Strengthen the Reporting of Observational Studies in Epidemiology (38). There is little doubt that the quality of all medical literature, including incontinence research, would be markedly improved if authors simply follow the recommendations of these texts.

**a) Sampling strategies**

Whether a study is analytic or descriptive (that is, whether or not a comparison is involved), the first practical issue to resolve is the selection of participants. A study may require a sample that is representative of the community overall or one representative of patient groups suffering the condition/disease. In principle, this is achieved by taking a simple random sample from a known population. In practice, a list of all eligible individuals is obtained and then a sample is drawn by a method in which each member of the population has an equal probability of selection (‘epsem’). Even in ideal circumstances, however, some sophistication on this basic method is usually desirable or necessary. For example, in stratified sampling, subjects are arranged into subgroups and the sampling is performed within each subgroup separately. This ensures that the sample is representative of the population in terms of these subgroup characteristics. In multi-stage random sampling, the population is first divided into ‘primary sampling units’ (such as hospital, health center, or surgeon), and a sample of primary units is selected. The ‘secondary sampling units’ (usually individual subjects) are then selected just within the primary sampling units that have been selected. A special case of multi-stage random sampling is cluster sampling where all individuals within each primary unit are included. Standard procedures for sampling should be followed [25,39].

It is important to note that, while the technicalities of random selection of subjects for a study are closely related to the random allocation of subjects in an RCT (and indeed there are similar issues in trials relating to stratification and clustering) [25], there is an important distinction in the objectives of the two procedures. First, the (ideally random) selection from the population of eligible subjects concerns the external validity or generalizability of the study findings (RCT or otherwise). Independent of this, the random allocation of subjects in an RCT is concerned with the internal validity or comparability of the trial groups.

In principle, sampling should involve random selection. In practice, however, this ideal is rarely met outside of large-scale epidemiological studies. Rather, RCTs are drawn from a subset of the population, often limited to those with access to academic medical centers plus the willingness and ability to participate. Where this is the case, it is crucial to provide descriptive information about the study sample, so that its representativeness can be judged. Guidelines for reporting of RCTs include requirements to state the study population, give details of inclusion and exclusion criteria, and present clearly the numbers of eligible subjects who were not randomized and the reasons [33, 34, 40]. Nevertheless, “the basic logic of clinical trials is comparative and not representative” [26]. In other words, the principal benefit of conducting a randomized trial is to provide groups that allow valid comparisons of the effect of the interventions.

**b) Randomization and stratification**

Randomization is the process of allocating subjects to groups by chance [19, 20]. Neither the subject nor the clinical staff responsible for recruitment to the trial should be able to predict to which group the subject will be assigned. Randomization removes treatment selection from the hands of the clinician thereby minimizing bias.

In order to minimize bias, the randomization process must be concealed from those recruiting subjects to the trial [33, 40]. This can be achieved most effectively by the use of central telephone randomization. In drug studies, a pharmacy can maintain identical treatment and placebo already randomly allocated into individual subject portions. These are distributed consecutively as subjects are enrolled in the study.

- **Simple randomization** can use computer-generated random numbers, either prepared specifically for the trial or using existing tables of random numbers where the digits of 0-9 appear with equal likelihood in each entry. Treatments are assigned to odd or even numbers. As the total number of subjects in the trial increases, the balance of numbers and characteristics of subjects between the groups improves. In small trials, however, balance is not assured by simple randomization. Appreciable imbalances in subjects per group may be particularly important in a multicenter study where imbalances in assignment can occur within individual institutions.

- **Block randomization** is one method used to prevent imbalances in subject numbers assigned to each group, particularly when the number of subjects in the trial is small. With block randomization, the total sample size is divided into blocks of a given size. Within each block, the group is assigned so that there are equal numbers allocated to each group. To prevent investigators from learning the block size and being able to guess order of assignment, the block size can be varied, usually at random from a small number of
alternatives. In any case, blocking prevents serious imbalances in characteristics across groups when used in conjunction with stratification as described below.

Most disease states have factors known to influence the outcome of treatment, for example, pre-and post-menopausal or male and female. A form of randomization that accounts for such factors is called *stratified randomization* [19, 20]. Stratified randomization ensures equal distribution of subjects with a particular characteristic in each group when blocking is employed within strata. Stratification is usually restricted to a small number of factors, in particular those most likely to influence outcome. Despite its complexity, stratified randomization is usually helpful in a multicenter trial, so that both the numbers of subjects in each group and the important factors influencing the outcome can be balanced within each site. An alternative method exists to cater for more factors at once, known as *minimization*, where the characteristics of individuals already randomized alter in a systematic manner the chances of a given subject being allocated to the different trial groups, so as to maximize the resulting balance of these factors [19, 20, 39].

c) Primary and secondary outcomes

Specific discussions of the most appropriate outcome measures for particular studies of incontinence will be dealt with elsewhere in this book; the purpose here is to define the general concepts of primary and secondary outcomes in the context of RCTs, which are relevant to both sample size determination and data analysis. The distinction between these two sets of outcomes depends on the context of the trial, and should be decided at the planning stage of the study. Primary and secondary outcomes should not be confused with the distinction between primary and secondary analyses of trial data, which will be discussed later. Primary outcomes are those viewed by the researchers to be of central interest. Trial results that lead to major changes in patient care will be based on primary outcomes.

The number of primary outcomes in a particular trial will depend on the nature of the interventions and the number of independent domains. The number of primary outcomes is usually limited to three, and rarely will there be reasonable justification for more than six. Sample size calculation is based on the primary outcomes and is unlikely to be based on more than two outcome measures. The number and nature of outcome domains in a particular study will vary depending on the study’s perspective (e.g., those of participants, clinicians, regulatory bodies, and health care purchasers). In almost all situations, the outcome set should include both a dimension representing the viewpoint of the patient (including symptom frequency, severity, and quality of life) as well as an appropriate objective clinical outcome measure. Secondary outcomes are the remaining outcome measures and could be relatively large in number. They are not the focus of the main study objectives and are rarely used directly in sample size estimation. Secondary outcomes are often subject to the dangers of multiple hypothesis testing, for which suitable statistical corrections should be considered as described below. Analyses of secondary outcomes are best viewed as exploratory, i.e., as hypothesis-generating exercises for which independent confirmation is essential. The ideal outcome for incontinence research has yet to be determined and is beyond the scope of this committee. However, there is a growing recognition that combined or composite outcomes may be the optimal. An early example of such an outcome is the SEAPI scale [40] which includes subjective and objective assessments of Stress leakage, Emptying ability, Anatomic support, use of Protection for incontinence, and Inhibition (problems with urge). Each item is scored 0-3 (none, mild, moderate, or severe). The recent SISTEr trial from the Urinary Incontinence Treatment Network [41] used a five item global outcome measure (no self-reported symptoms of urinary incontinence, <15gm urine loss on 24 hour home pad test, no reported incontinence episodes on a 3 day diary, a negative stress test at a standardized volume of 300cc, and no retreatment for urinary incontinence). The group also reported a stress-specific outcome using three items that only measure stress incontinence (no self-reported symptoms of stress urinary incontinence, a negative stress test at a standardized volume of 300cc, and no retreatment for stress urinary incontinence). Such composite outcomes naturally produce much lower “cure” rates but may provide much greater understanding of what the patient actually experiences.

d) Inclusion and exclusion criteria

Inclusion and exclusion criteria should provide a relevant population to address the study question, and together define the heterogeneity or homogeneity of the study population. The most important inclusion criterion is how the disease in question is defined. Eligibility criteria are critical to both the interpretation of the study and its reproducibility. If possible, established international criteria for the presence and severity of disease should be used. Broadening the inclusion criteria can make a study more generalizable and facilitate recruitment. Making the entry criteria too broad, however, may dilute the effect being sought in the most suitable subjects. If the study population is defined too narrowly with many exclusion criteria, applicability of the results may be limited and subject recruitment may be difficult.

Inclusion criteria govern what patient characteristics are required for eligibility to enter the study. Some exclusion criteria such as age, weight and gender are determined implicitly by corresponding inclusion parameters. Issues of patient safety determine other
exclusion criteria (e.g., avoiding nephrotoxic drugs in subjects with renal insufficiency). All criteria should be defined precisely enough to allow the study to be reproduced by other groups of researchers.

e) Informed consent

Peer review of protocols by a multidisciplinary team may include members of the scientific community, clinicians, pharmacists, the public/patient groups, the legal profession and individuals who can provide an ethical perspective. Each member of this team reviews the protocol from their particular type of expertise and in doing so aids in safeguarding patient health and well-being.

Informed patient consent is required for participation. The length and depth of detail in consent forms vary widely between institutions. In the extreme, they involve exhaustive pages of information, which explain every alternative treatment with its pros and cons in detail. A general list of requirements for a consent form includes: name of the investigators and contact numbers, a detailed description of the new treatment and its known side effects, rationale for why the new therapy may be preferred to standard therapy. A summary table of the results of previous studies using the drug can be helpful when available. A statement that the patient may decline to be in the study with no subsequent consequence to their ongoing medical care is generally provided and whether or not remuneration is expected. Additionally, there should be a statement about payment for medical care required during the course of the study if there is an adverse event associated with the intervention. An understanding that the patient will be randomly assigned to treatment should be included, written using terms that are meaningful to potential participants. [42, 43].

f) Data Safety Monitoring Board (DSMB)

An independent (of the study sponsor) review or oversight committee, typically called a Data and Safety Monitoring Board, should be established prior to initiation of the trial. In addition to reviewing results of the study for safety monitoring they may evaluate interim analyses to ensure that a treatment is not producing unacceptable levels of side effects and/or efficacy [43; 44]. Guidelines for stopping the study should be agreed upon, prior to the start of the trial. It is important to note that interim analyses (in particular those based on efficacy) will have implications for the study power – specifically, a larger sample size will be required eventually to achieve the same power/precision compared with if such analyses are not conducted (see section II 3h below). Specialist statistical advice and support will be essential to address these issues [46-48]. It might be argued that subject safety may not be properly ensured unless the monitoring committee knows which arm of the study is the treatment and which is the control (placebo). For the same reasons, clinical staff may not feel comfortable participating in such a study, and so an important role for the DMSC is to provide implicit reassurance on this point. Investigators should not be aware of the results of interim analyses, however, since this may cause bias by influencing how vigorously any given patient is recruited into or followed up in the study. Nevertheless, emergency procedures for unblinding a patient’s allocation are required in case of a severe side effect or concomitant serious illness where knowledge of treatment assignment is essential for patient management and safety.

g) Bias, blinding and effects on validity

Bias can be introduced at many stages of an RCT including patient selection, randomization, assessment of outcomes, and statistical analysis and interpretation. Bias occurs because of previously conceived ideas held by those involved, which consciously or unconsciously affect their actions and observations. In addition to observer bias, an amount of observer error is inherent in outcome measures that require clinical interpretation. To avoid or limit bias, blinding should be employed whenever possible, with concealment of allocation and blinding of outcome assessors being the most important. Blinding is the process by which key elements of knowledge are withheld that can otherwise lead to bias. Blinding should not be confused with concealment of allocation, referring to withholding knowledge of assignment in advance, which is a prerequisite for the validity of any trial [33, 49]. While blinding is important its effect is lower than that of concealment of allocation [50].

Unblinded trials are conducted in an open manner where both subjects and study investigators are aware of which treatment has been assigned. While certain types of therapy may require investigation in this manner (e.g., some surgical trials), there remains considerable opportunity for bias. Both subjects and investigators may have preconceived ideas regarding the benefits of a particular treatment that can influence the reporting of symptoms and/or their outcome.

In a single blind trial, the subject is blinded to treatment assignment. It may be advantageous for the clinical staff to be aware of the assignment to allow them to monitor the health and safety of individuals, since the potential effects of the treatment (side effects) will often be known in advance. Single blinding ameliorates biased reporting of symptoms and/or side effects by subjects. However, clinical staff can influence data collection and change other aspects of subjects’ care when they know which study treatment subjects are receiving.

In double blind trials, both parties who could influence outcome are unaware of group assignment. Often this is just the subjects and the clinical team
responsible for their care. More generally, the term double blind relates to the participants and the research personnel responsible for the measurement and assessment of outcome [20, 33]. While this reduces potential sources of bias considerably compared with unblinded or single blind trials, it does introduce other levels of complexity. For example, safety monitoring must be performed by a third party.

**Triple blind trials** include blinding of subjects, outcome assessors, and those involved in the final data analysis. This may be justifiable for the primary analysis of trial data, but at some point in the proceedings there is often a strong case for unblinding the data analyst. For example, another opportunity for bias occurs if an appreciable number of subjects drop out or withdraw from a study. Such attrition can be particularly problematic if it is related to group assignment and if it unequally affects one arm of a parallel group design. In this scenario, both the monitoring team and the trial data analyst must carefully consider the reasons for subject withdrawals, which may well necessitate unblinding in the final analysis.

In summary, research design should strive for the highest practical level of blinding. In most drug studies placebo pills are easily manufactured and complete blinding of all relevant participants is practical. In contrast, it is rarely possible to blind the clinician in surgical, device and physiotherapy/behavioral therapy trials. Here the effort should be focused on blinding the participant to the greatest degree feasible and to complete blinding of the evaluator.

**h) Sample size considerations**

Sample size should be calculated in the planning stage of all studies. There are many formal equations to assist in this process, details of which will not be given here [29, 51-53]. Rather, the emphasis for this discussion is on the concepts involved and the information required for the calculations to proceed. Determination of sample size is not an exact science. Many decisions about design and analysis are interrelated with specifications for sample size, and there is no single solution.

There are three fundamental approaches to sample size calculation. One is based on the required precision of an estimate. The second requires that the study have adequate probability (power) of detecting a given (target) magnitude of effect. The third aims to demonstrate non-inferiority between treatment groups.

The first of these approaches is relevant to both descriptive and analytical investigations. The basic issue is one of precision (measured by the standard error, SE) or margin of error (which depends on the SE but is more specifically defined as half the width of the 95% confidence interval [CI] around the estimate). The higher the level of precision specified in advance (i.e., the smaller the SE and the narrower the CI), the larger the sample size will need to be. However, the margin of error depends on the nature of the primary outcome variable, i.e., whether it is a continuous variable (such as maximum urinary flow rate) or a binary variable (such as the presence or absence of self-reported urgency incontinence). For a continuous variable, the variability (standard deviation) of the measure must be estimated for relevant subjects; this may be derived from some combination of clinical experience, the literature, or a pilot study. The larger the variability, the larger the sample size required. For a binary variable, its prevalence must be estimated in the population to be studied, since the SE for such variables depends on their prevalence.

The second approach, based on power, is the most commonly used. It requires similar prior information, including estimates of the variability for continuous measures and the magnitude of proportions for binary variables. In addition, it requires specification of three other quantities: the **significance level**, the **power**, and the **target difference**. Significance is a statistical term that tells how certain one can be that a difference or relationship exists. It does not necessarily imply that the result is clinically relevant, just that the result is likely to be accurate. The significance level, termed alpha, is conventionally, though not necessarily, set at 5%. Power is defined as the probability that the study will detect (as statistically significant at the alpha level specified) a given target difference between the groups, if such a difference exists. Power is commonly specified in the range of 80% to 90%, which implies a risk of not detecting the target difference of between 20% and 10%, respectively. For a trial involving anything other than minor risks and expenditure, a power closer to 90% than 80% would seem preferable [27], which leads to a larger sample size (as does a stricter alpha level of, say, 1%). This is most pertinent when a lack of statistical significance is obtained in a small trial, particularly when the sample size was not planned using a power calculation [20]. This is the basis for the adage that “the absence of evidence is not evidence of absence” [26]. A planned unequal allocation to the trial groups also requires an inflation of the sample size [20], as does interim analyses. By multiplying the number of significance tests performed, studies with interim analyses generally require stricter significance levels at each analytical point [26, 54].

The **target difference** is the last, and arguably the most important, quantity that must be specified for the power-based approach to sample size calculation. The target difference is defined as the minimum difference between treatment groups considered to be clinically significant. Clinical significance is an entirely different concept from statistical significance. Investigators must estimate the clinical significance as the magnitude of difference (in means or pro-
portions) that would lead to a change in clinical management for the target group of patients. For example, a study might propose that a 20% difference in incontinence episode frequency is a clinically meaningful response. Ideally, such an assumption would be based on surveys of patient behavior but in practice, the decision is often based on clinical judgement. In any case, the smaller the clinically significant target difference, the larger the required sample size. Statistical significance means that the observed difference, whatever its magnitude, cannot reasonably be considered as being due to chance. Statistical significance (denoted by the p-value) represents the strength of evidence against the null hypothesis [55]. The degree of clinical significance can be inferred only with the additional information of a confidence interval for the comparison between groups. A very large trial may achieve a high level of statistical significance with a very small effect size and therefore be of little clinical significance. A trial designed in such a way is ethically challenged; many extra subjects are exposed to risk without meaningful benefit.

The third general approach aims to demonstrate non-inferiority between the treatment under evaluation compared to another treatment or standard therapy. [56; 57]. The same specifications are made as in the power-based approach, except that instead of specifying a particular target difference to be detected, the calculation is centered on the magnitude of difference beyond which the researchers would no longer accept that the treatments are ‘equivalent’. The study is designed to have adequate power to produce a confidence interval for the difference between the groups that does not include values greater than this limit.

There is no single answer for sample size determination; often the calculation proceeds around a ‘circle of specifications’ (involving, say, power, target difference and sample size) many times, starting and stopping at different points. For instance, it is not uncommon to commence with the ‘textbook’ approach of specifying power and target difference (along with alpha and the standard deviation) and calculating the sample size, then to reverse the argument by starting with how many subjects could be recruited and determining what differences could be detected with various probabilities! Furthermore, the ideal of the target being the minimum for clinical significance cannot always be met; rather, the aim in practice is to produce a convincing argument (among the researchers themselves, and also to funding bodies and regulatory agencies) that the sample size has an adequate chance of detecting differences that are (a) feasible, and (b) worthwhile detecting in clinical terms. A common failing is selecting a target difference that is too large, often derived from differences that have been observed or published previously rather than based on considered clinical judgment. Preliminary investigations (often termed ‘elicitation exercises’) into the levels of treatment effects that patients themselves consider worthwhile should be carried out much more commonly than is the case at present.

In all cases, appropriate adjustment for attrition (loss to follow-up) should be performed. This is commonly achieved by simply increasing the planned sample size in proportion to the anticipated attrition (i.e. to predict the reduced effective sample size that will be available for the analysis).

1) Pragmatic and explanatory trials

There is an important distinction between pragmatic and explanatory trials [58, 59], and correspondingly, between intention-to-treat and per-protocol approaches to data analysis [26, 52]. This distinction has a number of facets. For example, data from pragmatic trials are analyzed by intention-to-treat, according to the group to which subjects were randomized, regardless of the extent of compliance with the intended treatment. In explanatory trials, data are analyzed accounting for compliance. This per-protocol approach may exclude serious non-compliers, analyze data according to treatment actually received, or allow for degree of compliance in a statistical model. At first sight, the explanatory approach appears more attractive. However, there are considerable limitations to the explanatory approach, particularly when the intention is to draw inferences from the trial to wider clinical practice (generalizability).

The purpose of randomization is to produce groups that are, on average, comparable. A per-protocol analysis retains this property only in the unlikely situation when non-compliance is unrelated both to the patient’s underlying state of health and the treatment received [26]. The intention-to-treat approach in pragmatic trials retains the full benefits of randomization and has the advantage that the comparison will more closely reflect the relative effectiveness of the treatments when applied in real clinical practice, where non-compliance is a common occurrence [60].

As regards other aspects of the distinction, in pragmatic trials the interventions are designed to be as close as possible to treatment options in clinical practice (including multiple patient management choices) and entry criteria are usually relatively liberal in comparison with explanatory trials. In addition, pragmatic trials may involve a wide variety of outcome domains, including patient-completed questionnaires, and an economic evaluation of outcomes. As a result of intention-to-treat data analysis, pragmatic trials will tend to yield lower estimates of treatment differences than explanatory trials. It may be of interest to gauge the effect of treatment given full compliance; therefore, full data analysis ideally incorporates both intention-to-treat and per-protocol approaches [26]. The primary
analysis, though, should follow the intention-to-treat principle.

The follow-up time for a trial should be at a fixed time (for logistical reasons, this is in practice often a short time window) relative to randomization rather than when treatment was actually received, since again this is the only way of ensuring a valid comparison. The planned timing of follow-up at a fixed time relative to randomization should, however, allow for any likely delays in receiving treatment, e.g., due to surgical waiting lists.

In summary, it is established practice that unless there are strong reasons to the contrary the primary analyses (for both primary and secondary outcomes) of an RCT should be on an intention-to-treat basis [33, 49]. Secondary analyses incorporating non-compliance and/or which treatment was actually received may be justified in addition to the primary analyses. Appreciable loss to follow-up in a trial (which is not the same as non-compliance with intended treatment, lack of efficacy, or the observation of adverse events) may present serious problems both in terms of generalizability of the findings to the wider population and, in the case of differential loss to follow-up across treatment groups, to the validity of the comparisons. Indeed, strictly speaking any missing outcome data means that not all of those allocated to the various randomization groups can be included in the analysis [61], and this might lead to the conclusion that the term ‘intention-to-treat’ should only be used if follow-up is complete. In practice complete follow-up occurs only rarely. Under current guidelines, intention-to-treat relates more to the broad strategy adopted by the researchers for data analysis [46; 62]. Results should always be accompanied by a full and clear statement of how deviations from intended treatment and missing outcome measures have been handled in the analysis. The discussion should include how missing outcome data may have affected the conclusions [61]. Sensitivity analyses can be used to test the exclusion of, or assumptions about, missing values; practical examples of such analyses are becoming more common [63]. Another design strategy, modified intent to treat (MITT), is common in drug trials. It requires the participant to take at least a single dose of the study medication in order to be included in the analysis.

**j) Data analysis**

This section will not contain any technical details of statistical methods, which are available in standard texts [20, 64, 65], but rather will summarize concepts of data analysis. The emphasis here will be on RCTs, although many of the complex methods mentioned (e.g., multiple logistic regression analysis) are used in similar ways to analyze observational data. Appropriate techniques of data analysis will depend on the nature of the outcome variable. In practically all situations, hypothesis tests should be two-sided (i.e., allowing for the possibility that the difference could have been in either direction, that is benefit or harm), rather than one-sided. One-sided tests are only appropriate if a difference in one direction is not just unlikely, but would not be of interest.

Regardless of the type and complexity of statistical techniques used in analysis, the general underlying principles behind hypothesis testing and estimation apply. In particular, the statistical significance of a hypothesis test should be interpreted critically. The actual p-value should be considered, rather than just whether or not it is below an arbitrary threshold such as 5% [33]; indeed, the p-value is better considered a measure of the strength of evidence against the null hypothesis, on a continuum or ‘shades-of-grey’ [65, 66]. The direction and magnitude of the trial comparison should be presented with an appropriate confidence interval to indicate the possible clinical significance and precision of the comparison [67, 33].

Data analysis for numerical outcome variables may use parametric or non-parametric methods. Simple parametric methods require that the data follow a normal or Gaussian distribution, while non-parametric methods do not have this requirement. Strictly speaking, the distributional assumption relates not to the raw data but to what are termed ‘residuals’—that is, the outcome variable after the effects of, for example, the treatment effects and baseline variation have been accounted for. For example, consider a comparison of mean urinary flow rates between two groups of men reporting that they either have or have not experienced a urinary symptom such as incomplete emptying of the bladder. If this comparison involved an unpaired t-test then the assumption of a normal distribution relates not to the urinary flow rates amongst all men, but to the distributions within each symptom group separately. As noted above, to cover simple and more complex analyses, in general this concept relates to the statistical residuals from the relevant regression model. In addition, parametric methods are extremely robust (dependent on the assumption of a normal distribution) since they relate to the mean value rather than individual values.

Parametric methods of testing mean values include t-tests, confidence intervals for differences between group means, and analysis of variance. Regression techniques address more advanced issues such as stratification in randomization and allowance for baseline measures. Non-parametric methods include the Mann-Whitney test to compare two independent samples as in a parallel groups trial and the Wilcoxon matched-pairs signed-ranks test for paired data such as from a crossover trial [22]. Binary outcome variables can be analyzed using chi-square tests and confidence intervals for comparing proportions, and multiple logistic regression [68]. For time-to-event data (such as survival data), methods of data analysis include:
life tables, Kaplan-Meier survival curves, log rank tests, and Cox’s proportional hazards regression [69]. How, then, should the analysis of data from an RCT proceed? An outline of the various stages of data analysis can be gleaned from the CONSORT statement [33, 49], and it is now considered good practice for the trial team to draw up a detailed analysis plan in advance for approval by the Trial Steering Committee, which includes independent members one of whom is a statistician/trials methodologist. The following discussion will concentrate on the underlying concepts of data analysis at a particular follow-up time relative to randomization, and considers initially the simplest case of just two trial groups. Multiple treatment groups will be covered briefly, but repeated measurements of outcomes and interim analyses involve considerably more complex methods of planning and analysis, for which expert help is essential [29, 70].

The first stage of data analysis is to address the representativeness of randomized subjects compared to the target population of eligible patients. The number of eligible patients who were and were not randomized should be provided, along with reasons for the latter. In order to reflect representativeness accurately, this should include all eligible patients: in practice there is a tendency for researchers to avoid approaching certain potentially eligible patients, for any of a wide variety of reasons, and this induces a subtle investigator bias. The presentation of this information is facilitated by use of the CONSORT flow diagram [33, 49] (Figure 1)—indeed, its use is associated with improved quality of reporting of trials generally [34]. Descriptive statistics should also be given of important characteristics of health care professionals approached for involvement in recruiting subjects to the trial, both for those taking part and those declining.

The second stage of data analysis is to compare the two groups at randomization (baseline) including demographic, prognostic, and outcome variables. A common error at this point is to rely on statistical testing for these comparisons [20, 26, 52]. If the randomization procedure has been performed correctly, then any statistically significant differences in baseline characteristics must be due to chance. Statistical testing of this kind is not a test of the comparability of trial groups; rather, it is a test of the allocation procedure [20, 26, 52]. It may be seriously misleading, particularly if lack of a statistically significant difference for a given characteristic is taken to imply comparability. Trials are not designed to detect potentially important differences in baseline characteristics that might be large enough to influence the comparison of the outcomes between the trial groups. The magnitude of this potentially influential difference for a baseline measure depends on the strength of its relationship with the outcome, and not on a p-value at randomization. Therefore, baseline comparability is best assessed by simply obtaining descriptive statistics for the groups and making a judgment as to whether any observed differences are likely to be influential or not. If differences are likely to be influential, they should be considered in the analyses. Notable exceptions to this are baseline measures of the outcome variables, which should be considered in the analysis regardless of the situation at baseline, since removing variance in the outcome measure that is purely attributable to differences between individuals at baseline has potentially marked benefits in terms of precision and power [26]. Investigators should consider stratifying the randomization on any strongly prognostic variable (for
reasons of efficiency rather than bias). Since there are practical limitations as to how many variables a trial can stratify for, as indicated above in section C.2, a technique known as minimization may also be considered [39, 19, 26]. Any variables stratified or minimized at randomization should be allowed for in the analysis [26]. In incontinence research, variables such as prior failure of therapy in drug and surgical studies or the degree of anatomic support in surgical or injectable trials might be considered important enough to stratify, or to include in the analysis if unequally distributed.

The next stage of data analysis is to perform the primary (comparative) analyses for the outcome variables. First, though, it is essential to derive and report actual numeric data – even if simply in the form of descriptive statistics – rather than just reporting for instance a percentage change, even if the latter are relevant and provided as well. Graphs can be misleading, especially when sub-sections of the scales are magnified, and should be used to supplement or clarify the numerical data, not to replace it. Primary outcomes should initially be analyzed by intention-to-treat comparisons of the groups as randomized, both using hypothesis tests for statistical significance and CIs for comparisons between the groups to assess clinical and statistical significance, usually adjusting for baseline measurements of the outcome variable. With a small number of primary outcomes, multiple testing is not a concern. However, when a large number of statistical tests are performed for secondary outcomes, corrections to the observed p-values should at least be considered.

The most commonly used procedure for multiple testing of many outcomes is the Bonferroni correction [20, 26, 64]. The Bonferroni correction is fairly conservative in reducing the risk of a statistically significant effect occurring purely by chance, at the cost of reduced power for individual outcomes. This is particularly pertinent when, as is usually the case, the outcomes are positively associated with one another. While there are alternative procedures that improve this deficiency, none of them are entirely satisfactory [26]. It is emphasized that whatever strategy is adopted to deal with multiple testing, the major errors are to rely solely on p-values rather than present CIs as well, to over-simplify the presentation of p-values to just “NS” or “p<0.05” rather than to quote the actual p-values, and above all to report selectively the results of significance tests.

Another example of a “multiplicity” is where there are more than two treatment groups, e.g., when different doses of a drug are being investigated or when more than one ‘active’ procedure is being compared with placebo [26]. Similar issues to multiple testing of different outcomes are involved here, but there are a greater variety of commonly used procedures available to deal with the central concern of finding a difference purely by chance. Standard methods for dealing with this multiple comparisons problem include the procedures attributed to Tukey, Newman-Keuls and Dunnett [71].

More complex primary analyses adjust for baseline measurements and potentially important prognostic variables (including but not exclusively those that were unbalanced at randomization). They may also involve adjustments for center effects and the investigation of differential treatment effects across centers in multi-center trials [27]. The correct approach for continuous outcome variables is to use the (regression-based) technique known as the analysis of covariance [26, 52]; the equivalent approach for binary outcomes is to use logistic regression. A commonly employed alternative for continuous outcome variables is to analyze simple change scores from baseline to follow-up (either in absolute or percentage terms), but for reasons of both bias and precision this is inferior to regression methods [26, 52]. It is good practice to present both the (unadjusted) simple intention-to-treat results alongside those from the regression methods. In any case, the results from alternative analyses such as these should be compared in a sensitivity analysis of the conclusions [27].

Secondary analyses of trial data include per-protocol analyses with adjustments using regression methods for pertinent process measures such as degree of compliance with the allocated treatments. Secondary analyses also include planned subgroup analyses, such as the investigation of different intervention effects across age, ethnic, or disease severity groups. Subgroups should be analyzed by using appropriate interaction terms in regression models [33, 52]. Using interaction terms rather than performing repeated, separate, subgroup-specific analyses considerably reduces the risk of false positive findings [72, 73]. Subgroup analyses should be carried out sparingly, specified in advance (preferably with a clinical rationale), and above all should not be reported selectively [33, 72, 74]. This last point relates not just to subgroup analyses but to all stages of reporting randomized trials. Pre-specification of the primary outcomes and clear statements about all the outcomes considered is essential to avoid selective reporting. The large volumes of data accumulated in major multicenter RCTs almost guarantee that something “significant” can be identified by “data-mining”. If not identified by the investigators as an a priori item of interest such findings should be viewed with great skepticism.

**k) Reporting of randomized controlled trials**

The CONSORT statement is specifically designed to provide standards for reporting RCTs [33, 49]. It includes a 22 item checklist (**Figure 2**) of critical items that should be included by authors preparing...
manuscripts. Adherence to these guidelines and the use of flow diagrams in particular is associated with improved quality in reporting of RCTs [79]. Errors in presentation of statistical information are extensively covered in many textbooks [20, 64]. This section will emphasize the most important points on reporting of RCTs, to ensure an objective and comprehensive presentation of the trial itself, and also to facilitate any subsequent synthesis of research evidence including formal meta-analyses of RCTs. Meta-analyses are themselves the subject of separate reporting guidelines, the QUORUM statement [76]. However, such guidelines are not a panacea [40]; deficiencies in reporting are still common [75].

The CONSORT statement recommends clear statements about the objectives of the trial, intended study population, and planned comparisons. Subgroup or covariate analyses should be clearly specified and justified. The method of randomization should be stated, as should the unit of randomization; in most cases, this will be the individual participant but occasionally an aggregate group of subjects will be allocated jointly in a cluster randomized design [25]. Cluster randomized designs are also now the subject of separate reporting guidelines [77], and involve particular complications in terms of data analysis [78]. For all trials, specifications for the sample size calculation (primary outcomes, target differences, etc.) should be stated and justified. In addition, the precision actually obtained in a study must be presented. This requires confidence intervals as well as the observed p-values, at least for primary outcomes but preferably for all outcome variables.

The principal confidence intervals should be for comparisons between the groups, rather than for differences in the outcomes within the trial groups [20, 26]. Results should include a trial flow diagram, with numbers and reasons for the exclusion of eligible subjects, the number randomized, and subsequent losses to follow-up [34]. Protocol deviations should be described and explained [52]. Finally, the discussion should include a brief summary of the trial’s findings, possible explanations for the results, interpretation of the findings in light of the literature, limitations of the trial including internal and external validity, and the clinical and research implications of the study [33].

Full disclosure also mandates that the manuscript includes statements defining the role of the sponsors
in the study, the role of the authors and their relationships to the sponsors and other relevant parties, and the registration of trial.

I) Conclusions

In conclusion, it is crucial that those intending to embark on research into incontinence plan the details of the study in advance. Many of the decisions to be made involve statistical issues; therefore it is vital that someone with relevant expertise is involved from the outset. Statistics has been described as a combination of mathematics, logic and judgment [26], and this applies to all phases of RCTs. Naturally, formally qualified biostatisticians are not the only professional group with the necessary expertise to address these issues, particularly since in the planning of studies the above three characteristics are probably stated in increasing order of importance. Furthermore, the benefits of such expertise will only fully be derived if the individuals are involved on an ongoing basis in the conduct of the trial. This is equally true of all the disciplines relevant to studies of health care technology and organization, including social scientists and health economists as well as statisticians and clinicians. Increasingly, the major funding bodies and international journals expect a sufficiently multidisciplinary team to carry out and report on health services research. If for no other reason than because of their central position in influencing the purchasing and provision of health care, this is especially important for randomized controlled trials. As noted in the Ethical Issues of Research section, planning is essential and it is ethically important when conducting human subject research. The study should be well planned, scientifically sound, with the ability to be completed, a reasonable assumption new knowledge will be provided at the end of the study and published to advance scientific knowledge [79, 80]

Recommendations on Study Conduct and Statistical Methods

- The role of quality RCTs as providing the strongest level of evidence in incontinence research should be fully acknowledged by researchers, journal reviewers, and editors. HIGH
- Careful attention to the planning and design of all research, especially RCTs, is of the utmost importance. HIGH
- Appropriate expertise in biostatistics and clinical trial design should be employed at the design phase of a RCT and thereafter on an ongoing basis. HIGH
- The design, conduct, analysis and presentation of RCTs must be fully in accordance with the CONSORT guidelines. HIGH

- The design, conduct, analysis and presentation of observational studies should follow STROBE guidelines. HIGH
- The design, conduct, analysis and presentation of meta-analyses should follow QUORUM guidelines. HIGH
- Reporting studies of diagnostic tests, including urodynamics, should follow the STARD statement guidelines. HIGH

4. OUTCOMES RESEARCH IN LUTS INCLUDING INCONTINENCE

An outcome is a specific result or effect that can be measured [81]. Careful selection of outcome measures that are valid and clinically relevant is intrinsic to the success of research; no single measure can fully express the outcome of an intervention. While every clinical trial must focus on a few primary endpoints, complete collection and reporting of data is essential to progress in understanding and treating disease. It is good to know that a drug or procedure appears to be “safe and effective”. It is better to know that treatment A is superior to treatment B, and by how much. It is ideal to understand why one treatment is better than another—to understand why a treatment works for a particular patient and not for another. Understanding at this level requires simultaneous consideration of outcomes, anatomic and physiologic variables. This degree of detail is often not obtained and is only rarely reported. Reports tend to concentrate on success or failure in achieving the primary endpoint (e.g., cure of stress incontinence); however, to understand outcomes, detailed data is needed on improvement and deterioration in anatomy, symptoms, lower urinary tract function, complications of the intervention, and the effect on quality of life.

The importance of using validated outcome measurements cannot be overstated. The tool must accurately measure what it intends to measure and must be reliable, i.e., it must measure outcome in a way that is consistent and dependable. Whenever possible, select a tool that has already been validated in a population similar to the one to be studied (for example, the age, education/language level and gender should be similar). An instrument that is appropriate for a young or middle-aged population may not be appropriate for older patients whose attention span and eyesight require a short questionnaire in a large font; similarly, scores written for an educated, English-speaking population may not be appropriate for a population for whom English is not the first language. Some LUTS-related instruments have already been validated in multiple languages [82-85]. These tools are optimal when studying populations who speak and read a variety of languages.
If there is no relevant, validated tool available, consider consulting an expert to get assistance with the validation process. Only as a last resort should a tool be used that has not been validated as this diminished the impact of the results. Consideration should also be given to whether the score is gender-specific or gender-neutral. Most validated LUTS outcome measures are gender-specific to target specific gender-related conditions, but for broader population studies, a gender neutral instrument is preferable.

In order to fully understand the outcome of an intervention data is needed far beyond the primary outcome measure. Change in anatomy, symptoms, and lower urinary tract function as well as complications, side effects, and impact on quality of life may influence the interpretation of a trial and may inform as to how an intervention produces an effect. It is also important to select instruments that provide enough data to give clarity without overwhelming the subject and swamping the investigator with irrelevant detail. Perceptions of the patient and clinician concerning outcome, which may be contradictory, must be reported. It is no longer enough for the physician to say treatment was successful; the patient must also have a voice. It is also useful to report the patients’ expectations, because a patient considers the trade-offs between symptom improvement, adverse events, and effects on daily life when assessing overall treatment benefit [86], which may influence the outcome of a study [87]. The following recommendations are adapted from the ICS Standardization Committee [11]

a) Baseline data:

b) Observations:
1. Patient’s observation/Subjective measures
2. Clinician’s observation/Objective measures
c) Tests
1. Quantification of symptoms—bladder diary and pad tests
2. Urodynamics
d) Follow-up
e) Quality of life measures
f) Socioeconomics

a) Baseline clinical and demographic data:

A complete demographic description of the study participants, essential for allowing comparison of studies among jurisdictions, includes [88]

- Age
- Race/ethnicity
- Gender
- Body mass index (height and weight)
- For women—obstetric history, including parity and menopausal status
- Smoking status
- Co-morbidities such as cardiovascular, respiratory and neurologic conditions and diabetes
- Medication use, including naturopathic medicines (e.g. herbs and botanicals [11]), dietary supplements (e.g., vitamins, minerals, fatty acids or amino acids [12] and other alternative treatments
- Past surgical history
- Level of education
- Mental and physical status
- Prior treatment for pelvic floor disorders, including behavioural, pharmacological and/or surgical interventions

Obstetric and gynecologic history is important in women. Recommendations for minimum data collection are made in the proceedings of the NIH Terminology Workshop for Researchers in Female Pelvic Floor Disorders [88]. While few trials will be large enough to analyze the effect of these demographic factors on outcome, the potential future use of meta-analysis makes a complete database valuable.

b) Observations:

1. Participants’ observations and Subjective measures

Validated patient completed symptom questionnaires and other validated instruments are recommended for all trials for LUTS and incontinence (see report from Committee 5). In addition to specific symptoms, the respondent’s overall opinion of the condition should be included. Different methods to obtain this measure include: a question with a forced choice, a graded response, a statement with a Likert scale agree-disagree response, and a statement with a visual analog graded scale response. An ideal instrument would record all symptoms related to the lower urinary tract and relevant associated organ systems. At a minimum, this would comprise:

- Storage symptoms
  - Incontinence, stress induced
  - Incontinence, urgency induced
  - Incontinence, other
  - Frequency and nocturia
  - Urgency
- Voiding/emptying symptoms
- Protection (e.g., pad use)
- Coping measures
• Pain
• Sexual function
• Bowel function

Items of great value in interpreting study results beyond the basic effect on patient symptoms include:
• Patient expectations of treatment
• Patient goals for treatment
• Quality of life

Measures should include the frequency of the symptom (e.g., daily urgency incontinence), the severity of the symptom (e.g., pads are saturated) and the impact or bother produced by the presence of the symptom (e.g., much greater for the individual who works in a public setting). There is no one instrument covering all of these areas which has established methodological reliability. Therefore, researchers should clearly describe their instrument and procedure and provide reliability data or indicate their absence. As there is no one universally accepted, ‘ideal’ instrument, trials are often conducted using multiple instruments to assess different domains. For a detailed discussion of available instruments see the report of Committee 5.

2. CLINICIAN’S OBSERVATION AND OBJECTIVE MEASURES

A detailed assessment of function and a complete description of anatomy complement the patient’s observations and subjective reporting. In some cases these measures could be the primary endpoint (physical exam assessment after prolapse repair or decrease in detrusor leak point pressure in neurogenic bladder patients) but in many other cases they provide important information about why interventions succeed or fail. Functional data, primarily urodynamic, are usually included in the evaluation of lower urinary tract disorders along with an investigation of possible anatomic changes in the lower urinary tract and its supporting structures. There are a few condition specific recommendations for evaluating male anatomy in the literature, such as those for urinary incontinence, recommended by the Urodynamics Society [100]. For women, the Pelvic Organ Prolapse Questionnaire - (POP-Q) is recommended

1 The POP-Q (Pelvic Organ Prolapse Questionnaire) provides a descriptive and quantifying system for the relative position of the organs within the pelvis and an objective system for staging pelvic prolapse. The system, adapted from several classifications by Baden and Walker [101], arose from the efforts of the International Continence Society Committee on Standardisation of Terminology, Subcommittee on Pelvic Organ Prolapse and Pelvic Floor Dysfunction, in collaboration with the American Urogynecologic Society and the Society of Gynecologic Surgeons [102] to develop a terminology standardization document.

2 The POP-Q descriptive system allows the clinician to quantify precisely a woman’s pelvic support without assigning a severity value, to make accurate, site-specific observations of the stability or progression of prolapse over time, and to accurately describe outcome of surgical repair. The system uses six reference points (Figure 3) and a three-by-three grid (Figure 4) for recording a quantitative description of pelvic organ support.

3 The POP-Q descriptive system uses the hymen as the best available fixed point of reference that can be consistently and precisely identified. Six points, two on the anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall, are located with reference to the plane of the hymen. The anatomic position of the six points are recorded as cm above or proximal to the hymen (negative number), or cm below or distal to the hymen (positive number), with the plane of the hymen recorded as 0.

**Recommendations on Observations During Incontinence Research**

- One or more validated symptom instruments should be selected in advance of the clinical trial and then administered during the initial phase of the trial to define the baseline symptoms of the population. HIGH
- Observations of anatomy should be recorded using standardized, reproducible measurements. HIGH
- Pelvic muscle and voluntary sphincter function should be reported using a quantifiable scale. HIGH
- All observations should be repeated after intervention and throughout a minimum one-year follow-up, and their relationships with primary clinical outcome measures analyzed. HIGH
- Complications of the intervention should be reported. HIGH
Figure 3: Six sites used for pelvic organ support quantitation (points Aa, Ba, C, D, Bp, and AP), genital hiatus (gh), perineal body (pb) and total vaginal length (tvl). From: Bump RC, Mattiasson A, Bo K, Brubaker LP, DeLancey PK, Shull BL, Smith, ARB. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996: 175(1): 10-17.

c) Tests

1. Quantification of Symptoms—Bladder Diary and Pad Tests

The diary (micturition time chart, bladder diary, or frequency-volume chart) is a self-monitored record of selected lower urinary function that is kept for a specific period of time. Recorded data may include fluid intake, voiding frequency (diurnal and nocturnal), frequency of incontinence episodes by type, pad use, and voided volumes. Urinary diaries are important in the evaluation of LUTS because they document functional bladder capacity, diagnose diurnal and nocturnal polyuria, and diagnose fluid restriction that may affect continence or other LUTS. The diaries measure what actually happens to the patient in day-to-day life in a way that no test or questionnaire can reproduce. Voided volumes provide additional insight into cause and effect. Diaries range from the very simple micturition time chart (frequency of voiding and incontinence episodes), to the complex bladder diary, which may include fluid intake, voiding frequency (diurnal and nocturnal), frequency of incontinence episodes by type, pad use, causes of incontinence, and voided volumes. Incontinence studies often use the number of incontinence episodes recorded in the diary as the primary endpoint. While this may provide a measurable endpoint, it does not provide the information necessary to interpret the data completely.

The accuracy of a diary is dependent on proper training of the subjects. Reproducibility depends on the parameters used and improves with the number of days that self-recording is obtained. Diaries are reliable for assessing the number of incontinent episodes [103,104]. Longer diaries are more reliable but have decreased subject compliance [104,105]. The length and degree of detail should be determined by the study design and specific requirements for data. Reliability and validity data for specific diaries should be provided if available, or their absence indicated [106,107]. The period of time the diary was used should be noted [108].

The pad test quantifies incontinence; therefore it can provide a key link in understanding outcome. A patient who experiences a decrease in the number of incontinence episodes from four to two per day may not be satisfied if the volume of urine loss is high. Similarly, cure of incontinence may not have a great impact on a patient with trivial volume of urine loss at baseline, particularly if any adverse effect is experienced with treatment.

Pad tests can be divided into short-term or provocative tests, generally performed under standardized conditions as in the 20-minute to 1-hour office tests [109], and long-term tests, generally performed at home over 24 to 48 hours [110,111]. 24-hour pad tests are reliable instruments for assessing the amount of urinary loss [112,113]. The longer pad tests are primarily used for research because of their complexity and the time required to complete them. Increasing the test duration to 48 or 72 hours increases reliability but decreases compliance [114]. For short-term tests, the experimental conditions must include standardized bladder volumes and the physical tasks must be described in detail. Instructions for pad tests have to be followed explicitly to ensure reproducibility.

2. Urodynamics

Urodynamics should be included in research where there is need to document physiologic measures of storage or emptying function. When urodynamics are incorporated, it is important to document equipment, conditions, and concurrent tests [88,115,116], including:

- Hardware and software
- Calibration
- Size of catheters
- Type of infusant and rate and temperature of infusion
- Patient position
- Specific annotations
- Lay language bladder sensation parameters
- Visual Leak point pressure techniques
- Modifications for prolapse
- Data recording
- Use of concurrent EMG and position of electrodes.

Measures of bladder sensation, capacity and urodynamic diagnoses should be made in accordance with current definitions as specified by the ICS Good Urodynamic Practices document [117]. Please refer to Chapter 6 for further discussion on the conduct of urodynamic investigations.

The tests are performed at entry and at conclusion of the study when used as primary or secondary outcome measures. In other instances, urodynamic studies might only be performed at the outset of a study as a means of defining the patient population and/or determining parameters that predict response to treatment. There is a great need for high quality, hypothesis driven research into the utility of using urodynamic studies to define patient populations or risk groups within clinical trials. Urodynamic studies are costly and greatly increase the complexity and expertise required to perform clinical trials. At this time urodynamic studies have not been proven to have adequate sensitivity, specificity or predictive value to justify routine use of testing as entry criteria or outcome measures in clinical trials [118-122]. Participants should generally not be stratified by urodynamic diagnosis; rather, more studies should be performed to define specific urodynamic parameters.
that predict outcome. There is evidence that urodynamics have a role in predicting outcome for some [123-124], but not all LUTS-related conditions [125, 126]. Valuable insights into the limitations of pre-operative urodynamic testing have been provided by the SISTEr trial [127] and the CARE trial [128]. The ongoing TOMUS trial comparing synthetic midurethral slings also employs blinded preoperative urodynamics and will further explore the utility of such investigations.

It would be ideal to use urodynamic studies routinely to accurately characterize baseline lower urinary tract function and dysfunction and the change after treatment. However this is impractical in most RCTs and unnecessary to answer the basic questions involved. At the same time, urodynamic tests are among the best tools currently available to understand the basic physiology and mechanisms of disease; these tests must somehow play a role in research. While routine incorporation of urodynamic testing is not warranted in clinical research, hypotheses driven inquiries aimed to refine the studies, define the utility of specific tests in different patient populations, and to develop new and better tools are needed.

Procedures for performing urodynamic studies must be carefully standardized in trials to ensure that consistent techniques are used for different subjects; this is particularly critical for different centers in a multicenter study. The exact same technique must be used at baseline and follow-up. Studies with urodynamic endpoints require an evaluation of whether or not the study reproduces the symptom under investigation. In multicenter studies investigator bias can be minimized by using a third party assigned to read the urodynamic tracings that have been annotated according to the agreed-upon definitions.

Recommendations on tests used in incontinence research

- Clinical trials of incontinence and LUTS should include frequency-volume charts as an essential baseline and outcome measure. HIGH
- The diary should include measured voided volume for at least one day. HIGH
- Pad tests should be considered in clinical trials whenever feasible. HIGH
- In all trials employing urodynamics, standardized protocols (based on ICS recommendations) should be defined at the outset. In multicenter trials, urodynamic tests should be interpreted by a central reader to minimize bias unless inter-and intra-rater reliability has already been established. HIGH

d) Follow-up

Minimal standards for evaluation of treatment outcomes in urinary incontinence have been presented in a report developed by a committee of the Urodynamic Society and approved by both the American Urologic Association and the Society for Urodynamics and Female Urology [129]. In addition to standard pre- and post intervention evaluation, they recommend evaluation of surgical, prosthetic, and implant therapies no less often than 1 to 3 months and 12 months after treatment, and thereafter at yearly intervals for as long as possible. Although early follow-up can provide important insights about outcomes, particularly adverse events, a great deal more emphasis needs to be placed on long-term effectiveness. Outcome reporting for surgery and some other interventions should begin at one year minimum (not mean) follow-up for all subjects.

The method by which follow-up data is collected should be specified, e.g., prospective questionnaires or retrospective chart review. Individuals collecting data should be identified, e.g., clinician or independent research nurse. The interval between the time of evaluation and the last treatment should be specified. The exact type of data collected at each time point in follow-up should be defined at the study’s outset. A minimum data set to be collected at each post-treatment interval includes: the total number of subjects evaluated versus the number of subjects actually enrolled in the study, and the total number of subjects lost to follow up and the reasons why they were lost. Indications for retreatment and the time interval since the last treatment should be specified. Efficacy assessment should be done at a specific time interval after the last treatment. The protocol should further specify the criteria by which treatment success or failure is determined.

Recommendations for follow-up

- More long-term follow-up is needed in all types of incontinence research. Conversion of RCTs to registries using structured annual follow-up with validated instruments is recommended whenever feasible. HIGH

e) Quality-of-life measures

Health related quality of life (HRQOL) refers to an individual’s perceptions of the effect of a health condition and its treatment on quality of life [130]. Primary domains of HRQOL include physical, psychological and social functioning; overall life satisfaction and well-being; and perceptions of health status. Secondary domains include somatic sensations (symptoms), sleep disturbance, intimacy and sexual functioning, and personal productivity (e.g., household, occupational, volunteer, or community activities). It is important to know not only how successfully
treatments decrease the frequency of incontinence episodes, but also how a treatment affects a patient globally. The combination of HRQOL data and more traditional objective endpoints will allow us to understand the reasons behind our success and failures.

Three measurement approaches are commonly used to assess HRQOL: generic, condition-specific and dimension-specific. These instruments are explained in the report from committee 5. Here only a few aspects of relevance to research are touched upon. Generic HRQOL instruments such as the SF-36 are designed to be used across groups by having established age and gender norms. Condition-specific instruments such as the Leicester Impact Scale for lower urinary tract symptoms [131] are designed to measure the impact of a particular condition. These instruments tend to be more responsive than generic instruments in detecting treatment effects. Symptom scales are considered condition-specific; generally, these scales should include measurement of the presence of a symptom as well as the “bother” related to it. The majority of generic and condition-specific instruments are multidimensional, i.e., they measure more than one aspect of HRQOL.

Dimension-specific instruments, in contrast, are designed to assess a single component of HRQOL, such as sleep disturbance. A practical approach to assessing HRQOL is to combine a multidimensional generic and/or condition-specific instrument with dimension-specific instruments appropriate for the trial.

The selection of an HRQOL instrument should be defined by the purpose of the study. Descriptive epidemiological studies should consider both generic and condition-specific instruments. Intervention studies should include a condition-specific instrument. Dimension-specific instruments should be used when more detail about a specific subdomain of HRQOL is desired. Researchers should define HRQOL for their study, clearly describe their instrument(s) and data collection, and provide reliability data if available. Selected instruments should be reliable and sensitive. In adopting HRQOL instruments, results obtained in the study population should be compared with published norms. If a new instrument will be used in a study, adequate pretesting should be done to establish its clinimetric characteristics (e.g., reliability and sensitivity) and an established instrument should also be used to provide a comparison.

**Recommendations on Health Related Quality of Life in Incontinence Research**

- Research in incontinence and LUTS should include both generic and condition-specific validated HRQOL instruments whenever practical and appropriate. HIGH

- Changes in HRQOL after therapy should be considered in relation to changes in individual symptoms, and with physiologic and anatomic outcome measures. LOW

- Changes in HRQOL are an important secondary outcome measure for incontinence research - HIGH

**f) Cost Analysis**

The financial burden on the health care system, the patient and patient’s family of various treatment options makes cost an important outcome to measure. A full discussion of the economic impact of urinary incontinence is detailed in the report of committee 22. We recommend that cost analyses be planned with clinical studies whenever possible. Costs may be influenced by economic and political factors that are subject to change at any time; however, when basic units of work, time, and resources are carefully defined, models of costs remain useful even if market forces change in an unforeseen manner.

In health and medicine, economic analyses are descriptive and/or comparative. Descriptive data include the socioeconomic cost caused by the disease and its current treatment, whereas comparative data provide an economic evaluation of different treatment strategies and interventions where costs are compared to health outcomes.

There are several relevant types of cost analysis, some of which require a high level of expertise to conduct:

- **Cost of illness analysis** (COI) typically quantifies the burden of medical expenses (direct costs) and the resulting value of lost productivity (indirect costs) attributable to a specific condition such as an illness or injury [132].

- **Cost effectiveness analysis** (CEA) measures the costs and consequences of two or more diagnostic or treatment pathways related to a single common effect or health outcome. It then summarizes the results in ratios that demonstrate the cost of achieving a unit of health effect for different types of patients and for variations of the intervention [133].

- **Cost utility analysis** (CUA) is a form of cost effectiveness analysis in which particular attention is paid to the quality of health outcome related to treatment. In CUA, health effects are expressed in terms of quality-adjusted life years (QALYs) [107]. A QALY is a measure of health outcome that assigns to a given period of time a weighting that corresponds to the health-related quality of life during that period, and then aggregates these weights across time periods. The QALY is important because it considers both quantity and quality of life.
- **Cost benefit analysis** estimates the net social benefit of an intervention by comparing the benefit of the intervention with the cost, with all benefits and costs measured in dollars [134]. Health outcomes are converted into monetary values using “willingness to pay” (the value an individual would pay for reduction in illness severity) or “risk of death” or “human capital” methods (an individual’s value to society based on productivity or future wages) [135,136].

**Recommendations on Cost Analysis in Incontinence**

- Cost analysis should be incorporated into clinical studies whenever possible [137].

### III. RECOMMENDATIONS FOR SPECIFIC PATIENT GROUPS

#### 1. MEN WITH LUTS, INCLUDING INCONTINENCE

Four unique factors influence research on lower urinary tract symptoms in adult men:

- the confounding influence of the presence of the prostate
- the likelihood of bladder outlet obstruction (BOO)
- the rarity of sphincteric incontinence, and

the rarity of any kind of incontinence at all in young and middle aged men except under two special circumstances – neurogenic bladder and after treatment for prostate cancer.

The presence of the prostate complicates research because of its known effect in causing bladder outlet obstruction (with or without benign prostatic enlargement—BPE), its propensity for developing prostate cancer and the effects of treatment for both conditions, resulting in sphincteric incontinence (after prostate surgery) and incontinence due to detrusor overactivity (after radiation based therapies). Further, prostate size itself may influence outcomes in some therapies of urinary incontinence, for example the type of surgical intervention in men with prostatic obstruction and urinary incontinence. Overall, about 2/3 of men with LUTS have urethral obstruction and over 50 % have detrusor overactivity, although a much smaller number have urinary incontinence due to detrusor overactivity [138]. The rarity of incontinence in men suggests that gender specific bother and quality of life instruments will be necessary.

**a) The presence of the prostate:**

Aside from obstruction (see below), the prostate impacts on outcomes research in incontinence in three ways – prostatic size, the possibility of undiagnosed malignancy, and prior therapy (prostatic surgery and other therapies for BOO, BPE or prostate cancer). If prostate size is believed to be a variable that could affect outcomes, measurement of prostate volume should be made before and after treatment. The method used to measure volume and its reliability and validity should be provided if available or their absence indicated. Timing of post-treatment testing depends of the treatment’s mechanism of action, but of course, prostate volume should be measured at the same time as the primary outcome measurements for incontinence are determined. The association between outcome and change in prostate size should be reported. Consideration should be given to stratifying participants by prostate volume when there is suspicion that response to therapy may be size dependent.

Since the presence of undiagnosed malignancy might affect outcomes, participants should be screened for prostate cancer by digital rectal examination and measurement of serum PSA and appropriate disposition should be made based on the outcome of such testing. A careful history of past surgery and other treatment of BPE, BOO, and prostate cancer should be obtained and dealt with based on the inclusion and exclusion criteria for the study.

**b) Likelihood of bladder outlet obstruction (BOO):**

Insofar as about 2/3 of men with LUTS have BOO, it is important in any research protocol to screen for its presence. At the least, uroflow and measurement of post-void residual urine should be recorded pretreatment and the effect of therapy on these parameters should be documented simultaneously with assessment of the primary outcome variables. While synchronous pressure-flow studies are generally desirable and should be included whenever feasible there should be a focus on hypothesis driven research that will refine our knowledge about the utility and cost-benefit of these studies. Results should be presented as stated in the ICS 1997 Standardization Report on Pressure Flow Studies of Voiding, Urethral Resistance and Urethral Obstruction.” Methods used for the assessment of bladder outlet obstruction should be stated and reliability and validity data should be provided if available or their absence indicated. Several pressure-flow nomograms have been proposed to diagnose obstruction in men so it is important to specify which if any nomogram is being used [139].

**c) The rarity of sphincteric incontinence:**

The rarity of sphincteric incontinence in men has one practical consequence – any man with sphincteric incontinence should undergo an exhaustive neurologic evaluation unless it is consequent to prostatic surgery or a neurologic condition known to cause sphincteric incontinence, such as a thoracolumbar neurologic lesion.
d) The relative rarity of incontinence other than post-micturition dribbling in young and middle aged men except as noted above:

Young and middle aged men only rarely have incontinence unless they have a neurologic condition, prior prostatic surgery or severe bladder outlet obstruction. With advancing age, there is a gradually increasing incidence of detrusor overactivity and incontinence. For this reason, it may be important to use gender and even age specific quality of life and bother scores when assessing these outcome measures.

Recommendations for Research in Men

- High quality, symptom and bother scores (e.g., IPSS, ICIQ-MLUTS, DAN-PSS) validated in men should be employed when assessing outcome in male incontinence research. HIGH
- Uroflow and measurement of post-void residual urine should be recorded pre-treatment and the effect of therapy on these parameters should be documented simultaneously with assessment of the primary outcome variables. MEDIUM
- Measurement of prostate size (or at least Prostatic Specific Antigen) should be performed before and after treatment (synchronous with other outcome measures) whenever prostate size is expected to change due to the treatment. HIGH
- Participants should be stratified by prostate size at randomization when size is considered to be a potentially important determinant of treatment outcome. LOW
- Further research in on the cost-utility of pressure-flow urodynamic studies and the ability to use such studies to define relevant subgroups of men who may respond differently to various treatments is desirable. LOW

2. WOMEN WITH LUTS AND INCONTINENCE

We concur with the 1997 Urodynamics Society recommendations for outcome research in women [15, 16]. We also refer to the ICS recommendations for outcome measures in women with lower urinary tract dysfunction [12] and the Proceedings of the NIH Terminology Workshop for Researchers in Female Pelvic Floor Disorders [88]. Unique factors influencing research on lower urinary tract symptoms in adult women include:

a) hormonal effects
b) obstetric history
c) pelvic organ prolapse
d) gender related outcome measures
e) sexual functioning

All of these potentially confounding variables can affect the outcome of treatment of incontinence.

a) Hormonal effects

Our knowledge of hormonal influences on the lower tract remains limited. Recent RCTs and prospective cohort studies have demonstrated that (HT) does not improve or may worsen incontinence [140-142]. It therefore seems appropriate that information about menstrual and hormonal status should be an integral part of the baseline history. Studies designed to examine the influence of hormones on incontinence should include menopausal status (premenopausal, postmenopausal without HT, post-menopausal with HT), whether or not oophorectomy has been performed, and the type, dosage and route of administration of HT if used.

b) Obstetric History

The unique influence of vaginal childbirth on the structure and function of the female pelvis remains incompletely understood. That childbirth may lead to incontinence and pelvic organ prolapse is indisputable; the potential effect of childbirth on treatment of incontinence has yet to be determined. The need for basic clinical data on the study population and the specific aims of each study will determine the level of detail obtained for obstetric history. Potentially confounding variables include: number and route of deliveries (vaginal/Cesarean), use of forceps or suction devices, infant birthweight, duration of second stage of labor, use of midline versus mediolateral episiotomy, obstetric analgesia, and obstetric complications such as lacerations and fistulae.

c) Pelvic Organ Prolapse

The effect of pelvic organ prolapse on lower urinary tract function remains controversial and understudied. It has been suggested pelvic organ prolapse may affect lower urinary tract function in at least four ways. It may cause urethral obstruction, it may mask sphincteric incontinence, it may cause urgency and urgency incontinence, and/or it may diffuse pressure transmission, making it more difficult to void by abdominal straining. Some of these effects may be immediately reversible with reduction of the prolapse. For all of these reasons, it is essential to include assessment of pelvic organ prolapse in incontinence research. Methods used for the assessment of pelvic organ prolapse should be stated and reliability and validity data should be provided if available or their absence indicated; the Pelvic Organ Prolapse Quantification System (POP-Q) [9] is recommended as discussed by committees 5 and 15. Further, whenever prolapse is present, instruments for assessing incontinence and LUTS should be reported with the prolapse reduced and again at its full extent whenever possible. In either event, prolapse should be graded at the same time as the outcome assessment for incontinence and LUTS is performed.
The degree of urethral mobility is considered an etiologic and prognostic factor in women with urinary incontinence, although its precise role has not been defined. At present, there is neither a well accepted method of assessment nor a classification system. Common methods of assessment include measurement of the Q-tip angle (cotton swab test), magnetic resonance imaging, ultrasound, and cystogram. In the absence of a classification system, it is recommended that data be presented as a continuum, such as the Q-tip angle, not as a dichotomous normal versus abnormal classification, at least until the terminology is better defined. Methods used for the assessment of urethral mobility should be stated and reliability and validity data should be provided if available or their absence indicated.

d) Definition of Outcomes Measures for LUTS & Incontinence

Treatment of urinary incontinence in women may have broad ranging effects on lower urinary tract function, prolapse, sexual function, and bowel function. It is therefore important that a broad perspective of outcome be presented. The NIH Terminology Workshop for Researchers in Female Pelvic Floor Disorders recommendations [88] for stress incontinence treatment define outcomes as cure/improved/failed in terms of incontinence symptoms, signs, and testing, but also in terms of associated symptoms and unwanted (side) effects resulting from an intervention, after return to baseline activities and medications.

The strength of the definitions proposed by NIH is the amalgamation of subjective and objective measures as well as the recognition of the potential adverse effects of incontinence therapy. However, there is as yet little experience with this system. Although these recommendations advance the concept of global pelvic floor evaluation and emphasize the interrelatedness of pelvic organ function, there are limitations in compressing such broad outcome measures into only three categories. It is still critical to know whether a treatment corrects the intended problem. For example, if an operation reliably cures stress incontinence but causes dyspareunia, it may be more useful to report that there is a high cure rate plus a high complication rate. It may not be appropriate to report a woman cured of stress incontinence as failed if she develops urinary tract infections or a rectocele several years later. While appropriately emphasizing the significance of complications and adverse events, this system does not provide a means to fully express such complex outcomes. It also leaves a rather broad range of “improved” patients that must be further defined; when complete cures are relatively uncommon, this may diminish the impact of the outcome. In any case, if these definitions are not adopted it is still imperative that researchers specify the outcome measures that will be used to define cure, failure, and improvement in the materials and methods section. Further, possible (and likely) discordant outcomes should be described and categorized. For example, a woman might state that she is cured of incontinence, have a negative pad test and diary, yet stress incontinence might be demonstrated on a stress test with a full bladder.

An alternative view of a global outcome measure has been described [143]. Here, incontinence is first assessed and the patient declared cured, improved or failed based on outcome measures derived from the criteria listed below. If the patient is not cured (i.e. dry) the reasons ascribed are defined as sphincteric incontinence, detrusor overactivity incontinence, extraurethral incontinence (fistula) or incontinence of undetermined etiology. The system can be used for studies of both stress and urgency incontinence. Once incontinence status has been determined, other LUTS should be described using LUTS outcome instruments. In all instances, methods used for the assessment of incontinence and LUTS should be stated and reliability and validity data should be provided if available or their absence indicated. In such a scheme, incontinence could be cured yet the patient might experience de novo or persistent LUTS that mitigate against the patient considering herself cured or improved. Examples of outcome instruments that take these objective, semi-objective and subjective measures into account are the SEAPI-QMM system [144] and the Simplified Urinary Outcome Scores [145].

Outcomes for detrusor overactivity should be defined separately for symptoms, as described above, and for urodynamic findings. Cure of detrusor overactivity is defined as the absence of involuntary phasic detrusor contractions on filling cystometry. Failure is defined as unimproved or worsened detrusor overactivity on urodynamics. Improvement has not been standardized and should be precisely defined for each study.

e) Sexual function

Urinary incontinence, LUTS and the treatment of these disorders all have potential effects on sexual function and yet little is known about the impact of incontinence treatment on sexual function. It is therefore appropriate that sexual function be considered one of the domains for investigation in all types of incontinence research. Validated instruments that deal with sexual function in women with LUTS and incontinence include the Incontinence Impact Questionnaire (IIQ) [143], the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ) [146], and the ICIQ-FLUTSSex (http://www.iciq.net/ICIQ_Fluttssex.html).

A final issue relating to research methodology in female incontinence is defining the population for studies of stress incontinence. One group has described a clinical algorithm that might be used to select patients without urodynamic testing [147].
Representative samples of well-defined target populations are necessary in different care settings including the community (independent and home-bound), acute inpatient, and nursing home or institutionalized (bedfast and non-bedfast). Well-conducted data collections are important to provide careful measurement of a wide variety of potential risk factors and a large sample to allow for statistical adjustment for multiple potential confounding variables to identify independent risk factors for incontinence. Cross-sectional studies are efficient to determine prevalence and identify potential risk factors while longitudinal studies are needed to estimate incidence, understand the natural history, and to define causality of risk factors. There have been few longitudinal studies of incontinence in this group. Unfortunately, most prior studies were small, did not differentiate functional or cognitive impairment, and failed to identify medical conditions or medication use. Most of the analyses were not adjusted for potential confounding variables as mentioned or age, body weight, parity, etc. It is important to include previously reported risk factors and potential risk factors. Validated instruments should be used when available. Otherwise, a detailed description of how the risk factor was measured is required to assess how well the variable represents the area of interest. In the frail elderly, important variables include:

- Demographic information: Advancing age, white race, and women [142, 149-151] are associated with an increase risk of incontinence and each of these variables should be adjusted for in most analyses.
- Reproductive History: Childbirth is an established risk factor for incontinence [152,153] and it is reasonable to collect data on the number of births. However, in women over 60 years of age, as chronic medical illnesses become more prevalent and impact incontinence, risk profiles change and parity may not remain a significant risk factor [151, 154-156]. Prior hysterectomy has also been suggested as a potential risk factor for incontinence in older women [157, 158].
- Medical Conditions: Medical conditions related and unrelated to the lower urinary tract have been shown to increase the risk of incontinence in older women and are especially important to assess in the frail older population [151,154-156].
- Medication Inventory: Certain medications may exacerbate incontinence and therefore a complete medication inventory is essential [158-161].
- Physical function: Mobility is often impaired in the frail elderly and impacts urinary control [163], therefore mobility should be assessed using validated instruments such as the Bartel Orcats or ADL scales [163, 164]. Data on walking aids or wheelchairs, gait speed, and manual dexterity may also be collected.

3. FRAIL OLDER AND DISABLED PEOPLE

We agree with recommendations for outcome research in frail older people as reported in the ICS Subcommittee on “Outcome Measures for Research of Lower Urinary Tract Dysfunction in Frail Older People” [14]. In addition, please refer to the full report of Committee 11 regarding conservative treatment in the elderly. Frailty is defined as “a state of reduced physiological reserve associated with increased susceptibility to disability [148].” There is a wide variation in functional capacity within this definition ranging from those requiring some assistance with activities of daily living to those suffering from dementia and severe physical handicaps. Consequently, the frail older population is a heterogeneous group residing in a broad range of care settings, with multiple medical conditions related and unrelated to the lower urinary tract, and often on numerous medications. There are a number of unique and pertinent research issues for this population.

a) Prevalence, natural history, and risk factors

There remains a paucity of research on the prevalence and incidence of urinary incontinence to assess the burden of disease in the frail older population. This information is vitally important to estimate health care costs and direct resource planning. Less information is available on risk factors and this lack of established risk factors limits preventive efforts and highlights the need for increased epidemiologic research.
• Cognitive function: Cognitive function impairment and/or dementia increase the risk of incontinence [162]. The Mini-Mental Status Scale Examination [165] assesses global cognitive function and the Confusion Assessment Method (CAM) [166] is a standardized assessment for delirium. A battery of neuropsychological tests to measure subtle impairments in cognitive function include the Buschke Selective Reminding Test (verbal learning and memory) [167], the Digit Symbol (incidental memory, visual scanning and motor speed) [168], and the Trails A (attention and visual) [169].

• Environmental factors: In the frail elderly, environmental factors may also contribute to incontinence: toilet access, the usual continence care available in the facility, and a description of caregivers and their training may be useful.

b) Outcome measures

An outcome measure should be reproducible (test-retest), accurate (sensitive and specific), feasible (balance of risks, costs, acceptability, ease of use), and sensitive to change over time. Additionally, the outcome measure should be clinically relevant and meaningful. It must be acknowledged that almost all outcome measures used in the study of incontinence that have been shown to be reliable and valid in the community dwelling population require separate validation for use with the frail elderly. Whatever outcome measures are chosen should be described in terms of applicability to the frail elderly.

Commonly used self-reported measures of frequency of urinary symptoms, severity, or level of bother may not be possible in the cognitively impaired frail elderly patient. Similarly, voiding diaries that have been shown to be valid and reliable in assessing urinary frequency, nocturia, and incontinence episodes by type [114, 107,169,170] may not be feasible or reliable. Motivated and trained staff, caregivers, or family members may be able to adequately collect diary data; however, this has not been validated.

In nursing home or inpatient settings, wet checks by staff at set intervals have been used in a number of studies. There are limitations to the measurement including visually determining what is “wet” because of new absorbent materials and staff reports not always being reliable or valid, due to underreporting [162, 171]. To overcome the limitation of defining wetness and underreporting, 24-hour pad weighing tests [172, 173] may be used. Pad weighing tests and wet checks are feasible and can provide important outcome data if staff are well trained and checks are often [174]. The usefulness of cystometry, simple or complex, as an outcome measure in the frail elderly remains unclear. Cystometry is invasive, difficult to perform, has poor reproducibility, and has not been shown to be clinically useful by demonstrating the improved outcomes in randomized controlled trials [172, 175]. A post-void residual volume is useful as a screening tool prior to an intervention that may exacerbate urinary retention (pharmacologic or surgical). It is also a useful outcome measure of adverse events in intervention studies by demonstrating the development of urinary retention. It is easily performed by ultrasound or catheter and has been shown to be reproducible and accurate [176-180].

Although a primary outcome is needed for sample size estimation, it is useful to have several outcome measures that assess different aspects of urinary incontinence. Evaluation of incontinence bother and effect on quality of life is pertinent to the patient and may also be important from the perspective of the staff, caregivers, and family members.

New outcome measures specific to the frail older population such as increased socialization or decreased caregiver burden need to be developed. Having multiple outcomes can provide a more detailed description of the effect on urinary incontinence.

c) Intervention trials

Prior to initiation of pharmacologic or surgical intervention trials in the frail elderly, careful consideration of the risks and benefits is important because of the increased risk of adverse side effects or events. In addition to the urinary incontinence outcome measures mentioned above, extensive outcome measures that will detect adverse effects from the intervention are important to demonstrate that the beneficial effect of the intervention outweighs the adverse events.

For example, in trials of new medications, using a battery of neuropsychological tests to measure subtle impairments in cognitive function would be important, but thus far have not been adequately used. In intervention trials of new medications or operations, clinically significant outcome measures (global patient satisfaction with improvement, and consideration of staff, caregiver, and family satisfaction perspectives) that demonstrate substantial effect sizes (clinical significance) rather than “statistically significant” improvements are particularly important in the frail elderly.

d) Conclusion

Research methodology for studying incontinence in the frail and housebound elderly is fraught with pitfalls. This has compromised the usefulness of past research. There is a great need for validation of practical and useful outcome measures that will allow meaningful results to be obtained. In addition, an understanding is required of the importance of defining clinical rather than statistical significance.
Recommendations for Research in Frail Older and Disabled People

- There is a need for validation of all instruments and procedures used in incontinence research for the population of frail elderly as well as development of new study measures in multiple domains of incontinence. These measures need to be evaluated for reproducibility, accuracy, feasibility, and effects on clinical decisions and outcomes. HIGH

- Clinically important outcome measures, and relationships of outcome to socioeconomic costs, are essential to establishing the utility of treating urinary incontinence in this population. HIGH

4. INCONTINENCE IN CHILDREN

The conduct of clinical research in children is generally more difficult than in adults. However, the need for quality clinical research in children has been emphasized in an official report from the United States National Institutes of Health (NIH) from March 1998, published in response to statements from the 1996 U.S. Congress Appropriations committees calling for increased and improved funding of pediatric medical research. The document [181] sets forth the policy and guidelines on the inclusion of children in research involving human subjects that is supported or conducted by the NIH. The goal of this policy is to increase the participation of children in research so that adequate data will be developed to support the treatment modalities for disorders and conditions that affect adults and may also affect children. The document points out that, “The policy was developed because medical treatments applied to children are often based upon testing done only in adults, and scientifically evaluated treatments are less available to children due to barriers to their inclusion in research studies”. The American Academy of Pediatrics has reported that only a small fraction of all drugs and biological products marketed in the U.S. have had clinical trials performed in a pediatric population and a majority of marketed drugs are not labeled for use in pediatric patients. Many drugs used in the treatment of both common childhood illnesses and more serious conditions carry little information in the labels about use in pediatric patients. It is the stated policy of NIH that children (i.e., individuals under the age of 21) must be included in all human subjects research, conducted or supported by the NIH, unless there are scientific and ethical reasons not to include them. Appropriate exceptions are listed in the document. The specific responsibilities of all involved parties—principal investigators, institutional review boards, involved institutions, peer review groups, and the NIH—are detailed. Finally, and perhaps most importantly, the document describes levels of risk and the corresponding nature of assent required for participation in research studies. All clinical investigators who work with children should be familiar with the contents of this NIH document.

Four overriding issues separate pediatric research from the general recommendations. First, physiology varies widely within the group referred to as “children”, differs from adults, and changes with time. Because children are growing, any treatment, especially pharmacological and surgical therapy, may affect them profoundly in the long term. This is particularly true of the immature brain, nervous system and other incompletely developed systems. Second, compliance with therapy is more complicated as children may depend on caregivers to administer treatment in many studies. Third, reporting of symptoms and outcomes may be difficult. The child may be unable or unwilling to respond. Symptoms reported by a caregiver may not be interpreted in the same way as the child. Finally, the issue of informed consent becomes even more complex with children.

The pediatric population is not a homogenous group; neonates, infants, pre-pubescent children, and adolescents clearly differ physiologically and psychologically. The effect of illness and the treatment of that illness must be carefully studied in each age group. Studies should be robust enough to allow for evaluation of varying age groups when relevant. Urinary incontinence in children falls into four main categories: neurogenic (myelomeningocele and other less common neurogenic etiologies), pure nocturnal enuresis, detrusor overactivity, and dysfunctional voiding without neurologic disease. This issue of age groups is most crucial in children with myelomeningocele. These children are often on medication beginning at a very young age and continuing for many years; the long-term safety of medications in children must be established in all age groups. Therapy for other causes of incontinence in children tends to start at a later age, by which time size is the main difference between children. We recommend that clinical studies have long-term (five years or more), open label extension arms to monitor safety, particularly focusing on normal growth and development and the effects on treatment of liver and central nervous system function. Most importantly for incontinence studies, normal maturation may significantly enhance or obscure response to an intervention.

Assessment of compliance with therapy is always difficult, and even more so with children. Compliance with voiding diaries, a significant issue in the adult population, may be even more problematic with children. Children may “act out” and refuse medications or other treatments. Children may be willing to comply with instructions from one parent or caregiver but not another. Personal problems of the caregiver may dramatically affect the child’s compliance with a
treatment protocol. We can only recommend that this potential problem be recognized and given even more attention than in trials with adults. Adequate support to the family member consenting to the trial may aid in compliance with treatment. Specific compliance issues should be identified whenever possible. If a treatment is not accepted by either the adult or the child (e.g., tablet size too large, taste of the medicine not acceptable, behavioral treatment schemes too rigid), then it cannot be effective in practice, no matter how theoretically beneficial it may be.

The NIH document details appropriate levels of consent required based on the risks inherent to a particular study. Depending on the age of the child, consent may be given by the parent in a purely surrogate role or the child may participate to some degree in the process. However, true informed consent of the subject is not possible in the vast majority of cases when children are involved. We recommend that an effort be made to include the child in the discussion of the trial with age-specific language and illustrations when appropriate. It is important to include the primary care giver, when the consenting adult will not be administering the treatment. Such complex relationships exist where childcare is shared amongst more than one adult, or where an employee for the purposes of childcare exists, either inside or outside the home. While children should always be offered the standard of care when such exists, so few treatments have ever been studied properly in children that there are many areas in which no treatment can properly be called “safe and effective”.

Outcome measures are not as well developed in children as in adults. Validated, age-specific symptom and disease-specific quality of life instruments must be developed for the pediatric population. Early efforts in this area have been reported for dysfunctional voiding [182] and daytime incontinence [183]; much more work remains to be done. Invasive urodynamics can rarely be used (except in the neurogenic population), as parents will not allow repeated instrumentation of the child. The reproducibility of urodynamic investigations in children is still under investigation.

**Recommendations for Research in Children**

- Long-term follow-up is of critical importance in the pediatric population in order to ascertain the effect of a treatment on normal growth and development. **HIGH**
- Research is needed to develop standardized outcome measures including validated, age-specific symptom and disease-specific quality of life outcome measures. **MEDIUM**
- We support the NIH statement calling for increased clinical research in children. All investigators that work with children should be aware of the details of the document and particularly the issues surrounding informed consent. **MEDIUM**

5. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION (NLUTD)

In the past, renal failure was a leading cause of death in the spinal cord injured population and a feared complication of many neurologic conditions. Modern neurorehabilitative care is generally successful in maintaining renal function and preventing other upper urinary tract complications, affording social continence, and advancing independence in self-care. Lifelong urological follow-up is mandatory and there are many areas for further research to improve the lives of these patients. These recommendations add to the General Recommendations above and focus on the specific characteristics of the neurogenic patient. Specific discussion of treatment in the neurogenic population is contained in reports from committee 10. Statistical methods and research outcomes are applicable as described in the general recommendations. Emphasis should be given to:

- classification of the neurogenic patient
- the specifics of history and evaluation, necessary for research studies
- the urodynamic evaluation, which is the key investigational tool in the evaluation of this specific, complex and difficult patient population

**a) Classification**

Classification of NLUTD has three primary aims—to aid in discriminating or identifying an unknown underlying neurological disease process, to characterize the nature of the dysfunction so as to develop a treatment plan, and to assess the risk of secondary effects (e.g. on the upper tract) which may influence the necessity and aggressiveness of treatment. The latter two are clearly relevant to research in neurogenic incontinence and must be reflected in study design and patient description.

It is difficult to find a classification system of NLUTD as a base for research that is satisfactory for each of the three aims. The published systems have been reviewed in detail [184]. Both the disease process and the site of the neurologic lesion(s) are relevant in the study of NLUTD, yet even this information is inadequate to predict the functional characteristics for an individual patient. There is no one method that meets the broad needs of classification in this group. Typical or classic cases are often well described but
it is especially difficult to describe mixed and incomplete lesions. Thus, classification systems necessarily oversimplify or become extremely cumbersome. Finally, it must be acknowledged that the complexity of neurologic diseases and variations in individual behavior almost always call for a customized approach to therapy, further complicating research in the neurogenic patient. All of these factors complicate study design as it becomes difficult to create workable inclusion and exclusion criteria that apply to other than a narrow segment of the neurogenic population. Ideally a broad population of potentially relevant participants would be enrolled in research studies with full characterization of both the neurologic condition and the nature of the lower urinary tract dysfunction so as to allow for subgroup analysis.

b) History and evaluation

Study planning is best undertaken with the cooperation of urologist, neurologist, and other clinicians, who have a specific interest and special training in the neurogenic patient. Baseline data collected by history in subjects with neurogenic lower urinary tract disorders should include:

- bladder volumes by diary or examination (maximum voided or catheterized volume, post voiding residual urine, total capacity);
- mechanism of bladder evacuation: normal or volitional, reflex evacuation, spontaneous involuntarily, Credé, sterile intermittent catheter (SIC), clean intermittent catheter (CIC), intermittent catheter by second person, suprapubic or urethral catheter;
- use of external appliances (e.g., diaper or pad use, condom catheter, urethral catheter, suprapubic tube);
- the typical time span of continence (continence interval) following last bladder evacuation and maximal continent bladder volume.
- bowel function, sexual function, and specific neurologic deficits

Issues such as mobility, independence in activities of daily living, cognition, skin breakdown and faecal impaction frequently become relevant in this population compared to neurologically intact individuals. Standardized disability scales would be useful in clinical trials.

c) Urodynamics

In contrast to the general recommendations, baseline urodynamics are required for research studies of neurogenic incontinence. Because the nature of the lower urinary tract dysfunction cannot be accurately predicted, based on the history and physical findings, urodynamic classification is mandatory. Neurogenic disorders commonly cause complex and generalized lower tract dysfunction, often with combined bladder and urethral sphincter abnormalities. In addition, data should be collected on symptoms and the underlying neurologic disease. While urodynamic classification alone is suboptimal, it is clearly preferable to classification by symptoms or disease alone (e.g., a study involving subjects with neurogenic detrusor overactivity and coordinated sphincters will be easier to interpret than one of neurogenic urgency incontinence or multiple sclerosis).

Urodynamic studies in neurogenic disorders are qualitatively different compared to non-neurogenic disorders. For each subject, bladder function, sphincter function, and the coordination between the two must be fully described. In addition to the usual data on unstable contractions during the filling phase, compliance is also of major importance. Elevated detrusor leak point pressure predicted upper urinary tract deterioration in a small group of children with myelomeningocele [185]; non-compliant filling is presumed to be important in all neurogenic patients although complete evidence is lacking. Detailed analysis of voiding dynamics becomes more important (e.g., simultaneous pves/pabd during voiding, voiding time, shape of the Pdet and Q curves) because of the possibilities of functional obstruction and impaired contractility, which are uncommon outside of the neurogenic population. Because the detrusor and sphincter may be dyssynergic, assessment of sphincteric activity is particularly relevant. This may be accomplished by surface electromyography of the pelvic floor, needle electrodes, fluoroscopy, ultrasound, or direct measurement of urethral pressure. Videourodynamic studies are generally considered to be the gold standard for evaluation of LUT function in the neurogenic population.

Recommendations for Research in Neurogenic Lower Urinary Tract Dysfunction

- Detailed urodynamic studies are required for classification of neurogenic lower urinary tract disorders in research studies because the nature of the lower tract dysfunction cannot be accurately predicted from clinical data. Videourodynamic studies are preferred but are not mandatory. MEDIUM
- Change in detrusor leak point pressure should be reported as an outcome for spina bifida subjects and others with non-compliant filling. MEDIUM
- An area of high priority for research is the development of a classification system to define neurogenic disturbances. Relevant features could include the underlying diagnosis, the symptoms, more precise documentation of the neuromuscular lesion by clinical neuromy- siologic testing, and the nature of the urodynamic abnormality. LOW
6. FAECAL INCONTINENCE

Men and women with urinary incontinence frequently have coexistent problems with the posterior compartment, such as faecal incontinence, faecal urgency, constipation, chronic pain (such as levator syndrome or proctalgia fugax), solitary rectal ulcer syndrome, or rectal prolapse. Discussion of all these conditions is beyond the scope of this committee (see Chapters 16 & 17 for more detail), which will focus on research methodology in the study of faecal incontinence.

Faecal incontinence has been among the least studied of all pelvic floor disorders. There is a high degree of coexistence of urinary symptoms and faecal incontinence [186]; this warrants focusing more attention to comprehensive evaluation and management of pelvic symptoms. Many definitions for faecal incontinence have been created for use in clinical research, but there is still no consensus on a single instrument or group of instruments that is ideal for the assessment of outcomes, although the ICIQ-BS (bowel symptoms) is now available (see Chapter 5). Therefore, the following comments are by necessity non-prescriptive; we anticipate that future research findings will guide the development of more specific recommendations.

For the purposes of this discussion, faecal incontinence includes impaired ability to control either stool (liquid or solid) or gas. It is important to emphasize that faecal incontinence is a symptom and, as such, must be measured through subjective assessment [187]. The subjective evaluation of faecal incontinence in clinical research requires measurement of at least two aspects of the condition: severity and impact. Severity can be assessed by either grading scales or summary measures [188-190], and includes a component of frequency of episodes over a specified period of time.

Faecal urgency, while not an integral part of the definition of faecal incontinence itself, may have a marked impact on quality of life as patients restrict their activities to avoid faecal incontinence [190]. The impact of faecal incontinence is best measured by disease-specific quality of life instruments [191, 192]. The need for one standardized system of evaluation and quantitation of symptoms (which may include questionnaires, diaries, and quality of life assessment) is a high priority for further research in this field. The lack of standard accepted tools affect the study of this disorder. In past years and in one recent RCT on sacral nerve stimulation for severe faecal incontinence (193), the Wexner’s incontinence score [194] and the faecal incontinence quality of life index (FQIL) [195] have gained broad recognition. However, other tools such as the Manchester Health questionnaire [196] and the Faecal incontinence severity index (FISI) [197] are popular as well.

In contrast to urinary incontinence, the objective demonstration of faecal incontinence is not a component of current definitions. Because patients can significantly alter their lifestyle to avoid an accident, the physician needs to understand the patient’s symptoms and how it affects their life through a detailed history. Physical examination should include screening for pelvic organ prolapse (in some studies such as surgical studies of faecal incontinence, the standardized quantification system for staging of prolapse [9] should be used); rectal examination; assessment of pelvic muscle function; and screening pelvic neurologic examination. Other specific test results are not included in the definitions.

However, certain tests may be useful in identifying different subcategories of faecal incontinence, such as a specific sphincteric defect versus generalized atrophy. If any component of anorectal anatomy or function could reasonably be expected to change with treatment, consideration should be given to performing such tests before and after intervention. For example, if anal ultrasonography is used to detect sphincter defects preoperatively, it would be beneficial to obtain anal ultrasound postoperatively as well, to study the association between anatomic change and change in subjective assessment (i.e., symptoms).

In defining the impact of interventions on faecal incontinence, cure is defined as complete resolution of the symptom. Failed treatment ( persistence or recurrence) is defined as no improvement or worsening of symptoms. Without evidence, improvement cannot be specifically defined at this time but may include a favorable change in symptoms related to severity or impact or both.

Simply reporting a statistically significant average improvement in grading or summary scores in a group of subjects is not very informative; measuring within-patient change is more informative as to the true impact of the intervention. Like for urinary incontinence, it is important at the outset to establish some goals and expectations. Realistically, improvement in quality of life is a far more likely outcome than perfect continence. Further research is needed to develop clinically meaningful levels of improvement after intervention.
The authors found that 90% of the subjects meeting the NIDDK criteria [202]. Pain) and exclusion criteria that serve to create a consensus conference resulting in a research definition for research studies. In 1987 the NIDDK sponsored the definition of BPS/IC and the appropriate population database suggests that the prevalence of symptoms in women and 8-41 per 100,000 men [199]. The same database suggests that the prevalence of symptoms of BPS/IC is between 6.2% and 11.2% for women and 2.3-4.6% for men [201]. It is clearly an important problem for which a great deal more research is needed. The report of committee 19 reviews the knowledge base for this disease in detail.

There continues to be considerable controversy over the definition of BPS/IC and the appropriate population for research studies. In 1987 the NIDDK sponsored consensus conference resulting in a research definition of interstitial cystitis [201]. The definition encompasses inclusion criteria that describe the syndrome (centered on cystoscopic findings and the presence of pelvic pain) and exclusion criteria that serve to create a relatively homogeneous patient population. One study examined the performance of the NIDDK criteria [202]. The authors found that 90% of the subjects meeting NIDDK criteria were felt to have interstitial cystitis by experts. However, over 60% of participants diagnosed with interstitial cystitis by the same experts did not meet the strict criteria. Therefore, the use of the strict NIDDK criteria may exclude 2/3 of appropriate subjects and diminish the impact of trials because the patient population is not representative of the BPS/IC population at large. Such criteria could also select for patients with more severe/chronic disease who may be less likely to respond to intervention. It has been suggested [204] that very inclusive criteria be used in BPS/IC trials to improve the generalizability of results.

In 2002 the ICS defined “painful bladder syndrome” as, “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology” [204]. Cystoscopic findings were not part of this definition. It is further proposed that, “interstitial cystitis is a specific diagnosis and requires confirmation by typical cystoscopic and histological features”. This issue may not easily be settled as there appear to be markedly different worldwide perceptions as to the true nature of BPS/IC as manifest by willingness of different investigators to make the diagnosis [205]. For now, it would appear that there is much to be gained from trials with both inclusive and restricted entry criteria and there will be some that will be most appropriate for each strategy. Ultimately, identifying clinically significant patient phenotypes through biomarkers (e.g., antiproliferative factor and associated bladder growth factors), cystoscopic findings (ulcers and objective inflammation), associated diseases (autoimmune disorders), or associated pain syndromes (fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome) may be useful in defining homogeneous and biologically meaningful patient populations for research.

Once the population to be studied is decided there has been considerable progress in defining appropriate methods of conducting clinical trials. Key clinical trial design issues have been reviewed [203]. TheInterstitial Cystitis Collaborative Research Network (ICCRN, http://porter.cceb.upenn.edu:7778/servlet/page?pageid=234,238&_dad=portal30&_schema=PORTAL30), a group funded by the NIDDK, is composed of 10 centers in North America and a Data Coordinating Center. The ICCRN has completed randomized clinical trials using both oral [204] and intravesical agents [206]. These provide excellent templates for the investigator in the planning phase of a project. A first of its kind, double blind clinical trial of newly diagnosed, previously untreated patients, evaluating the effects of amitriptyline has recently been completed. This trial will also add to our knowledge of the treated natural history of the disease in a unique population of IC patients. A pilot study suggested that pelvic floor physical therapy may be an effective treatment for urologic pelvic pain [206] and

### 7. BLADDER PAIN SYNDROME (INCLUDING INTERSTITIAL CYSTITIS)

The prevalence of Bladder Pain Syndrome (including interstitial cystitis) (BPS/IC) has been estimated at 52 to 67 per 100,000 adult women in the United States [198]. However, more recent work suggests that the prevalence of the diagnosis in a managed care practice is somewhere between 45 and 197 per 100,000 adult women and 8-41 per 100,000 men [199]. The same database suggests that the prevalence of symptoms of BPS/IC is between 6.2% and 11.2% for women and 2.3-4.6% for men [201]. It is clearly an important problem for which a great deal more research is needed. The report of committee 19 reviews the knowledge base for this disease in detail.

There continues to be considerable controversy over the definition of BPS/IC and the appropriate population for research studies. In 1987 the NIDDK sponsored consensus conference resulting in a research definition of interstitial cystitis [201]. The definition encompasses inclusion criteria that describe the syndrome (centered on cystoscopic findings and the presence of pelvic pain) and exclusion criteria that serve to create a relatively homogeneous patient population. One study examined the performance of the NIDDK criteria [202]. The authors found that 90% of the subjects meeting NIDDK criteria were felt to have interstitial cystitis by experts. However, over 60% of participants diagnosed with interstitial cystitis by the same experts did not meet the strict criteria. Therefore, the use of the strict NIDDK criteria may exclude 2/3 of appropriate subjects and diminish the impact of trials because the patient population is not representative of the BPS/IC population at large. Such criteria could also select for patients with more severe/chronic disease who may be less likely to respond to intervention. It has been suggested [204] that very inclusive criteria be used in BPS/IC trials to improve the generalizability of results.

In 2002 the ICS defined “painful bladder syndrome” as, “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology” [204]. Cystoscopic findings were not part of this definition. It is further proposed that, “interstitial cystitis is a specific diagnosis and requires confirmation by typical cystoscopic and histological features”. This issue may not easily be settled as there appear to be markedly different worldwide perceptions as to the true nature of BPS/IC as manifest by willingness of different investigators to make the diagnosis [205]. For now, it would appear that there is much to be gained from trials with both inclusive and restricted entry criteria and there will be some that will be most appropriate for each strategy. Ultimately, identifying clinically significant patient phenotypes through biomarkers (e.g., antiproliferative factor and associated bladder growth factors), cystoscopic findings (ulcers and objective inflammation), associated diseases (autoimmune disorders), or associated pain syndromes (fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome) may be useful in defining homogeneous and biologically meaningful patient populations for research.

Once the population to be studied is decided there has been considerable progress in defining appropriate methods of conducting clinical trials. Key clinical trial design issues have been reviewed [203]. The Interstitial Cystitis Collaborative Research Network (ICCRN, http://porter.cceb.upenn.edu:7778/servlet/page?pageid=234,238&_dad=portal30&_schema=PORTAL30), a group funded by the NIDDK, is composed of 10 centers in North America and a Data Coordinating Center. The ICCRN has completed randomized clinical trials using both oral [204] and intravesical agents [206]. These provide excellent templates for the investigator in the planning phase of a project. A first of its kind, double blind clinical trial of newly diagnosed, previously untreated patients, evaluating the effects of amitriptyline has recently been completed. This trial will also add to our knowledge of the treated natural history of the disease in a unique population of IC patients. A pilot study suggested that pelvic floor physical therapy may be an effective treatment for urologic pelvic pain [206] and...
this is being examined in a larger trial of women with BPS/IC. There is general agreement that the primary outcome must be patient driven and the ICCRN has used the Global Response Assessment. The Global Response Assessment asks subjects to rate their symptoms, as compared to baseline, on a seven-point centered scale: markedly worse, moderately worse, slightly worse, no change, slightly improved, moderately improved, and markedly improved. Typically those responding as moderately or markedly improved are considered responders. A full spectrum of objective and subjective secondary endpoints will be required to fully characterize the treatment effect. However, not only changes in symptoms themselves but also bother of the symptoms and its impact on health related QOL should be focused on for outcome measurement. Special consideration should be given to examination of specific subgroups such as patients with Hunner’s ulcers, newly diagnosed patients, and male patients. As mentioned in the ICCRN trials above, attention should also be paid to the duration of symptoms prior to initiating a given therapy and to the number of prior unsuccessful treatments.

**Recommendations for Research in Bladder Pain Syndrome and Inter-stitial Cystitis**

- The patient population for BPS/IC trials must be carefully defined; improved diagnostic criteria such as biomarkers are needed. When appropriate, broader entry criteria should be used to reflect the full spectrum of the BPS/IC patient population. MEDIUM
- Study design should incorporate outcomes that are most relevant to these patients and should be standardised. LOW
- The primary endpoint of BPS/IC trials should be patient driven and the Global Response Assessment is recommended. A wide spectrum of secondary endpoints will be useful in defining the effect of treatments. MEDIUM

**8. PELVIC ORGAN PROLAPSE**

For the purposes of this discussion, pelvic organ prolapse includes anterior vaginal prolapse (previously known as cystocele), apical or uterine prolapse, posterior vaginal prolapse (previously known as rectocele), enterocoele, and perineal descent; it does not include rectal prolapse. Ideally, for clinical research purposes, prolapse would be defined by three components: (1) by the presence and severity of symptoms, with some indication of bother or impact on quality of life; (2) by signs obtained at physical examination; and (3) by testing, depending on specific study goals. However, singly or in combination, all three components are severely limited in their capacity to distinguish “normal” from “abnormal” regarding prolapse.

Most pelvic symptoms are highly nonspecific and do not show strong associations with the location (anterior, apical, or posterior compartment) or stage of prolapse [207-208]. One exception to this is the patient’s awareness of an actual bulge or protrusion, which has high positive and negative predictive values for Stage III or IV prolapse (but not the affected compartment of prolapse). As a consequence, specific symptoms cannot currently be required in the definition of prolapse (with the possible exception of tissue protrusion). By the same token, the resolution of specific symptoms cannot be required in the definition of “cure” after treatment; however, surgeons should state which symptoms (other than the local bulge) that he/she plans/hopes to cure/improve. Nevertheless, it is essential to include a comprehensive survey of pelvic symptoms to be able to describe what symptoms are present at baseline and which symptoms change with treatment. For example, the Pelvic Floor Distress Inventory (PFDI) includes subscales on prolapse, urinary function, and coloanal function; its companion, the Pelvic Floor Impact Questionnaire, surveys the degree to which symptoms impact quality of life [209]. These condition-specific instruments are relatively new and, although validated, have not yet been shown to be sensitive to change with treatment; however, their comprehensiveness makes them attractive for inclusion in studies where women may have or develop different pelvic floor disorders. Sexual function should be specifically assessed, especially in studies of surgical treatment for prolapse. The ICI questionnaire, the ICIQ-VS (vaginal symptoms), is one instrument that covers all of these areas of interest although experience with its use is limited.

Unfortunately, the relationship between symptoms and anatomy as measured by the POP-Q are poorly understood. The point at which symptoms may be attributed to the anatomical prolapse is not known. The POP-Q system is a validated, quantitative system with excellent inter- and intra-rater reliability. It includes measurement in centimeters of six vaginal sites relative to the hymen, plus three other measurements for total vaginal length, perineal body, and genital hiatus [9] as described in Outcomes section above.

Other measurements have not been standardized, such as assessment of urethral mobility (e.g., estimation on physical exam, cotton swab testing, perineal ultrasound, lateral cystogram), identification of paravaginal defects and perineal descent, pelvic muscle assessment, and pelvic imaging (e.g., defecating proctography, static or dynamic pelvic magnetic resonance imaging). Detailed descriptions of their measurement should be included if they are used. Data should be presented as a continuum, not as a dichotomy of “normal” versus “abnormal” until those terms are clearly defined by evidence of clinical relevance.

At the time of the 1999 NIH Terminology Conference
permanent synthetic mesh for prolapse repairs has for example, the dramatic increase in use of meshes, is also not known, and is discussed further in Chapter 15.

Although clinical experience strongly supports that prolapse develops gradually over years, it is not known whether Stage II prolapse predicts future support loss or, if it does, in how many women and over what time course. This is particularly controversial in choosing a cutoff for what constitutes clinically significant persistent or recurrent prolapse after surgical treatment. The location of prolapse is important in this choice as well. While both Stage II anterior and apical vaginal prolapse may be asymptomatic, most surgeons would not be willing to accept Stage II apical prolapse as a successful surgical treatment, yet Stage II anterior (or posterior) asymptomatic vaginal prolapse is often considered to be acceptable. While planning clinical trials, the goal of the surgical treatment (restoration to Stage 0, restoration to Stage 1, etc. with or without symptoms) should be clearly specified. Durability of all types of prolapse surgery requires longitudinal, long-term follow-up, which is generally not available in the current literature. The utility of supplementary materials, e.g. synthetic and biologic meshes, is also not known, and is discussed further in Chapter 15.

Primarily due to lack of evidence, prolapse is not currently defined based on specific test results. We recommend that further research be performed to investigate the usefulness of various tests (for example, imaging by X-ray contrast, ultrasound, MRI) in determining definitions and outcomes of prolapse treatment. In a specific study, if an aspect of anatomy will be directly influenced by surgery, it may be reasonable to perform imaging before and after surgery to assess whether any change seen on imaging is correlated with changes in symptoms and physical findings.

We recommend that interventional studies in POP employ both anatomic (POP-Q) and functional outcomes whenever possible. It is equally important that adverse events/treatment complications be reported in detail. For example, the dramatic increase in use of permanent synthetic mesh for prolapse repairs has created the possibility of new and delayed complications. These risks were highlighted by the United States Food and Drug Administration in a recent bulletin (http://www.fda.gov/cdrh/safety/102008-surgicalmesh.html). In particular, reoperations to excise mesh or granulation tissue, whether performed in the office or hospital, dyspareunia, and partner sexual pain “hispärenia” should be reported. Finally, key factors to patient satisfaction must be identified in order to develop better patient driven outcome measures. Goal achievement appears to be one such promising area of research in understanding outcomes after POP surgery. (Hullfish 2004 and Mahajan 2006)

9. NOCTURIA

While nocturia has often been viewed as just one of the manifestations of lower urinary tract dysfunction, there has been a recent appreciation that it is an important independent symptom that does not “belong to” another clinical problem. Waking at night to void can be the result of abnormal fluid intake or other behavioral issues, cardiac conditions, peripheral venous disease, and sleep disorders as well as lower urinary tract dysfunction. This complexity makes clinical research in nocturia very difficult; the fact that the condition is affected by so many different issues mandates a multidisciplinary research team. Although nocturia is one of the most bothersome of symptoms there has been little progress in treatment of nocturia outside of studies in pediatric nocturnal enuresis. On the other hand, major contributions to the understanding of nocturia and the methodology for research in nocturia have been made that should facilitate future research. The 2002 ICS Standardization sub-committee report on nocturia should greatly facilitate research efforts; it defines the relevant terms, introduces a flow-chart for evaluation, and presents tables of the causes for the various subtypes of nocturia [211]. Potential investigators should carefully review this document in the planning stage of research.

One major randomized controlled trial in adults was identified in a literature search. It found that desmopressin was significantly more effective than
placebo in reducing nocturia in a population of adult women with at least two voids per night [212]. Other studies suggest that celecoxib (213) and melatonin or other hypnotics [214] may benefit certain patients.

**Recommendations for Research in Nocturia**

- Population or community based research is needed to define the epidemiology of nocturia and how the symptom relates to normal aging. MEDIUM
- Clinical research in treatment of nocturia should begin with classification of subjects by frequency volume chart categories—polyuria, nocturnal polyuria, and apparent bladder storage disorders. If desired, those with low bladder capacity can be further divided into those with sleep disturbances and those with primary lower urinary tract dysfunction. HIGH
- The impact of nocturia on falls and fractures deserves further investigation MEDIUM

**IV. CONSIDERATIONS FOR SPECIFIC TYPES OF INCONTINENCE RESEARCH**

**1. BEHAVIORAL AND PHYSIOTHERAPY TRIALS**

Non-pharmacologic, non-surgical treatments for incontinence comprise a wide variety of tools often grouped under the name of behavioral treatment. Although these treatments are generally very safe and applicable to most incontinent patients, there should be no compromise in the quality of clinical research. Treatment may be time consuming for both patient and therapist and should not be suggested without a reasonable hypothesis and sufficient evidence.

The type of therapy must be defined with sufficient detail for other investigators to reproduce the study. The type of behavioral therapy should be clearly stated, including the duration of the total treatment period, duration of each treatment session, and number of treatment sessions. The time between qualification for study entry and start of therapy must be specified. Any devices used must be properly described. The background and training of the therapist should be defined. All instructions, training, and educational materials given the subjects should be reproduced or referenced. A complete description of all differences in the experience of the treatment and control groups should be provided.

As in other studies, the study population should be characterized. The usual clinical outcome measures suffice. In order to progress in our understanding of these treatments it is important to consider clinical outcome alongside physiologic changes. If the intervention is intended to increase the strength of pelvic floor muscle contraction, this should be measured and correlated with continence.

Outcome measures to assess effects on other related organ systems (e.g., gastrointestinal and sexual functioning) should also be considered, as well as possible adverse outcomes.

It is important to distinguish between **specific and non-specific** effects, such as improvement related to the extra attention of the therapist, leading to a gain in motivation, confidence, etc. The goal is to isolate what a particular therapy achieves on its own. However, in behavioral therapy, the non-specific effect is widely considered to be an essential, desirable and important part of the effect of the therapy. It therefore needs to be evaluated along with the specific effect.

Carefully designed randomized controlled studies should allow separation of specific and non-specific effects. This is particularly important with techniques such as electrical stimulation and biofeedback where particular instrumentation or equipment may be credited with results that could be due to the efforts of the therapist. Recent studies using a standardized self-help booklet are commended as important steps in defining this issue [215,216].

There have been many trials of various physical therapies and these are summarized in Chapter 12; there have been relatively fewer regarding the many behavioral issues suggested to affect incontinence. It can be difficult to perform double-blind studies of behavioral technique.

Clinicians and subjects often cannot be blinded. In quality assessment of studies, double blinding is often one of the criteria of methodological quality. It may not be reasonable to demand double-blinding in all behavioral studies, or, if double blinding is not accomplished, to consider such research less valuable. It is more realistic to demand the ‘most optimal and possible level of blinding’.

A relevant control group is established, allocation to treatment groups is concealed, as many persons as possible are blinded (in particular, those individuals recording outcome measures), and appropriate measures surrounding this issue are discussed in the manuscripts. A recently completed trial studying obese women with urinary incontinence undergoing a weight loss program—the Program to Reduce Incontinence by Diet and Exercise (PRIDE) trial—presents a model of high quality work in behavioral therapy.
Recommendations for Behavioral and Physiotherapy Research

- There is a great need for long term data to define the durability of effect for all conservative treatment modalities in all population groups. HIGH
- Intervention protocols must be detailed to the degree that the work can easily be reproduced. HIGH
- A structured examination of pelvic floor neuromuscular function should be included before and after treatments that are aimed at pelvic muscle training. HIGH
- More work is needed to separate the specific and non-specific effects of treatment. MEDIUM
- Consider a variety of methodologies in development, evaluation, and interpretation of these interventions. MEDIUM

2. DEVICE TRIALS

In the United States, devices for urinary incontinence are regulated by the Center for Devices and Radiological Health (http://www.fda.gov/cdrh), a branch of the United States Food and Drug Administration (FDA). Although urethral devices and bulking agents differ considerably in risks to research subjects, they are grouped together for the purpose of FDA regulation. Requirements for the protection of human subjects are appropriate for the study of these treatments, yet other devices used in incontinence therapy may elude careful scrutiny. For example, materials for reconstructive surgery are primarily approved based on biocompatibility testing. However, implantation in less than a sterile environment (e.g. vagina), placement during concomitant operations (e.g. hysterectomy, prolapse repair) and effects of biofilms adjacent to the urinary tract could pose unique conditions with subsequent complications in the long term. Very little is known about the effectiveness of such devices at the time of approval.

Detailed guidelines for studies on intra-urethral urethral bulking agents were published in 1995 [217]. Guidelines for implantable devices such as used for neuromodulation fall under different criteria. Guidelines for engineered tissues and cell therapy are evolving. Neuromodulation therapies and would be evaluable in the context of all population groups. MEDIUM

1. Inclusion in trials has been limited to subjects with “urinary incontinence due to ISD (intrinsic sphincter deficiency), as evidenced from urodynamic studies or radiographic assessment”. While the basic concept of ISD is understood, there is no consensus on its definition for clinical care or research and little evidence for use of specific tests such as the abdominal leak point pressure in defining eligibility for research or clinical care.

2. The potential study population should be defined as broadly as is reasonable in include the majority of patients who could potentially benefit from such therapies and would be evaluable in the context of a clinical trial.

3. The recommendations for urethral inserts and injectable urethral bulking agents could be refined and separated in appropriate areas as injections represent a different level of risk.

4. The Stamey grading scale (0-3) for stress urinary incontinence has been recommended as the primary outcome measure. There is little evidence that this measure is as valid or reliable as other measures such as voiding diaries, pad tests, and leak point pressure measurements.

5. The need for follow-up beyond one year in all areas, to include: effectiveness, adverse events including retreatment, and patient satisfaction.

An important area of concern in device studies is patient recruitment procedures. We strongly support reporting according to the CONSORT guideline, including the flow diagram (Figure 2) for subject enrollment and follow-up. Subjects should be enrolled in a manner that minimizes selection bias. The protocol should detail the procedure by which consecutive patients meeting the inclusion criteria are selected. All situations in which a patient meets the inclusion/
exclusion criteria but is not offered enrollment by the investigator should be documented. The number of patients who decline enrollment should be stated, along with the reasons. There should be a complete accounting of all participants in the study including the reasons for subject withdrawal.

**Recommendations for Research in Incontinence Devices**

- Safety and serious side effects of incontinence devices must be completely defined with adequate follow-up, especially for use of implantable devices and biologic materials, so that risks can be weighed against efficacy. At a minimum, this requires more use of large scale, prospective, multicenter prospective cohort studies when RCTs are not feasible. HIGH
- Physiologic testing such as urodynamics should be considered, in addition to survey instruments, to substantiate the proposed biologic effect of devices especially when a placebo or sham is not available. MEDIUM
- Clear, updated guidelines for each of the categories of new devices should be developed that protect patient safety while promoting research in a practical manner. LOW
- Patients deserve complete information about implantable devices when considering surgical therapy. New devices may be introduced into the market with no or minimal track record of safety and efficacy for the proposed use. In such cases it may be best to have separate surgical consents for the operation and use of the new device. LOW

**3. PHARMACOTHERAPY TRIALS**

Drug trials are necessary so that new drugs can be clinically and scientifically evaluated for quality, efficacy and safety [219-224]. Since the 1960's administrative bodies such as the Food and Drug Administration have required that new pharmaceuticals undergo controlled investigations to establish efficacy. The specific stages of development and of study design have been discussed in detail in section IIB. Many large RCTs have been conducted in recent years and incontinence research has generally benefited from the attention to the field and emphasis on valid outcomes. As the financial backing of the pharmaceutical industry has been largely responsible for this research, new conflicts of interest and problems have arisen due to the changing economics. As stated in a joint editorial endorsed by members of the International Committee of Medical Journal Editors, "published evidence of efficacy and safety rests on the assumption that clinical trials data have been gathered and are presented in an objective and dispassionate manner. We are concerned that the current intellectual environment in which some clinical research is conceived, study subjects are recruited, and the data analyzed and reported (or not reported) may threaten this precious objectivity" [225]. Several of these issues are discussed in Section V3 below.

Although many RCTs have been published in recent years on pharmacotherapy for urinary incontinence a great deal more remains to be learned. The trials have almost all been limited to 8-12 weeks of treatment giving very little information about long term safety and efficacy of drug therapy. Studies have typically been performed in isolation, i.e. drug vs. placebo, as opposed to a real life scenario where drug therapy is combined with behavioral and pelvic floor therapy. There is less than adequate information about special patient groups—men, children, neurogenic patients, and especially the frail elderly. Because incontinence creates such an impact on the older population, good studies to define the utility and safety of drug therapy are greatly needed in this group. There are many practical concerns in employing pharmacotherapy, particularly regarding long term use of medication. The BE-DRI Study [226] from the Urinary Incontinence Treatment Network, is a good example of a trial designed to optimize use of medical therapy. It showed that combining behavioral therapy with pharmacotherapy did not improve patient’s likelihood of discontinuing drug treatment.

An issue of special relevance in trials of pharmaceutical agents (although germane to other treatment modalities) is the controversy regarding placebos in clinical trials. Regardless of whether a drug is effective or not, simply giving a drug to a patient may produce a beneficial response. To assess if a drug has an effect over and above the placebo response, it is usually tested against an inactive substance (placebo). In incontinence, the placebo effect may be quite large, anywhere from 30-50% in recent published studies. To account for this, investigators and regulators have generally demanded a placebo arm in most clinical trials of medication. On the other hand, the Helsinki Agreement (1989) states that "far from being useful, a placebo is unethical: in any medical study every patient including those in the control group, if any, should be assured of the best proven diagnostic and therapeutic method". Clinicians need to know how a new drug compares with established treatment. The FDA does not require placebo-controlled trials of drugs for approval. However, the sponsor will generally prefer to compare the drug with a placebo and not with a competitor, since it is usually easier to detect a difference between treatment and no treatment, compared to two active treatments. For drugs in that same class that are already available, an active control agent should be used whenever possible. In addition, comparator trials of behavioral therapy versus drug or device versus drug are lacking, as are combination
studies. Combination studies are especially relevant since such strategies are common in clinical practice despite the absence of data. Researchers must carefully consider these issues in designing a relevant, ethical study.

**Recommendations for Pharmacotherapy Trials**

- Every consideration should be given to making sure that the interests of the subjects are kept at the forefront in designing safe, ethical research. In urinary incontinence, safe and effective conservative therapy is available for the vast majority of patients. In most trials, comparison should be with "standard therapy" rather than placebo/no treatment. This approach respects practical patient management where placebo is not an option. HIGH

- As effective drug therapy is available for most forms of incontinence comparator arms are recommended for most trials. Claims of superiority of drugs even within the same class are unfounded in the absence of randomized comparator trials. HIGH

- Very little is known about the safety, efficacy and tolerability of drug therapy beyond 12 week trials. A concerted effort is needed to create this type of information base. Long-term follow-up of RCT cohorts in an observational cohort is recommended HIGH

**4. SURGICAL TRIALS**

Standards for surgical trials are detailed in recommendations from the CONSORT Organization (http://www.consort.org), ICS, SUFU, and the AUA [12-17]. We support the adoption of these standards by clinical and basic science researchers, the peer review process, specialty and sub-specialty organizations, the health care industry, regulatory agencies and ultimately by clinicians. While discussion of surgical therapy for incontinence mainly applies to females with stress incontinence, most of these points are equally applicable to males undergoing surgery for post-prostatectomy incontinence and related problems (and females undergoing surgery for repair of pelvic organ prolapse). Unique research issues for surgical research using observational studies and randomized controlled trials will be presented and insights from other surgical specialties will be discussed.

**a) Observational studies**

Observational studies are important major sources of descriptive data to understand the patterns of use for surgical procedures and of factors that influence these patterns. A few observational studies that included representative samples with well-conducted data collections have been reported and will serve as examples for future research.

Cross-sectional studies of surgical procedures by type can provide estimates of prevalence, variation by age, race, and region as well as morbidity and mortality. Using the US National Hospital Discharge Survey, it has been determined that incontinence operations have increased in frequency over time, are the third most common surgery in women, that there are large regional and racial differences in the rates of incontinence surgery, and morbidity and mortality are low [227,228]. This type of information raises important health policy questions regarding physician practices, patient preferences for incontinence treatment, and differential access to and the utilization of care. In another large US national cross-sectional study, participants reported satisfaction with surgery even if they had not achieved complete continence, demonstrating the importance of patient reported outcomes [229].

The largest prospective cohort study published to date included all women undergoing the three most common operations for stress incontinence at 18 representative hospitals in the United Kingdom [230]. A variety of measures of incontinence, symptom severity, symptom impact and complications were used, and participants were followed for 1 year. Overall, 87% of the women reported some improvement in incontinence one year after surgery, but only 28% reported complete continence [21, 231, 232]. This prospective cohort demonstrated that it is possible to collect standard data on multiple outcomes of surgery for stress incontinence to provide women with better information on the likely outcomes and effectiveness of the procedure in community practice. Lessons learned from this study will drive improvements in surgical research in incontinence as discussed below.

**b) The importance of surgical randomized controlled trials**

Observational studies can also provide important information for designing and selecting potential randomized clinical trials. The randomized controlled trial is the accepted "gold standard" for research of treatment effects. However, case series are far more common in the surgical literature, especially for new "innovative" surgical procedures. This is true despite the fact that case series cannot account for selection bias on the part of both the patient and surgeon, non-reporting bias of failures or loss to follow-up, lack of long-term follow-up, and provide the lowest level of evidence for treatment effects. In all surgical specialties, there has been growing concern regarding the limited number of randomized controlled trials for surgical procedures, poor methodological standards in those that have been performed, and a perception that surgeons are reluctant to rigorously test new surgical interventions [233-236]. A number of reasons
for the paucity of surgical trials have been suggested including the lack of a regulatory board similar to the Food & Drug Administration responsible for the development of new medications [165]. Surgeons can therefore perform new procedures with little or no limitations from hospital or ethics committees and without any substantive trials [234]. In the United Kingdom, the National Institute of Health and Clinical Excellence’s (NICE www.nice.org.uk) Interventional Procedures Advisory Committee, which analyzes all new procedures and seeks to provide commissioners and providers of health care with objective guidance, regarding their value, with respect to safety and efficacy.

The importance of surgical randomized controlled trials was demonstrated in a sham trial of arthroscopic surgery for osteoarthritis of the knee, one of the most widely used orthopedic operations. Numerous uncontrolled case series had reported substantial pain relief after arthroscopic surgery. The trial provided strong evidence that the surgical procedure was no better than the placebo procedure [238].

There have been few methodologically rigorous randomized trials of surgical procedures for incontinence. In reviewing the literature to prepare the 1997 AUA Guidelines for surgical treatment of stress incontinence, 943 studies identified but there were only 11 randomized controlled trials [239]. Overall, the randomized trials were considered of poor quality because they had few participants and were underpowered to detect small differences between groups, lacked blinding of the participants and/or individuals assessing the outcomes, and had short follow-up. It is particularly important that operations for incontinence undergo methodologically rigorous randomized trials because surgery is elective and non-emergent, the effect difference between two techniques will be at best modest, and patients as well as surgeons need accurate data to make informed choices using risk and benefit data to compare operations [240,241]. It has also been suggested that the first anti-incontinence procedure provides the highest success rate and subsequent procedures have a far higher failure and complication rate [239]. The last decade has brought us several new trials with strong methodology, as discussed below.

The Urinary Incontinence Treatment Network is one example of a multi-center consortium created to conduct randomized controlled clinical trials enrolling patients with urinary incontinence. The UITN, established by the U.S. National Institutes of Health in 2000, consists of 9 recruiting centers and a data coordinating center. The clinical expertise includes a mixture of urology and urogynecology specialists. The first clinical trial undertaken by the Network compared standardized forms of the Burch colposuspension (Tanagho modification) and the autologous rectus fascia sling procedures for overall treatment success and stress urinary incontinence success at 24-month post-operatively (the trial is known as the Stress Incontinence Surgical Treatment Efficacy Trial or SISTEr) [243]. A second trial, the Behavior Enhances Drug Reduction of Incontinence, BE-DRI tested whether the addition of behavior treatment to tolterodine therapy will increase the number of patients who can discontinue tolterodine therapy and sustain a significant reduction of incontinence. The work of this and other cooperative groups will inform surgical practice to a much greater degree than historical literature that was primarily composed of single institution case series.

c) Surgical trial methods

“Surgeons should realize that using the right tools for clinical research is comparable to selecting and using the right instruments for an operation.” [243]

To ensure surgical trials are relevant and credible, detailed information about the study design is essential [233]. Reports of randomized trials should follow the current CONSORT flow diagram [30]. In order to understand how surgical results can be generalized to the population at large it is critically important that researchers carefully record the number of patients with incontinence who were not offered enrollment in the trial and those who refused to participate as well as the reasons for each. All participants should undergo a comprehensive baseline evaluation as discussed in the general recommendations and baseline comparability of the intervention groups should be demonstrated using descriptive statistics. The randomization technique must be clearly described to confirm random allocation and that none of the study team has influenced the assignment, resulting in selection bias.

Differential drop out after randomization can introduce bias. In the largest and most methodologically sound randomized controlled trial to date comparing the tension-free vaginal tape (TVT) and colposuspension (referred to as the UK TVT RCT), a large number of women withdrew from the colposuspension arm after randomization [244,245].

The loss of participants after randomization introduced bias in favor of the TVT because the drop outs had less severe incontinence resulting in the colposuspension group having more severe incontinence. It has been suggested that participants were only willing to continue if they were randomized to the “new and better” TVT procedure [245,246]. Accounting for subjects “lost to follow-up” must also be detailed as per the CONSORT flow diagram. In the UK TVT RCT, drop out after surgery was similar for both procedures. In contrast, the UITN study discussed above had no drop outs with 850 participants randomized in the operating room at the time of surgery [242].
The surgical procedure should be described in such detail that it could easily be reproduced in another study. Standardization of the procedure may vary depending on the research question [247]. Trials where the surgical technique is tightly controlled (i.e. small number of highly skilled surgeons) are analogous to medical trials where only compliant patients are randomized, reflecting efficacy of the procedure in an ideal setting. If the surgical procedure is less controlled, it may be more generalizable to a mixture of skill level among surgeons in the community, and so reflect effectiveness of the procedure in usual practice [240].

Masking of participants as to their assigned intervention and those assessing the outcome is particularly important for surgical trials for incontinence because there may be enthusiasm by the patient or surgeon for a new procedure, many outcomes are based on the patient's own assessments such as symptom and quality of life scores, and the intervention is primarily for improvement of symptoms [249]. In the previously mentioned UK TVT RCT, neither the participants nor the staff collecting the post-operative assessments were blinded and this may have resulted in a biased assessment of the outcome.

It is unfortunately clear that much remains to be done to improve the quality of the surgical literature in incontinence and LUTS. Using a standardized evaluation form based on the CONSORT statement published in 1996, 152 reported RCTs were identified in the Urology literature across 4 leading urology journals between 1996 and 2004 [251]. The most prevalent topic was voiding dysfunction (38%) and only 40% of the studies reported information about funding, of which 63% was from industry support. Although progress was identified in sample size justification and randomization implementation, reporting of these key methodological criteria remained consistently below 50% in 2004. The authors recommended more graduate and postgraduate education be offered in trial design to improve on RCT reporting. Another article by the same group, “Evidence based clinical practice: a primer for urologists”, is recommended as an excellent reference. [252].

d) Outcomes of UI

Surgical outcomes are discussed in detail in Chapters 13 & 14 as well as in the specific patient groups discussed above and will not be repeated here. The key issues are that validated outcome measures should be decided in advance and data collected prospectively, as well as throughout the study.

e) Development & assessment of new surgical procedures

Surgical research presents unique challenges to efforts at optimizing patient care. It is important to create a pathway for real advances while simultaneously protecting patient safety. It would be desirable to have RCTs of all operations for incontinence; while one may argue that resources are inadequate it is also very costly to introduce ineffective or unsafe procedures without proper research. When new procedures are substantially different from prior operations there should be a broad based preliminary exploration leading to a comparative trial if warranted. At the same time, many minor modifications of surgical procedures are inappropriate for randomized trials and if required, surgical progress would be slowed [253].

It has been argued that the first patient in whom a procedure is performed should be randomized [234, 250]. Alternatively, it has been suggested that case series for new procedures are allowed until the procedure finds its intended use and to avoid doing studies while those performing the procedures are on the “learning curve”. Typically, new surgical procedures for incontinence have been reported as case series [108, 254]. Not only do surgical case series provide the lowest level of evidence for treatment effects, case series may be “harmful”. An accumulation of “positive” case series may present a premature certainty about benefits of a procedure and make it even more difficult to perform randomized trials [233,240]. Influential members of the surgical community may endorse a new procedure and if the procedure is considered better it may be difficult to get surgeons and patients to randomize or a trial may appear to be unethical with a “proven” procedure [233, 234, 255].

For new surgical procedures, important issues of adequate informed consent and conflicts associated with incentives for developing, starting and using new procedures have been raised. Informed consent for a new procedure must include:

• acknowledgement that the procedure is new and has not been shown to be more effective than a traditional approach
• discussion of potential complications, especially any integrally related to the procedure or device
• disclosure that information on complications are limited, and
• disclosure that the long-term benefits are unclear [254].

Incentives for adopting new procedures prior to sufficient evidence can arise from self-interest by attracting patients to one’s practice, industry marketing, and patient desire for “cutting edge” techniques. Industry sponsorship or a surgeon’s financial interest must be disclosed.

It has been recently suggested that innovations in maternal-fetal surgery be conducted in centers of excellence, evaluated as research, and that randomized controlled trials are necessary before...
procedures become available outside the research setting or are integrated into clinical practice [256]. This recommendation is based on the premise that evidence is critical to ensuring that promising therapies are in fact safe and efficacious. [256]. Unfortunately, clinical trials and systematic analysis of outcomes have not preceded integration of new surgical therapies for incontinence into clinical practice [21, 239, 254, 257].

On the other hand, organizations and treatment networks have been established to address many issues related to surgical interventions. Examples include the UK National Institute of Clinical Excellence (NICE www.nice.org.uk), the Australian Safety and Efficacy Register of New Interventionsal Procedures-Surgical (ASERNIP-S www.surgeons.org/asernip-s), and the US treatment networks: Urinary Incontinence Treatment Network (UITN http://www.niddk.nih.gov/patient/uitn/uitn.htm) for the NIDDK and the Pelvic Floor Dysfunction Network (PFDN). The NICE and ASERNIP-S provide systematic reviews of new operations, assessment of effectiveness, and recommendations that the technique has sufficient data for widespread use, or that the techniques appear unsafe, or that further audit/research are required before its widespread usage. The UITN and PFDN were established to provide the infrastructure for multicenter large randomized controlled trials for incontinence and prolapse.

The PFDN is a multicenter network in the United States, supported by the National Institute of Child Health and Human Development, one of the institutes of the NIH. Started in 2001, the network has seven clinical sites and a data coordinating center, with the primary goal of performing clinical trials related to the prevention, evaluation, and treatment of pelvic floor disorders in women, including pelvic organ prolapse, and urinary and faecal incontinence as well as other abnormalities of the lower urinary and gastrointestinal tracts. The Colpopexy and Urinary Reduction Efforts (CARE) trial studied 322 women to test whether the addition of Burch colposuspension prevents postoperative stress incontinence when continent women with advanced prolapse undergo abdominal sacrocolpopexy [259]. It was stopped early due to a lack of benefit from the prophylactic incontinence procedure. Interestingly, the urodynamic analysis showed that demonstration of stress incontinence, by any method of prolapse reduction predicted postoperative stress incontinence, regardless of whether or not a Burch suspension was performed.[260] Other studies are either underway or have finished enrollment including:

- a cohort study of 900 primiparous women after their first birth, determining the prevalence and incidence of faecal and urinary incontinence among women who did and did not have an anal sphincter laceration at vaginal delivery, compared to women delivered by cesarean without labor; comparing symptoms, physical examination, and imaging (pelvic magnetic resonance imaging and endoanal ultrasound) in 255 women after vaginal delivery with and without anal sphincter laceration and in women after cesarean delivery without labor
- the OPTIMAL trial (sacrospinous ligament fixation versus uterosacral vaginal vault suspension with and without perioperative behavioral therapy/pelvic muscle training)
- the OPUS trial (vaginal prolapse repair with or without concomitant TVT procedure to address the issue of surgical stress incontinence prophylaxis).

To make ethical and evidence-based progress in surgical knowledge for incontinence, a new paradigm to balance surgical innovation and research is essential. Cooperative collaboration of investigators and possibly industry, a preliminary phase to develop new procedures and training, prospectively collected comprehensive data, and ongoing assessment as to the need for randomized controlled trials has been suggested [254]. Strong position statements have been issued by individuals [261,262] and organizations [263] regarding the marketing of new procedures and the legal/ethical implications for physicians. Registries have been suggested to track complications and their management but they can fall short by lack of denominator information and incentivization in reporting. It has regrettably become easier to try new surgical procedures in women with stress urinary incontinence without much knowledge of their effectiveness or potential complications than to develop a new drug and receive FDA clearance. Although the FDA has a reporting site (MAUDE), it has remained vastly under-utilized. As stated by Dr Ostergard in his article’s concluding comments: “…do not let industry control how we practice medicine.” As surgeons, we have the opportunity and responsibility to improve our understanding of surgical interventions and improve patient care.

**Recommendations for Surgical Trials**

- The safety and serious side effects of new operations must be completely defined with adequate follow-up so that risks can be weighed against efficacy. At a minimum, this requires more use of large scale, independent, prospective, multicenter cohort studies when RCTs are not practical. HIGH
- Valid informed research consent is required in all trials of surgical interventions, which is separate from the consent to surgery. HIGH
- We recommend ongoing research into the usefulness of pre- and post-operative urodynamics in surgical trials. One of the primary...
It is appreciated that both device and surgical research trials present significant challenges to trial design. Although decades of experience have refined the conduct of drug trials the absence of comparable robust device and surgical trials derives from these design challenges. Table 2 lists adherence to Design criteria between Behavioral, Drug, Device and Surgical Trials as specified in General Recommendations for Clinical Research in Incontinence. The net result of failure to adhere to these principles may be that the efficacies of the latter two approaches for urinary incontinence are over-estimated. By analogy to intervention trials for pain, the more invasive the

5. SUMMARY OF SPECIFIC TYPES OF TRIALS

It is appreciated that both device and surgical research trials present significant challenges to trial design. Although decades of experience have refined the conduct of drug trials the absence of comparable robust device and surgical trials derives from these design challenges. Table 2 lists adherence to Design criteria between Behavioral, Drug, Device and Surgical Trials as specified in General Recommendations for Clinical Research in Incontinence. The net result of failure to adhere to these principles may be that the efficacies of the latter two approaches for urinary incontinence are over-estimated. By analogy to intervention trials for pain, the more invasive the

• Long-term follow-up of RCT cohorts in an observational cohort is recommended HIGH
• There needs to be a standardized procedure for classifying adverse events (e.g., Dindo) HIGH

research goals should be to collect data to determine the predictive value of urodynamic testing prior to intervention for stress urinary incontinence. Other important areas include the utility and performance of urodynamics for continent women undergoing pelvic organ prolapse repair. HIGH

• Reports of successful treatment should be limited to subjects with a minimum (not mean) of one year follow-up and should include a patient perspective measure. Specific assumptions about subjects lost to follow-up should be stated; last observation carried forward may not be the most appropriate method of handling this data as most patients lost to follow-up should be considered to have failed treatment. HIGH
• Randomization for surgical trials should occur at the time of surgery to minimize drop-outs and switch of procedure HIGH
treatment, the greater the placebo effect and desire by the patient to self report better outcomes. For urinary incontinence, like pain, this is especially relevant in that even purported “objective” outcomes of diary and pad tests rely on patient reporting and can be circumvented.

V. ETHICAL ISSUES IN INCONTINENCE RESEARCH

1. GENERAL CONCEPTS
This section will highlight the important aspects of the Introduction to Responsible Conduct of Research from the US Office of Research Integrity (ORI) [277] on planning, conducting, and reporting human research. It is beyond the scope of this section to review the rules of conducting human subject research in depth and extensive coverage is available elsewhere [263-267] Responsible conduct of animal research will not be covered and can be found at the National Institutes of Health, Office of Laboratory Animals Welfare (http://grants2.nih.gov/grants/olaw/olaw.htm). International rules of human research were first presented in the Nuremberg Code [268] and later the Helsinki Code. [269]

All investigators should understand the difference between “research” and “practice”. Research is defined as “systematic investigation designed to develop or contribute to generalizable knowledge” [270] and participants accept risks to advance scientific knowledge and to benefit others [271]. Practice is directed toward benefiting the individual patient [272].

The 3 primary guiding ethical principles for human research as outlined by the 1979 Belmont Report on “Ethical Principles and Guidelines for the Protection of Human Subjects of Research” [273] are:

1. Respect for Persons that includes informed consent without undue influence
2. Beneficence to maximize benefits and reduce risks to the subject
3. Justice that the benefits and risks be distributed fairly (i.e. not only using people without access to health care, prisoners, or those impaired).

a) Respect for Persons

Research protocols are required to be approved by an Institutional Review Boards (IRB). IRB’s can adequately evaluate consent forms, however IRB’s have been criticized because they lack the resources to review the scientific merit/design or monitor if the research is being carried out as designed. For these reasons, IRB approval should be regarded only as a minimal ethical standard for research. Ultimately it is the responsibility of the investigator to ensure the research is ethically acceptable [272].

b) Beneficence

The primary concern of the investigator should be the safety of the research participant and careful consideration of the risk/benefit ratio; this includes an ongoing responsibility to monitor research and medical literature as the research proceeds. The investigator needs to critically consider within the expert medical community if there is clinical equipoise for the proposed interventions in their trial [274]. Is one treatment no better than another? Are the research risks reasonable in relation to anticipated benefits? It is the responsibility of the investigator to ensure risks are minimized and potential benefits enhanced as well as that the knowledge gained outweighs the risks [275]. Of note, invalid research cannot be ethical no matter how favorable the risk–benefit ratio for study participants [263].

c) Justice

Justice is of particular concern in Phase I testing of pharmaceutical agents and in early investigation of surgical devices/implants. Payment offered for participation in such drug trials may be extremely attractive to poor and disenfranchised subjects. Early device studies may target countries with lax regulatory environment even if there is little intent to market the device there in the long term.

As pointed out in the ORI Introduction to Responsible Conduct of Research, although the rules set by the investigator’s institution and/or government are important, they are often set at a minimum standard, and it is the personal responsibility of the investigator to strive for a higher standard of conduct [277]. The rules for research need to be supplemented with good judgment and a strong sense of personal integrity. A simple test was recommended for the investigator to use when resolving an ethical research dilemma: “Imagine what you are preparing to do will be reported the next day on the front page of your local newspaper. If you are comfortable having colleagues, friends, and family know what you did, chances are you acted responsibly”.

2. PLANNING

As noted in the section on the Study Conduct and Statistical Consideration, planning is essential and it is ethically important when conducting human subject research. Minimal criteria for an ethical study are:

• the study is well planned and scientifically sound,
• the study is feasible with a realistic chance to be completed,
• there is a reasonable assumption that new knowledge will be provided at the end of the study, and
3. FINANCIAL CONFLICTS OF INTEREST

Many investigators are involved in testing new drugs or devices developed by industry. Especially in the US, proceeds from clinical trials (primarily pharmaceutical but also surgical and device trials) have become an increasingly important supplement to clinician income. Clinical research, previously limited to a few academic institutions, is now spread through all segments of the medical community. While this may improve the variety of patient representation in studies, it also makes safeguarding the rights of research subjects more difficult. Competition for revenue from research, aggressive advertising for research subjects, and dependence of clinicians on income from pharmaceutical companies are trends that bear close attention.

It is acceptable for investigators to receive contracted financial support to perform this research and a principled partnership between industry and investigators is essential if we are to preserve medical progress [278]. Financial conflict of interest policies have been developed due to ethical concerns about potential biases that may influence trial design, conduct, over interpretation of positive results or not publishing negative results [272; 279]. It is important that investigators do not receive money directly from industry sponsors but rather through a research contract. Most quality peer-review scientific journals require a declaration of conflict of interest. While declaration does not in and of itself eliminate bias, allowing the audience to evaluate potential biases is a step toward retaining trust. Although there is no one definition, significant financial conflict has been defined as [277].

1. additional earnings in excess of $10,000 a year outside of a research contract
2. equity interests in excess of 5 percent in an entity that stands to benefit from the research

These guidelines are inadequate and arbitrary—5% of an entity could vary from an inconsequential amount to many millions of dollars, others have argued that any financial reimbursement is too much [281]—but as yet there is no other commonly adopted definition. Ideally, the focus would not be on specific rules but on the constant obligation to consider ethics in all phases of research.

An investigator’s institution may have additional definitions and reporting requirements for financial conflict of interest disclosures. There are many potential relationships between physicians and industry; it is preferable that the nature of the relationship and its financial magnitude if any, be fully defined rather than categorized (i.e. “consultant”) so that the reader can appropriately assess the actual and potential conflict of interests.

4. CONFLICT OF INTEREST IN CONDUCTING AND REPORTING RESEARCH, AUTHORSHIP

a) Conducting Research

The investigator has an ethical responsibility to take responsibility for all aspects of the research, ensuring that the work is done rigorously and to maintain the integrity of the research [272]. Prior to participant enrollment, the International Committee of Medical Journal Editors (ICMJE) recommends information about trial design be placed into an accepted clinical trials registry [281]. A clinical trial is considered “any research study that prospectively assigns human participants or groups of humans to one or more health-related interventions to evaluate the effects on health outcomes.” Registration is required if investigators wish to publish in an ICMJE journal. It is felt that public registration of trials increases the probability of the results being published. Additionally, in human research, data management is key to providing valid research. Clinical data management includes accurate recording of data, data systems, and appropriate statistical methods (See Study Conduct and Statistical Consideration, Section II 3 above), as well as data protection and storage. [282].

As discussed previously, a plan for statistical analysis and publication should be established in the design phase. This inherently implies, and it should be made explicitly clear, that the data belongs to the investigators and there is an expectation that the results will be published regardless of the outcome. All data must be made available to the writing team; summary tables alone are not acceptable. Similarly, the goal of the publication should be to present the data in the most transparent means possible so that the readers can reasonably draw their own conclusions.

Depending on the study and most often in randomized controlled trials, a data safety monitor (DSM) or data safety monitoring board (DSMB) is important to evaluate the study on an ongoing basis to determine early evidence of significant harm or benefit [283, 284]. Depending on the size, complexity, and risks of a trial, the DSMB is comprised of experts needed to monitor interim data to ensure the safety of the participants. A priori stopping rules or boundaries are established to assess if the study should continue or be terminated due to futility (no conclusion will be drawn due to low enrollment, few outcome events, or high drop out rates etc.), reaching an endpoint, or identifying increased risks. [272]. Further details on statistical issues for DSMB’s are included in the Study Conduct and Statistical Considerations section.

b) Reporting Research

Clear guidelines for authorship have been established by medical journals [285]. Beginning with the research contract, authorship rules should be established
according to accepted guidelines. In general, authorship credit should be based on 1) substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data; 2) drafting the article or revising it critically for important intellectual content; and 3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

For multi-center trials, a Publication Committee should be established to develop guidelines on: membership (chair, representatives of principal investigators, and a limited number of representatives of a sponsoring company; if the principal investigators are not adequately trained in statistical methods, independent statisticians should also be included); publication & presentation proposal rules and reviews; authorship requirements; disclosure of author conflicts of interest (financial & personal); defined period of sponsor review (30-60 days); and disclosure of use of scientific writers. There has been growing concern that industry sponsored studies have contributed to the proliferation of guest authorship (only minor contributions to a manuscript and perhaps only contributed by providing participants) and ghost authorship (those who have provided substantially to the manuscript for example employees or writing consultants of a pharmaceutical company) [286].

c) Useful Websites

- International Bioethics Organizations Database (http://bioethics.georgetown.edu/databases/Organizations/index.htm)
- International Committee of Medical Journal Editors (http://www.icmje.org)

Recommendations for ethical research

It is the personal responsibility of investigators to maintain the highest level of ethical research as outlined in the above section. We recommend:

- Clinical trials should be registered and results should be published regardless of outcome. HIGH
- All authors should be able to accept responsibility for the published work and all potential conflicts of interest should be fully disclosed. HIGH
- Continuity in clinical direction from design through authorship is mandatory. Investigators should be involved in the planning stage and a publications committee should be named at the beginning of the clinical trial. The Uniform Requirements for Manuscripts Submitted to Biomedical Journals, from the International Committee of Medical Journal Editors should be followed. HIGH

Authorship requires:

1) Substantial contributions to conception and design or acquisition of data or analysis and interpretation of data,
2) Drafting the article or revising it critically for important intellectual content,
3) Final approval of the version to be published

• Authors should provide a description of what each contributed and editors should publish that information. HIGH
• Authors should have access to all raw data from clinical trials, not simply selected tables. HIGH
• The funder should have the right to review manuscripts for a limited period of time prior to publication but the manuscript is the intellectual property of its authors, not the funder. HIGH

VI. CONCLUSIONS

The goal of this Consultation has been to examine and classify data in order to determine the level of evidence that supports our care of incontinent patients. The goal of this Committee has been to provide a roadmap for the investigators who will produce the high quality research for the next Consultation. Ultimately, good research is credible. Credibility creates impact and generates strong recommendations. Credible research draws others to follow and expand on the work while simultaneously guiding clinical care of patients. Unfortunately, it is clear that much of the published work in incontinence has not been of high quality and thus has not effectively changed patient care. However this can be remedied in the future for, in most cases, the failure has been due to preventable deficiencies in planning and data collection.

The Committee has emphasized that all quality research, be it prospective or retrospective, clinical or preclinical, begins with detailed planning—establishing a clear and relevant hypothesis, developing a trial of appropriate magnitude to accept or reject the hypothesis, and defining methods of adequate sensitivity and specificity to produce credible data. If investigators will work together in true multidisciplinary teams, following the methodology presented here, we will make great strides in the care on incontinent people throughout the world.

A Brief History of Urinary Incontinence and its Treatment

DIRK SCHULTHEISS (GERMANY)

I. INTRODUCTION

Ancient reports on urinary incontinence are rather rare and mainly address cases of extraurethral incontinence (e.g. due to a fistula acquired during childbirth) or overflow incontinence (e.g. in males with urinary retention or after spinal cord injury). In later centuries several authors dealt with the problem of postoperative incontinence after perineal lithotomy. Defined surgical techniques for the cure of urinary incontinence were not introduced before the 19th century. First this was limited to fistula repair but at the end of the 19th century new procedures for stress incontinence were introduced and became standard clinical procedures. Other modern techniques, like artificial sphincters or electrostimulation, were alternatives developed in urology in the second half of the 20th century.

II. EARLY REPORTS ON URINARY INCONTINENCE FROM ANTIQUITY TO THE 18TH CENTURY

In contrast to frequent diseases like bladder stones, urinary retention and urinary fistula, descriptions of urinary incontinence and its treatment are rarely mentioned in early medical writings. Associated with the above listed entities only a few episodes of overflow incontinence and extraurthral incontinence are reported. On the other hand the use of different catheters for the relief of urinary retention is described in many early cultures [1, 2].

The first sources dealing briefly with urinary incontinence are Egyptian manuscripts from the 2nd millennium B.C.: the „Papyrus Smith“ [3] and the „Papyrus Ebers“ [4]. In the 31st case of the „Papyrus Smith“ incontinence resulting from spinal injury is described as followed: “...if thou examinest a man having a dislocation in a vertebra of his neck, shouldst thou find him unconscious of his two arms and his two legs on account of it, while his phallus is erected on account of it and urine drops from his member without his knowing it ...” [3, 5]. The „Papyrus Ebers“ consists of a collection of about 900 recipes for the treatment of a wide variety of partly poorly defined diseases. Among them one can find remedies “to remove the urine which runs to often” and “to remove constant running of the urine” [4, 6, 7]. Furthermore these Egyptian sources already mention devices for the collection of urine in males and also pessaries for women.

An examination of the mummy Henhenit (about 2050 B.C.) by D. E. Derry in 1935 revealed a large vesicovaginal fistula which is most likely due to a birth trauma as it was accompanied by a laceration of the perineum [8, 9].

Greek medicine was dominated by the outstanding work of Hippocrates (460-377 B.C.) who was writing extensively about the diseases of the urinary tract. Despite his discussion on perineal lithotomy he also dealt with the management of urinary incontinence [7, 10].

Giving a detailed description of the technique of perineal lithotomy the Roman author Aulus Cornelius Celsus (25 B.C.-50 A.D.) emphasized the importance of a wide incision that allows extraction of the stone without further uncontrolled rupture of the surrounding tissue, as this would increase the danger of urinary fistula [7].

Claudius Galen (129-201 A.D.) from Pergamon was one of the first do undertake physiological experiments on the lower urinary tract and postulated that micturition is conducted by contraction of the abdominal muscles. Concerning the causes of urinary retention he differentiated clinically between paralysis of the bladder after spinal injury and subvesical obstruction due to bladder stones [7, 11].

Even from the standpoint of medical sciences the Middle Ages represent a dark period for Europe. At this time the ideas of Greek and Roman authors were preserved and tradicted by Arabian medicine, as e.g. in the writings of Avicenna (930-1037 A.D.), until they were finally rediscovered by European scientist of the Renaissance.
Today we are highly impressed by the studies of Leonardo da Vinci (1452-1519), who performed several dissections on human bodies and over a period of about 25 years created a large anatomical work including the lower urinary tract. In his drawings of the bladder he is mainly presenting an open and funnel-shaped bladder neck and only in some of them he is indicating a circular structure at the bladder neck, the internal sphincter (Figure 1), which he describes as followed: "...and how the gate of the bladder is shut." or "...muscles which open and close the passage of the urine into the mouth of the bladder neck." On the other hand he is not aware of the contractile power of the detrusor muscle and does not mention the problem of urinary incontinence. As Leonardo failed to finish his studies and publish them in the form of a textbook on anatomy his work is only of medico-historical interest and did not influence the scientific development at his time [12].

Ambroise Paré (1510-1590), the most famous surgeon of the Renaissance, also showed great interest in the urinary tract and was one of the first to resect "carnosities" of the urethra with sharp sounds. He described the alterations caused by subvesical obstruction and realized the mechanism of synchronized sphincter relaxation and detrusor contraction during micturition. Figure 2a shows one of the first illustrations of a urinal for incontinent males. Another instrument facilitates urination in the standing position after loss of the penis (Figure 2b): "Those that have their yards cut off close to their bellies, are greatly troubled in making urine, so that they are constrained to sit downe like women, for their ease. I have devised this pipe or conduit ... that must be applied to the lower part of the os pectinis ... serving instead of the yard in making of water, which therefore wee may call an artificiall yard." [13]

Wilhelm Fabricius Hildanus (1560-1634) provided a modified urinal for the treatment of incontinence in his work "De ardore et incontinentia urinae, et nova inventione instrumenti, quo inter deambulandum coligitur" consisting either of glass or the bladder of a pig that was attached to the body by straps (Figure 3) [14].

In his book "Chirurgie", which was edited several times between 1718 and 1779, the German Lorenz Heister (1683-1758) dedicated two chapters on male and female incontinence: "Wenn Manns- und Frauen-Personen den Urin nicht halten können" [15]. In his opinion bladder stones or paralysis of the bladder sphincter are the two reasons for incontinence in males. The first has to be treated by lithotomy whereas the second is cured by "Nerven-stärckenden Medicamenten" (nerve-strengthening drugs).

Besides the use of a urinal as described by Paré or Fabricius Hildanus he suggested a penile clamp (Figure 4a) that was covered with leather and removed by the patient at the time of micturition. With reference to his colleague Winslow, Heister designed a belt that produces perineal compression to the bulbular urethra (Figure 4b). He saw no effective treatment for female urinary incontinence but mentioned a vaginal pessary, formed like a ring, in this case compressing the female urethra.
III. CONSERVATIVE TREATMENT

Empiric therapy with a variety of different recipes was used since antiquity and was for the most part effective on the lower urinary tract due to antidiuretic, cholinergic and anticholinergic ingredients. Some examples from the medical literature of the 18th and 19th century are ergotamine, chloral hydrate, opium ( Laudanum), colchicine, strychnia and atropine ( belladonna) [16, 17]. One of the first modern milestones in pharmacotherapy are the works of Samuel Hahnemann (1755-1843). In his books „Reine Arzneimittellehre” (1833) and “Die chronischen Krankheiten, ihre eigentümliche Natur und homöopathische Heilung” (1835) he already differentiated correctly the different types of urinary incontinence and suggested an adequate medical therapy [18, 19].

Hydrotherapy was a major aspect of mechanical therapy using cold water baths, hypogastric douches, aromatic baths and vaginal douches [16].

In 1762 T. Dickson applied blisters to the area of the os sacrum for reflectory therapy of urge incontinence [20]. One of the first bladder distensions for successful cure of the same disease in elderly patients was performed by J. Rhodes in 1858 using a mixture of carbonic acid gas with chloroform [21].

Another alternative were the sacral epidural injections of Fernand Cathelin (1873-1960) from the Hôpital Necker in Paris. Before 1903 he used saline or cocaine solutions for the treatment of different forms of urinary incontinence ( Figure 5 ) [22]. One year later M. Babinski reported on successful therapy of neurogenic bladder dysfunction with lumbar puncture and drainage of cerebrospinal fluid [23].

IV. EXTERNAL DEVICES

Some early examples of urinals and external compression instruments have been presented above. Compared to the devices listed in a medical catalogue from 1906 ( Figure 6 ) we recognize the same principles improved by new materials like India rubber [24]. The „Appliance for Amputation of Penis” seen on the upper part of this figure is designed for micturition in the standing position, an aspect of quality of life in male patients that was already addressed with the “artificiall yard” of Ambroise Paré (compare Figure 2b). Comparable to these devices the use of vaginal pessaries also has a long tradition in the treatment of female incontinence as mentioned above [25]. In 1826 T. Brown designed a sophisticated self-retaining instrument made from ivory that fitted anatomically to the female urethral orifice and avoided urinary
leakage. A removable stopper at the end of the hollow device allowed controlled emptying of the bladder without removing the whole device [26].

The idea of perineal compression, as introduced by Heister, was revived as lately as 1960 by S. A. Vincent, using an air-inflatable cushion that was fixed to the perineum with a special belt and expanded manually via bellows to obstruct the male bulb urethra (Figure 7) [27].

External devices of all kind have been perfected in our century [25] and were even partly replaced by modern surgery and its advances in continent urinary diversion, a development that will not be outlined any further in this chapter [see 7, 28].

A final remark addresses the cultural aspect of urinals and urine receptacles in the history of mankind. Although chamber pots ("matula") are described in antiquity, the daily use of a urine collecting receptacle (e.g. "bourdaloue") was only introduced in the late Middle Ages and early Renaissance [29].

With the development of electro-physiology in the 19th century the application of direct or alternating current for bladder dysfunction became of therapeutic interest. Robert Ultzmann (1842-1889) from Vienna mentioned three indications in his outstanding book „Die Krankheiten der Harnblase“ from 1890 for the use of electricity in the treatment of „Neurosen oder Neuropathien der Harnblase“: acquired paralysis of the detrusor or sphincter vesicae in adults and idiopathic enuresis in children [30]. The catheter-like electrode ("Rheophor") was introduced either into the bladder (for stimulation of the detrusor muscle) or into the prostatic urethra (for stimulation of the sphincter muscle). Therapy of enuresis in children was suggested with a rectal electrode. Earlier experiments of electrotherapy for incontinence had been undertaken by Nardin in 1864 and were the basis for Ultzmann’s work [31].

In 1898 L. Frankl-Hochwarth and Otto Zuckerandl (1861-1921) published their experience with local electrotherapy in nervous diseases of the bladder [32] and „Blasendiathermie“ with vaginal or rectal sounds was still used in hypertonic conditions of the detrusor in 1930 by Josef Kowarschik form Vienna [33]. Modern concepts of electrostimulation of the pelvic floor with so-called plug electrodes were finally initiated by B. R. Hopkinson and R. Lightwood in the 1960ies [34].

A different approach is the permanent intracorporeal implantation of stimulating electrodes or even complete stimulator systems [overview in 35]: For the treatment of detrusor hypocontractility mainly in spinal cord injured patients W. H. Boyce sewed stimulating electrodes directly onto the bladder in 1954 [36]. A direct stimulation of insufficient sphincteric muscles was tried by K. P. S. Caldwell in 1963 [37]. Another 4 years later T. Burghel attached stimulators to the pelvic splanchnic nerves [38] and H. N. Habib to segmental sacral nerves in patients with spinal cord injuries [39]. Finally the development of the first system for long-term spinal anterior root stimulation, tested in animals in 1969, and the first clinical implantation of such a system in a human being in 1976 by Giles S. Brindley represents the beginning of modern neurostimulation and neuromodulation in urology [35].

In the second half of the 19th century the introduction of antisepsis and asepsis as well as anaesthesia revolutionized modern surgery. With respect to urinary incontinence this activity was mainly restricted to the surgical correction of vesicovaginal fistulas in the beginning, i.e. extraurethral or extraanatomic incontinence [40]. First efforts were made by Franz C. Naegle from Heidelberg in 1812 who experimented with transvaginal closure of fistulas in human corpses [41]. Many well-known surgeons, as G. Dupuytren, J.
Figure 6: Several urinals from the catalogue of Down Bros., London (1906) [24]
M. Delpech, C. F. Lallemand and J. J. de Lamballe, followed this example over the next few decades [9].

In 1845 Johann Friedrich Dieffenbach (1792-1847), founder of modern plastic surgery, described the disease of urinary fistula, mainly arising from a birth trauma in younger women, and its social consequences for the patient in the following words:

“A vesico-vaginal fistula is the greatest misfortune that can happen to a woman, and the more so, because she is condemned to live with it, without the hope to die from it; to submit to all the sequelae of its tortures till she succumbs either to another disease or to old age. There is not a more pitiable condition than that of a woman suffering from a vesico-vaginal fistula. The urine constantly flowing into the vagina, and partially retained there, and heated, runs down the labia, perineum, and over the nates and thighs, producing a most intolerable stench. ... The husband has an aversion for his own wife; a tender mother is exiled from the circle of her own children. She sits, solitary and alone in the cold, on a perforated chair. This is not fiction, but naked truth; and the cure for such an evil is the prize for which we labor.” Although he contributed many aspects to fistula surgery he still emphasized that the results of the treatment were still poor at his time and that only very few advances had been achieved [40, 42].

Only 2 years later Gustav Simon (1824-1876) presented another milestone of fistula surgery, the so-called “German method” with a double row of sutures, one of the whole thickness of the bladder and the other one of the vaginal tissue [46a]. Moreover Simon suggested the “kolpokleisis” in which the vagina is completely closed below the level of the vesicovaginal fistula, a method that did not find wide acceptance (Figure 9) [46b].

As late as 1890 Friedrich Trendelenburg (1844-1924) finally published the first transvesical approach for fistula repair. In the same paper he introduced the operating position that is still named after him in our days [47].

In the very same year, 1845, the American James Marion Sims (1813-1883) performed his first surgery for transvaginal fistula repair in three black slaves. The owners lent Sims the three women for the period of treatment and they lived in a small hospital shack behind his house and office. His early techniques were obviously not to successful as 42 surgical procedures are reported on those three women over the next four years. Finally he succeeded with his special technique using silver wires for closure of the defect (Figure 8), published in 1852 [43], and therefore he is known to us as the founder of urinary fistula surgery. Seen from the ethical standpoint the circumstances of his early clinical research remain controversial [40, 44, 45].
Today extraurethral urinary incontinence due to complications during childbirth is hardly seen in western countries any longer, but is still a major medical problem in many developing countries with low standard obstetric care [48].

In contrast to the above outlined methods for fistula surgery the operative treatment of stress urinary incontinence developed far later and the reports mentioned before 1900 never became standard of therapy. One of these very early reports came from Frank in 1882, who was an assistant doctor of the well-known German surgeon Bernhard Bardenheuer (1839-1913) from Cologne [49].

In 1881 Frank had operated a 37 year old woman transvaginally by excising a wedge-shaped piece from the posterior urethral wall from the external orifice to a point 1 cm before the bladder neck, including the vaginal and urethral mucosa, (distance e to c on Figure 10). Furthermore he resected a part of the vaginal wall at the level of the bladder neck (area a, b, c, d on Figure 10). The defect was then closed with transverse sutures so that the passage of a 9 French catheter was just possible. The patient was continent at the time of control 4 months later.

Similar methods were reported by F. Winckel from Munich a few years later, who had performed the operation in two sessions in 1881/1882 [50], and by B. S. Schultze in 1888 [cited in 16]. Apposition of the urethral walls by flattening of the outer end of the urethra was suggested by Karl Pawlik (1849-1914) from Vienna (later Prague) in 1883 [cited in 16, 51]. He achieved this by drawing the external orifice of the urethra forward to the clitoris and sharply to each side and fixing it in that position with sutures. R. Gersuny from Vienna performed the first torsion of the urethra in 1888 and published this technique as an improvement of Pawlik’s method one year later [51]. In each session he dissected the entire urethra beginning from the external orifice to the bladder neck and twisted it to one direction before suturing it in the new position. In his first patient he operated three times within two months making a torsion of the urethra of 180°, 90° and again 180° (total of 450°). 5 months later the patient reported a lasting success of this treatment, although micturition time was up to 4 minutes for a volume of half a litre of urine.

VII. SURGICAL TREATMENT: STRESS URINARY INCONTINENCE
Comparable methods of urethral torsion and transfer of the urethral orifice towards the clitoris followed by Alfred Pousson and by Joaquin Albarrán (1860-1912), both in 1892, and E. C. Dudley three years later [cited in 16].

The first surgical technique that became a routine clinical procedure was initiated by the uro-gynecologist Howard A. Kelly (1858-1943) from Baltimore in 1900. It consisted of anterior colporraphy and plication of the bladder neck with deep mattress sutures. In 1914 Kelly presented the first detailed analysis and follow-up of twenty patients [16], a milestone in the history of urogynecology and standard of care for the next 60 years [52].

In two male patients with postoperative incontinence after perineal urethral and prostatic surgery a combined procedure through a transvesical and perineal approach was performed by Hugh H. Young (1870-1945), also from Baltimore, in 1907 and 1916. In the first step the interior of the bladder was exposed, the mucosa of the trigone denuded and finally the bladder wall was plicated with deep sutures that were inserted with a special boomerang needle holder (Figure 11a). The result of this plastic operation upon the internal bladder sphincter is shown in Figure 11b. In the second part of the operation periurethral scar tissue was resected via a perineal incision before plicating the remaining tissue of the external urethral sphincter [53].

Another principle, that is still one of the most common procedures for female stress urinary incontinence in our days, is the use of a retropubic sling made from different materials. The first method was described by D. Giordano in 1907 by using the gracilis muscle [54]. He detached the muscle from the thigh and translocated it retropubically as a sling around the urethra.

Three years later R. Goebell performed a sling operation with the pyramidalis muscles in two girls [54]. He separated the muscles from the fascia and postulated an active muscular closure effect on the urethra. Paul Frangenheim (1876-1934) used the same muscles together with the onlying fascia in 1914 [56] and Walter Stoeckel (1871-1961) suggested the combination of this muscle-fascia sling, as shown in Figure 12, with a transvaginal muscular plication of the bladder neck in 1917 [57]. This procedure is known as the Goebell-Frangenheim-Stoeckel operation in clinical terminology.

Another modification is the pubo-vaginal sling with bilateral stripes of the rectus fascia described by Albert H. Aldridge in 1942 [58] and later by Terence Millin (1903-1980) [59]. Both of them attached the sling to the rectus muscle and, besides from the mere suspension effect, they also expected an active closure during contraction of the rectus muscles.

Several perineal procedures were suggested using muscles that are anatomically in close relation to the urethra. The first one was introduced by J. B. Squier in 1911 who took parts of the levator ani muscle [60]. In 1926 C. L. Deming again used the gracilis muscle

Figure 11: Transvesical approach, denudation of the trigone and deep sutures of the bladder wall (a) for plication of the internal bladder (b) in male patients with postoperative urinary incontinence according to Hugh H. Young (1907 and 1916) [53]
and in 1936 Oswald S. Lowsley (1894-1955) provided a method with the ischiocavernous muscle.

Figure 13 shows a modified technique of Albert Vergés-Flaqué and Oswald S. Lowsley from New York in 1951 [63]. They separated the outer parts of the anal sphincter and formed a sling around the bulbar urethra in 7 males suffering from postoperative or posttraumatic incontinence.

Cystourethropexy and colposuspension, as it is still used today in urogynecology, was introduced by V. F. Marshall, A. A. Marchetti and K. E. Krantz in 1949 [64] and J. C. Burch in 1961 [65]. As a minimal invasive procedure A. J. Pereyra inaugurated vaginal needle suspension in 1959 [66] and T. A. Stamey first introduced cystoscopic control for this type of operation in 1973 [67].

The variety of different techniques that have been developed for urinary diversion, not only in cancer surgery but also as an ultima ratio for the treatment of urinary incontinence, are not discussed in detail in this chapter. It is worth while mentioning that first attempts were already undertaken in the 19th century. As early as 1864 Baker Brown created an artificial channel under the pubic bone that allowed the permanent introduction of a catheter and D. C. Rutenberg closed the urethra and performed a vesico-abdominal fistula in 1875 for the cure of urinary incontinence [cited in 16]. Several techniques of ureter-bowel implantation were established in clinical practice before the turn of the last century in patients with bladder ectrophy, vesicovaginal fistula or after cystectomy [see overview in 7, 28].

VIII. INJECTION THERAPY

Periurethral paraffin injection for compression of the urethra and cure of urinary incontinence was first suggested at the end of the 19th century by R. Gersuny from Vienna [cited in 57]. H. A. Kelly discussed the danger of embolism after injection of these unabsorbable foreign bodies and pointed out that this treatment only showed a temporary improvement of symptoms [16]. A further report came from B. C. Murless in 1938, who injected cod liver oil (sodium morrhuate) into the anterior vaginal wall [68]. Since 1953 several authors presented endoscopic transurethral injection with sclerosing agents, mostly containing paraffin, like Dondren® [see overview in 69].

The intraurethral injection of polytetrafluoroethylene (Teflon) was first described in 1973 by Victor A. Politano [70] and Soloman Berg [71]. In 1989 the use of collagen by Linda M. Shortliffe [72] and the injection of autologous adipose tissue by A. S. Gonzalez de Gariby followed [73]. Silicone was not used before the 1990’s.

IX. ALLOPLASTIC SPHINCTER

The oldest device for external compression of the male urethra is the penile clamp [15]. It was brought into use again by J. H. Cunningham as an helpful instrument for performing retrograde urethrography, a radiographic method that was introduced by him into urology in 1910, and is still named after Cunningham today [74].

The first artificial sphincter that was designed as an inflatable circular cuff and applied to the male urethra by surgical means was created by Frederic E. B. Foley (1891-1966) from St. Paul, Minnesota and published in 1947 [75]. This ingenious urologist is best known for the improvement of the principles of the transurethral balloon catheter and played a major...
role in the introduction of commercially manufactured balloon catheters in the 1930's [2]. Figure 14a shows the operative steps of dissecting the corpus spongiosum from the corpora cavernosa and closure of the skin around these two separated structures. After wound healing the external cuff of the urinary sphincter ("pneumatic clamp") was put around the urethra, that was now completely covered with skin, and inflated or deflated manually via a pneumatic piston (Figure 14b).

It was not before the 1960's that first operations with completely implantable devices were undertaken [see overview in 76]. In 1961 J. L. Berry provided perineal acrylic implants producing a permanent compression on the bulbar urethra [77]. The silicone-gel-prosthesis of Joseph J. Kaufman from 1973 was based on the same concept [78]. M. Rosen from Australia developed an inflatable urethral compression prosthesis in 1976 [79] and Udo Jonas in 1983 an internal penile clamp, that was implanted at the penoscrotal angle and opened for micturition by external pressure through the skin from both sides [80].

In June 1972 F. Brantley Scott, together with William E. Bradley and Gerald W. Timm, implanted the prototype of the so-called "Scott-sphincter" in a 45 year old woman [81].

Finally, 25 years after Foley's publication, the idea of an inflatable cuff for the treatment of stress urinary incontinence had been adopted again and became a standard clinical procedure.
Figure 14 a: In- or deflation of a cuff via pneumatic piston. Surgical dissection of the corpus spongiosum

INDEX

Indexer: Dr Laurence Errington
www.errington-index.demon.co.uk

Figures and tables are comprehensively referred to from the
text. Therefore, significant material in figures and tables
has only been given a page reference in the absence of their
concomitant mention in the text referring to that figure.
Abbreviations: AI (or FI), anal (faecal) incontinence; EMG,
electromyography; LUT, lower urinary tract; LUTS, lower
urinary tract symptoms; POP, pelvic organ prolapse; QoL,
quality of life; SUI, stress urinary incontinence; UI, urinary
incontinence. UK and not US spellings have been used
throughout the index, although the text uses both.

The page contains a list of medical terms and concepts, mainly related to pelvic floor dysfunction and neurostimulation therapies. Some key terms and concepts include:

- **Electrical stimulation (and neuromodulation)**: Techniques used to treat pelvic floor disorders.
- **Elderly**: Population group often affected by pelvic floor issues.
- **Elastin**: Structural protein involved in vaginal and supportive tissues.
- **Dyspareunia**: Painful sexual intercourse.
- **Dysfunctional Voiding**: A type of urinary problem.
- **Dynamic Muscle Transposition (DST)**: A surgical technique for treating pelvic floor disorders.
- **Dysport**: A botulinum toxin used in medicine.
- **Duloxetine**: A medication used for various conditions.
- **Dry Bed Training**: A type of bladder training.
- **Dynamic MRI**: Imaging technique used in pelvic floor research.
- **Ectopic Ureterocele**: A birth defect involving the ureter.
- **Ectopic Ureter**: An abnormal ureter location.
- **Electrodiagnostic Tests**: Tests used to diagnose neurological disorders.
- **Electroencephalography (EEG)**: A test to record the electrical activity of the brain.

The page also includes references to various studies and treatments, such as:

- Recommendations for practice based on literature searches.
- Future research directions in pelvic floor disorders.
- Economic analyses of treatments for pelvic floor problems.

Various medical conditions and procedures are mentioned, such as detrusor overactivity, neurogenic injury, and bladder pain syndrome. The text also references specific therapies and treatments, indicating a comprehensive approach to pelvic floor management.

INTRODUCTION

The 4th International Consultation on Incontinence met from July 5th – 9th 2008 in Paris and was organised by the International Consultation on Urological Diseases, in order to develop recommendations for the diagnosis evaluation and treatment of urinary incontinence, faecal incontinence, pelvic organ prolapse and bladder pain syndrome.

The recommendations are evidence based following a thorough review of the available literature and the global subjective opinion of recognised experts serving on focused committees. The individual committee reports were developed and peer reviewed by open presentation and comment. The Scientific Committee, consisting of the Chairmen of all the committees then refined the final recommendations.

These recommendations published in 2009 will be periodically re-evaluated in the light of clinical experience, technological progress and research.

International Consultation on Incontinence Modular Questionnaire (ICIQ) - ICIQ UI SF(short-form)
Annex 1 : Bladder Charts and Diaries
1. Definitions

The consultation agreed to use the current International Continence Society definitions (ICS) for lower urinary tract dysfunction (LUTD) including incontinence, except where stated. These definitions appeared in the journal Neurourology and Urodynamics (2002; 21:167-178 and 2006; 25: 293) or can be viewed on the ICS website: www.icsoffice.org

The following ICS definitions are relevant:

1. Lower Urinary Tract Symptoms (LUTS)

LUTS are divided into storage symptoms and voiding symptoms.

Urinary incontinence is a storage symptom and defined as the complaint of any involuntary loss of urine. This definition is suitable for epidemiological studies, but when the prevalence of bothersome incontinence is sought, the previous ICS definition of an "Involuntary loss of urine that is a social or hygienic problem" can be useful.

Urinary incontinence may be further defined according to the patient’s symptoms:

- Urgency Urinary Incontinence is the complaint of involuntary leakage accompanied by or immediately preceded by urgency.
- Stress Urinary Incontinence is the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing.
- Mixed Urinary Incontinence is the complaint of involuntary leakage associated with urgency and also with effort, exertion, sneezing and coughing.
- Nocturnal Enuresis is any involuntary loss of urine occurring during sleep.
- Post-micturition dribble and continuous urinary leakage denotes other symptomatic forms of incontinence.

Overactive bladder is characterised by the storage symptoms of urgency with or without urgency incontinence, usually with frequency and nocturia.

2. Urodynamic Diagnosis

- Overactive Detrusor Function, is characterised by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked.

The overactive detrusor is divided into:

- Idiopathic Detrusor Overactivity, defined as overactivity when there is no clear cause.
- Neurogenic Detrusor Overactivity is defined as overactivity due to a relevant neurological condition.

- Urodynamic stress incontinence is noted during filling cystometry, and is defined as the involuntary leakage of urine during increased abdominal pressure, in the absence of a detrusor contraction.

3. Bladder Pain Syndrome *

- Bladder pain syndrome is defined as an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes.

4. Pelvic Organ Prolapse

- Uro-genital prolapse is defined as the symptomatic descent of one or more of: the anterior vaginal wall, the posterior vaginal wall, and the apex of the vagina (cervix/uterus) or vault (cuff) after hysterectomy. Uro-genital prolapse is measured using the POPQ system.

- Rectal prolapse is defined as circumferential full thickness rectal protrusion beyond the anal margin.

5. Anal Incontinence *

- Anal incontinence, defined as “any involuntary loss of faecal material and/or flatus” and may be divided into:
  - Faecal incontinence, any involuntary loss of faecal material
  - Flatus incontinence, any involuntary loss of gas (flatus)

* To date, these definitions are not included in the current ICS terminology
The following phrases are used to classify diagnostic tests and studies:

- **A highly recommended test** is a test that should be done on every patient.
- **A recommended test** is a test of proven value in the evaluation of most patients and its use is strongly encouraged during initial evaluation.
- **An optional test** is a test of proven value in the evaluation of selected patients; its use is left to the clinical judgement of the physician.
- **A not recommended test** is a test of no proven value.

The recommendations are intended to apply to children and adults, including healthy persons over the age of 65.

These conditions are highly prevalent but often not reported by patients. Therefore, the Consultation strongly recommends case finding, particularly in high risk groups.

The main recommendations for this consultation have been abstracted from the extensive work of the 23 committees of the 4th International Consultation on Incontinence (ICI, 2008).

Each committee has written a report that reviews and evaluates the published scientific work in each field of interest in order to give **Evidence Based recommendations**. Each report ends with detailed recommendations and suggestions for a programme of research.

The main recommendations should be read in conjunction with the management algorithms for children, men, women, the frail older person, neurogenic patients, bladder pain, pelvic organ prolapse, and anal incontinence.

The initial evaluation should be undertaken, by a clinician, in every patient presenting with symptoms/signs suggestive of these conditions.

### 1. History and General Assessment

Management of a disease such as incontinence requires caregivers to **assess** the sufferer in a holistic manner. Many factors may influence a particular individual’s symptoms, some may cause incontinence, and may influence the choice and the success of treatment. **The following components of the medical history are particularly emphasized:**

**a) Review of Systems:**

- Presence, severity, duration and bother of any urinary, bowel or prolapse symptoms. Identifying symptoms in the related organ systems is critical to effective treatment planning. It is useful to use validated questionnaires to assess symptoms.
- Effect of any symptoms on sexual function: validated questionnaires including impact on quality of life are a useful part of a full assessment.
- Presence and severity of symptoms suggesting neurological disease

**b) Past Medical History:**

- **Previous conservative, medical and surgical treatment,** in particular, as they affect the genitourinary tract and lower bowel. The effectiveness and side effects of treatments should be noted.
- **Coexisting diseases** may have a profound effect on incontinence and prolapse sufferers, for example asthma patients with stress incontinence will suffer greatly during attacks. Diseases may also precipitate incontinence, particularly in frail older persons.
- **Patient medication:** It is always important to review every patient’s medication and to make an assessment as to whether current treatment may be contributing to the patient’s condition.
- **Obstetric and menstrual history.**
- **Physical impairment:** individuals who have compromised mobility, dexterity, or visual acuity may need to be managed differently

**c) Social History:**

- **Environmental issues:** these may include the social, cultural and physical environment.
• **Lifestyle**: including exercise, smoking and the amount and type of food/fluid intake.

**d) Other Treatment Planning Issues:**

• **Desire for treatment** and the extent of treatment that is acceptable.

• **Patient goals** and expectations of treatment

• **Patient support** systems (including carers).

• **Cognitive function**: all individuals need to be assessed for their ability to fully describe their symptoms, symptom bother and quality of life impact, and their preferences and goals for care, and to understand proposed management plans and to discuss, where appropriate, alternative treatment options. In some groups of patients formal testing is essential e.g. cognitive function testing for individuals for whom the clinician has concerns regarding memory deficits and/or inattention/confusion, and depression screening for individuals for whom the clinician has concerns about abnormal affect. Proxy respondents, such as family and carers, may be used to discuss history, goals of care, and treatment for individuals with dementia only if the individual is incapable of accurate reporting or weighing treatment decisions.

### 2. Physical Examination

The **more complicated** the history and the more extensive and/or invasive the proposed therapy, the **more complete** the examination needs to be. Depending on the patients symptoms and their severity, there are a number of components in the examination of patients with incontinence and/or pelvic organ prolapse.

**a) General status:**

• Mental status

• Obesity (BMI)

• Physical dexterity and mobility

**b) Abdominal/flank examination**: for masses, bladder distention, relevant surgical scars

**c) Pelvic examination:**

• Examination of the perineum and external genitalia including tissue quality and sensation.

• Vaginal (half-speculum) examination for prolapse

• Bimanual pelvic and anorectal examination for pelvic mass, pelvic muscle function, etc.

• Stress test for urinary incontinence.

**d) Neurological testing (see chapter on assessment)**

Neurological examination should be performed regardless of whether the patient is a child, a woman, a man, someone with neurological disease or a frail elderly person.

### 3. Urinalysis

In patients with urinary symptoms a **urinary tract infection** is a readily detected, and easily treatable cause of LUTS, and urine testing is highly recommended. Testing may range from dipstick testing, to urine microscopy and culture when indicated.

**Conclusion**

For simple treatments, particularly non-invasive and inexpensive therapies, management may start without the need for the further investigations listed below.

---

### II. RECOMMENDED FURTHER ASSESSMENT PRIOR TO, OR DURING, SPECIALIST ASSESSMENT

The tests below are recommended when the **appropriate indication(s) is present**. Some recommended tests become highly recommended in specific situations.

This section should also be read in conjunction with the relevant committee reports.

#### 1. Further Symptom and Health-Related QoL Assessment

In patients with **urinary symptoms** the use of a **simple frequency volume chart** or **bladder diary** (examples in Annex 1) is highly recommended to document the frequency of micturition, the volumes of urine voided, incontinence episodes and the use of incontinence pads.
The use of the highest quality questionnaires (Grade A, where available) is recommended for the assessment of the patient’s perspective of symptoms of incontinence and their impact on quality of life.

The ICIQ is highly recommended (Grade A) for the basic evaluation of the patient’s perspective of urinary incontinence; with other Grade A questionnaires recommended for more detailed assessment. Further development is required in the areas of pelvic organ prolapse, bladder pain syndrome and faecal incontinence, and for specific patient groups, as only Grade B questionnaires are currently available (see Appendix).

### 2. Renal Function Assessment

Standard biochemical tests for renal function are recommended in patients with urinary incontinence and a probability of renal impairment.

### 3. Uroflowmetry

Uroflowmetry with the measurement of postvoid residual urine is recommended as a screening test for symptoms suggestive of urinary voiding dysfunction or physical signs of POP or bladder distension.

### 4. Estimation of Post Void Residual Urine (PVR)

In patients with suspected voiding dysfunction, PVR should be part of the initial assessment if the result is likely to influence management, for example, in neurological patients.

### 5. Imaging

Although routine imaging is not recommended, imaging of the lower urinary tract and pelvis is highly recommended in those with urinary symptoms whose initial evaluation indicates a possible co-existing lower tract or pelvic pathology. Initial imaging may be by ultrasound, or plain X ray.

Imaging of the upper urinary tract is highly recommended in specific situations. These include:

- Haematuria
- Neurogenic urinary incontinence e.g. myelodysplasia, spinal cord trauma,
- Incontinence associated with significant post-void residual,
- Co-existing loin/kidney pain,
- Severe pelvic organ prolapse, not being treated
- Suspected extra-urethral urinary incontinence,
- Children with incontinence and UTIs, where indicated
- Urodynamic studies which show evidence of poor bladder compliance.

In anorectal conditions anal US or MRI prior to anal sphincter surgery is highly recommended, when obvious anatomic defects are not evident (cloacal formations). Defaecating proctography or dynamic MRI is recommended in suspected rectal prolapse which cannot be adequately confirmed by physical examination.

### 6. Endoscopy

Although routine cystourethroscopy is not recommended, LUT endoscopy is highly recommended:

- When initial testing suggest other pathologies, e.g. haematuria
- When pain or discomfort features in the patient’s LUTS: these may suggest an intravesical lesion
- When appropriate in the evaluation of vesicovaginal fistula and extra-urethral urinary incontinence (in childbirth fistulae, endoscopy is often unnecessary).

In anorectal conditions, proctoscopy or flexible sigmoidoscopy should routinely be performed in the evaluation of patients with faecal incontinence. Colonoscopy, air contrast barium enema or CT colography is highly recommended in the presence of unexplained change in bowel habit, rectal bleeding or other alarm symptoms or signs (see Basic Assessment chapter).

### 7. Urodynamic Testing

**a) Urodynamic evaluation is recommended**

- When the results may change management, such as prior to most invasive treatments for UI and POP
- After treatment failure, if more information is needed in order to plan further therapy.
- As part of both initial and long-term surveillance programmes in some types of neurogenic lower urinary tract dysfunction
- In “complicated incontinence” (for details please see relevant subcommittee reports).
b) The aims of Urodynamic Evaluation are

- To reproduce the patient's symptoms and correlate these with urodynamic findings
- The assessment of bladder sensation
- The detection of detrusor overactivity
- The assessment of urethral competence during filling
- The determination of detrusor function during voiding
- The assessment of outlet function during voiding
- The measurement of residual urine

These tests are recommended in the presence of unexplained diarrhoea or when Crohn's disease is suspected.

III. OPTIONAL DIAGNOSTIC TESTS

1. Additional Urodynamic Testing

**Video-urodynamics** may be useful in the management of UI in children, in patients who fail surgery and in some neurogenic patients, to obtain additional anatomical information. Both US and X-ray imaging can be used.

If a more detailed estimate of urethral function is required, then the following optional tests may give useful information:

- Urethral pressure profilometry
- Abdominal leak point pressures
- Video-urodynamics
- Electromyography

**If initial urodynamics have failed** to demonstrate the cause for the patient's incontinence then the following tests are optional:

- repeated routine urodynamics
- ambulatory urodynamics

2. Pad Testing

Pad testing is an optional test for the routine evaluation of urinary incontinence and, if carried out, a 24 hr test is suggested.

3. Neurophysiological Testing and Imaging

The information gained by clinical examination and urodynamic testing may be enhanced by neurophysiological testing of striated muscle and nervous pathways.

Appropriately trained personnel should perform these tests. The following neurophysiological tests can be considered in patients with peripheral lesions prior to treatment for lower urinary tract or anorectal dysfunction.

- Concentric needle EMG
- Sacral reflex responses to electrical stimulation of penile or clitoral nerves.

**Pudendal nerve latency** testing is **not recommended**.

**Further imaging of the central nervous system**, including spine, by myelography, CT and MRI may prove useful if simple imaging, for example by spinal X-rays in patients with suspected neurological disease, proves normal.

4. Further Imaging

**Cysto-urethrography**, US, CT and MRI may have an indication in case of:

- Suspected pelvic floor dysfunction
- Failed surgery, such as recurrent posterior vaginal wall prolapse or failed sling surgery
- Suspected fixed urethra

5. Cysto-urethroscopy

This is an optional test in patients with complicated or recurrent UI (e.g. after failed SUI surgery)

6. Anorectal physiology testing

**Anal manometry** is useful to assess resting and squeeze anal pressures.
3. Management Recommendations

The management recommendations are derived from the detailed work in the committee reports on the management of incontinence in children, men, women, the frail elderly and neurological patients, obstetric fistula, pelvic organ prolapse, bladder pain syndrome, and faecal incontinence. The management of incontinence is presented in algorithm form with accompanying notes.

The Consultation recognised that no algorithm can be applied to every patient and each patient's management must be individualised.

There are algorithms for

- I. Urinary Incontinence in Children
- II. Urinary Incontinence in Men
- III. Urinary Incontinence in Women
- IV. Obstetric Fistulae
- V Urinary Incontinence in Frail Older Men and Women
- VI. Urinary Incontinence in Neurological Patients
- VII Bladder Pain Syndrome
- VIII. Pelvic Organ Prolapse
- IX. Faecal Incontinence in Non-Neurological Patients
- X. Faecal Incontinence in Neurological Patients

These algorithms are divided into two for groups I to III, IX, XI and X: the two parts, initial management and specialised management require a little further explanation.

Although the management algorithms are designed to be used for patients whose predominant problem is incontinence, there are many other patients in whom the algorithms may be useful such as those patients with urgency and frequency, so-called "OAB dry".

The algorithms for initial management are intended for use by all clinicians including health care assistants, nurses, physiotherapists, generalist doctors and family doctors as well as by specialists such as urologists and gynaecologists. The consultation has attempted to phrase the recommendations in the basic algorithms in such a way that they may be readily used by clinicians in all countries of the world, both in the developing and the developed world.

The specialised algorithms are intended for use by specialists. The specialised algorithms, as well as the initial management algorithms are based on evidence where possible and on the expert opinion of the 700 healthcare professionals who took part in the Consultation. In this consultation, committees ascribed levels of evidence to the published work on the subject and devised grades of recommendation to inform patient management.

It should be noted that these algorithms, dated March 2009, represent the Consultation consensus at that time. Our knowledge, developing from both a research base and because of evolving expert opinion, will inevitably change with time. The Consultation does not wish those using the algorithms to believe they are “carved in tablets of stone”: there will be changes both in the relatively short term and the long term.

Essential components of basic assessment

Each algorithm contains a core of recommendations in addition to a number of essential components of basic assessment listed in sections I to III.

- General assessment
- Symptom assessment
- Assessment of quality of life impact
- Assessment of the desire for treatment
- Physical examination
- Urinalysis

Joint decision making

The patient’s desires and goals for treatment:

Treatment is a matter for discussion and joint decision making between the patient and his or her health care advisors. This process of
consultation includes the specific need to assess whether or not the sufferer of incontinence wishes to receive treatment and, if so, what treatments he or she would favour. Implicit in this statement is the assumption that the health care provider will give an appropriate explanation of the patient’s problem and the alternative lines of management, and the indications and the risks of treatment. The assumption that patients almost always wish to have treatment is flawed, and the need to consult the patient is paramount.

In each algorithm, treatments are listed in order of simplicity, the least invasive being listed first. This order does not imply a scale of efficacy or cost, two factors which need to be considered in choosing the sequence of therapy. The order is likewise not meant to imply a suggested sequence of therapy, which is determined jointly by the treating health care providers and the patient, considering all the relevant factors listed above.

In the initial management algorithms, treatment is empirically based, whilst, the specialized management algorithms usually rely on precise diagnosis from urodynamics and other testing.

The assumption is made that patients will be reassessed at an appropriate time to evaluate their progress.

◆ Use of Continence Products

The possible role of continence products should be considered at each stage of patient assessment, treatment and, if treatment is not (fully) successful, subsequent management.

- **Firstly**, intermittent catheterisation or indwelling catheter drainage often have a role to play in addressing urinary retention.
- **Secondly**, assisted toileting using such devices as commodes, bedpans, and handheld urinals may help to achieve dependent continence* where access, mobility and / or urgency problems under-mine a patient’s ability to maintain independent continence*, be it urinary and / or faecal.
- **Finally**, containment products (to achieve contained incontinence*) for urine and / or faeces find an essential role in enhancing the quality of life of those who:
  - Elect not to pursue treatment options
  - Are awaiting treatment
  - Are waiting for treatment to take effect
  - Are unable to be (fully) cured

Further guidance and care algorithms on which products might be suitable for a given patient are given in Committee 20.

1. **Initial management**

Children produce specific management problems for a variety of reasons: assessment requires help from their parents and carers; consent to treatment may be problematic; and cooperation in both assessment and treatment may be difficult.

Referrals for specialist treatment are recommended for a group of children who have complicated incontinence associated with:

- recurrent urinary infection
- voiding symptoms or evidence of poor bladder emptying
- urinary tract anomalies,
- previous pelvic surgery
- neuropathy

**Initial treatment is recommended for the remaining patients who have:**

- Nocturnal enuresis without other symptoms (mono-symptomatic enuresis).
- Daytime symptoms of frequency, urgency, urgency incontinence with or without night-time wetting

2. **Treatment**

- Initial treatment for *mono-symptomatic nocturnal* enuresis should include:
  - parental counselling and motivation
  - a choice between either alarm (Grade A) and anti-diuretic hormone analogues desmopressin (Grade A)*. It may be a parental choice if advantages and disadvantages are well explained.

- *Daytime incontinence* should be managed holistically including:
  - counselling, bladder training (timed voiding), behaviour modification and bowel management when necessary (Grade B).
  - antimuscarinics may be used if there are symptoms that suggest detrusor overactivity (Grade C).

Should initial treatment be unsuccessful for either enuresis or daytime symptoms, then after a reasonable period of time (8-12 weeks), referral for a specialist’s advice is highly recommended.

* A regulatory warning exists for the danger of overhydration in children on desmopressin.
Initial Management of Urinary Incontinence in Children

**HISTORY/SYMPOTOM ASSESSMENT**
- Nocturnal enuresis (monosymptomatic)
- Daytime ± Nighttime wetting ± Urgency / frequency

**CLINICAL ASSESSMENT**
- General assessment (see relevant chapter)
  - Physical examination: abdominal, perineal, ext. genitalia, back/spine, neurological
  - Assess bowel function -> if constipated, treat and reassess
  - Urinalysis ± Urine culture -> if infected, treat and reassess
  - Assess post-void residual urine by abdominal examination (optional: by ultrasound)

**PRESUMED DIAGNOSIS**
- Monosymptomatic Nocturnal Enuresis

**TREATMENT**
- Failure

**URGENCY INCONTINENCE**
- Bladder training
- Antimuscarinics
- Alarm
- Desmopressin

**RECURRENT INFECTION**
- Failure

**DYSFUNCTIONAL VOIDING**
- Any other abnormality detected e.g. Post void residual

**“Complicated” Incontinence**
- Associated with:
  - Urinary tract anomaly
  - Neuropathy
  - Pelvic surgery
  - Voiding (emptying) symptoms
  - Recurrent urinary infection

**SPECIALIZED MANAGEMENT**
I. CHILDREN

B. SPECIALIZED MANAGEMENT

Two groups of children with “complicated” incontinence should have specialist management from the outset.

- Children whose incontinence is due to, or associated with, urinary tract anomalies and neuropathy.
- Children without urinary tract anomalies, but with recurrent infection and, proven or suspected, voiding dysfunction.

Children who failed the basic treatment, but who have neither neurogenic nor anatomical problems, should also receive specialist management:

1. Assessment

As part of further assessment, the measurement of urine flow (in children old enough), together with the ultrasound estimate of residual urine and the upper urinary tracts is highly recommended.

Those who fail treatment and have neither neurogenic nor anatomical problems should be reassessed using micturition charts, symptom scores, urinalysis, Uroflowmetry and residual urine determination.

If there are recurrent infections, upper tract imaging and possibly a VCUG should be considered. However, endoscopy is rarely indicated.

Urodynamics should be considered:

- If the type and severity of lower tract dysfunction cannot be explained by clinical findings
- If invasive treatment is under consideration, for example, stress incontinence surgery or bladder augmentation, when there is sphincteric incompetence, or if there is detrusor overactivity.
- If upper tract dilatation exists and is thought to be due to bladder dysfunction.

Urodynamic studies are not recommended if the child has normal upper tract imaging and is to be treated by non invasive means.

Spinal Imaging (US/Xray/MRI) may be needed if a bony abnormality or neurological condition is suspected.

2. Treatment

The treatment of incontinence associated with urinary tract anomalies is complex and cannot easily be dealt with in an algorithm. In many children, more than one pathophysiology demands treatment. If there are complex congenital abnormalities present, the treatment is mostly surgical and it should be individualised according to the type and severity of the problem (please see Children's Committee Report).

Care should be given by specialist children’s nurses and therapists.

Initial treatment should be non-surgical.

- For stress urinary incontinence (SUI): pelvic floor muscle training (Grade C)
- For suspected detrusor overactivity (DO): bladder training and antimuscarinics (Grade C)
- For voiding dysfunction: timed voiding, biofeedback to teach pelvic floor relaxation, intermittent catheterisation (when PVR > 30% of bladder capacity). (Grade B/C)
- For bowel dysfunction: as appropriate

The child’s progress should be assessed and, if quality of life is still significantly impaired, or if the upper urinary tracts are at risk, surgical treatment is likely to be necessary.

If surgical treatment is required, then urodynamics is recommended to confirm the diagnosis.

- For SUI, sling surgery, bulking agent injection and AUS may be considered
- For DO/poor compliance, botulinum toxin * and bladder augmentation may be performed.
- If the child cannot do IC then a Mitrofanoff channel may be needed.

* At the time of writing, botulinum toxin is being used “off label” for refractory DO and must be used with caution.
Specialized Management of Urinary Incontinence in Children

**Expert History & Physical Examination**

- Urinalysis: if UTI, treat and reassess as appropriate
- Treat bowel dysfunction and reassess
- Renal / bladder ultrasound
- Assess Post void residual
- Flow rates ± electromyography
- Behavioral Evaluation

**Clinical Assessment**

- Timed voiding
- Pelvic floor relaxation ± biofeedback.
- Pharmacotherapy:
  - Antimuscarinics
  - α-blucers
- Intermittent cath.
- Bowel Management
- Antibiotic if infection

**Diagnosis**

- Incontinence without suspicion of urinary tract anomaly:
  - Urinalysis: if UTI, treat and reassess as appropriate
  - Treat bowel dysfunction and reassess
  - Renal / bladder ultrasound
  - Assess Post void residual
  - Flow rates ± electromyography
  - Behavioral Evaluation

- Incontinence with suspicion of urinary tract anomaly:
  - Consider:
    - Micturating cystogram
    - Renal scintigram
    - Urodynamics
    - Cystourethroscopy
    - Spinal imaging

**Treatment**

- Stress Urinary Incontinence:
  - Pelvic floor and muscle training

- Detrusor Overactivity / Poor Compliance:
  - Bladder training
  - Antimuscarinics
  - Bowel management.

- Voiding Dysfunction:
  - Timed voiding
  - Pelvic floor relaxation ± biofeedback.
  - Pharmacotherapy:
    - Antimuscarinics
    - α-blockers
  - Intermittent cath.
  - Bowel Management
  - Antibiotic if infection

- Anatomic Causes of Urinary Incontinence:
  - Correct anomaly (see: surgical treatment in children)

- Failure:
  - AUS
  - Sling
  - Bulking agent injection
  - Botulinum toxin
  - Bladder augmentation

- Mitrofanoff if IC fails
II. MEN

A. INITIAL MANAGEMENT

1. Initial Assessment should identify:

» **Complicated** incontinence group

Those with pain or with haematuria, recurrent infections, suspected or proven poor bladder emptying (for example due to bladder outlet obstruction), or incontinence following pelvic irradiation, are recommended for **specialized management**.

**Poor bladder emptying** may be suspected from symptoms, physical examination or if imaging has been performed by X-ray or ultrasound after voiding.

» **Four other main groups** of men should be identified by initial assessment as being suitable for **initial management**.

- Those with **post-micturition dribble** alone,
- Those with **overactive bladder** (OAB) symptoms: urgency with or without urgency incontinence, together with frequency and nocturia
- Those with **stress incontinence** (most often post-prostatectomy), and
- Those with **mixed** urgency and stress incontinence (most often post-prostatectomy)

2. Management

» For men with **post-micturition dribble**, this requires no assessment and can usually be treated by teaching the man how to do a strong pelvic floor muscle contraction after voiding, or manual compression of the bulbous urethra directly after micturition. (Grade B)

» For men with **stress, urgency or mixed** urgency / stress incontinence, initial treatment should include appropriate lifestyle advice, physical therapies, scheduled voiding regimes, behavioural therapies and medication. In particular:

- Lifestyle interventions (Grade D)
- Supervised pelvic floor muscle training for men with post radical prostatectomy SUI (Grade B)
- Scheduled voiding regimes for OAB (Grade C)
- Antimuscarinic drugs for OAB symptoms with or without urgency incontinence (Grade B) and the patient has no evidence of significant post-void residual urine
- **α**-adrenergic antagonists (a-blockers), can be added if it is thought that there may also be bladder outlet obstruction. (Grade C)

» **Should initial treatment be unsuccessful** after a reasonable period of time (for example, 8-12 weeks), **specialist advice** is highly recommended.

Clinicians are likely to wish to treat the **most bothersome symptom** first in men with symptoms of **mixed** incontinence.
Initial Management of Urinary Incontinence in Men

**HISTORY**
- Post-micturition dribble
- Incontinence on physical activity (usually post-prostatectomy)
- Incontinence with mixed symptoms
- Urgency / frequency, with or without urgency incontinence

**CLINICAL ASSESSMENT**
- General assessment (see relevant chapter)
- Urinary Symptom Assessment and symptom score (including frequency-volume chart and questionnaire)
- Assess quality of life and desire for treatment
- Physical examination: abdominal, rectal, sacral, neurological
- Urinalysis ± urine culture -> if infected, treat and reassess
- Assessment of pelvic floor muscle function
- Assess post-void residual urine

**PRESUMED DIAGNOSIS**
- STRESS INCONTINENCE presumed due to sphincteric incompetence
- MIXED INCONTINENCE (treat most bothersome symptom first)
- URGENCY INCONTINENCE presumed due to detrusor overactivity

**MANAGEMENT**
- Urethral milking
- Pelvic floor muscle contraction

**DISCUSS TREATMENT OPTIONS WITH THE PATIENT**
- Lifestyle interventions
- Pelvic floor muscle training ± biofeedback
- Scheduled voiding (bladder training)
- Incontinence products
- Antimuscarinics (OAB ± urgency incontinence) and α-adrenergic antagonists (if also bladder outlet obstruction)

**“Complicated” incontinence**
- Recurrent or “total” incontinence
- Incontinence associated with:
  - Pain
  - Hematuria
  - Recurrent infection
  - Prostate irradiation
  - Radical pelvic surgery

Any other abnormality detected e.g. significant post void residual

**SPECIALIZED MANAGEMENT**

Failure
The specialist may first reinstitute initial management if it is felt that previous therapy had been inadequate.

1. Assessment

- Patients with “complicated” incontinence referred directly to specialized management, are likely to require additional testing, cytology, cystourethroscopy and urinary tract imaging.

If these tests prove normal then those individuals can be treated for incontinence by the initial or specialized management options as appropriate.

If symptoms suggestive of detrusor overactivity, or of sphincter incompetence persist, then urodynamic studies are recommended in order to arrive at a precise diagnosis, prior to invasive treatment.

2. Treatment

When basic management has failed

and if the patient’s incontinence markedly disrupts his quality of life then invasive therapies should be considered.

- For sphincter incompetence the recommended option is the artificial urinary sphincter (Grade B). other options, such as a male sling, may be considered (Grade C).

- For idiopathic detrusor overactivity, (with intractable overactive bladder symptoms) the recommended therapies are bladder augmentation (Grade C) and neuromodulation (Grade B). Botulinum toxin continues to show promise in the treatment of symptomatic detrusor overactivity unresponsive to other therapies *

- When incontinence has been shown to be associated with poor bladder emptying and detrusor underactivity, it is recommended that effective means are used to ensure bladder emptying, for example, intermittent catheterisation (Grade B/C).

- If incontinence is associated with bladder outlet obstruction, then consideration should be given to effective treatment to relieve obstruction (Grade B). α-blockers and/or 5α-reductase inhibitors would be an optional treatment (Grade C). There is increased evidence for the safety of antimuscarinics for overactive bladder symptoms in men, chiefly in combination with an α-blocker (Grade B).

* Note: At the time of writing, botulinum toxin is being used “off-label”.

When basic management has failed

and if the patient’s incontinence markedly disrupts his quality of life then invasive therapies should be considered.
Specialized Management of Urinary Incontinence in Men

**HISTORY/SYMPOM ASSESSMENT**

- Post-prostatectomy incontinence
- Incontinence with urgency / frequency
- “Complicated” Incontinence:
  - Recurrent incontinence
  - Incontinence associated with:
    - Prostate or pelvic irradiation
    - Radical pelvic surgery

**CLINICAL ASSESSMENT**

- STRESS INCONTINENCE due to sphincteric incompetence
- MIXED INCONTINENCE Treat major component first
- URGENCY INCONTINENCE due to detrusor overactivity (during filling)

**DIAGNOSIS**

- Post-prostatectomy incontinence
- Incontinence with urgency / frequency

**TREATMENT**

- If initial therapy fails:
  - STRESS INCONTINENCE: Artificial urinary sphincter, Male sling (see chapter)
  - MIXED INCONTINENCE: ρ-blockers, 5ARI, Correct anatomic bladder outlet obstruction, Antimuscarinics (See note)
  - URGENCY INCONTINENCE: Intermitent catheterisation, Antimuscarinics

- If initial therapy fails:
  - Neuromodulation

- “Complicated” Incontinence:
  - Artificial urinary sphincter
  - Male sling
  - ρ-blockers, 5ARI
  - Correct anatomic bladder outlet obstruction
  - Antimuscarinics

- Consider:
  - Urethrocystoscopy
  - Further imaging
  - Urodynamics

- Correct anomaly
- Treat pathology

Consider:
- Urethrocystoscopy
- Further imaging
- Urodynamics

- Lower urinary tract anomaly/pathology

If initial therapy fails:
- Intermitent catheterisation
- Antimuscarinics
- Correct anomaly
- Treat pathology

If initial therapy fails:
- Neuromodulation

If initial therapy fails:
- Intermittent catheterisation
- Antimuscarinics
- Correct anomaly
- Treat pathology

If initial therapy fails:
- Neuromodulation

If initial therapy fails:
- Intermittent catheterisation
- Antimuscarinics
- Correct anomaly
- Treat pathology
III. WOMEN

A. INITIAL MANAGEMENT

1. Initial assessment should identify:

   ➤ “Complicated” incontinence group.
   Those with pain or haematuria, recurrent infections, suspected or proven voiding problems, significant pelvic organ prolapse or who have persistent incontinence or recurrent incontinence after pelvic irradiation, radical pelvic surgery, previous incontinence surgery, or who have a suspected fistula, for specialist referral.

   ➤ Three other main groups of patients should be identified by initial assessment.
   • Women with stress incontinence on physical activity
   • Women with urgency, frequency with or without urgency incontinence
   • Those women with mixed urgency and stress incontinence
   Abdominal, pelvic and perineal examinations should be a routine part of physical examination. Women should be asked to perform a “stress test” (cough and strain to detect leakage likely to be due to sphincter incompetence). Any pelvic organ prolapse or uro-genital atrophy should be assessed. Vaginal or rectal examination allows the assessment of voluntary pelvic floor muscle function, an important step prior to the teaching of pelvic floor muscle training.

2. Treatment

   ➤ For women with stress, urgency or mixed urinary incontinence, initial treatment should include appropriate lifestyle advice, physical therapies, scheduled voiding regimes, behavioural therapies and medication. In particular:
   • Advice on caffeine reduction (Grade B) and weight reduction (Grade A)
   • Supervised pelvic floor muscle training (Grade A), vaginal cones for women with stress incontinence (Grade B)
   • Supervised bladder training (Grade A) for OAB.
   • If oestrogen deficiency and/or UTI is found, the patient should be treated at initial assessment and then reassessed after a suitable interval. (Grade B).
   • Antimuscarinics for OAB symptoms with or without urgency incontinence (Grade A); duloxetine* may be considered for stress urinary incontinence (Grade B)
   Initial treatment should be maintained for 8-12 weeks before reassessment and possible specialist referral for further management if the patient has had insufficient improvement.
   Clinicians are likely to wish to treat the most bothersome symptom first in women with symptoms of mixed incontinence. (Grade C).

   ➤ Some women with significant pelvic organ prolapse can be treated by vaginal devices that treat both incontinence and prolapse (incontinence rings and dishes).

   * Duloxetine is not approved for use in United States. It is approved for use in Europe for severe stress incontinence (see committee report on pharmacological management for information regarding efficacy, adverse events, and ‘black box’ warning by the Food and Drug Administration of the United States).
Initial Management of Urinary Incontinence in Women

**HISTORY**
- Incontinence on physical activity
- Incontinence with mixed symptoms
- Incontinence / frequency with urgency

**CLINICAL ASSESSMENT**
- **Complicated incontinence**
  - Recurrent incontinence
  - Incontinence associated with:
    - Pain
    - Hematuria
    - Recurrent infection
    - Significant voiding symptoms
    - Pelvic irradiation
    - Radical pelvic surgery
    - Suspected fistula

**PRESUMED DIAGNOSIS**
- **Stress incontinence**
  - Presumed due to sphincteric incompetence
- **Mixed incontinence**
  - (treat most bothersome symptom first)
- **OAB - with or without urgency incontinence**
  - Presumed due to detrusor overactivity

**MANAGEMENT**
- **If other abnormality found e.g.**
  - Significant post void residual
  - Significant pelvic organ prolapse
  - Pelvic mass

**General assessment** (see relevant chapter)
- Urinary symptom assessment (including frequency-volume chart and questionnaire)
- Assess quality of life and desire for treatment
- Physical examination: abdominal, pelvic and perineal
- Cough test to demonstrate stress incontinence if appropriate
- Urinalysis ± urine culture -> if infected, treat and reassess
- If appropriate
- Assess oestrogen status and treat as appropriate
- Assess voluntary pelvic floor muscle contraction
- Assess post-void residual urine

**Stress incontinence**
- Life style interventions.
- Pelvic floor muscle training for SUI or OAB
- Bladder retraining for OAB
- Duloxetine* (SUI) or antimuscarinic (OAB ± urgency incontinence)

**Mixed incontinence**
- Other adjuncts, such as electrical stimulation
- Vaginal devices, urethral inserts

**SPECIALIZED MANAGEMENT**
- * Subject to local regulatory approval (see black box warning).
III. WOMEN

B. SPECIALIZED MANAGEMENT

1. Assessment

Women who have “complicated” incontinence (see initial algorithm) may need to have additional tests such as cytology, cystourethroscopy or urinary tract imaging. If these tests are normal then they should be treated for incontinence by the initial or specialized management options as appropriate.

(STD)

⇒ Those women who have failed initial management and whose quality of life is impaired are likely to request further treatment. If initial management has been given an adequate trial then interventional therapy may be desirable. Prior to intervention urodynamic testing is highly recommended, when the results may change management. It is used to diagnose the type of incontinence and therefore inform the management plan. Within the urodynamic investigation urethral function testing by urethral pressure profile or leak point pressure is optional.

⇒ Systematic assessment for pelvic organ prolapse is highly recommended and it is suggested that the POPQ method should be used in research studies. Women with co-existing pelvic organ prolapse should have their prolapse treated as appropriate.

2. Treatment

⇒ If urodynamic stress incontinence is confirmed then the treatment options that are recommended for patients with some degree of bladder-neck and urethral mobility include the full range of non-surgical treatments, as well as retropubic suspension procedures, (Grade A) and bladder neck/sub-urethral sling operations: (Grade A). The correction of symptomatic pelvic organ prolapse may be desirable at the same time.

⇒ For patients with limited bladder neck mobility, bladder neck sling procedures, (Grade A) injectable bulking agents (Grade B) and the artificial urinary sphincter (Grade B) can be considered.

⇒ Urgency incontinence (overactive bladder) secondary to idiopathic detrusor overactivity may be treated by neuromodulation (Grade A) or bladder augmentation (Grade C). Botulinum toxin can be used in the treatment of symptomatic detrusor overactivity unresponsive to other therapies (Grade C).*

⇒ Those patients with voiding dysfunction leading to significant post-void residual urine (for example, >30% of total bladder capacity) may have bladder outlet obstruction or detrusor underactivity. Prolapse is a common cause of voiding dysfunction.

* At the time of writing, botulinum toxin is being used “off-label” and with caution.
Specialized Management of Urinary Incontinence in Women

**HISTORY/SYMPTOM ASSESSMENT**
- Incontinence on physical activity
- Incontinence with mixed symptoms
- Incontinence with urgency / frequency

**CLINICAL ASSESSMENT**
- Assess for pelvic organ mobility / prolapse
- Consider imaging of the UT/pelvic floor
- Urodynamics (see notes)

**DIAGNOSIS**
- URODYNAMIC STRESS INCONTINENCE (USI)
- MIXED INCONTINENCE (USI/DOI) (Treat. most bothersome symptom first)
- DETRUSOR OVERACTIVITY INCONTINENCE (DOI)
- INCONTINENCE associated with poor bladder emptying

**TREATMENT**
- If initial therapy fails:
  - Stress incontinence surgery
  - bulking agents
  - tapes and slings
  - colposuspension
- If initial therapy fails:
  - Botulinum toxin
  - Neuromodulation
  - Bladder augmentation
- Correct anatomic bladder outlet obstruction (e.g. genito-urinary prolapse)
- Intermittent catheterization

“Complicated” incontinence:
- Recurrent incontinence
- Incontinence associated with:
  - Pain
  - Hematuria
  - Recurrent infection
  - Voiding symptoms
  - Pelvic irradiation
  - Radical pelvic surgery
  - Suspected fistula

Consider:
- Urethrocystoscopy
- Further imaging
- Urodynamics

Lower urinary tract anomaly/pathology
- Bladder outlet obstruction
- Underactive detrusor
- Correct anomaly
- Treat pathology
IV. VESICOVAGINAL FISTULA IN THE DEVELOPING WORLD

I. INTRODUCTION

• Obstructed labour is the main cause of vesicovaginal fistula in the developing world. The obstructed labour complex not only induces the vesicovaginal fistula and fetal death in most cases, but can also have urological, gynaecological, neurological, gastro-intestinal, musculoskeletal, dermatological and social consequences.

• Other aetiologies such as sexual violence or genital mutilation are less frequent. For these causes the general principles listed here should be adapted according to the patient’s need.

• Patients with vesicovaginal fistula should be treated as a person, and they deserve the right to adequate counseling and consent to the treatment they will eventually undergo, despite language and cultural barriers that may exist.

• Surgeons embarking on fistula surgery in the developing world should have appropriate training in that setting and should be willing to take on a long-term commitment.

• Prevention of fistula is the ultimate goal. Collaboration between fistula initiatives and maternal health initiatives must be stimulated.

II. ASSESSMENT

It is important to make a distinction between simple fistulae, which have a good prognosis, and complex fistulae, which have a less favourable outcome.

Careful clinical examination will allow the type of fistula to be determined, although no generally accepted classification system is available. Key items are the size and location of the fistula, the extent of the involvement of the urethra and the urethral closure mechanism, and the amount of vaginal scarring.

Associated pathologies should be actively searched for and should be taken into account in the treatment plan: all components of the ‘obstructed labour injury complex’ should be examined and defined.

III. TREATMENT

The treatment for vesicovaginal fistula is surgical. (Grade A)

➤ Simple fistula

A vaginal approach is preferred, since most simple fistula can be reached vaginally and since spinal anaesthesia carries less risk than general anaesthesia needed for an abdominal approach. A trained surgeon should be able to manage these simple fistula.

After wide dissection a tension-free single layer closure of the bladder wall and closure of the vaginal wall in a separate layer are advocated. A Martius flap in primary simple obstetric fistula repair is optional.

A care program for failed repairs and for persisting incontinence after a successful repair needs to be installed.

➤ Complex fistula

Complex fistulae should be referred to a fistula expert in a fistula centre. (Grade B)

In principle, most complex fistulae can be dealt with by the vaginal approach, but an abdominal approach may be needed in some cases (e.g. concommitant reconstructive procedures). Advanced training and surgical skills are prerequisites for treating this type of fistula.

If the urethra and/or the urethral closure mechanism is involved, a sling procedure, using an autologous sling, should be performed at the same time as the fistula correction. There is no place for synthetic sling material in this setting. (Grade B)

➤ After care

The majority of patients with a simple fistula will be cured after the repair. However, a proportion of them, and an even larger proportion of the patients after complex fistula repair, will remain incontinent. Depending on the local possibilities an after care program should be installed.
SURGICAL MANAGEMENT OF OBSTETRIC FISTULA

**HISTORY/SYMPOM ASSESSMENT**

**CONSTANT URINARY LEAKAGE**
- Single vesico-vaginal fistula
- No urethral involvement
- Fistula < 4 cm
- Acceptable vaginal access

**CONSTANT URINARY LEAKAGE AND/OR FECAL INCONTINENCE**
- Fistula > 4 cm
- Urethral involvement
- Intravaginal ureters
- Rectovaginal fistula
- Poor vaginal access
- Secondary fistula repair

**CLINICAL ASSESSMENT**

**SIMPLE FISTULA**
- Primary vaginal fistula repair by trained surgeon

**COMPLEX FISTULA**
- If urethral involvement with stress incontinence add autologous sling
- Refer to fistula specialist/ Fistula center

**DIAGNOSIS**

**TREATMENT**
Pelvic organ prolapse includes urogenital and rectal prolapse. Treatment for pelvic organ prolapse should be reserved for symptomatic women, except in rare, selected, cases.

1. ASSESSMENT

Symptom enquiry may reveal a variety of symptoms. Symptom severity may not correlate with the severity of the anatomic changes.

Physical examination should:
- define the severity of maximum anatomic support defect,
- assess pelvic muscle function and
- determine if epithelial/mucosal ulceration is present.

Post void residual should be measured; nearly all elevated post void residuals resolve with treatment of urogenital prolapse. Imaging of the upper tract is indicated when treatment of vaginal prolapse beyond the hymen is observation only (i.e. no pessary or surgery).

2. MANAGEMENT

- **Observation** is appropriate when medically safe and preferred by the patient (Grade C).

- **Pelvic floor muscle training may:**
  - reduce the symptoms of urogenital prolapse (Grade B), although topographic change is not expected
  - prevent or slow deterioration of anterior urogenital prolapse (Grade B)

- **Pessaries**, when successfully fitted, may improve protrusion symptoms (Grade B). Regular follow up is mandatory. **Support pessaries** that concurrently treat stress incontinence should be considered when appropriate.

- **Local oestrogens** may benefit hypoestrogenic women for the prevention and/or treatment of vaginal epithelial ulceration (Grade C).

- **Reconstructive surgery** should aim to optimise anatomy and function (see full text for grades of recommendation for specific surgical techniques). Pre and postoperative pelvic floor muscle training may promote quality of life and fewer symptoms after surgery for urogenital prolapse (Grade C).

- **Obliterative surgery** is reserved for selected women who agree to permanent vaginal closure (Grade B).
Management of Pelvic Organ Prolapse
(including urogenital prolapse, and recta prolapse)

HISTORY

- Bothersome pelvic organ prolapse
- Complex or recurrent prolapse

Symptoms Screening: assess bothersomeness, frequency and severity of urinary, ano-rectal, genital and sexual symptoms

- Urinary: PVR, cough stress test, urinalysis.
- Physical Examination: Sufficient to determine the site and severity of prolapse and detect other significant findings
  - Selective use of urodynamics when results would alter planned treatment
  - Selective use of upper tract imaging when observation is planned
- Ano-Rectal: Endoscopy, lower GI tract

CLINICAL ASSESSMENT

Investigation by specialist

DIAGNOSIS

UROGENITAL PROLAPSE WITH OR WITHOUT OTHER PELVIC SYMPTOMS

- observation
- lifestyle interventions
- pelvic floor muscle training
- pessary
- reconstructive surgery
- obliterative surgery

RECTAL PROLAPSE WITH OR WITHOUT OTHER PELVIC SYMPTOMS

- observation
- lifestyle interventions
- transperineal surgery
- transabdominal surgery

MANAGEMENT

Specialist management
VI. NEUROGENIC URINARY INCONTINENCE

A. INITIAL MANAGEMENT

I. STRONG GENERAL RECOMMENDATIONS

- Patients with known neurologic disease often need evaluation to exclude neurologic bladder, not only if symptoms occur, but as a standard diagnostic approach as **neurogenic bladder** has a high prevalence in this disease (for prevalence figures see chapter).

- A possible neurologic cause of “idiopathic” incontinence should always be considered. Diagnostic steps to evaluate this include basic assessments, such as history and physical examination, urodynamics and specialised tests.

- **Incontinence in neurologic** patients does not necessarily relate to the neurologic pathology. **Other diseases** such as prostate pathology, pelvic organ prolapse, et al might have an influence. These have to be ruled out.

- **Extensive diagnostic workout** is often useful and necessary only to tailor an individual treatment based on complete neurofunctional data. This may not be needed in every patient e.g. patients with suprapontine lesions or in patients where treatment will consist merely of bladder drainage due to bad medical condition or limited life expectancy.

- There is often a need to manage **bladder** and **bowel** together.

II. INITIAL ASSESSMENT

- The management of neurologic urinary incontinence depends on an understanding of the likely mechanisms producing incontinence. This can in turn depend on the site and extent of the nervous system abnormality.

- Therefore neurogenic incontinence patients can be divided into those having

- **peripheral lesions** (as after major pelvic surgery) including those with lesions of the cauda equina (eg. lumbar disc prolapse);

- **central lesions below the pons** (suprasacral infrapontine spinal cord lesions);

- **central lesions above the pons** (cerebro-vascular accidents, stroke, Parkinson’s disease).

- **History** and **physical examination** are important in helping distinguish these groups.

III. INITIAL TREATMENT

- Patients with **peripheral nerve lesions** (e.g. denervation after pelvic surgery) and patients with **suprasacral infrapontine spinal cord lesions** (e.g. traumatic spinal cord lesions) should get **specialised management** (A).

- Initial treatment for patients with incontinence due to **suprapontine pathology**, like stroke; need to be assessed for degree of mobility and ability to cooperate. Initial recommended treatments are behavioural therapy (C) and anti-muscarinic drugs for presumed detrusor overactivity (A). Appliances (B) or catheters (C) may be necessary for non-cooperative or less mobile patients.
Initial Management of Neurogenic Urinary Incontinence

HISTORY, level of lesion

- Suprapontine cerebral lesion (e.g. Parkinson’s disease, stroke, multiple sclerosis)
- Suprasacral infrapontine spinal cord lesion (e.g. trauma, multiple sclerosis)
- Peripheral nerve lesion (e.g. radical pelvic surgery) Conus/cauda equina lesion (e.g. lumbar disc prolapse)

CLINICAL ASSESSMENT

- Further history
- General assessment including home assessment
- Urinary diary and symptom score
- Assessment of functional level, quality of life and desire for treatment
- Physical examination: assessment of sensation in lumbosacral dermatomes, anal tone and voluntary contraction of anal sphincter, bulbocavernosus and anal reflexes, gait
- Urine analysis + culture (if infected: treat as necessary)
- Urinary tract imaging, serum creatinine: if abnormal: specialised management
- Post void residual (PVR) by abdominal examination or optional by ultrasound

This assessment will give basic information, but does not permit a precise neurourological diagnosis

PRESUMED DIAGNOSIS

- Stress urinary incontinence due to sphincter incompetence
- Urinary incontinence due to detrusor overactivity

MANAGEMENT

- Stress urinary incontinence due to sphincter incompetence:
  - Behavioural modification
  - External appliances

- Urinary incontinence due to detrusor overactivity:
  - With Poor bladder emptying (Significant PVR):
    - Intermittent catheterisation with or without
    - Antimuscarinics
  - With Negligible PVR:
    - Depending on cooperation and mobility:
      - Behavioural modification,
      - Antimuscarinics,
      - External appliances,
      - Indwelling catheter

Failure

Specialised management preferable for more "tailored" treatment
VI. NEUROGENIC URINARY INCONTINENCE

B. SPECIALIZED MANAGEMENT

I. ASSESSMENT

- Most patients with neurogenic urinary incontinence require specialized assessment: urodynamic studies are mandatory with videourodynamics if available.
- Upper tract imaging is needed in most patients and more detailed renal function studies will be desirable if the upper tract is considered in danger: high LUT pressure, UUT dilatation, recurrent or chronic upper tract infection, (major) stones, (major) reflux.
- In patients with peripheral lesions clinical neurophysiological testing may be helpful for better definition of the lesion.

II. TREATMENT

Also for specialized management conservative treatment is the mainstay (A). Management of neurogenic urinary incontinence has several therapeutic options. The algorithm details the recommended options for different types of neurologic dysfunction of the lower urinary tract. The dysfunction does not necessarily correspond to one type/level of neurologic lesion but must depend mostly on urodynamic findings. One should always ascertain that the used management is urodynamically safe (low pressure, complete emptying).

It is recommended to look at urinary and bowel function together if both systems are affected, as symptoms and treatment of one system can influence the other and vice versa (A).

As therapeutical approach can differ in various neurological diseases, the most prevalent diseases are discussed separately in the chapter

III. TREATMENT MODALITIES (often in combination)

- **Conservative**
  - Intermittent catheterization (A)
  - Behavioural treatment(C)
  - Timed voiding (C)
  - Ext. Appliances (B)
  - Antimuscarinics(A)
  - Alpha 1 blockers (C)
  - Intravesical electrical stimulation (C)
  - Bladder expression (B)
  - Triggered voiding (C)
  - Indwelling catheter (C)

- **Surgical treatment**
  - Artificial sphincter (A)
  - Bladder neck Sling (B)
  - Sub-urethral tapes (D)
  - Bulking agents (D)
  - Bladder neck closure (D)
  - Stents intraurethral (B)
  - TUI sphincter (B)
  - Botulinum toxin for: sphincter(C) detrusor (A)
  - Sacral deafferentation (B)
  - Sacral anterior root stimulator (B)
  - Enterocystoplasty (B)
  - Autoaugmentation (D)
Specialized Management of Neurogenic Urinary Incontinence

**LEVEL AND EXTENT OF LESION, HISTORY AND CLINICAL ASSESSMENT**

- Peripheral nerve lesion (e.g. radical pelvic surgery)
- Conus cauda equina lesion (e.g. lumbar disc prolapse)
- Suprasacral infrapontine spinal cord lesion (e.g. trauma, multiple sclerosis)
- Suprapontine cerebral lesion (e.g. Parkinson's disease, stroke, multiple sclerosis)

**SPECIALIZED ASSESSMENT**
- Urodynamic testing (consider the need for simultaneous imaging / EMG)
- Urinary tract imaging: if abnormal renal ultrasonography.
- Neurophysiological testing in peripheral lesions

**DIAGNOSIS**

- Stress UI due to sphincteric incompetence
- Incontinence associated with poor bladder emptying due to detrusor underactivity / sphincter overactivity
- UI due to detrusor overactivity

**CONSERVATIVE TREATMENT**

- Timed voiding
- Ext. Appliances
- Artificial sphincter
- Bladder neck Sling
- Sub-urethral tapes
- Bulking agents
- Bladder neck closure

- IC
- \(\alpha\)-1 blockers
- Intravesical ES
- Bladder expression
- Stents intraurethral
- TUI sphincter
- *Botulinum toxin to sphincter
- SDAF + IC
- SDAF + SARS

**SURGICAL TREATMENT**

- IC + AM
- Indwelling cath. + AM
- SDAF + IC
- SDAF + SARS
- Behavioural
- IC + AM
- Triggered voiding
- Indwelling cath. + AM
- Ext. Appliances + AM
- Botulinum toxin to detrusor
- Enterocystoplasty
- Autoaugmentation

**Stoma/diversion may be an option in selected cases**
Healthy older persons should receive the similar range of treatment options as younger persons, but frail older persons require a different approach addressing the potential role of comorbid disease, current medications (prescribed, over-the-counter, and/or naturopathic), and functional and/or cognitive impairment in UI. The extent of investigation and management should take into account the degree of bother to the patient and/or carer, goals for care, cooperation, and overall prognosis and life expectancy. Effective management to meet the goals of care should be possible for most frail elderly.

### I. HISTORY AND SYMPTOM ASSESSMENT

- **Active case finding and screening** for UI should be done in all frail older persons (Grade A). **History** should include comorbid conditions and medications that could cause or worsen UI. The physical should include rectal exam for faecal loading or impaction (Grade C), functional assessment (mobility, transfers, manual dexterity, ability to toilet) (Grade A), screening test for depression (Grade B), and cognitive assessment (to assist in planning management, Grade C). The mnemonic DIAPPERS (see algorithm) covers some of these comorbid factors, with two alterations: 1) **atrophic vaginitis** does not itself cause UI and **should not be treated for this purpose** (Grade B); and 2) current consensus diagnostic criteria for urinary tract infection (UTI) are poorly sensitive and specific in nursing home residents.

- The patient and/or carer should be asked about the degree of bother of UI (Grade B), goals for UI care (dryness, decrease in specific symtom[s], quality of life, reduction of comorbidity, lesser care burden) (Grade B), likely cooperation with management (Grade C), and the patient’s overall prognosis and remaining life expectancy (Grade C).

- **Urinalysis** is recommended for all patients, primarily to screen for hematuria (Grade C); treatment of otherwise asymptomatic bacteriuria/pyuria is not beneficial (Grade D), and it may cause harm by increasing the risk of antibiotic resistance and severe adverse effects, e.g., *Clostridium difficile* colitis (Grade C).

- **Utility of clinical stress test** in this population is uncertain (Grade D).

- **Wet checks** can assess UI frequency in long-term care residents (Grade C).

- **Post Voiding Residual volume** (PVR) testing is impractical in many care settings, and there is no consensus for the definition of "high" PVR in any population. Yet, there is compelling clinical experience for PVR testing in selected frail older persons with: diabetes mellitus (especially longstanding), prior urinary retention or high PVR; recurrent UTIs; medications that impair bladder emptying (e.g., opiates); severe constipation; persistent or worsening urgency UI despite antimuscarinic treatment; or prior urodynamic showing detrusor underactivity and/or bladder outlet obstruction (Grade C). Treatment of contributing comorbidity may reduce PVR. **Trial with catheter** may be considered for PVR > 200–500 ml if the PVR is felt to contribute to UI or frequency (Grade C).

- **Nocturia** Assessment of frail elders with bothersome nocturia should identify potential underlying cause(s) including nocturnal polyuria (by bladder diary [frequency-volume chart] or wet checks; oedema on exam) (Grade C) and primary sleep problem (e.g., sleep apnoea); low voided volumes (e.g., from high PVR).

### II. CLINICAL DIAGNOSIS

The most common types of UI in frail older persons are urgency, stress, and mixed UI. Frail elderly with urgency UI also may have detrusor underactivity and high PVR (without outlet obstruction), called detrusor hyperactivity with impaired contractility (DHIC). There is no evidence that antimuscarinics are less effective or cause retention in DHIC (Grade D).
III. INITIAL MANAGEMENT

- Initial treatment should be individualized and influenced by goals of care, treatment preferences, and estimated remaining life expectancy, as well as the most likely clinical diagnosis (Grade C). In some frail elders the only possible outcome may be contained UI (managed with pads), especially for persons with minimal mobility (require assistance of ≥ 2 persons to transfer), advanced dementia (unable to state their name), and/or nocturnal UI.

- Conservative and behavioural therapy for UI include lifestyle changes (Grade C), bladder training for more fit alert patients (Grade B), and prompted voiding for frailer, more impaired patients (Grade A).

- For select cognitively intact patients, pelvic muscle exercises may be considered, but there are few studies (Grade C). Antimuscarinics may be added to conservative therapy of urgency UI (Grade A-C, depending on agent).

- Alpha-blockers may be cautiously considered in frail men with suspected prostatic outlet obstruction (Grade C). All drugs should be started at the lowest dose and titrated with regular review until either care goals are met or adverse effects are intolerable.

- DDAVP (vasopressin) has a high risk of severe hyponatremia in frail persons and should not be used (Grade A).

IV. ONGOING MANAGEMENT AND REASSESSMENT

Optimal UI management is usually possible with the above approaches. If initial management fails to achieve desired goals, next steps are reassessment and treatment of contributing comorbidity and/or functional impairment.

V. SPECIALIZED MANAGEMENT

If frail elderly have either other significant factors (e.g., pain, haematuria), UI symptoms that cannot be classified as urgency, stress, or mixed, or other complicated comorbidity which the primary clinician cannot address (e.g., dementia, functional impairment), then specialist referral should be considered. Referral also may be appropriate for insufficient response to initial management. Type of specialist will depend on local resources and the reason for referral: surgical specialists (urologists, gynecologists); geriatrician or physical therapist (functional and cognitive impairment); continence nurse specialists (homebound patients). Referral decisions should consider goals of care, patient/carer desire for invasive therapy, and estimated remaining life expectancy.

Age per se is not a contraindication to UI surgery (Grade C), but before surgery is considered, all patients should have:

- Evaluation and treatment for any comorbidity, medications, and cognitive and/or functional impairments contributing to UI and/or that could compromise surgical outcome (e.g., dementia that precludes patient ability to use artificial sphincter) (Grade C)

- Adequate trial of conservative therapy (Grade C)

- Discussion (including the carer) to insure that the anticipated surgical outcome is consistent with goals of care in the context of the patient’s remaining life expectancy (Grade C)

- Urodynamic testing, because clinical diagnosis may be inaccurate (Grade B)

- Preoperative assessment and perioperative care to establish risk for and minimise common geriatric post-operative complications such as delirium and infection (Grade A) and dehydration and falls (Grade C).
Management of Urinary Incontinence in Frail Older Persons

**Active Case Finding in Frail Elderly**
- Assess, treat and reassess potentially treatable conditions, including relevant comorbidities and ADLs (see text)
- Assess QoL, desire for Rx, goals for Rx, pt & caregiver preference
- Targeted physical exam including cognition, mobility, neurological and rectal exams
- Urinalysis
- Consider frequency volume chart or wet checks, especially if nocturia present

**URGENCY UI***
- Lifestyle interventions
- Behavioral therapies
- Consider addition and trial of antimuscarinic drug

**SIGNIFICANT PVR***
- Treat constipation
- Review medications
- Consider trial of alpha-blocker (men)
- Catheter drainage if PVR 200-500 ml, then reassess (see text)

**STRESS UI***
- Lifestyle interventions
- Pelvic floor muscle exercises

**If insufficient improvement, reassess for treatment of contributing comorbidity ± functional impairment**

**If continued insufficient improvement, or severe associated symptoms are present, consider specialist referral as appropriate per patient preferences and comorbidity (see text)**

---

**CLINICAL ASSESSMENT**
- Delirium
- Infection
- Pharmaceuticals
- Psychological
- Excess urine output
- Reduced Mobility
- Stool impaction and other factors
  Avoid overtreatment of asymptomatic bacteriuria

**CLINICAL DIAGNOSIS**
* Other

**HISTORY/SYMPTOM ASSESSMENT**

---

* These diagnoses may overlap in various combinations, e.g., Mixed UI, DHIC (see text)
Bladder Pain Syndrome (In the absence of a universally agreed definition, the European Society for the Study of Interstitial Cystitis – ESSIC – definition is given along with a slight modification made at a recent international meeting held by the Society for Urodynamics and Female Urology – SUFU)

• ESSIC: Chronic pelvic pain, pressure or discomfort of greater than 6 months duration perceived to be related to the urinary bladder accompanied by at least one other urinary symptom like persistent “urge” to void or urinary frequency. Confusable diseases as the cause of the symptoms must be excluded.

• Consensus Definition from SUFU International Conference (Asia, Europe, North America) held in Miami, Florida February 2008: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes.

The scientific committee of the International Consultation voted to use the term “bladder pain syndrome” for the disorder that has been commonly referred to as interstitial cystitis (IC). The term painful bladder syndrome was dropped from the lexicon. The term IC implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. Painful Bladder Syndrome, as defined by the International Continence Society, is too restrictive for the clinical syndrome. Properly defined, the term Bladder Pain Syndrome appears to fit in well with the taxonomy of the International Association for the Study of Pain (IASP), and focuses on the actual symptom complex. There is at this time no universally accepted nomenclature.

II. BLADDER PAIN SYNDROME (BPS)

1. NOMENCLATURE

Males or females with pain, pressure, or discomfort, that they perceive to be related to the bladder, with at least one urinary symptom, such as frequency not obviously related to high fluid intake, or a persistent need to void should be evaluated for possible bladder pain syndrome. The diagnosis of associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms also suggests the diagnosis. Abnormal gynecologic findings in women and well-characterized “confusable” diseases that may explain the symptoms must be ruled out, for example UTI.

The initial assessment consists of a frequency-volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology and cystoscopy are recommended if clinically indicated. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and/or hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms, are they diagnosed with BPS. (Grade of recommendation: C).

III. INITIAL TREATMENT

• Patient education,
• dietary manipulation,
• non-prescription analgesics, and
• pelvic floor relaxation techniques comprise the initial treatment of BPS.
The treatment of pain needs to be addressed directly, and in some instances concurrent consultation with an anesthesia/pain center can be an appropriate early step in conjunction with ongoing treatment of the syndrome.

Treatment should be focused on the most bothersome or distressing symptoms(s).

➢ When conservative therapy fails or symptoms are severe and conservative management is unlikely to succeed,
  • oral medication,
  • intravesical treatment, or
  • physical therapy
  can be prescribed.

It is recommended to initiate a single form of therapy and observe results, adding another modality or substituting another modality as indicated by degree of response or lack of response to treatment. (Grade of recommendation: C).

4. SECONDARY ASSESSMENT

➢ If initial oral or intravesical therapy fails, or before beginning such therapy, it is reasonable to consider further evaluation which can include urodynamics, pelvic imaging, and cystoscopy with bladder distension and possible bladder biopsy under anaesthesia.

Findings of detrusor overactivity suggest a trial of antimuscarinic therapy is indicated.

The presence of a Hunner’s lesion diagnosed at any stage in the evaluation suggests therapy with transurethral resection or fulguration of the lesion. Distension itself can have therapeutic benefit in 30-50% of patients, though benefits rarely persist for longer than a few months. (Grade of recommendation: C).

5. REFRACTORY BPS

➢ Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. Many of these are best administered within the context of a clinical trial if possible. These may include neuromodulation, intravesical botulinum toxin, or newly described pharmacologic management techniques. At this point, most patients will benefit from the expertise of an anaesthesia pain clinic.

➢ The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urinary stream.
  • Urinary diversion with or without cystectomy has been used as a last resort with good results in selected patients.
  • Augmentation or substitution cystoplasty seems less effective and more prone to recurrence of chronic pain in small reported series. (Grade of recommendation: C).
Bladder Pain Syndrome

SYMPTOM

Pain, pressure or discomfort perceived to be related to the bladder with at least one other urinary symptom (eg frequency, nocturia)

BASIC ASSESSMENT

- History
- Frequency / Volume Chart
- Focused Physical Examination
- Urinalysis, Culture, Cytology

"SIMPLE BPS" Conservative therapy

- Patient education
- Dietary manipulation
- Non-prescription analgesics
- Pelvic Floor Relaxation

FIRST LINE TREATMENT

"Complicated PBS"

- Incontinence
- Urinary infection
- Haematuria
- Gynecologic signs / symptoms

UTI

Consider:

- urine cytology
- further imaging
- endoscopy
- urodynamics

ABNORMAL

BPS : requiring more active intervention
when treatment response inadequate

Consider:

- Oral therapies
- Intravesical therapies
- Physical therapy

SECOND LINE TREATMENT

NORMAL

Improved with acceptable quality of life: Follow and Support

Consider:

- Cystoscopy under anesthesia with hydrodistention;
- Fulgeration of Hunner's lesion

THIRD LINE TREATMENT

Consider in context of clinical trial:

- Neuromodulation
- Botulinum toxin intramural
- Pharmacologic management

FOURTH LINE TREATMENT

- Urinary diversion with or without cystectomy
- Substitution cystoplasty

Consider:
Patients present with a variety of symptom complexes. As many people are reluctant to admit to symptoms of FI, it is important to proactively enquire in known high risk groups (such as women with obstetric injuries, patients with loose stool and neurological patients).

- **Serious bowel pathology** needs to be considered if the patient has symptoms such as an unexplained change in bowel habit, weight loss, anaemia, rectal bleeding, severe or nocturnal diarrhoea, or an abdominal or pelvic mass.

- **History** will include bowel symptoms, systemic disorders, local anorectal procedures (e.g. haemorrhoidectomy), childbirth for women, medication, diet and effects of symptoms on lifestyle.

- **Examination** will include anal inspection, abdominal palpation, a brief neurological examination, digital rectal examination and usually anoscopy and proctoscopy.

- **Two main symptoms are distinguished:** *urgency faecal incontinence* (FI) which is often a symptom of external anal sphincter dysfunction or intestinal hurry; and *passive loss of stool* may indicate internal anal sphincter dysfunction. Both urgency and passive FI may be exacerbated in the presence of loose stool.

---

**I. INITIAL ASSESSMENT**

Once local or systemic pathology has been excluded, *initial management includes*:

- Discussion of *options* with the patient
- Patient *information* and *education*,
- *Diet* and fluid advice, adjusting fibre intake (Grade A), and establishing a regular bowel habit with complete rectal evacuation and

- **Simple exercises** to strengthen and enhance awareness of the anal sphincter (Grade C).
- **Anti-diarrhoeal** medication can help if stools are loose (Grade B).
- **Irrigation** is helpful in a small number of patients (mainly neurological - Grade C).
- **Initial management can often be performed in primary care.** If this is failing to improve symptoms after 8-12 weeks, consideration should be given to referral for further investigations.

**III. INVESTIGATIONS**

A variety of anorectal investigations, including manometry, EMG, and anal ultrasound can help to define structural or functional abnormalities of anorectal function.

**IV. FURTHER MANAGEMENT**

- **BIOFEEDBACK**
  
  therapy is usually a package of measures designed to enhance the patient’s awareness of anorectal function, improve sphincter function and coordination and retrain the bowel habit (Grade C).

- **PRODUCTS**
  
  to manage severe faecal incontinence are ineffective in most cases.

- **SEVERE FAECAL INCONTINENCE**
  
  which fails to respond to initial management requires specialised investigations and a surgical opinion.

**V. SPECIAL PATIENT GROUPS**

The main chapter (refer to the book) also gives algorithms for the management of complex vesicovaginal fistulae and faecal incontinence in frail older adults. Committees 10 and 16 gives information on neurogenic FI.
Initial Management of Faecal Incontinence

Active Screening in High Risk Groups

Patient presents with FI

Basic assessment (history, examination, medication and diet review)

Take out of pathway:
- **Alarm signals**: referral for investigation
- **Impaction**: treat then evaluate
- **Surgical evaluation needed**: e.g. rectal prolapse, recent sphincter injury, recto-vaginal fistula, cloacal deformity

Address reversible risk factors e.g. Medication; toilet access; loose stools
- **Patient and / or carer education**
- **Bowel habit and training**
- **Manage constipation**
- **Diet (e.g. soluble fibre for loose stool)**
- **Medication (e.g. loperamide for loose stool)**
- **PFMT / anal sphincter exercises**
- **Adequate containment (e.g. pads or plugs) and practical management advice (Committee 20)**

If initial management fails to achieve adequate symptom relief consider:
- Diagnostic testing; Biofeedback; Irrigation

Surgical evaluation or symptom management if adequate relief not obtained from conservative management, depending on symptom severity and patient preference
The reader is referred to the relevant sections on "Dynamic Testing" and "Conservative Treatment for Faecal Incontinence." In general, patients referred for surgical management of faecal incontinence must either have failed conservative therapy or not be candidates for conservative therapy due to severe anatomic, physiologic or neurologic dysfunction.

Prior to surgical management of faecal incontinence, the morphological integrity of the anal sphincter complex should be assessed. This assessment is best performed with endoanal ultrasound (EAUS), though pelvic MRI may also be useful. Ancillary tests include anal manometry, electromyography (EMG), and defecography. [GRADE OF RECOMMENDATION C]

Patients with rectal prolapse, rectovaginal fistulae, and cloacas often have associated faecal incontinence. Initial therapy should be directed at correction of the anatomic abnormality (in the case of rectovaginal fistula or cloaca, this surgical repair may include overlapping sphincteroplasty.) If the patient has persisting faecal incontinence, he or she should undergo repeat assessment, including especially endoanal ultrasound.

Patients with sphincter defects of greater than 180° or major pereneal tissue loss require individualized treatment. In some cases, initial reconstruction can be performed. Should incontinence persist, alternatives include stimulated muscle transposition, artificial anal sphincter implantation, or sacral nerve stimulation. [GRADE OF RECOMMENDATION C]

Patients who remain incontinent following sphincteroplasty, repeat endoanal ultrasound should be undertaken to reassess the status of the repair. If there is a persisting sphincter defect, repeat sphincteroplasty can be considered. Alternatively, such patients can undergo individualized therapy, including sacral nerve stimulation. [GRADE OF RECOMMENDATION C]. For patients who remain incontinent despite an anatomically satisfactory sphincteroplasty, sacral nerve stimulation is recommended.

Patients who have failed sacral nerve stimulation can be considered for sphincteroplasty if a sphincter defect is present. Other alternatives include stimulated muscle transposition and implantation of an artificial anal sphincter. [GRADE OF RECOMMENDATION C]

Patients who fail surgical therapy for faecal incontinence, or who do not wish to undergo extensive pelvic reconstruction, should consider placement of an end sigmoid colostomy. [GRADE OF RECOMMENDATION C]. While this procedure does not restore continence, it does restore substantial bowel control and appears to improve social function and quality of life.

Individuals with severe spinal cord dysfunction (due, e.g., to injury or congenital abnormality) should be considered for an Antegrade Continence Enema (ACE) procedure or colostomy. [GRADE OF RECOMMENDATION C]
Surgical Management of Faecal Incontinence

Candidate for surgery for FI

EVALUATION
EAUS± Manometry, EMG, MRI, Defecography

Persistent Surgical treatment for anatomical abnormality

COMPLETE SPINAL CORD IMPAIRMENT

SPHINCTER DEFECT

None

< 180°

>180° or perineal tissue loss

Sphincteroplasty

Individualized treatment:
- Sphincteroplasty
- Muscle transposition
- Artificial sphincter
- Sacral nerve stimulation
- Biomaterial injection
- ACE
- Colostomy
- Conservative therapy

ACE Colostomy

Repeat EAUS

* = inadequate symptom relief
FI: fecal incontinence;
ACE: antegrade continence enema;
EAUS: endoanal ultrasonography;
EMG: electromyography;
MRI: magnetic resonance imaging
SNS: sacral nerve stimulation

SPHINCTER DEFECT

Sphincteroplasty

* = inadequate symptom relief
FI: fecal incontinence;
ACE: antegrade continence enema;
EAUS: endoanal ultrasonography;
EMG: electromyography;
MRI: magnetic resonance imaging
SNS: sacral nerve stimulation
Patients with known neurologic disease may present with symptoms related to neurologic bowel dysfunction – difficulty in defecation, constipation and faecal incontinence which disturb their activities of daily living and quality of life. Many have permanent impairments and functional limitations and disabilities, which are due to neurological deficits and complications.

**A. Initial management**

**I. Initial assessment**

- **History taking:** this includes
  - Neurological diagnosis and functional level;
  - Previous and present lower gastrointestinal (LGIT) function and disorders
  - Severity of neurogenic bowel dysfunction
  - Current bowel care and management including diet, fluid intake, medications affecting bowel functions
  - Co-morbidity / complication e.g., urinary incontinence, autonomic dysreflexia, pressure sores, sexual dysfunction
  - Patient's satisfaction, needs, restrictions and quality of life
  - Environmental factors and barriers and facilitators to independent bowel management.

- **Physical examination:**
  - Cognitive functions; motor, sensory and sacral reflexes – voluntary anal sphincter contraction, deep perianal sensation, anal tone, anal and bulbocavernous reflexes
  - Spasticity of the lower limbs
  - Abdominal palpation for faecal loading and rectal examination

**II. Basic investigations:**

- **Functional assessment:**
  - hand and arm use, fine hand use, mobility – maintaining body position, transfer and walking ability.

- **Environmental factors assessment:**
  - toilet accessibility; assistive devices for bowel care and mobility; carer’s support and attitude;

Stool exam, plain abdomen XRay

**III. Initial treatments**

- **Patient education and goals-setting** - complete defecation on a regular basis and faecal continence based on right time, right place, right trigger and right consistency
- **Adequate fibre diet and fluid intake**; appropriate trigger according to preservation of sacral (anorectal) reflex – digital rectal stimulation; suppository and enema; if no anorectal reflex, manual evacuation; abdominal massage can also be helpful
- **Prescribe medications** – stool softener, laxative, prokinetic agents, anti-diarrhea drugs as necessary
- Assistive techniques may be necessary for
  - defecation – irritation
  - for incontinence – anal plug.

The diagram does not apply to management in acute neurologic patients that need regular bowel emptying.
**Initial Management of Neurogenic Faecal Incontinence**

**HISTORY, level of lesion**
- Conus/cauda equina lesion (e.g. lumbar disc prolapse) Peripheral nerve lesion (e.g. radical pelvic surgery)
- Suprasacral spinal cord lesion (e.g. trauma, multiple sclerosis,)
- Suprapontine lesions (e.g. Parkinson)

**CLINICAL ASSESSMENT**
- History taking including diagnosis, pre-morbid bowel function and sensation and their disorders, current bowel and bladder programme, co-morbid diseases/disorders, QOL and needs
- Physical & neurological examination including cognitive function, voluntary anal contraction, sensation, sacral reflexes, per rectal examination, abdominal palpation for faecal impaction in the colon
- Functional assessment including hand and arm use, fine hand use, balance, transfer and walk
- Environmental factors assessment including toilet accessibility, assistive device, carer’s support and attitude
- Basic investigation: stool exam, plain film abdomen in selected patients (diarrhea, impaction not felt on rectal examination)

This assessment will give basic information but does not permit a precise diagnosis of neurogenic bowel dysfunction

**PRESUMED DIAGNOSIS**
- Incontinence due to sphincter incompetence
- Incontinence due to lack of cognitive function, sensory awareness disorders, unable to control by voluntary anal contraction
- "False incontinence" due to faecal impaction

**TREATMENT**
- Manual evacuation
- Assistive device – anal plug
- Digital rectal stimulation
- Chemical stimulant: suppository, mini-enema, stool softener, laxative; transanal/transrectal irrigation
- Faecal disimpaction

Patient education, adequate fibre diet and fluid intake; regular bowel care, preferable ± 3 times a week

Specialised management preferable for more "tailored" treatment
Some patients with neurogenic faecal incontinence will need specialized assessment, especially if initial management is unsuccessful to look for comorbidity and certainly before performing invasive treatment.

Do not assume that all symptoms are due to neuropathy, e.g. women with neurologic pathology might have had childbirth injury to the sphincter.

Special investigations: manometry, endoanal ultrasound, (dynamic) MRI, (needle) EMG. These specific bowel functional tests and electro-diagnostic tests must be considered optional as their value in neurologic pathology is not sufficiently demonstrated so far.

Management of neurogenic incontinence does not include very extensive treatment modalities and many conservative are still empirical.

Transanal irrigation (C)

Electrical stimulation sphincter, (C)

Percutaneous neuromodulation: further research is required.

Surgical management of neurogenic faecal incontinence has different options which need a very strict patient selection.

Antegrade Continence Enema ACE (C)

Graciloplasty (C)

Artificial sphincter (C)

Sacral Anterior Root Stimulation SARS (C)

Botulinum Toxin (C)

Neuromodulation (C)

It is recommended to look at urinary and bowel function together if both systems are affected, as symptoms and treatment of one system can influence the other and vice versa (A).

As therapeutical approach can differ in different neurological diseases, the most prevalent diseases are discussed separately in the chapter.
Specialised Management of Neurogenic Faecal Incontinence

**SPECIALIZED ASSESSMENT**
- Primary assessment, history, level and extent of lesion, clinical assessment
- Conus/cauda equina lesion (e.g. lumbar disc prolapse) Peripheral nerve lesion (e.g. radical pelvic surgery)
- Suprasacral spinal cord lesion (e.g. trauma, multiple sclerosis)
- Suprapontine lesions (e.g. Parkinson)

**DIAGNOSIS**
- Faecal Incontinence through loss of bowel sensation, sphincter deficiency or, severe rectum prolaps no anal control, comorbidity,
- Functional bowel testing / functional imaging
- Neurophysiological testing especially external anal sphincter needle electromyography, in addition to anorectal manometry, to identify or confirm neurogenic cause of faecal incontinence.

**CONSERVATIVE TREATMENT**
- Transanal irrigation
- Electrical stimulation sphincter,
- Percutaneous neuromodulation : further study

**SURGICAL TREATMENT**
- ACE
- Graciloplasty
- Artificial sphincter
- SARS
- Botulinum Toxin
- Neuromodulation

**Stoma/diversion may be an option in selected cases**

ACE = Antegrade Continence Enema
SARS = Sacral Anterior Root Stimulation

Faecal impaction
- Faecal disimpaction
  - Failure consider
  - Failure consider
4. Recommendations for Continence Promotion, Education and Primary Prevention

Continence promotion, education and primary prevention involves informing and educating the public and health care professionals that urinary incontinence and faecal incontinence are not inevitable, but are treatable or at least manageable. In addition, other bladder disorders such as bladder pain syndrome and pelvic organ prolapse can be treated successfully. Progress has been made in the promotion of continence awareness through advocacy programs, organization of the delivery of care, and public access to information on a worldwide basis. These have also been advocated in the education of professionals and primary prevention of mainly urinary incontinence. However, not much has changed in help-seeking behaviour for these disorders. This chapter updates previous International Consultation on Incontinence (ICI) chapters on three areas: continence promotion, education and primary prevention and the following are the recommendations in these individual areas.

### CONTINENCE AWARENESS AND PROMOTION

- Continence awareness should be included in any national advocacy program that is working towards an effective health literacy system, as it is consistent with and requires the involvement of many levels of educational, health-care, and community service providers. (Grade D)
- Continence awareness should be part of the main stream and on-going health education and advocacy programs with emphasis on eliminating stigma, promoting disclosure and help-seeking behaviour and improving quality of life. (Grade D)
- There is a need for research to provide higher level of evidence on the effectiveness of continence promotion programs to increase awareness, be it for primary prevention, treatment or management. (Grade D)
- There is a need for research on the most effective means to educate the public and professional groups on continence issues. (Grade D)

### CONTINENCE ADVOCACY

- Government support and co-operation are needed to develop services, and responsibility for this should be identified at a high level in each Health Ministry. Incontinence should be identified as a separate issue on the health care agenda. There is a need for funding as a discrete item and for funding, not to be linked to any one patient group (e.g. elderly or disabled), and should be mandatory. (Grade D)
- No single model for continence services can be recommended. Because of the magnitude of UI prevalence, detection and basic assessment will need to be performed by primary care providers. Specialist consultation should generally be reserved for those patients where appropriate conservative treatments have failed, or for specified indications. (Grade D)
- There is a need for research on patient-focused outcomes, should include evaluation of the outcomes for all sufferers who present for care, use validated audit tools/outcome measures and longitudinal studies of the outcomes of services provided. (Grade D)
- There is a need for cost-effectiveness studies of current services. (Grade D)

### PROFESSIONAL EDUCATION

- There remains a need for rigorously evaluated continence education programmes which adhere to defined minimum standards for continence specialists and, generalists, utilizing web-based and distance learning techniques alongside audit and feedback, train-the trainer models and leadership models as well as traditional methods. (Grade D)
- There is a need for research on the most effective means to educate professional groups on continence issues. (Grade D)

### PRIMARY PREVENTION

- Primary prevention studies efforts should be aimed at interventions to promote a healthy body weight to assist in the prevention of incontinence (Grade A).
- Primary prevention studies should not be limited to individual interventions, but also test the impact of population-based public health strategies (Grade C)
- PFMT should be a standard component of prenatal and postpartum care and to instruct women who experience incontinence prior to pregnancy PFMT (Grade C)
- Randomised controlled trials (RCTs) should be conducted to test the preventative effect of PFMT for men post-prostatectomy surgery (Grade B)
- Further investigation is warranted to assess the efficacy of PFMT and BT for primary prevention of UI in well older adults (Grade B)
5. Recommendations for Further Basic Science Research

1. Integrate data from reductionist experiments to formulate better systems-based approaches in the investigation of the pathology of the lower urinary tract (LUT), the genital tract (GT) and the lower gastro-intestinal tract (LGIT).

2. Generate and improve experimental approaches to investigate the pathophysiology of the LUT and LGIT by:
   - The development of fully characterised animals models
   - Use of human tissue from well-characterised patient groups

3. Encourage greater emphasis on basic research into our understanding of tissues receiving relatively little attention: ie the lower gastrointestinal tract; the bladder neck and urethra.

4. Generate a more disciplinary approach to investigate the function of the lower urinary tract through collaborations between biological, physical and mathematical sciences.

5. Increase interaction between higher education institutions (HEIs), industry and medical centres to encourage translational approaches to research.

6. Bring about a greater emphasis on the importance of research to medical trainees through:
   - establishing research training as a core component of medical training
   - increased access to support funds, especially scholarships and personal awards
   - organisation of focussed multidisciplinary research meetings, either stand-alone or as part of larger conferences
   - greater interaction between medical centres and HEIs

7. Increase emphasis on research into lower urinary tract and gastro-intestinal tract in HEIs through:
   - greater representation on grant-funding agencies
   - encouragement of submission to high impact-factor journals and recognition of research published in specialty journals
   - more integrated teaching and training opportunities

6. Recommendations for Further Research in Epidemiology

1. Longitudinal study designs are needed to estimate the incidence of urinary incontinence (UI), anal incontinence (AI) and pelvic organ prolapse (POP) and to describe the natural course of these conditions and to investigate risk factors and possible protective factors. In addition similar studies regarding other lower urinary tract symptoms (LUTS) should be initiated.

2. There is still little knowledge regarding prevalence, incidence, and other epidemiological data in developing countries. It is recommended that fundamental research regarding prevalence, incidence and other epidemiological data in developing countries should be encouraged, and tailored to the cultural, economic and social environment of the population under study.

3. Some potential risk and protective factors deserve more attention. For example, the role of pregnancy and childbirth in the development of UI, AI and POP must be studied in a fashion that links population-based methods to clinical assessment of pregnancy, delivery and the birth trauma and follows women over many years. Such a design is necessary because the effect of pregnancy and childbirth may become clear only years later when the woman is older and because the woman will not then be able to report the exact nature of the tear and episiotomy, etc.

4. There should be more emphasis on the associations between UI, AI and POP and specific diseases like stroke, diabetes, and psychiatric diseases.

5. The variation of disease occurrence in groups of different racial origin yet similar environmental exposures, lend support to the presumed genetic influence on the causation of UI, AI and POP. This again provides circumstantial evidence for a genetic contribution to pelvic floor disorders since most of these studies have been unable to control for heritability in relation to the complex interaction of environmental factors.

6. The ethiology of UI, AI and POP is widely recognised to be multifactorial, yet the complex interaction between genetic predisposition and environmental influences is poorly understood. Genetic components require further investigation. Twin studies provide a possible means of studying the relative importance of genetic predisposition and environmental factors. By comparing monozygotic female twins with identical genotype, and dizygotic female twins who on average share 50 percent of their segregating genes, the relative proportions of phenotypic variance resulting from genetic and environmental factors can be estimated. A genetic influence is suggested if monozygotic twins are more concordant for the disease than dizygotic twins whereas evidence for environmental effects comes from monozygotic twins who are discordant for the disease.
7. Recommendations for Clinical Research Methodology

PART I: GENERAL RECOMMENDATIONS

I. RECOMMENDATIONS ON STUDY CONDUCT AND STATISTICAL METHODS

- Randomized controlled trials (RCTs) eliminate most of the biases that can corrupt research and provide the strongest level of evidence to direct clinical care. The primacy of RCTs in incontinence research should be fully acknowledged by researchers, reviewers, and editors.

- Careful attention to the planning and design of all research is of the utmost importance. This should begin with a structured literature review which should be described in the manuscript. High quality, systematic reviews on many topics in incontinence have been published by the Cochrane Incontinence Group (www.otago.ac.nz/cure) and provide a valuable starting point.

- The design, conduct, analysis and presentation of RCTs must be fully in accordance with the Consolidated Standards of Reporting Trials (CONSORT) guidelines. Statistical expertise is required at the start of the design of a RCT and thereafter on an ongoing basis.

- Equivalence trials are underutilized. Failing to find a difference between two treatments is not the same as proving equivalence if the correct design is not used.

- Inclusion and exclusion criteria inherently reflect a conflict between detecting a specific treatment effect and generalizability of the results. It is recommended that the study population in RCTs comprise a sample that is representative of the overall population. All patients who have the disorder in question, who could benefit from the treatment under investigation, and who are evaluable should be eligible. Exclusion criteria should be limited and related to clearly defined, supportable hypotheses.

II. RECOMMENDATIONS ON OBSERVATIONS DURING INCONTINENCE RESEARCH

- One or more high quality, validated symptom instruments should be chosen at the outset of a clinical trial representing the viewpoint of the patient, accurately defining baseline symptoms as well as any other areas in which the treatment may produce an effect. The objective severity and subjective impact or bother should be reflected.

- Whenever relevant, observations of anatomic support and pelvic muscle/voluntary sphincter function should be recorded using standardized, reproducible measurements.

- All observations should be repeated after intervention and throughout follow-up and their relationships with primary clinical outcome measures investigated. Most research follow-up has been inadequate in the past. Given the nature of the disorder, short term follow-up in incontinence trials should begin with all participants having reached one year.

III. RECOMMENDATIONS ON TESTS USED IN URINARY INCONTINENCE RESEARCH:

- Clinical trials of incontinence and LUTS should include a validated frequency volume chart or bladder diary as an essential baseline and outcome measure. Pad tests are a desirable adjunctive measure and should be considered in clinical trials when practical.

- Urodynamic studies have not been proven to have adequate sensitivity, specificity or predictive value to justify routine use of testing as entry criteria or outcome measures in clinical trials. Most large scale clinical studies should enroll subjects by carefully defined symptom driven criteria when the treatment will be given based on an empiric diagnosis.

- High quality, hypothesis driven research into the utility of using urodynamic studies to define patient populations or risk groups within clinical trials is greatly needed.
In all trials employing urodynamics, standardized protocols (based on ICS recommendations) are defined at the outset. In multicenter trials, urodynamic tests should be interpreted by a central reader to minimize bias unless inter- and intrarater reliability has already been established by standardized procedures within the trial.

High quality, gender specific quality of life and bother scores should be employed when assessing outcome in male incontinence research.

Uroflow and measurement of post-void residual urine should be recorded pre-treatment and the effect of therapy on these parameters should be documented simultaneously with assessment of the primary outcome variables. The value of invasive pressure-flow urodynamics in stratifying patients deserves further investigation.

Measurement of prostate size (or at least PSA, as a surrogate) should be performed before and after treatment (synchronous with other outcome measures) whenever prostate size is expected to change due to the treatment. Patients should be stratified by prostate size at randomization when size is considered to be a potentially important determinant of treatment outcome.

Specific information about the menopause, hysterectomy, and hormonal status, parity and obstetric history should be included in baseline clinical trial data

Strict criteria for cure / improve / fail should be defined based on patient perception as well as objective and semi-objective instruments such as validated questionnaires, diaries and pad tests.

“Clinically significant” outcome measures and relationships of outcome to socioeconomic costs are critically important to establishing the utility of treating urinary incontinence in the frail elderly.

Entry into RCTs should be defined by performance status rather than an arbitrary age limit.

Establishing the safety of incontinence treatment is even more important in the frail elderly than in other populations.

We support the NIH statement (http://grants.nih.gov/grants/guide/notice-files/not98-024.html) calling for increased clinical research in children. All investigators that work with children should be aware of the details of the document.

Long-term follow-up is of critical importance in the pediatric population with a primary focus of establishing safety of chronic treatments.

Detailed urodynamic studies are required for classification of neurogenic lower urinary tract disorders in clinical trials because the nature of the lower tract dysfunction cannot be accurately predicted from clinical data.

Change in detrusor leak point pressure should be reported as an outcome as appropriate, and can be considered a primary outcome for spina bifida patients.

An area of high priority for research is the development of a classification system to define neurogenic disturbances. Relevant features would include the underlying diagnosis, the symptoms, and the nature of the urodynamic abnormality.

Data should be collected on fecal incontinence whenever practical as part of research in urinary incontinence.

Well designed and adequately powered studies are needed to define best practice in investigation and for all treatment modalities currently available.

Further consideration should be given to new approaches and adoption of technologies/interventions that are of established value in treating urinary incontinence.
The patient population for BPS trials must be carefully defined. When appropriate, relaxed entry criteria should be used to reflect the full spectrum of the BPS patient population.

The primary endpoint of BPS trials should be patient driven and the Global Response Assessment is recommended. A rich spectrum of secondary endpoints will be useful in defining the effect of treatments.

Investigation of antiproliferative factor as an entry criteria for clinical research is desirable.

There should be a focus on patient reported outcomes with the goal of determining “clinically significant” prolapse. The implications of stage 2 prolapse in terms of natural history and treatment outcome are key issues.

Research is needed to define the epidemiology of nocturia and how the symptom relates to normal aging.

Clinical research in treatment of nocturia should begin with classification of patients by voiding diary categories, 24 hour polyuria, nocturnal polyuria, and apparent bladder storage disorders. If desired, patients with low bladder capacity can be further divided into those with sleep disturbances and those with primary lower urinary tract dysfunction.

Treatment protocols must be detailed to the degree that the work can easily be reproduced.

The highest practical level of blinding should be used.

More work is needed to separate the specific and non-specific effects of treatment.

Safety and serious side effects of new devices must be adequately defined with adequate follow-up, especially for use of implantable devices and biologic materials, so that risks can be weighed against efficacy. All new devices and procedures require independent, large scale, prospective, multicenter case series when RCTs are not feasible.

Valid informed research consent is required in all trials of surgical interventions, which is separate from the consent to surgery.

Reports of successful treatment should be limited to subjects with a minimum (not mean) of one year follow-up and should include a patient perspective measure. Specific assumptions about patients lost to follow-up should be stated; last observation carried forward is generally not the appropriate method of handling this data.

In urinary incontinence safe, effective non-invasive therapy is available for the vast majority of patients. Most trials should offer “standard therapy” rather than a pure placebo where efficacy is established.

Effective drug therapy is available for most forms of incontinence. Comparator arms are recommended for most trials.
Continuity in clinical direction from design through authorship is mandatory. Investigators should be involved in the planning stage and a publications committee should be named at the beginning of the clinical trial. The Uniform Requirements for Manuscripts Submitted to Biomedical Journals, from the International Committee of Medical Journal Editors should be followed. Authorship requires:

- Substantial contributions to conception and design or acquisition of data or analysis and interpretation of data,
  - Drafting the article or revising it critically for important intellectual content,
  - Final approval of the version to be published
- Authors should provide a description of what each contributed and editors should publish that information.
- Authors should have access to all raw data from clinical trials, not simply selected tables

Clinical trial results should be published regardless of outcome. The sponsor should have the right to review manuscripts for a limited period of time prior to publication but the manuscript is the intellectual property of its authors, not the sponsor.

- All authors should be able to accept responsibility for the published work and all potential conflicts of interest should be fully disclosed.
Many people leak urine some of the time. We are trying to find out how many people leak urine, and how much this bothers them. We would be grateful if you could answer the following questions, thinking about how you have been, on average, over the PAST FOUR WEEKS.

1. Please write in your date of birth: DAY MONTH YEAR

2. Are you (tick one): Female Male

3. How often do you leak urine? (Tick one box)

   never 0
   about once a week or less often 1
   two or three times a week 2
   about once a day 3
   several times a day 4
   all the time 5

4. We would like to know how much urine you think leaks.
   How much urine do you usually leak (whether you wear protection or not)?
   (Tick one box)

   none 0
   a small amount 2
   a moderate amount 4
   a large amount 6

5. Overall, how much does leaking urine interfere with your everyday life?
   Please ring a number between 0 (not at all) and 10 (a great deal)

   0 1 2 3 4 5 6 7 8 9 10
   not at all a great deal

   ICIQ score: sum scores 3+4+5

6. When does urine leak? (Please tick all that apply to you)

   never – urine does not leak
   leaks before you can get to the toilet
   leaks when you cough or sneeze
   leaks when you are asleep
   leaks when you are physically active/exercising
   leaks when you have finished urinating and are dressed
   leaks for no obvious reason
   leaks all the time

Thank you very much for answering these questions.
The scientific committee which met at the end of the 1st ICI in 1998 supported the idea that a universally applicable questionnaire should be developed, that could be widely applied both in clinical practice and research.

The hope was expressed that such a questionnaire would be used in different settings and studies and would allow cross-comparisons, for example, between a drug and an operation used for the same condition, in the same way that the IPSS (International Prostate Symptoms Score) has been used.

An ICIQ Advisory Board was formed to steer the development of the ICIQ, and met for the first time in 1999. The project’s early progress was discussed with the Board and a decision made to extend the concept further and to develop the ICIQ Modular Questionnaire to include assessment of urinary, bowel and vaginal symptoms. The first module to be developed was the ICIQ Short Form Questionnaire for urinary incontinence: the ICIQ-UI Short Form. The ICIQ-UI Short Form has now been fully validated and published [2].

Given the intention to produce an internationally applicable questionnaire, requests were made for translations of the ICIQ-UI Short Form at an early stage, for which the Advisory Board developed a protocol for the production of translations of its modules. The ICIQ-UI Short Form has been translated into 30 languages to date. Two further, newly developed and fully validated, modules have been finalised since the third consultation and are now being incorporated into clinical practice and research, and translated accordingly for international use. The ICIQ-VS [7] provides evaluation of vaginal symptoms and the ICIQ-B [3] can be used to assess bowel symptoms including incontinence. Both questionnaires also provide assessment of the impact of these symptoms on quality of life (Table 1).

Where high quality questionnaires already existed within the published literature, permission was sought to include these within the ICIQ in order to recommend them for use. Eleven high quality modules have been adopted into the ICIQ which are direct (unchanged) derivations of published questionnaires (Table 1).

www.ICIQ.net provides details of the validation status of the modules under development for urinary symptoms, bowel symptoms and vaginal symptoms and provides information regarding the content of existing modules. Information regarding production of translations and the ICIQ development protocol is also available for those interested in potential collaborations to continue development of the project.

### REFERENCES

Three types of Bladder Charts and Diaries can be used to collect data:-

**Micturition Time Chart**
- times of voiding and
- incontinence episodes

**Frequency Volume Chart**
- times of voiding with voided volumes measured,
- incontinence episodes and number of changes of incontinence pads or clothing.

**Bladder Diaries**
- the information above, but also
- assessments of urgency,
- degree of leakage (slight, moderate or large) and descriptions of factors leading to symptoms such as stress leakage, eg. running to catch a bus
- time and location of leakage

It is important to assess the individual’s fluid intake, remembering that fluid intake includes fluids drunk plus the water content of foods eaten. It is often necessary to explain to a patient with LUTS that it may be important to change the timing of a meal and the type of food eaten, particularly in the evenings, in order to avoid troublesome nocturia.

The micturition time and frequency volumes charts can be collected on a single sheet of paper (Fig. 1). In each chart/diary, the time the individual got out of bed in the morning and the time they went to bed at night should be clearly indicated.

Each chart/diary must be accompanied by clear instructions for the individual who will complete the chart/diary: the language used must be simple as in the suggestions given for patient instructions. There are a variety of designs of charts and diaries and examples of a detailed bladder diary are given. The number of days will vary from a single day up to one week.

**INSTRUCTIONS FOR COMPLETING THE MICTURITION TIME CHART**

This chart helps you and us to understand why you get trouble with your bladder. The diary is a very important part of the tests we do, so that we can try to improve your symptoms. On the chart you need to record:-

1. When you get out of bed in the morning, show this on the diary by writing ‘Got out of bed’.
2. The time, eg. 7.30am when you pass your urine. Do this every time you pass urine throughout the day and also at night if you have to get up to pass urine.
3. Each time you pass urine, collect the urine in a measuring jug and record the amount (in mls or fluid ozs) next to the time you passed the urine, eg. 1.30pm - 320 mls.
4. If you leak urine, show this by writing ‘W’ (wet) on the diary at the time.
5. If you have a leak, please add ‘P’ if you have to change a pad and ‘C’ if you have to change your underclothes or even outer clothes. So, if you leak and need to change a pad, please write ‘WP’ at the time you leaked.
6. At the end of each day please write in the column on the right the number of pads you have used, or the number of times you have changed clothes.

When you go to bed at the end of the day show it on the diary - write ‘Went to Bed’

**INSTRUCTIONS FOR USING THE BLADDER DIARY**

This diary helps you and us to understand why you get trouble with your bladder. The diary is a very important part of the tests we do, so that we can try to improve your symptoms. On the chart you need to record:-

1. When you get out of bed in the morning, show this on the diary by writing ‘GOT OUT OF BED’.
2. During the day please enter at the correct time the drinks you have during the day, eg. 8.00am - two cups of coffee (total 400 ml).
3. The time you pass your urine, eg. 7.30am. Do this every time you pass urine throughout the day and night.
4. Each time you pass urine, collect the urine in a measuring jug and record the amount (in mls or fluid ozs) next to the time you passed the urine, eg. 1.30pm/320ml.
5. Each time you pass your urine, please write down how urgent was the need to pass urine:
   - ‘O’ means it was not urgent.
   - + means I had to go within 10 minutes.
   - ++ means I had to stop what I was doing and go to the toilet.
6. If you leak urine, show this by writing an ‘W’ on the diary at the time you leaked.
7. If you have a leak, please add ‘P’ if you have to change a pad and ‘C’ if you have to change your underclothes or even outer clothes. So, if you leak and need to change a pad, please write ‘WP’ at the time you leaked.
8. If you have a leakage please write in the column called ‘Comments’ whether you leaked a small amount or a large amount and what you were doing when you leaked, eg. ‘leaked small amount when I sneezed three times’.
9. Each time you change a pad or change clothes, please write in the ‘Comments’ column.
10. When you go to bed at the end of the day show it on the diary - write ‘Went to Bed’.
**Frequency - Volume chart - Standard Version - 7 days**

**Date** | **7:00 am** | **Mid-day** | **Midnight** | **6:00 am** | **Pads used**
---|---|---|---|---|---
16th April | Up 150 | 60 | 275 | 200 | 150 | Bed | 2.30 | 6.30 | 1
