The great tragedy of science:
The slaying of a beautiful hypothesis by an ugly fact
Thomas Huxley (1825-1895)

ISBN 0-9546956-8-2

LAY-OUT: Stéphanie Taïeb
FOREWORD

The First International Consultation on Incontinence held in 1998 highlighted the plight of some 200 millions sufferers from urinary incontinence worldwide. Urinary incontinence represents a particular and severe problem in certain developing areas of the world, where labour and birth injuries lead to catastrophic leakage. Untreated vesico-vaginal fistula (VVF), particularly in sub Saharan Africa, affects millions of women causing ostracism from society. Because of the enormity of this particular problem, at the second consultation we added a specific committee to highlight the subject, to advance the understanding of the causes of birth injury, to lead to improved treatment for the many untreated women, and most importantly, to begin preventative programmes. At this Fourth Consultation we were delighted by the active participation of the WHO in our work on VVF.

There were two other new committees in the 2nd ICI: Pelvic Organ Prolapse and Faecal Incontinence. The first consultation stressed the importance of a multidisciplinary approach to continence care, and the new committees on pelvic organ prolapse and faecal incontinence recognize that, particularly in women, urinary incontinence coexists with prolapse and faecal incontinence in many instances. This is also true, to a more limited extent, in men with coexisting faecal incontinence. The task of these two committees was very considerable and they had to outline the basic science, and investigation and management techniques within a single chapter. The report of these two chapters laid the foundation for a broadening of the multidisciplinary approach to pelvic disorders which was further developed in the 3rd ICI and now in the 4th ICI. New patterns by which care is delivered are emerging and depend on the close collaboration between urologists, gynaecologists and coloproctologists, working within a multidisciplinary team with nurses and physiotherapists. From the research and investigation point of view, we are very dependent on our colleagues from other disciplines such as the basic sciences, epidemiology, social science and engineering.

The 4th Consultation on Incontinence was held in Paris in July 2008. In this consultation we gave a special attention the VV fistula in the developing world in collaboration with the WHO and many other associations working in this field. The structure of the consultation followed the successful formula developed by the ICUD and used for the previous 3 consultations. Once again an international faculty of over 150 individuals from a wide range of professions and specialities were grouped into a series of subcommittees, each with a specific area of responsibility. The spectrum of subcommittees spanned from Basic Science through assessment and investigation to therapy. These committees were further divided into specific patient groups for children, women, men, neurological patients and the frail elderly. In addition to fully integrating faecal incontinence and pelvic organ prolapse into the consultation, there was the renamed committee “Bladder Pain Syndrome”.

Subcommittee members were selected according to their academic reputation giving due recognition to the need to provide balance between specialities and geographical regions. A chairperson was selected for each subcommittee and was responsible for the drafting of that committees’ chapter. Most committees met at least once before the consultation in Paris, to progress their report.

Each chairperson presented his or her committees’ main discussions and recommendations in Paris. Their chapter was then modified accordingly, in the light of the consultation. This book details the evidence reviewed by each committee. Each committee used the ICUD System for evaluating evidence and providing recommendations with five levels of evidence (1 to 5) and four grades of recommendation (A to D).

This system worked well for the treatment committees but, as yet, it cannot be applied systematically to evaluate the evidence from the basic science and investigation committees. Nevertheless, the consultation feels that continued efforts to specify the evidence base for all recommendations are of vital importance.

The book’s final chapter is the Recommendations of the International Scientific Committee which includes all subcommittee chairs together with the members of the Steering Committee. This chapter has been expanded to include algorithms for the treatment of faecal incontinence, pelvic organ prolapse and bladder pain syndrome. Furthermore, the 2004 algorithms have been reconfigured in the light of new evidence and in order to facilitate their use.

These recommendations represent the evidence based opinion of a group of experts. They are not to be considered as guidelines or standards of care which are the responsibility of official organisations, governments and regulators.

We hope that the huge amount of effort put into the consultation and the production of this book will also be reflected in an increased prominence for all aspects of the consultation’s findings. We shall make the book more widely available and publish sections of the book in peer reviewed journals.

Paul Abrams and the Scientific Committee

Dr. William C. de Groat is Professor of Pharmacology at the University of Pittsburgh Medical School. He received a Ph.D. in Pharmacology from the University of Pennsylvania Medical School in 1965 and then obtained postdoctoral training in Pharmacology at the University of Pennsylvania (1965-1966) and in Neurophysiology at the John Curtin School for Medical Research in Canberra, Australia (1966-1968).

He joined the faculty at the University of Pittsburgh in 1968 and was promoted to Professor in 1977. He has been a Visiting Scientist at the NIH (1988-1989) and at the University College London (1998).

He is an Honorary Member of the American Urological Association and the Japanese Urological Association. Dr. de Groat has published more than 400 papers primarily in the fields of autonomic neuroscience and neurourology. He has served on numerous editorial boards including: The Journal of Pharmacology and Experimental Therapeutics, American Journal of Physiology, Urology, Neuurology and Urodynamics, Autonomic Neuroscience, and Life Sciences.

Dr. de Groat has been Treasurer and a member of the Executive Council of the Society for Neuroscience and the Executive Vice President of the International Society for Autonomic Neuroscience. He is the recipient of a number of awards including: a National Institutes of Health (NIH) Method to Extend Research in Time (MERIT) Award, an NIH Research Career Development Award, a Lifetime Achievement Award from the Urodynamics Society and a Fellow of the American Association for Advancement of Science.

He has been recognized with the Carl Ludwig Distinguished Lectureship of the American Physiological Society, the University of Pittsburgh President’s Distinguished Research Award, the Pharmacia-ASPET Award for Experimental Therapeutics from the American Society for Pharmacology and Experimental Therapeutics, the Elsevier-JANS Lectureship of the International Society for Autonomic Neuroscience, the Sir Ludwig Guttman Lectureship of the International Society of Paraplegia and the University of Pittsburgh Chancellor’s Distinguished Teaching Award.

SYNOPSIS OF AREA OF INTEREST: Dr. de Groat is interested in the neural control of the lower urinary tract and the mechanisms underlying urinary incontinence and painful bladder conditions.
EVIDENCE-BASED MEDICINE OVERVIEW OF THE MAIN STEPS FOR DEVELOPING AND GRADING GUIDELINE RECOMMENDATIONS.

INTRODUCTION
The International Consultation on Urological Diseases (ICUD) is a non-governmental organization registered with the World Health Organisation (WHO). In the last ten years Consultations have been organised on BPH, Prostate Cancer, Urinary Stone Disease, Nosocomial Infections, Erectile Dysfunction and Urinary Incontinence. These consultations have looked at published evidence and produced recommendations at four levels; highly recommended, recommended, optional and not recommended. This method has been useful but the ICUD believes that there should be more explicit statements of the levels of evidence that generate the subsequent grades of recommendations.

The Agency for Health Care Policy and Research (AHCPR) have used specified evidence levels to justify recommendations for the investigation and treatment of a variety of conditions. The Oxford Centre for Evidence Based Medicine have produced a widely accepted adaptation of the work of AHCPR. (June 5th 2001 http://minerva.minervation.com/cebm/docs/levels.html)

The ICUD has examined the Oxford guidelines and discussed with the Oxford group their applicability to the Consultations organised by ICUD. It is highly desirable that the recommendations made by the Consultations follow an accepted grading system supported by explicit levels of evidence.

The ICUD proposes that future consultations should use a modified version of the Oxford system which can be directly ‘mapped’ onto the Oxford system.

1. 1st Step: Define the specific questions or statements that the recommendations are supposed to address.

2. 2nd Step: Analyse and rate (level of evidence) the relevant papers published in the literature.

   The analysis of the literature is an important step in preparing recommendations and their guarantee of quality.

2.1 What papers should be included in the analysis?

   • Papers published, or accepted for publication in the peer reviewed issues of journals.

   • The committee should do its best to search for papers accepted for publication by the peer reviewed journals in the relevant field but not yet published.

   • Abstracts published in peer review journals should be identified. If of sufficient interest the author(s) should be asked for full details of methodology and results. The relevant committee members can then ‘peer review’ the data, and if the data confirms the details in the abstract, then that abstract may be included, with an explanatory footnote. This is a complex issue – it may actually increase publication bias as “uninteresting” abstracts commonly do not progress to full publication.

   • Papers published in non peer reviewed supplements will not be included.

An exhaustive list should be obtained through:

I. the major databases covering the last ten years (e.g. Medline, Embase, Cochrane Library, Biosis, Science Citation Index)

II. the table of contents of the major journals of urology and other relevant journals, for the last three months, to take into account the possible delay in the indexation of the published papers in the databases.

It is expected that the highly experienced and expert committee members provide additional assurance that no important study would be missed using this review process.

2.2 How papers are analysed?

   Papers published in peer reviewed journals have differing quality and level of evidence.

   Each committee will rate the included papers according to levels of evidence (see below).

   The level (strength) of evidence provided by an individual study depends on the ability of the study design to minimise the possibility of bias and to maximise attribution.

   is influenced by:

   • the type of study

   The hierarchy of study types are:

   - Systematic reviews and meta-analysis of randomised controlled trials
   - Randomised controlled trials
   - Non-randomised cohort studies
   - Case control studies
   - Case series
   - Expert opinion

   • how well the study was designed and carried out

   Failure to give due attention to key aspects of study methodology increase the risk of bias or confounding factors, and thus reduces the study’s reliability.

   The use of standard check lists is recommended to ensure that all relevant aspects are considered and that a consistent approach is used in the methodological assessment of the evidence.

   The objective of the check list is to give a quality rating for individual studies.

   • how well the study was reported

   The ICUD has adopted the CONSORT statement and its widely accepted check list. The CONSORT statement and the checklist are available at http://www.consort-statement.org

2.3 How papers are rated?

   Papers are rated following a «Level of Evidence scale». ICUD has modified the Oxford Center for Evidence-Based Medicine levels of evidence.

   The levels of evidence scales vary between types of studies (i.e. therapy, diagnosis, differential diagnosis/symptom prevalence study).

   the Oxford Center for Evidence-Based Medicine Website: http://minerva.minervation.com/cebm/docs/levels.html

3. 3rd Step: Synthesis of the evidence

   After the selection of the papers and the rating of the level of evidence of each study, the next step is to compile a summary of the individual studies and the overall direction of the evidence in an Evidence Table.

4. 4th Step: Considered judgment (Integration of individual clinical expertise)

   Having completed a rigorous and objective synthesis of the evidence base, the committee must then make a judgement as to the grade of the recommendation on the basis of this evidence. This requires the exercise of judgement based on clinical experience as well as knowledge of the evidence and the methods used to generate it. Evidence based medicine requires the integration of individual clinical expertise with best available external clinical evidence from systematic research. Without the former, practice quickly becomes tyrannised by evidence, for even excellent external evidence may be inapplicable to, or inappropriate for, an individual patient: without current best evidence, practice quickly becomes out of date. Although it is not practical to lay our “rules”
for exercising judgement, guideline development groups are asked to consider the evidence in terms of quantity, quality, and consistency; applicability; generalisability; and clinical impact.

5. 5th Step: Final Grading
The grading of the recommendation is intended to strike an appropriate balance between incorporating the complexity of type and quality of the evidence and maintaining clarity for guideline users. The recommendations for grading follow the Oxford Centre for Evidence-Based Medicine.

The levels of evidence shown below have again been modified in the light of previous consultations. There are now 4 levels of evidence instead of 5. The grades of evidence have not been reduced and a “no recommendation possible” grade has been added.

6. Levels of Evidence and Grades of Recommendation Therapeutic Interventions

All interventions should be judged by the body of evidence for their efficacy, tolerability, safety, clinical effectiveness and cost effectiveness. It is accepted that at present little data exists on cost effectiveness for most interventions.

6.1 Levels of Evidence

Firstly, it should be stated that any level of evidence may be positive (the therapy works) or negative (the therapy doesn’t work). A level of evidence is given to each individual study.

- **Level 1** evidence (incorporates Oxford 1a, 1b) usually involves meta-analysis of trials (RCTs) or a good quality randomised controlled trial, or ‘all or none’ studies in which no treatment is not an option, for example in vesicovaginal fistula.

- **Level 2** evidence (incorporates Oxford 2a, 2b and 2c) includes “low” quality RCT (e.g. < 80% follow up) or meta-analysis (with homogeneity) of good quality prospective ‘cohort studies’. These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts, where those with the condition in the first group are compared with those in the second group.

- **Level 3** evidence (incorporates Oxford 3a, 3b and 4) includes:
  - good quality retrospective ‘case-control studies’ where a group of patients who have a condition are matched appropriately (e.g. for age, sex etc) with control individuals who do not have the condition.
  - good quality ‘case series’ where a complete group of patients all, with the same condition/disease/therapeutic intervention, are described, without a comparison control group.

- **Level 4** evidence (incorporates Oxford 4) includes expert opinion were the pinion is based not on evidence but on ‘first principles’ (e.g. physiological or anatomical) or bench research. The Delphi process can be used to give ‘expert opinion’ greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of ‘options’; the options are serially ranked; if a 75% agreement is reached then a Delphi consensus statement can be made.

6.2 Grades of Recommendation

The ICUD will use the four grades from the Oxford system. As with levels of evidence the grades of evidence may apply either positively (do the procedure) or negatively (don’t do the procedure). Where there is disparity of evidence, for example if there were three well conducted RCT’s indicating that Drug A was superior to placebo, but one RCT whose results show no difference, then there has to be an individual judgement as to the grade of recommendation given and the rationale explained.

- **Grade A** recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. However, there will be occasions where excellent evidence (level 1) does not lead to a Grade A recommendation, for example, if the therapy is prohibitively expensive, dangerous or unethical. Grade A recommendation can follow from Level 2 evidence. However, a Grade A recommendation needs a greater body of evidence if based on anything except Level 1 evidence.

- **Grade B** recommendation usually depends on consistent level 2 and or 3 studies, or ‘majority evidence’ from RCTs.

- **Grade C** recommendation usually depends on level 4 studies or ‘majority evidence’ from level 2/3 studies or Delphi processed expert opinion.

- **Grade D “No recommendation possible”** would be used where the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Delphi.

7. Levels of Evidence and Grades of Recommendation for Methods of Assessment and Investigation

From initial discussions with the Oxford group it is clear that application of levels of evidence/grades of recommendation for diagnostic techniques is much more complex than for interventions. The ICUD recommend, that, as a minimum, any test should be subjected to three questions:

1. does the test have good technical performance, for example, do three aliquots of the same urine sample give the same result when subjected to ‘stix’ testing?
2. Does the test have good diagnostic performance, ideally against a “gold standard” measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

For the third component (therapeutic performance) the same approach can be used as for section 6.

8. Levels of Evidence and Grades of Recommendation for Basic Science and Epidemiology Studies

The proposed ICUD system does not easily fit into these areas of science. Further research needs to be carried out, in order to develop explicit levels of evidence that can lead to recommendations as to the soundness of data in these important aspects of medicine.

CONCLUSION

The ICUD believes that its consultations should follow the ICUD system of levels of evidence and grades of recommendation, where possible. This system can be mapped to the Oxford system. There are aspects to the ICUD system that require further research and development, particularly diagnostic performance and cost effectiveness, and also factors such as patient preference.

Epidemiology of Urinary (UI) and Faecal (FI) Incontinence and Pelvic Organ Prolapse (POP)

I. MILSOM, D. ALTMAN, M. C. LAPITAN, R. NELSON, U. SILLÉN, D. THOM

A. INTRODUCTION

In this report we focus on the epidemiology (distribution and determinants) of urinary incontinence (UI), faecal incontinence (FI), and pelvic organ prolapse (POP). We also discuss important topics such as differences between epidemiological and clinical approaches to health problems, help seeking behaviour, and methodological issues for this research.

Overactive bladder (OAB) is an evolving concept with close relationship to UI, and we have included a section on this topic. A worldwide estimation of the current and future number of individuals with lower urinary tract symptoms (LUTS)\[1\] including urinary incontinence and overactive bladder is also included at the end of this chapter.

The epidemiological population under study for this review will mainly be community dwelling non-institutionalized persons. The review will include discussion of the prevalence, incidence, natural history, and presence of racial and ethnic differences. We also review correlates and potential risk factors that have been revealed in epidemiological studies. Progress has clearly been made during the 4 years since our previous report when the 3rd International Consultation on Incontinence (3rd ICI) was published [2]. We are however greatly indebted to the authors of the previous chapter on epidemiology from the 3rd ICI who contributed important information which has in some instances been utilised in this chapter (S. Hunskaar, K Burgio and A Clark). Some new important areas have been studied with increasing regularity and quality. We have searched the literature for relevant new articles, thus reviewing a large number of high-quality and population based studies, as well as clinical trials that might include relevant epidemiological data. Because of an abundant number of studies, only a small fraction can be presented in a text like this. Other studies not presented here may have equally useful information, but lack of space precluded their inclusion.

Summary points:

- This review includes discussion of the prevalence, incidence, natural history, and presence of racial and ethnic differences in the epidemiology of UI, OAB, FI and POP.
- Correlates and potential risk factors that have been revealed in epidemiological studies are also reviewed.

B. BASIC EPIDEMIOLOGICAL CONSIDERATIONS

Epidemiology is the scientific study of the distribution and determinants of disease in people. **Descriptive epidemiology** is the description of disease prevalence, incidence, (and mortality) by persons, place and time, while the term **analytical epidemiology** describes the search for determinants of disease risk. The discovery of risk factors and protective factors may then in turn lead to primary or secondary prevention.

In order to collect knowledge about risk factors or natural history, observational studies are needed. Cohort studies and case-control studies are the most common. However, caution is always needed when interpreting the results from such studies, as associations found in epidemiological studies may not be the same as causes. Longitudinal study designs and appropriate control for confounding factors are preferred, as these increase the validity of epidemiologic studies. For practical and ethical reasons, experimental designs are seldom used.

Recommendations and conclusions should always be based on the best available evidence. Studies of interventions, and studies of risk factors generally cannot be randomised because they relate to inherent human characteristics or practices, and exposing subjects to harmful risk factors is unethical. No uniform guidelines for assessing the results of observational studies exist, and the level of evidence for risk factors
from observational studies should be judged on the soundness of the exclusion of alternative explanations by statistical and other controls. But some initiatives for how to report meta-analyses of observational studies have been taken.[3]

Studies of disease frequency should rely on a very specific definition of the condition under investigation. The absence of unifying definitions for the conditions reviewed here is a fundamental problem which has not been resolved. Definitions used and problems associated with them are discussed in the subsections for the particular populations below.

**Prevalence** is defined as the probability of experiencing a symptom or having a condition or a disease within a defined population and at a defined time point. The concept is important for establishing the distribution of the condition in the population and for projecting the need for health and medical services.

**Incidence** is defined as the probability of developing the condition under study during a defined time period. Incidence is usually reported for one-, two- or five-year time interval.

Even in many of the recent studies reviewed analyses are very simple. Often only proportions or percentages are used to describe differences in different subgroups. Many analyses do not control for confounders (by stratification or multivariate analysis techniques). There is an obvious need for more advanced epidemiological analyses of risk factors and comorbidity, and strength of associations should be determined by relative risks and odds ratios.

**The relative risk (RR)** estimates the magnitude of an association between exposure and a condition, and indicates the likelihood of having the condition in the exposed group relative to those who are not exposed (e.g. do not have the risk factor). A RR of 1.0 indicates that the rates in the exposed and non-exposed groups are identical and thus that there is no association between the exposure and the condition in that specific dataset. A value greater than 1.0 indicates a positive association or an increased risk. A RR of 2.5 for UI indicates that there is a 2.5 times increased risk or that the persons in question are 150 percent more likely to have incontinence than those without the risk factor.

**The odds ratio (OR)** is the odds for having a risk factor in persons with a condition divided by the odds among those without the condition. An OR of 2.5 for UI my be interpreted as meaning that in this sample the odds in favour of having incontinence are 2.5 times higher among those with the risk factor than among those without.

For a condition with high prevalence, like UI or POP, OR and RR will not be identical, but in practice the results can be interpreted similarly. Results should always be given with a 95% confidence interval (CI).

Words like well established and established may be used about risk factors and findings with a high level of evidence in the literature. For less documented findings words like “indications of” or “data are suggestive” may be used.

**Summary points:**

- Descriptive epidemiology reports disease incidence, prevalence (and mortality) by persons, place and time.
- Analytical epidemiology searches for determinants of disease risk. There is a need for good longitudinal cohort studies.
- Variations in definitions and measurement issues are fundamental, and lead to problems with assessing the findings in epidemiological studies.
- There is a need for more advanced epidemiological analyses of risk factors and comorbidity using multivariable techniques, and strength of associations should be determined by relative risks and odds ratios.

---

**C. EPIDEMIOLOGY OF ENURESIS AND UI IN CHILDREN**

---

**I. GENERAL COMMENTS AND DEFINITIONS**

The International Children's Continence Society (ICCS) has issued new recommendations regarding terminology of bedwetting or **nocturnal enuresis** (NE) [4]. NE is now the term for all urinary incontinence during sleep taking place in discrete episodes, regardless of the presence or absence of concomitant daytime symptoms. **Monosymptomatic nocturnal enuresis** (MNE) denotes bedwetting without any other lower urinary tract (LUT) symptoms, and **non-monosymptomatic nocturnal enuresis** (NMNE) should be used for those with any concomitant LUT symptom.

NE is caused by relative nocturnal polyuria [5] and/or nocturnal bladder over-activity [6], combined with the lack of arousal at the time when the bladder needs to be emptied. The most important cause is, of course, the lack of arousal, otherwise the child would have had nocturia.

Any other leakage of urine in children during both the day and night is referred to as **urinary incontinence** (UI), just as it is in the adult population. UI with no obvious cause, i.e. without neurological or congenital anatomic alterations, is often seen together with other
urinary symptoms such as frequency, urgency and infections. Altogether these symptoms are referred to as functional LUT dysfunction, which is the term used to describe the entire spectrum of functional filling-voiding disturbances. Several sub-classifications have been used for children who present with varying degrees of “functional” urinary symptoms. Some are based on urodynamic patterns, others on clinical presentation.

According to recent definitions by the ICCS [1], based on symptoms and flow-residual studies rather than invasive urodynamic investigations, incontinence as a result of a filling-phase dysfunction, is in most cases due to an overactive bladder (OAB), which can also be referred to as “urge syndrome” and “urge incontinence”. Children with OAB usually have detrusor overactivity, but this label cannot be applied to them without cystometric evaluation. When incontinence is the result of a voiding-phase dysfunction, the diagnosis is often dysfunctional voiding (DV), which is induced by increased activity in the sphincter and pelvic floor during voiding. It is subdivided into staccato and fractionated voiding, and the terms cannot be applied unless repeat uroflow measurements have been performed. Voiding postponement (VD) is another common LUT dysfunction causing UI in children, but differs from the other since it is induced by habitual postponement of voiding and not a LUT dysfunction per se.

NE and UI due to functional LUT dysfunction are the wetting problems addressed in this paper. Both can be either primary (the child has not been dry for more than six months) or secondary (the wetting has recurred after a dry period lasting more than six months). If the complaints are secondary, they may signify psychological, neurological or even structural anomalies and therefore require careful consideration.

The healthy infant is socially incontinent but physiologically continent, because micturitions (about once every hour) are discrete and there is no leakage of urine between micturitions [7]. Bladder control develops during the first four to six years of life and is a highly complex process, which is still not fully understood. Most children are toilet trained by the age of three years, although there is huge social and cultural variation. By the age of five years, the child is normally able to void at will and to postpone voiding in a socially acceptable manner [8]. By this age, nighttime and daytime involuntary wetting becomes a social problem and a cause for therapeutic intervention.

II. PREVALENCE OF NOCTURNAL ENURESIS (NE)

As bladder control is something that develops over time, longitudinal studies are the best way of defining the dynamics of this process. Studies giving us the prevalence for all children between five and 15 years of age, for example, are not appropriate, as all the developmental stages are clustered together. It is therefore better to give the prevalence for an age cohort, such as seven-year-olds. Furthermore, random sampling should preferably be used in order to be able to say anything about the population. These problems associated with understanding epidemiology were summarised by Krantz [9], who also reviewed the epidemiological studies that had been published by 1993.

One explanation for the variation in prevalence in different studies is the fact that some studies include only monosymptomatic enuresis (MNE), whereas others also include what is defined as nonmonosymptomatic enuresis (NMNE). Another explanatory factor is that the frequency of enuretic episodes differs or is not taken into account in some studies. Moreover, most epidemiological studies link primary and secondary enuresis together.

1. PREVALENCE OF ALL NIGHT WETTING (MNE+ NMNE) ACCORDING TO AGE

Longitudinal cohort studies should be the ideal when analysing epidemiology in childhood NE, as there is a successive reduction in prevalence. Only a few of these studies are available[10-14] and cross-sectional studies at different ages therefore have to be used.

Most studies investigate cohorts of children in an age span of six to 12 years of age, for example, and give the prevalence for the entire group. Some of them also give the age-related prevalence [12, 15-24] which is summarised in Table 1. Cross-sectional studies of a specific age are also included [25-29] in Table 1.

In most studies (Table 1), the prevalence for seven-year-olds was between 7% and 10%. In two studies, the prevalence was higher; 15.1% and 16.4% for Turkish [19] and Korean [20] children respectively, despite the fact that the inclusion criteria were very similar in all the studies dealing with seven-year-olds (NE=night wetting once/month or more), apart from the studies by Hellström [25] (once/3 months or more) and Järvelin [26] (once/6 months or more). The prevalence of more frequent wetting (once/week or more) was lower compared to the prevalence for all wetting (once/month or more) by age, which have been illustrated in Figure 1.

In nine studies at age seven years [13, 15, 18, 20-23, 25, 26] (Table 1) the numbers of both non-enuretic and enuretic children were given and the definitions for enuresis were similar (MNE and NMNE, wetting once/1-3 months or more). A prevalence of 10% was obtained by meta-analyses of these studies (cohort of 14372 seven-year-old children, of whom 1422 were enuretic). Only four studies included groups of children that were chosen at random from the population [15, 20, 23, 26].
At age 11-12 years, the prevalence of NE had decreased and from the studies shown in Table I the prevalence varied between 1.7% and 4.7%. In seven of the studies, the number of non-enuretics and enuretics were available and the definition of NE was similar (once/month or more), apart from Swithinbank’s study (once/3 months or more). In these studies, the total number of children included was 8947, while the number of children with NE was 278, giving a prevalence of 3.1%. So, of those children with NE at age seven years, almost 15% spontaneously grow out of the wetting every year. In a recent Japanese study a higher resolution rate was reported in children with MNE compared to NMNE in children 7 to 12 years of age (21% and 15%, respectively) [21]. Similar results was found in a study from Hong Kong in which the proportion of children with NMNE was significantly greater in adolescent boys than in boys aged 5-10 years (32% vs 14.6%), even if the total prevalence of NE was decreasing as in other studies [23].

The variation in the prevalence of NE at 11-12 years between the studies is less than that seen at age seven years. The highest prevalence is no longer found in Turkey or Korea, as was the case at age seven years, but instead comes from a non-randomised cross-sectional study of 11- to 12-year-old schoolchildren (n=1145) in the UK (4.7%). It can therefore be suggested that the high prevalence seen in the studies from Turkey and Korea at age seven is not due to differences in genetic predisposition, but rather to phenotypic differences, such as the age of toilet training and the subsequent attainment of bladder control, socio-economic status, or cultural differences.

At age 16-17, three cross-sectional studies show a further reduction in prevalence to 0.5-1.7%. Two of the studies re-investigate children who had previously been studied; at age seven years [27] and 11-12 years [28] respectively. The prevalence when the cohorts were added together was 1.3% (cohort=3819, NE=51) [23, 27, 29], which gives a spontaneous cure rate of 11% a year among those who wet at age 11-12 years. In a study of 13,081 adults randomly sampled in the Netherlands [30], an overall prevalence of NE of 0.5% was found. There was no significant difference between age groups. Primary NE was reported by 50% of the men and 19% of the women, indicating that a small group of the enuretic children remain enuretic as adults.

### Figure 1: Prevalence of nocturnal enuresis (NE) by frequency of enuretic episodes and age. The data were obtained from metaanalyses of the epidemiological studies included in table III.1. NE>1 episode/6months: at 7 years [15, 18, 20-26], 11-12 years [15, 18, 20-23, 28] and 16-17 years [23, 27, 29]. NE>1 episode/week: at age 7 years [22, 23, 25, 26], 11-12 years [22, 23, 28] and 16-17 years [23, 27].
2. PREVALENCE OF MONOSYMPTOMATIC ENURESIS (MNE)

Very few studies make a distinction between MNE and NMNE and it is therefore difficult to obtain relevant figures for MNE (Table 2). In two studies from Scandinavia dealing exclusively with seven-year-olds, there was agreement between the studies; 6.4% [26] and 7.4% [25]. Recently, a Japanese study gave similar figures for MNE: 6.2% at age 7 years. In this latter study MNE corresponded to approximately 60% of all NE in ages from 7 to 12 years [21]. When it comes to studies in which all ages were mixed (5-12 years), four studies were identified in which those without daytime voiding problems could be identified. However, the difference in prevalence of MNE varied in these studies; 3.5% [16], 6.9% [31], 9.4% [20] and 15% [32].

3. PREVALENCE OF NE VERSUS GENDER

Almost all epidemiological studies of NE report a higher prevalence in boys than in girls, with a ratio of 2:1 in western countries [15-22, 25, 26, 28, 31-33]. It appears that the gender difference diminishes with age and becomes less visible and less proven among older children [27, 29, 34] (Figure 2).

4. PREVALENCE OF NE VERSUS ETHNICITY

In a study from The Netherlands [17], a higher prevalence was reported in the Turkish/Moroccan group (14%) than in the Dutch children (6%) (OR 3.76 (95%CI 1.98-7.12)). An equally high prevalence was found in a Turkish study of children with NE [19] at age seven years (15.1%). In a study from Korea [20], the same high prevalence at age 7 years was identified (16.4%). However, other studies from South-East Asia had comparable [18, 21, 23] or even lower levels of prevalence to those in western countries. In fact, two Chinese studies have shown a low prevalence of nocturnal enuresis [16, 35], 3.6% and 4.3% for children aged 4-12 and 6-16 respectively, which they attribute to earlier nocturnal urinary control in Chinese children, due to earlier toilet training.

5. PREVALENCE OF NE VERSUS FREQUENCY OF WET NIGHTS AND AGE

Yeung et al [23] showed in a large epidemiological study that the relative proportion of subjects with frequent bed-wetting increased with age. Overall 82% of the adolescence had >3 wet nights/week versus enuretic children aged 5-10 (42%) (Figure 3).

IIII. POTENTIAL RISK FACTORS FOR NE

Several risk factors have been established or suggested by epidemiological studies and the most important ones will be discussed here.
1. FAMILY HISTORY

NE is a hereditary disorder and this has been demonstrated in many studies (for example, [15, 16, 19, 26, 31, 32, 36]). The mode of inheritance appears to be autosomal dominant. Järvelin [26] showed that, if both parents were enuretics as children, the RR (95% CI) for the child to have NE was 16 (6.3-20.1), while if only one was enuretic, the RR was 7.8 (5.1-9.8). Using molecular genetic methods, foci have been found on chromosomes 13, 12, 8 and 22 [37, 38]. A picture of pronounced heterogeneity for both genotype and phenotype emerges [39].

2. PSYCHOPATHOLOGY

There are evident connections between childhood enuresis and mental well-being [13, 14, 35, 36, 40-42]. Evidence is accumulating to show that psychological consequences are probably caused by the enuresis and not a cause of primary NE, which has been thought for a long time [41]. The findings presented by Feehan [14] support this latter statement, as he only found an association between psychopathology and secondary NE, while children with NE did not display a connection of this kind.

3. DEVELOPMENTAL DELAY AND MENTAL RETARDATION

Children with developmental delay and mental retardation have been shown to have a higher prevalence of NE [12, 17, 26, 43]. Spee-van der Wekke [17] found that children who were given special education, including both those with and without mental retardation, had an OR of 3.74 (95% CI 2.32-6.03) for NE.

Perinatal events such as toxaemia (pre-eclampsia) and low birth weight, possibly involving an increased risk of minor neurological dysfunction, have also been shown to be associated with NE [12, 26, 36]. A connection between NE and minor neurological dysfunction of this kind has also been shown by Lunsing [44] in 12-year-old enuretic children. Furthermore, children with attention deficit hyperactivity disorders (ADHD) are more likely to have enuresis than the general child population [42, 45, 46].

4. SLEEP AND AROUSAL

The main pathology behind NE in children is the inability to wake up to the sensation of a full bladder. Parents often say that their enuretic child “sleeps very deeply”. Some recent studies support this view. By using auditory signals [47], computerised EEG [48] or questionnaires [31], a defect in arousal has been largely validated. In the study by Neveus [31], the odds ratios were significantly higher for a high arousal threshold (2.7), pavour nocturnus (2.4) and confusion when awoken from sleep (3.4). Computerised EEG energy analysis has indicated both greater depth of sleep and impaired arousal in enuretics [49]. Difficulty in arousal from sleep has also been shown in children with NE compared to children with isolated day-wetting problems and controls, by using a scoring system in a questionnaire [50].

5. SOCIO-CULTURAL FACTORS

Differences in the prevalence of NE [16, 19, 20, 35, 51] at early ages in different parts of the world are probably partly due to socio-cultural differences and not to differences in genetic predisposition [17]. It has been suggested that socio-economic status correlates with NE in some studies [15, 42], whereas in others no correlation was found [12].

6. OTHER RISK FACTORS

Sleep apnoea has been associated with enuresis in some patients [52]. Upper airway obstruction due to large adenoids or tonsils also appears to be a cause of NE, as it has been reported that the removal of these obstructions significantly reduced or cured NE [53]. Constipation may cause secondary NE or make primary NE persist [54]. Sexual abuse must also be included among the factors that may lead to NE [55]. Organic conditions such as infravesical obstruction and neuropathic bladder may also present as NE. In most cases, however, additional symptoms are present to make detection possible. Type 1 diabetes was reported to be a risk factor for secondary MNE due to the polyuria seen at presentation [56].

IV. PREVALENCE OF FUNCTIONAL INCONTINENCE IN CHILDREN

In children with functional LUT dysfunction, the OAB is far more common than dysfunctional voiding. In a urodynamic study of 1,000 patients with functional LUT dysfunction, approximately two-thirds had an
overactive bladder and one-third had dysfunctional voiding [57]. Based on clinical information, another study comprising 226 children revealed that 76% were considered to have an overactive bladder and only 1% dysfunctional voiding. The difference illustrates that different inclusion criteria influence the rate of prevalence [58]. When considering the total prevalence of UI (all frequencies of UI included) (Table 3), there was a variation between 3.2% and 9% in different studies at the age of seven years. In the earliest studies the prevalence was lower (3.2%-5.0%), whereas in the studies performed later in the 2000 [20, 22, 59, 60], the prevalence was higher 6.3%-9.0%. One explanation for the difference was probably an increased recognition of the problem in the population through information via media etc. At 11-13 years the reported prevalence varied between 1.1% and 12.5%. Swithinbank’s study [28] showed a very high prevalence (12.5%) and differed most from the rest (1.1%-4.2%). The difference could probably partly be explained by different limits for frequency of UI (occasionally [28] vs once/month or more). The fact that the studies were performed in different parts of the world was also a possible explanatory factor (UK and Korea).

The frequency of UI decreased with age (Table 3), which was clearly demonstrated in the subjects with frequent episodes of UI (>1/week) (Figure 4). The prevalence at 7 years, 11-13 years and 15-17 years was 2.6%, 1.1% and 0.3% respectively. There were only two authors who investigated the same cohort of children on two occasions; Hellström [25, 27] in Sweden and Swithinbank [28, 29] in the UK. According to the studies by Hellström, the reduction from seven years to 17 years was 0.2% per year in those with wetting at least once a week and 0.3% when including all kinds of wetting. Swithinbank reported a far higher frequency for all kinds of wetting at age 11-12 years but not at 15-16 years and the reduction in her cohort of children was therefore approximately 2% per year. UI was more common in girls in most studies, especially in the older age groups (Table 3, fig.4). From the prevalence found in the different studies, daytime UI could be suggested to be 1.5 times more common in girls than in boys at age seven years, whereas at age 16 years the difference was even more pronounced: 5-10 times more common in girls than in boys (Table 3).

1. PREVALENCE OF OVERACTIVE BLADDER (OAB)

In a Japanese study [59], the prevalence in children between 7 and 12 years of age, OAB was seen in 17.8%, with no significant difference between boys and girls. There was a gradual decrease in prevalence from 19.8% at the age of 7 years to 12.8% at 12 years.

2. COMORBIDITY: PREVALENCE OF BOWEL PROBLEMS

Urinary and faecal incontinence often coexist in different combinations. Constipation in childhood is a very common condition and when functional faecal incontinence is seen, constipation is often the cause. The term enuresis can be used synonymously with functional faecal incontinence. Soiling, on the other hand, is a confusing term that is poorly defined and should therefore not be used [4].

An increasing number of epidemiological studies reporting the frequency of bowel problems are accumulating, either in terms of constipation or functional faecal incontinence, in children with daytime wetting. Table 4 shows that the prevalence of bowel problems in day-wetting children approximately corresponded to a third of the children (24%-35%) [22, 50, 59, 60, 62], with even higher prevalence in the subgroup with dysfunctional voiding (43%) [62]. A significant association between day-wetting and bowel problems was shown [22]. These results support the new treatment concept of day-wetting children, with treatment of bowel problems as the first step. Children with MNE, on the other hand, seldom have bowel problems (0%-1%), whereas in NMNE it is more

Figure 4 : Prevalence of day UI (including mixed day/night) >1 episode/week by age and gender. Data are from: at age 6 years [63], 7 years [22, 25], 11-12 years [22, 28] and 16-17 years [27]

common (16%-24%) [50, 62]. In an epidemiological study from Japan including 5282 children, ages between 7-12 years, 81.5% were reported to have daily bowel movements. A significant higher prevalence of NMNE was found in those with constipation, compared to among those with regular daily bowel movements (3.4% vs 2.2%) [21].

V. POTENTIAL RISK FACTORS FOR DAY WETTING

1. FAMILY HISTORY

Day wetting, also including those subjects with mixed day and night wetting, has been shown to be correlated to hereditary factors, in parallel to what is known about children with NE. However, the number of studies are limited (Table 5).

2. PSYCHOPATHOLOGY

Children under stress as a result of marital separation, for example, have a higher incidence of diurnal or mixed UI, according to some authors [15, 36, 63]. Moreover, psychopathology investigated by Järvelin [36] using the Children’s Apperception Test (CAT) revealed a significant increase in the signs of repression, including an inability to express one’s emotions and feelings (p=0.027), when comparing day wetting children with controls. Neveus [31] found that day-wetting children had more difficulty falling asleep (OR 2.4, CI 1.4-4) and he interpreted them as “anxious children”. Lettgren [64] found a significant increase in attention problems and delinquent behaviour in a certain form of day-wetting children (voiding postponement) using the Child Behaviour Check List (CBCL, Achenbach). In a recent paper [65] similar results was found with the highest rate of psychiatric comorbidity in children with UI due to voiding postponement and the lowest in children with MNE. In the group with encopresis 65% were considered to have severe behavioural problems [62], meaning that children with both wetting and bowel problems are at the highest risk for psychopathology. In a population-based study investigating psychological problems associated with day UI, 8213 children were included of whom 643 suffered from daytime wetting at median age 7.5 years [60]. Overall the results indicated a rate of psychological problems that was twice the rate reported for children with no daytime wetting, particularly notable was the increase in externalising problems. After adjustment for developmental delay, gender, stressful life events, variables associated to family sociodemographic background and soiling, there was still an independent association of daytime wetting and behaviour problems (OR 2.04, CI 1.67-2.51). It is not clear whether the behavioural problems described are a cause or a consequence of daytime wetting.

3. MINOR NEUROLOGICAL DYSFUNCTION AND DEVELOPMENTAL DELAY

Children with minor neurological dysfunction have also been shown to have an increased rate of day wetting. Duel [45] found that children with ADHD are three times more likely to have day UI than controls (p<0.0005). Also in children with delayed maturation or with mental retardation, the risk of day wetting is increased (OR 1.9 and 4 respectively), according to studies by Järvelin [26]. Perinatal events, which can also be suggestive of minimal brain dysfunction, have also been shown to be over-represented in day-wetting children. For example, Järvelin [36] found that the children of mothers who had suffered from toxaemia had an RR of 8.5 (CI 1.4-51.9) for day UI.

4. OTHER RISK FACTORS FOR DAY UI

Sometimes, functional day UI is difficult to distinguish from UI due to organic anomalies. The most prominent examples are the adolescent form of posterior urethral

*Only children with mixed day and night wetting, **compared with 45% in dry children
valves in boys and epispadias in girls. In many papers, UTI is regarded as a risk factor for day UI. Järvelin [36] found an RR of 8.6 (2.3-32.3) for UTI in day UI children. Neveus [31] was able to demonstrate similar connections; OR 2.3 (1.3-3.9). However, these infections should probably be regarded as a consequence of the functional bladder disturbance with UI and not the other way round as a cause of the UI.

Nocturnal enuresis (NE)
- The prevalence of NE at age 7 seems to be around 10% for most countries, at age 11-12 years around 3% and at age 16 around 1.3%.
- The spontaneous cure rate seems to be around 15% annually between 7 and 12 years, and between 12 and 17 years 11%.
- In an adult population the prevalence of NE seems to be 0.5%. The prevalence was 0.1% when including only those with a history of NE during childhood. Thus the risk for NE as adult if having the condition at 7 years of age can be calculated to 1%.
- Potential risk factors for NE in children include OAB, polyuria, family history, psychopathology, developmental delay, mental retardation, socio-cultural factors, sleep and arousal problems, sleep apnoea, constipation, sexual abuse and organic conditions such as infravesical obstruction.

Functional incontinence
- Children who are and remain dry in the day seem to attain their diurnal continence already between age 4 and 5 years.
- Diurnal UI, or combined diurnal and nocturnal UI, in children is caused by overactive bladder in the great majority of cases.
- Prevalence for functional UI decrease with age. At age 7 years prevalence figures varies between 3.2% and 9%, with the highest prevalence in recent studies. At age 15-17 years the corresponding prevalence is 1.2-3%.
- Variation in prevalence figures is mainly dependant on differences in frequency of incontinence episodes in the studies.
- Potential risk factors for diurnal UI in children include bowel problems such as constipation and functional faecal incontinence, family history, psychopathology, socio-cultural factors, minor neurological dysfunction, developmental delay, organic anomalies such as infravesical obstruction in boys and sexual abuse.

VI. SUMMARY POINTS

D. EPIDEMIOLOGY OF UI IN WOMEN

UI is a common symptom that may affect women of all ages, and there is a wide range of severity and nature of symptoms. UI is not a life-threatening disease, but the symptoms may seriously influence the physical, psychological, and social well being of the affected individuals.

Virtually all epidemiologic studies rely on participant self-report of UI. Multiple studies have examined the association between self-reported incontinence and clinically demonstrable incontinence, and by type of incontinence based on self-reported compared to type based on clinical diagnosis. While self-report and clinical diagnosis are highly correlated, they are inherently different. For example, Sandvik and coauthors [66] validated diagnostic questions used in a survey against a final diagnosis made by a gynaecologist after urodynamic evaluation. The percentage of stress only incontinence increased from 51% to 77%, mixed incontinence was reduced from 39% to 11% while the proportion with urge only UI remained virtually the same (10% vs. 12%). For public health purposes, self-report has the advantage of reflecting the woman’s experience and allows further characterisation of the incontinence by frequency and quantity of urine loss. Despite the uncertainty in determining type of incontinence, the differences in the epidemiology of urge and stress incontinence are potentially important given the presumed differences in underlying pathophysiology. Differences in the association of stress and urge UI (based on self-report) with respect to age, race/ethnicity, and risk factors suggest that questionnaire-based determination of UI type is useful and should be included in all epidemiologic studies of UI [67].

Usually incontinence is defined by the episode frequency, for example one or more episodes in the past year or past month, or typically leaking at least once a week or daily. UI can also be defined by severity (a combination of frequency and quantity). Probably the most widely used measure of severity is the Sandvik Severity index [68-69] which is calculated by multiplying the reported frequency (four levels) by the amount of leakage (three levels). Incontinence can also be characterized by impact, with is usually assessed either in terms of bothersomeness, or by the degree to which it restricts a woman’s activity (for example, the Incontinence Impact Questionnaire) [70].

The vast majority of epidemiological studies of female UI have been conducted in the U.S, Canada, Europe,
Australia or Japan. A few additional studies have been reported from other Asian countries. Thus we know very little about the prevalence, incidence and risk factors for UI in Africa or other parts of the developing world.

II. PREVALENCE

Estimates of UI prevalence differ for a variety of reasons other than variation in true prevalence:

1. Sampling frame. Representative samples drawn from a large, usually geographically defined, population (e.g. via random digit dialling) are thought to provide prevalence estimates that are the most generalisable. In contrast, studies of hospitalized patients or patients seen in specialty clinics are likely to provide estimates biased by self-selection and local referral patterns. In this chapter, we will cite population-based studies unless otherwise stated.

2. Response rates. Even population-based studies can provide biased prevalence estimates due to poor response rates [71]. Women with incontinence may be more predisposed to enroll in studies of incontinence or women’s health. One study that asked about continence status among women declining to enroll did find a higher proportion of enrollment by women who were incontinent compared to those who were continent, particularly among minority women [72]. While the degree of bias is often unknown, as a general rule response rates above 80% are considered good, while those between 60 and 80% are marginal.

3. Threshold definition of UI. Usually incontinence is defined by a threshold frequency, for example one or more episodes in the past year or past month, or typically leaking at least once a week or daily. Severity of degree of bother may also be used. The threshold chosen to define UI obviously affects the prevalence and incidence.

4. Types of UI. UI in women is typically classified as stress, urge or mixed. Stress UI is urine leakage resulting from increased intra-abdominal pressure (e.g., coughing, standing up) while urge UI is leakage immediately preceded and accompanied by a strong physical ‘urge’ to urinate, while mixed UI is a combination of the two. Other UI – neither stress or urge – is uncommon in women. Prevalence estimates for each type of UI are sensitive to the wording of the questions and to definitions of stress and urge UI, with some definitions requiring all UI episodes to be of one type to be classified as stress or urge, while other definitions may require only that the majority of episodes be of that type.

5. Survey methods. While there are few data comparing differences in prevalence based on method of ascertainment [73-74], variation it ascertainment (e.g., in person interviews, phone interviews, mailed questionnaires, or diaries) have been shown to affect prevalence estimates for other socially sensitive conditions.

6. Culture and language. While this area has not been investigated, it is likely that there are cultural differences in the perception of and terms used to describe UI that may affect prevalence estimates. Similarly, differences in language may lead to differences in ascertainment.

In the following sections, we attempt to account for variation from the above sources by using population-based estimates with high response rates whenever possible and examining prevalence by age, by type of incontinence, and among major subgroups of interest (pregnant and post-partum women, women in long term care, and by race/ethnicity). Even so, there remain substantial variations in prevalence estimates likely related to remaining differences in study methods or sample characteristics.

1. PREVALENCE IN GENERAL POPULATION OF ADULT WOMEN

A review of 36 general population studies from 17 countries in the 2004 3rd ICI edition found that the prevalence estimates for the most inclusive definitions of UI (‘ever’ ‘any’ or ‘at least once in the past 12 months’) ranged from 5% [75] to 69% [76], with most studies reporting a prevalence of any UI in the range of 25% to 45%. For daily incontinence, prevalence estimates typically range between 5 and 15%.

As seen in Table 6, studies since 2004 have added important information on prevalence of incontinence in women younger than 30 and older than 80 years of age, particularly for prevalence of incontinence by type. These studies are consistent with previous studies reporting that older women are more likely to have mixed and urge incontinence [103-106] while young and middle-aged women generally report stress incontinence [78-79, 107-109]. Overall, approximately half of all incontinent women are classified as stress incontinent. A smaller proportion are classified as mixed incontinent and the smallest fraction as urge incontinent. A recent study which included the entire adult age range by Hannested et al.[79] demonstrated a fairly regular increase in prevalence of mixed incontinence across the age range, and a decrease in prevalence of stress incontinence from the 40-49 year old age group through the 60-69 year old group.

</table>
The prevalences shown in Table 6 generally fall into ranges previous reported. There is no hard evidence for different prevalences of UI among Western countries. Comparing prevalence between countries based on separate studies is difficult due to differences in methods and definitions, as well as language, cultural and social differences. One of the few studies to estimate the prevalence of UI in more than one country found similar prevalences of any UI (41% to 44%) in 3 of the 4 countries examined (France, Germany and UK) but a lower prevalence (23%) in the fourth country (Spain) [110]. There was no apparent reason for the lower prevalence in Spain. Virtually no population based studies of UI prevalence have been done in developing countries.

Only 3 population-based studies were located which reported prevalence of UI based on the Sandvik severity score. In one US study of over 3300 women age 42 to 52, the prevalence of severe UI was 10% [111], while in another US study of over 3500 women age 30 to 90, the prevalence was 18% [87]. In the Norwegian EPINCONT study, the prevalence of UI was moderate to severe by the Sandvik score and of at least some bother was 7%. Unfortunately, while there is wide recognition that ‘any incontinence’ which has a prevalence of 40 to 70 percent among middle aged and older women, is overly broad for many purposes, including estimating economic and health burden, there is no generally agreed upon criteria for what might be called “significant incontinence.” Frequency, severity, impact and bother all have their own drawbacks as the sole basis for defining significant incontinence. Reporting UI prevalence using different threshold definitions, including severity, bothersomeness, impact, and desire for treatment or treatment seeking allows for flexibility, but by itself does not move us toward consensus.

2. PREVALENCE IN SPECIFIC POPULATIONS

The following section reviews UI prevalences among women living in long term care facilities, during pregnancy and post-partum period, and among women of different race/ethnicity.

3. PREVALENCE IN LONG TERM CARE FACILITIES

Several studies have documented a higher prevalence of UI in women residing in long-term care facilities compared to community dwelling women [112-116]. Because UI is associated with dementia, limited mobility and other co-morbid conditions, prevalence of UI is higher in facilities with residents requiring a higher level of care. In addition to being more frequent, UI in long term care residents tends to be more severe, costly, and have greater burden on caregivers compared to UI in the community [117].

Estimating the prevalence of UI women in institutions is complicated by the variety of definitions of long term care, ranging from supervised residential living facilities to nursing homes specialising in patients with advanced dementia. Some facilities offer a mixture of levels of care. In addition, differences in methods used to ascertain incontinence in nursing home residents resulting in wide differences in prevalence estimates. For example, a US study found a prevalence of just 1.4% based on medical record diagnosis, compared to 56% of patients with UI documented by the nursing staff [118]. Another study which analysed nearly 30,000 nursing home residents in US found that 30% had UI recorded (usually at admission) in the required ‘minimum data set’ (MDS) [119], similar to the prevalence of 34% found in smaller, study in Switzerland [113]. Studies that directly survey patients, family and/or staff consistently generally find higher prevalences of 50% to 80% among current residents [100, 112, 114].

4. PREVALENCE DURING PREGNANCY AND POST-PARTUM

Studies of UI during pregnancy have reported period prevalences of 32% to 64% for all UI and 40% to 59% for stress (including mixed) UI as documented in the 3rd ICI edition. Period prevalence is higher in parous than in nulliparous women [120-123], whereas new onset of UI (cumulative incidence) during pregnancy is higher in primagravida [121-123]. Point prevalence of UI is low in the first trimester, rising rapidly in the second trimester and increasing further, though less rapidly, in the 3rd trimester [121-122]. Severity of incontinence appears to increase during pregnancy as well [124]. Data recently reported from the Norwegian Mother and Child Cohort Study, a large (N=43,279) population-based study, confirms these observations [125]. In this study, the prevalence of stress incontinence from before to during pregnancy, rose from 9% to 31% in nulliparous women, and from 24% to 42% in parous women. In contrast, mixed incontinence showed a similar rise in both groups (from 6% to 16% and from 8% to 20%, respectively). Urge incontinence remained virtually unchanged in both groups at less 5%.

Estimating the post-partum prevalence of urinary incontinence is complex because in addition to differences in study design, method of ascertainment and choices of definition of incontinence, prevalence may also depend on number of previous births, type of delivery, and history of previous incontinence. The table below summarizes studies which report the prevalence of UI in the first year post-partum for primiparous women by mode of delivery. These studies were chosen because they enrolled consecutive women delivered at one or more large hospitals serving a defined population, and were able to recruit and evaluate over 50% of women.

As shown in Table 7, nearly all post-partum UI is stress related. Most studies did not provide information

* Restricted to women with no UI prior to pregnancy

VD=all vaginal deliveries; SVD=spontaneous (non-instrumental) vaginal delivery; IVD=instrumental vaginal delivery (forceps and/or vacuum); CS=all Cesarean sections; ECS=elective Cesarean section (prior to labor); CSL=Cesarean section after onset of labor
on frequency of leakage or degree of bother. Overall, it appears that any incontinence is reported by 15% to 30% women during the post-partum year, while weekly or greater incontinence is reported by 5% to 10% and daily UI by less than 5% of women. Excluding women with UI prior to pregnancy reduced the prevalence of post-partum incontinence by 3% to 4% in the one study reporting separate prevalences for each group [126].

Studies which included women delivered by Caesarean section and delivered vaginally consistently found a lower prevalence in those delivered by Caesarean section. Studies reporting prevalence in women delivered by elective Caesarean section and by Caesarean section after initiation of labor showed a substantially lower prevalence of post-partum UI in the elective Caesarean section group. The relatively high prevalence of post-partum incontinence among women having had an elective Caesarean section in the study reported by Borello-France is not consistent with other studies [127].

5. PREVALENCE IN DIFFERENT RACIAL AND ETHNIC GROUPS

While most epidemiological studies of UI have been conducted on Caucasian populations in the US, Canada and Europe, there are now a substantial number of studies in Asian countries [73, 91, 118-126], and among other racial/ethnic groups in the US [72, 89, 91, 97, 108, 111, 140-147]. Because of the substantial variation in prevalence of incontinence between studies, it is best to examine differences by race and ethnicity in the same study. Several population-based studies comparing the prevalence of UI among white women and women from one or more racial or ethnic groups are summarised in the table below. Most striking is the lower prevalence of stress UI in Black and Asian compared to White women. In most studies, Blacks have half to a quarter the prevalence of stress UI compared to White women but the same or slightly higher prevalence of urge UI and a slightly lower prevalence of mixed UI. Thus the difference in prevalence of UI between White and Black women appears to be almost entirely the result of a markedly lower prevalence of stress UI symptoms in Black women. The consistency of this difference across all studies and different frequencies and severities of UI suggest this is a real difference and not simply reporting bias. In contrast, the lower prevalence of UI seen in Asian women compared to White women reflects a lower prevalence of both stress and urge UI. The comparison of prevalences between Hispanic and non-Hispanic White women is complex in that some studies have found a lower prevalence of UI in Hispanic women while others have reported the prevalence to be higher in this group. This heterogeneity may be explained, at least in part, by differences in prevalence among sub-population of Hispanic women. Studies, such as the SWAN study, [46] that include Hispanic women who are primarily of Caribbean origin have reported lower UI prevalence, while those enrolling primarily Mexican-American women have reported higher UI prevalences [72, 144, 148]. This relationship is further supported by the NHANES data reported by Anger et al which found prevalences of any UI to be 36% in Mexican-American women and 30% in other Hispanic women [97, 148] (Figure 5).

Most studies used multivariate analysis to adjust for differences in parity, age, BMI, hysterectomy, oestrogen use, and other variables potentially related to both race and UI and have found that White women continue to have a significantly elevated risk of UI compared to Blacks or Asians [72, 89, 91, 140-145]. For studies in which Hispanic women report a higher prevalence of UI, adjusting for these variables reduces the difference with White women [72, 144, 148] (Table 8).

A few studies have compared physiological parameters between Black and White women to try to explain the lower prevalence of stress incontinence in Black women. These studies have reported Black women to have higher urethral closure pressures, greater urethral length and puboccocygeal muscle strength, larger urethral volumes and, paradoxically, greater vesical mobility [150-151]. The extent to which these differences, if confirmed, can explain differences in the prevalence of stress incontinence is not yet clear.

III. INCIDENCE AND REMISSION

In summarizing rate data, several factors should be borne in mind. Incontinence is a dynamic condition and both remission and reoccurrence are possible. As a practical matter, incidence is usually defined as the percent of continent women who later report incontinence. Some women who are continent at the time of enrollment may have been incontinent in the

past. Also, women who are continent at baseline may develop incontinence which then remits (either spontaneously or due to treatment) prior to the follow-up survey. Depending on the study design, such women may or may not be counted as incident cases. For follow-up periods of a few years, the impact of such development and remission on estimates of new incontinence, particularly incontinence at least weekly, is probably negligible. The one study of more than 5 years duration included cases where new incontinence remitted as a part of the cumulative incidence [152]. As with prevalence, incidence will depend on the exact definition of UI used. It is worth noting that remission rates are usually higher than incidence rates even if the overall prevalence of incontinence is increasing, because the denominator for remission, the number of continent women, is usually smaller than the denominator for incidence of new incontinence (continent women).

Table 9 summarises population based studies reporting incidence and remission; 6 are new since 2004. Several studies report rates by age groups, frequency of UI, and type of UI. Annual incidence of any new UI ranged from 3 to 11% and increased with age. Rates of complete remission ranged from 0 to 13% per year and tended to increase with age, though not as consistently as did incidence.

IV. POTENTIAL RISK FACTORS

Many epidemiological studies have investigated potential risk factors for UI. The design of most of these studies has been cross-sectional using prevalent UI. In cross-sectional studies, the temporal relationship between some potential risk factors such as diet, physical activity, medications or body weight is ambiguous as the development of UI can lead to changes in behaviour. Since 2004, there have been several prospective studies looking at risk factors for incident UI which have alloweds for evaluation of the temporal relationship. Associations in all observational studies are subject to potential confounding, necessitating multivariate analysis to estimate the independent association between risk factors and UI. The risk factors of oestrogen use and body mass (obesity) have been examined in randomised controlled trials. With the exception of age, the following risk factors are considered to be at least potentially modifiable.

1. AGE

Virtually all studies have found an increase of UI prevalence with age [66, 77, 79, 81, 112, 159-168]. While incontinence is not considered to be an inevitable part of aging; there are changes in the bladder and the pelvic structures that occur with age and which can contribute to UI [169-170]. Further, UI is often attributable to medical problems or diseases that can disrupt the mechanisms of continence (e.g., diabetes mellitus, cognitive impairment, physical disability), many of which are more common among older adults. Several investigators have noted that the prevalence of any UI appears to increase up to middle age, with a leveling off between ages 50 and 70, followed by a steady increase among the aged [79, 110, 160]. Cross-sectional studies suggest that this pattern reflects an increase in the prevalence of stress incontinence during middle age followed by little increase or even a decline after age 50. In contrast, urge and mixed UI continue to rise after age 50. As a result, while stress incontinence predominates in younger and middle aged women, urge and mixed incontinence are more common in older women [79].

2. PREGNANCY, PARITY AND PARTURITION EVENTS

Stress UI is reported by most women at some time during pregnancy, usually in the third trimester, but is generally self-limited and resolves after delivery. For some women, UI that began during pregnancy persists after delivery as chronic UI [171-173]. In addition, women who are incontinent during pregnancy, even if they become continent after delivery, are more likely to develop incontinence later [128, 174]. The interpretation of this association is not clear. It may be that physiological changes during pregnancy cause incontinence later in life, but it is also possible that the temporary physiological changes during pregnancy may ‘uncover’ women with a predisposition to incontinence who are destined to become incontinent later in life regardless of the effects of pregnancy.

The vast majority of studies have found an association between parity and later UI [78, 124, 160, 167-168, 175-187]. Some studies have reported a threshold effect at one delivery and little or no additional risk with increasing parity [78, 185-186, 188]. However, other studies suggest that increasing parity increases the risk of UI [179, 185, 187, 189-190].

The effect of parturition on risk of incontinence is difficult to separate from the effect of pregnancy. Possible mechanisms by which vaginal birth could lead to incontinence include stretching damage to pudendal and other nerves and tearing of connective tissue reducing pelvic floor support for urethral competence [191]. One approach to estimating the impact of vaginal delivery separately from the impact of pregnancy itself is to compare the risk of incontinence in women who deliver vaginally compared to those who have a Caesarean delivery. Most such studies have found vaginal delivery to be a risk factor for both post-partum incontinence and incontinence in later life, particularly for stress incontinence, compared to delivery by Cesarean section [134, 167-168, 171-172, 192-200]. For example, in a large study of over 15,000 women under the age of 65 years,

* 1+ / month of sufficient quantity to at least soak underwear
Rortveit et al demonstrated that women who had delivered only by cesarean section were at increased risk of stress or mixed UI compared to nulliparous women (OR = 1.5) [198]. Further, those who had delivered vaginally only were at even greater risk of stress UI compared to those who had a Caesarean section only (OR = 2.4). Other studies of primiparous women have shown similar results with odds ratios (or relative risks) for UI in later life ranging from 1.7 to 2.8 [134, 167-168, 171, 201] for vaginal delivery compared to Caesarean section only.

Studies of maternal and fetal factors have found conflicting evidence regarding older maternal age at delivery and birth weight to be independent risk factors for UI. Foldspang et al found increased risk of UI with increasing age at the last childbirth for women aged 30-44 years [182]. Other studies have reported that older age at first birth is associated with an increased risk of later UI [183, 202-203]. Greater birth weight may also predispose the mother to UI [165, 193].

Studies have also examined the association between specific parturition factors during vaginal delivery and the risk of both post-partum UI and UI in later life. While several studies have reported forceps delivery [134, 171, 204], induced labour [190, 205], and episiotomy [206] to increase the risk of incontinence, these associations tend to become non-significant in multivariate analyses [138, 171-172, 183, 187, 189-190, 193, 205, 207-208] suggesting that risk of UI associated with vaginal delivery is not primarily the result of any single aspect of delivery or limited to any subset of women. Virtually all these studies have been conducted in developed countries. For women in developing countries with limited access to modern obstetrical care, traumatic vaginal delivery is a major cause of UI, including vesico-vaginal fistula [209].

Importantly, the association between parity, as well as between mode of delivery and specific parturition variables, appears to diminish and even disappear over time [160, 182, 185, 200]. A large study in Australia found that parity was strongly associated with UI for young women (18-23 years). For women 45-50 years there was only a modest association, and for older women (70-75 years) the association disappeared [160]. In a Norwegian study [185], the relationship between UI and parity was significant for younger women (age 20-34 years), weaker in middle-aged women, (35-64) and absent in older women (> 65 years).

3. OBESITY AND BODY MASS

Obesity is well established as a factor that can cause UI or contribute to the severity of the condition. It is believed that the added weight of obesity, like pregnancy, may bear down on pelvic tissues causing chronic strain, stretching and weakening of the muscles, nerves, and other structures of the pelvic floor. Some studies have found central obesity, measured by waist to hip ratio, to be more strongly associated with UI than is the traditional body mass index (BMI) [91, 210]. Because obesity has also been associated with urge UI it is thought that obesity may also act via pathways other than increased intra-abdominal pressure.

Data from numerous cross-sectional studies indicate that UI in women is associated with higher body mass index and greater weight [85, 87, 89, 92-94, 108, 111, 140, 160, 162, 165-166, 168, 171, 178, 180, 183-184, 187-188, 204-205, 211-222]. The relationship between BMI and UI has been reported in studies of younger women [160], middle aged women [111, 160, 184, 204], older women [160], and both parous and nulliparous women [171, 216]. Several studies have reported an association between body mass and all 3 major incontinence types (stress, urge and mixed) [188, 213, 218]. The association appears to increase with increasing body mass with women in the highest body mass quartile being 2 to 4 times more likely to have UI compared to women in the lowest quartile. One large cross-sectional study estimated that the risk of UI increased by 60% for every 5 unit increase in body mass index (BMI) [143]. In another study, risk of UI increased by about 50% and risk of severe UI increased by approximately 100% for each 5 unit increase in body mass [218].

In addition to cross-sectional data, several longitudinal studies have found that weight at baseline predicts later incontinence, and that an increase in body weight is associated with an increased risk of new incontinence or progression of existing incontinence [91, 223]. In one study, a weight gain of 5-10 kg increased the risk of incontinence by nearly 50% while in another, a gain of 5 units on the body mass index (BMI) was associated with a 30% increase in risk of stress UI and a 15% increase in risk of urge UI [91].

Finally, intervention studies for weight reduction have reported that loss of weight is associated with partial remission or complete resolution of UI. Several studies of incontinent women who sustained substantial weight loss from bariatric surgery found that a majority experienced resolution of stress and urge incontinence with the probability of resolution strongly correlated to the degree of weight loss [224-226]. Weight reduction has also resulted in a significant reduction in UI frequency in a randomized controlled trial of nonsurgical weight reduction for obese women [227] and in a large intervention trial for women with type 2 diabetes [228]. Thus, there is strong evidence to support the causal role of excess weight in the development of UI.

4. HORMONES

Oral oestrogen replacement therapy has been widely used to treat urinary incontinence during or after menopause for many years, despite equivocal data from clinical trials. The positive association between
oestrogen use and incontinence noted in cross-sectional studies [205, 229-230] was generally assumed to be the result of women with incontinence receiving estrogen for treatment of their incontinence. In 2001, Grady et al published data from the Heart Estrogen/Progestin Replacement Study (HERS), a large placebo-controlled randomized trial of estrogen replacement therapy which showed that postmenopausal women randomized to conjugated oral estrogen plus medroxyprogesterone were more likely then women taking the placebo to experience worsening of their incontinence over 4 years (39% vs 27%, p<.001) [231-232] A similar association was later found in women age 50-79 enrolled in the Womens’ Health Initiative (WHI) Hormone Replacement Trial [233]. In this large randomized controlled trial, continent women receiving estrogen, with or without progestogen, were approximately twice as likely to have developed stress incontinence at 1 year (16% vs 9%, p<.0001). The risks of mixed and urge incontinence were also significantly increased, though more modestly. The effect was seen primarily in women 55 and older. Thus, while oral estrogen as a risk factor for stress UI may be unexpected, the evidence from these 2 large randomized controlled trials supports this conclusion for stress UI, at least in women age 55 and older. The effect of estrogen on urge incontinence, and on incontinence in women less 55 years of age, is less clear.

While relatively little is known about the effects of the newer class of selective estrogen receptor modulators (SERMs) on incontinence, two SERMs, levormeloxifene and idoxifene have been associated with an increased risk of pelvic organ prolapse surgery in clinical trials [234], and women taking levormeloxifene have experienced a 4-fold increase in urinary incontinence [235]. In contrast, no increase in UI was seen an a randomized controlled trial of raloxifene [236].

5. DIABETES

Many, though not all, cross sectional studies have reported urinary incontinence to be more common in women with type 2 diabetes than among women with normal glucose levels even after adjusting for common risk factors, including age and obesity [87, 89, 91, 111, 143, 228, 237-238]. In the analysis of the large, prospective Nurses’ Health Study cohort, diabetes was a significant predictor for new incontinence [237], and the strength of the association increased after 5 years of diabetes and by severity of incontinence. Women with diabetes of more than 5 years duration had approximately 50% more risk of severe UI and twice the risk of very severe UI. Data from another prospective cohort study did not find an association between new diagnosis of diabetes and UI up to 1 year later [239], suggesting that diabetes needs to have been present for more than a year to substantially increase the risk of UI.

6. HYSTERECTOMY

Approximately 600,000 women have hysterectomies in the U.S. each year, usually for non-cancerous conditions. There has been concern that hysterectomy may be associated with development of urinary incontinence via damage to the pelvic nerves and pelvic supportive structures [240-242]. However, most studies have not found an increase in reported incontinence in the first two years following hysterectomy [243-247] and at least two studies have reported a statistically significant decrease in incontinence following hysterectomy [248-249]. Most of these studies have been uncontrolled and limited by small sample sizes (fewer than 35 patients per study). However, a larger (n=158) prospective study that did include a control group (women undergoing a dilatation and curettage), also found no increase in incontinence 3 to 21 months after hysterectomy [250]. A 2-year, randomized controlled trial of 160 women who had undergone either hysterectomy or endometrial ablation for menorrhagia found no difference in incontinence or in cystometric abnormalities between the two groups [251]. A third, large, retrospective study, of 415 hysterectomised women and 335 women who had undergone laparoscopic sterilization, also found no difference in the prevalence of urinary incontinence between the two groups 2 to 8 years after hysterectomy [252].

While most prospective studies have failed to find an association between hysterectomy and subsequent incontinence, several epidemiologic studies have reported an association between a history of hysterectomy and current UI, with relative risks ranging from 1.2 to 2.1 after controlling for other variables using multivariate analysis [87, 89, 93, 145, 205, 229]. In two studies, the association between hysterectomy and incontinence was found to be stronger if the hysterectomy was performed before age 50 [81,205].

Some studies have reported an increased prevalence of UI in women receiving a subtotal, compared to a total, hysterectomy [253-254] while others found no difference by techniques [255]. Additional factors, such as indication for hysterectomy (fibroids, endometriosis, or prolapse) and concomitant oophorectomy, have not been well studied.

Prospective studies of the association between a history of hysterectomy and incident UI have provided conflicting results. One prospective study reported a significant association between history of hysterectomy at baseline and subsequent incidence of new urge, but not stress, UI [221]. In contrast, two other studies failed to find a significant association between baseline hysterectomy status and UI [153, 256].

Based on the available data, hysterectomy does not appear to increase the risk of UI in the short term. While several cross-sectional studies have reported an association between a history of hysterectomy and
current UI, the strength of the adjusted association has been weak to moderate. The few prospective studies have given mixed results on whether a history of hysterectomy is an independent risk factor for new onset UI. While two studies have suggested that hysterectomy at a younger age may be a stronger risk factor, this needs to be confirmed in future studies.

7. URINARY TRACT INFECTIONS AND LOWER URINARY TRACT SYMPTOMS

Urinary tract infection (UTI) has long been considered to be a cause of transient UI. The role UTIs with respect to the development of chronic UI is less clear. While several cross-sectional epidemiologic studies have found that women with UI are more likely to report having had one or more UTIs [73, 145, 159, 164, 211-213, 219, 221, 257-265] these results should be treated cautiously. UTIs are often diagnosed and treated based on symptoms without culture confirmation and therefore in some cases women may have received a diagnosis of a UTI for what is actually urge incontinence. In addition, lower urinary tract symptoms, including burning on micturition, frequency and nocturia may increase the likelihood of being diagnosed with a UTI in addition to being associated with UI. UI may also be a risk factor for UTI. A recent prospective 2 year study of 913 women age 55-75 found that baseline prevalence of UI was nearly twice as high in women who subsequently developed a UTI compared to those who did not [266]. Without additional data, it is not possible to say if UTIs actually increase the risk of later UI, if UI increases the risk of being diagnosed with a UTI, or if both UI and UTIs are manifestations of a common underlying process.

8. IMPAIRED PHYSICAL FUNCTION

Functional impairments, particularly mobility limitations, a history of falls, arthritis, dizziness, need to use walking aid, and poor lower extremity strength, have been correlated with UI in many community-based and nursing home studies [102-103, 112, 115, 140-141, 146-147, 159, 161, 165, 219, 221, 262, 267-274]. Odds ratios for UI from a study of 839 nursing home residents demonstrated the increasing likelihood of incontinence with an ORs=1.8, 5.6 and 7.4 for needing partial assistance, needing full assistance, or being wheelchair or bed bound, respectively [112]. A study of 2025 older women indicated that several functional impairments, particularly mobility limitations, may have received a diagnosis of a UTI for what is actually urge incontinence. In addition, lower urinary tract symptoms, including burning on micturition, frequency and nocturia may increase the likelihood of being diagnosed with a UTI in addition to being associated with UI. UI may also be a risk factor for UTI. A recent prospective 2 year study of 913 women age 55-75 found that baseline prevalence of UI was nearly twice as high in women who subsequently developed a UTI compared to those who did not [266]. Without additional data, it is not possible to say if UTIs actually increase the risk of later UI, if UI increases the risk of being diagnosed with a UTI, or if both UI and UTIs are manifestations of a common underlying process.

9. COGNITIVE IMPAIRMENT

Research on UI in nursing home residents has consistently supported an association between UI and dementia [99,112,267,270, 275-279]. In studies using multivariate analyses, patients lacking mental orientation had a 3.6 times greater risk of being incontinent than those with normal mental status [112] and the presence of dementia increased the odds of UI by 1.5 to 2.3 [267, 270]. A link between incontinence and mental status has also been demonstrated in the acute care setting. In a sample of women admitted to the hospital for hip fracture, presence of confusion increased the odds of developing UI during the hospitalization (OR = 3.4) [272]. In the Canadian Study of Health and Aging a strong association was found between severity of dementia and UI in elderly women [115]. Odds ratios were 1.2, 4.0, and 12.6 for mild, moderate and severe dementia, respectively, after controlling for age, residence, and ambulatory function. However, in a study of community dwelling women, no relationship was found between mental status and difficulty holding urine [280]. Another, more recent community-based study found an association between cognitive impairment, defined as a score of < 24 on the mini mental status exam (MMSE), and prevalent UI, though after adjusting for physical functioning and other variables the association became substantially weaker and of borderline statistical significant (OR=1.3, 95% CI-1.0-1.6) [279]. A recent longitudinal study of 6349 community women found that a decrease in mental functioning more than 1 standard deviation, as measured by the modified mini mental status exam (MMSE) and by Trails making A and B, was not associated with increased risk of UI; however it did predict a greater impact of UI [275]. Another study of over 5000 women age 65 and older found no significant association between moderate or severe cognitive impairment, defined by the modified
MMSE, and incident UI over 10 years [99]. Together these studies suggest that mild dementia in community dwelling women is at most weakly associated with UI, while moderate to severe dementia has a consistent moderate to strong association. No studies were found which investigated whether an intervention to maintain or improve mental functioning would also improve or prevent UI.

10. DEPRESSION

Several cross-sectional studies have documented an association between depression and incontinence with estimates of the relative risk ranging from 1.4 to 2.7 [87, 91, 93, 141, 143, 147, 259, 261]. The cross-sectional and observational nature of studies linking depression and incontinence means that while depression may predispose a woman to developing UI, it is also possible that UI leads to depression (for example by reducing a woman’s social network), that depression and UI share one or more common neurochemical or hormonal pathways [281], or that women with depression are more likely than non-depressed women to be bothered by, and hence report, having incontinence. One prospective cohort study found no association between baseline depression or new depression and subsequent UI [91, 239, 281]. A second prospective study reported a weak association between baseline depression and subsequent UI over 3 years (OR=1.2, 95% CI=1.0-1.4) [96].

11. MENOPAUSE

Historically, menopause has been considered a risk factor for UI. However, establishing a relationship between menopause and UI has been difficult, probably in part because changes in endogenous hormone levels vary over a period of at least several years and only approximately correspond to amenorrhea or vasomotor symptoms used to define clinical menopause. Many cross-sectional studies have found that the prevalence of incontinence does not increase with natural menopause [81, 177, 179, 188, 145, 164, 282] and some studies have found a significantly lower prevalence of UI among postmenopausal women than among premenopausal women [108, 177, 179, 188]. Two recent longitudinal studies have confirmed this neutral or protective effect of the natural menopausal transition (without hormone replacement therapy) on UI [222, 239]. There is evidence that menopause may have a different association with stress incontinence than with urge incontinence [76, 175]. In one study, the prevalence of urodynamic stress incontinence decreased from 21% to 12% after menopause while the prevalence of detrusor overactivity increased from 9% to 19% [283].

12. PHYSICAL ACTIVITY

Evaluating physical activity as a potential risk factor or protective factor for incontinence has been difficult. Incontinence, particularly stress UI, can be a barrier to exercise [284], which could lead to the spurious appearance of a protective effect of physical activity on UI. Alternatively, engaging in physical activity could ‘unmask’ an existing propensity toward stress incontinence by increasing intra-abdominal pressure, resulting in physical activity being identified as a risk factor in the short term even if it is protective in the long term. Some cross-section studies have found a protective association between exercise and UI [84, 229, 262]. However establishing physical activity as a risk factor for incontinence using observational data is challenging due to difficulties in measuring and classifying physical activity prospectively over sufficient time to see an effect. In a longitudinal study of 4291 women age 65+ “regular exercise” at baseline was not associated with either prevalent UI or new UI 10 years later in multivariate analysis [99]. In contrast, a study of over 80,000 US nurses age 54-79 found that a higher level of physical activity, averaged from 7 reports over 14 years, was associated with a reduced risk of new UI [285]. Specifically, the investigators found that that being in the top quintile for overall physical activity reduced the risk of new UI by about 20% (OR=0.81, 95% C=0.71-0.93) compared to the bottom quintile. For walking, being in the top quintile reduced the risk of UI by about 25% (OR=0.74, 95% CI=0.63-0.88). Both total activity and walking significantly reduced stress UI, but not urge or mixed UI.

13. SMOKING, COUGH AND CHRONIC LUNG DISEASE

Smoking has been reported to be an independent risk factor for incontinence in women in some cross-sectional studies [85, 89, 109, 111, 141, 171, 189, 204, 218, 222, 285-287] but not in others [87, 93, 165-166, 186, 207, 211-213, 262, 288] possible mechanisms by which smoking could be associated with UI is by increased intra-abdominal pressure due to increased coughing among smokers. Other mechanisms, such as inhibition of collagen formation [286], also have been suggested.

Recent data from the Nurses’ Health Study II, with over 83,000 US women age 37 to 54 years old, supports smoking as a weak risk factor for UI, with the odds ratio for current smoking vs. never smoking increasing 0.91 to 1.20 to 1.34 for occasional, frequent and severe incontinence respectively, by multivariate analysis [89]. Former smokers had a risk intermediate between never and current smokers. In contrast, four prospective cohort studies failed to find a significant association between either past or current smoking and incident UI in multivariate analysis [99, 153, 239, 256].

The conflicting data from cross-sectional studies and lack of association between smoking and incident UI
14. DIET

Studying diet as a risk factor for UI is challenging. While some dietary constituents such as coffee, alcohol or carbonated beverages have been suspected as worsening UI, there is little reason to suspect other dietary constituents as causing, or protecting from, UI. Studies of dietary factors must adjust for confounders, notably age and body mass, and should consider the tradeoffs made with other constituents. Dietary data are difficult to obtain reliably. Finally, women may change dietary intake in response to UI, making cross-sectional studies of diet and UI difficult to interpret.

Several studies have examined the consumption of alcohol, coffee as risk factors for UI. While a few studies have reported coffee drinking to be associated with an increased risk of UI [99, 289], others have not found an association [211, 218, 229, 262]. Similarly, a positive association between alcohol consumption and UI has been reported by some [166, 290] but not others [211, 218, 222, 229]. Drinking 1 or more carbonated beverage daily compared to less than 1 per week was associated with a higher incidence of stress UI in one study (adjusted OR= 1.6, 95% CI =1.2-2.2) [291]. Tea drinkers were found to be at slightly higher risk of all types of incontinence in another study [218].

15. FAMILY HISTORY AND GENETICS

Since 2004 several family and twin studies of UI have been published. One twin study of 161 monozygotic (identical) and 249 dizygotic (fraternal) twins age 75+ found evidence for significant inheritability for urge, but not for stress UI [292]. Another twin study estimated that genetics accounted for nearly 60% of the variation in bladder neck descent as measured by ultrasound [293]. Several family history studies have found a two to three fold greater prevalence of stress UI among first degree relatives of women with stress UI compared to first degree relatives of continent women [294-296]. In one study, relative risks for stress UI was 2.8, 2.9, and 2.3, respectively, for mothers, sisters, and daughters of women with stress incontinence compared to women without first degree relatives with stress UI [294]. A large study of sisters, daughters, mothers and grandmothers of women with UI found an association between incontinence status in first-degree relatives with an increased risk for stress and mixed UI after adjustment for body mass index and parity [297]. In general the risk was somewhat higher for sisters of a woman with UI than for daughters.

16. ISCHEMIC HEART DISEASE

A recent community-based study of urinary tract symptoms reported an adjusted association between UI and ischemic heart disease in Black, but not White or Hispanic women [298] an association previously reported, though unadjusted [94]. However, at least 3 other cross-sectional studies have not found an association between coronary heart disease and UI [143, 299-300]. In a prospective cohort study, “heart attack/angina” was associated with stress UI cross-sectionally but not longitudinally in age-adjusted analysis, and became non-significant after adjusting for other variables [273]. In contrast, a prospective analysis of the Nurses’ Health Study found that coronary heart disease was associated with frequent UI (OR=1.5, 95% CI=1.2-1.8) and severe UI (OR=1.8, 95% CI=1.3-2.4) [256]. Given these mixed associations and the difficulty of completely controlling for common risk factors for heart disease and UI, it is not clear if heart disease is an independent risk factor for UI.

17. OTHER FACTORS

Additional variables reported as associated with UI include constipation [84, 160, 184, 187, 270], faecal incontinence [103, 112], genit al prolapse [107, 189], congestive heart failure [301], use of diuretics [138, 187, 262], benzodiazepines [302], and other drugs [161, 303-304], and childhood enuresis [188, 215, 305-306]. In a review of medical records of 5986 members aged 65+ of a large health maintenance organization in California an increased risk of UI was associated with Parkinson’s disease, dementia, stroke, depression, and congestive heart failure [307].

V. IMPACT AND CONSEQUENCES

The impact of urinary incontinence is typically assessed by degree of bother or by scales that measure the impact of incontinence on functional status and quality of life. A single question asking patients to report the degree of bother they experience from their incontinence provides an important dimension to characterising UI in addition to frequency and amount of urine lost. Typically incontinence that is more severe, of longer duration, and is urge or mixed, is also more bothersome [308]. There are validated scales that measure the impact of UI. One of the first scales, the Incontinence Impact Questionnaire [70], uses 30 items asking whether incontinence limits activities in 4 domains. There are several other similar scales, some specific for urge or stress incontinence or for overactive bladder [70, 309-314]. In addition to severity of UI, interference with sexual activities and incontinence at night are associated with greater reported impact on quality of life [315]. Incontinence has been identified as a potential risk factor for falls and nursing home admissions. In a prospective study of over 6000 older women, women with weekly urge, but not stress, incontinence were more likely to fall during the 3 year follow-up, adjusting
for multiple other factors (adjusted OR=1.3, 95% CI=1.1-1.4) [316]. Similarly, in a study of 472 long term care residents in Germany, UI at baseline predicted falls over the next 12 months after adjusting for a variety of patient factors and co-morbid conditions [317]. UI was the second strongest predictor of falls (a history of falls being first). However, it is possible that both falls and UI are markers for frailty that cannot completely be adjusted for. Whether treatment of UI would reduce the number of falls has not been established.

UI has also been reported as a risk factor for nursing home admissions even after adjusting for multiple co-morbid conditions [301,326]. However, another study that also adjusted for additional measures of frailty, including activities of daily living, found that the association became weaker and non-significant [101].

UI has substantial, well documented, economic consequences as well. Annual costs of urinary incontinence are estimated to be over $20 billion in direct costs (primarily costs of routine care, including out of pocket costs) [318] which is greater than the annual costs for breast, cervical, uterine and ovarian cancer combined [319]. There are also substantial indirect costs from work loss and missed volunteer work as well [320].

VI. TREATMENT SEEKING AND TREATMENT

Since 2004, at least 8 papers have been published which report the proportion of women with incontinence who have sought treatment [84, 95, 98, 110, 321-325] (Table 10). Combined with previously published studies [78, 81, 105, 111, 308, 322, 326-328], the proportion of women with any UI in the past 12 months who report having sought medical treatment ranges from 12% [46] to 53% [30] with about half the studies showing 25% to 30% [81, 98, 322, 326]. All studies that have examined treatment seeking by type of incontinence have found that a women with urge or

* Serious defined as >weekly and > few drops; minor defined as other then serious
# low severity = minor amount of urine loss less than daily; moderate = either more then a minor amount of urine loss or daily urine loss; severe = daily loss of greater than a minor amount of urine
mixed incontinence are more likely to seek treatment than women with stress incontinence [84, 89, 322]. As expected, the proportion of women seeking treatment is strongly associated with frequency, severity and bothersomeness, with several studies reporting proportions of 50% to 80% of women with daily, moderate to severe, or bothersome incontinence [321-322, 325, 327].

Reasons given by people for not seeking help include: not regarding incontinence as abnormal or serious [78, 330-331], embarrassment [332-334], considering incontinence to be a normal part of ageing [331, 335], having low expectations of treatment [78, 330] and thinking they should cope on their own [332, 335]. Several studies have identified factors associated with seeking care for UI, including severity, duration and type of UI, nocturnal symptoms, and the bother or impact of UI [78, 105, 322, 326-327, 330-331]. Other characteristics such as age, general health, or attitude toward health care may also play a role [327].

Even when women seek care for incontinence, treatment is often limited or not provided at all [336-337]. For those receiving medical treatment, most discontinue within 12 months. Probably less than 20% of women with mild to moderate incontinence are actively being treated for incontinence [325]. In a study of management of incontinence in general practice, 30% of the women who had told their doctor about their symptoms perceived that they were offered no help [335]. It is probable that many primary health care providers lack confidence in managing UI, and that this contributes to under treatment in those seeking help [338].

Only a small proportion of incontinent community-residing women have had surgery, medication, or exercise regimens [110, 327, 339-341]. In addition to seeking help from the formal health care system, common responses to symptoms of illness are self-management and self-treatment behaviour. The major method of actively managing UI among community residents is the use of absorbent products [339, 342-345]. For many women with very mild or occasional UI it is probably adequate not to seek help from the health care system. Others are satisfied with information and understanding about the causes and in many cases self-care may be quite appropriate. A Danish study has shown that simple information and advice was adequate “treatment” for 23% of the women seeking an open access incontinence clinic [346]. A Swedish study found that among 136 women with UI, 36% wanted clinical evaluation, and only 24% subsequently started treatment [109].

Both epidemiological and qualitative research in this field should be encouraged in order to understand cultural, religious, and personal factors including attitudes and perceptions of health care, for help seeking behaviour world wide [331, 333, 337].

VII. SUMMARY POINTS

1. The estimated prevalence of UI in middle-aged and older women in the general population appears to be in the range of 30% to 60% (increasing with age); while the prevalence of daily UI ranges from 5% to 15%, rising to over 15% in women over age 70 who are institutionalized. Some studies have found prevalences outside theses ranges, demonstrating that there remains a large variation in the estimated prevalence of urinary incontinence in women, even after taking into account differences in definitions, ascertainment, and demographic characteristics. At least part of this variation is likely to be due to the sensitivity of the subject and subtle differences in the conduct of studies. (LE 1)

2. Multiple observational studies have confirmed that White, non-Hispanic women have a substantially higher prevalence of stress UI than Black or Asian women that is not explained by differences in known risk factors for UI. (LE 1)

3. Pregnancy, labour and vaginal delivery (vs C-section) are significant risk factors for later UI, but the strength of this association diminishes substantially with age. (LE 1)

4. While several specific parturition factors such as instrumental delivery and birth weight are risk factors for UI in the post-partum period, their association with UI in later life is weak or nonexistent, suggesting that changes in birthing practices in developed countries are unlikely to affect UI in older age. (LE 2)

5. Additional evidence has now established body mass as an important, modifiable risk factor for UI. (LE 1)

6. Physical function also appears to be an independent risk factor for UI in older women. Whether improvement in physical function leads to a reduction in UI remains to be established. (LE 2)

7. Evidence from 2 blinded, randomised controlled trials indicate that oral oestrogen, with or without progestogen, is a significant risk factor for UI in women age 55 and older (LE 1).

8. Diabetes is a risk factor for UI in most studies. While diabetic neuropathy and/or vasculopathy are possible mechanisms by which diabetes could lead to UI, no mechanism has been established, nor is it clear whether prevention or treatment of diabetes, separate from weight reduction, will reduce the risk of UI. (LE 2)

9. Menopause, as generally defined, does not appear to be an independent risk factor for stress UI. (LE 2)
10. Hysterectomy remains a possible risk factor for later UI, but the evidence is inconsistent. (LE 2) 

11. Moderate to severe dementia in older women is a moderate to strong independent risk factor for UI (LE 2). Whether interventions to maintain or improve cognitive functioning also reduce UI has not been evaluated.

12. Mild loss of cognitive function in community-dwelling women, separated from physical function and other factors, increases the risk of UI slightly if at all, but may increase the impact of UI. (LE 2)

13. Data from twin studies suggests that there is a substantial genetic component to UI. (LE 1)

14. Other potential risk factors, including smoking, diet, depression, constipation, UTIs, and exercise, while associated with UI, have not been established as etiologic risk factors and are in fact difficult to study with observational data because of the potential for unmeasured confounding and questions of direction of the association. (LE 3).

Since the 3rd ICI in 2004, the quantity and quality of epidemiologic studies of UI has continue to increase. Most notable are the availability of prospective data from several studies that can examine risk factors for incident incontinence and a growing number of studies comparing the prevalence and incidence of UI among Caucasian, Black, Asian and Hispanic women using population-based samples and multivariate analysis. Below are several suggestions for research over the next 5 years.

- Obesity is now an established, modifiable risk factor for UI. Investigation and dissemination of strategies to reduce the risk of UI through weight control or reduction should be a priority.

- Poor physical function is a consistent risk factor for incontinence, particularly in the elderly. Whether or not it is modifiable is not clear. Intervention studies are needed to assess the impact of improvement of physical function on prevention or reduction of UI in frail elderly.

- Moderate to severe dementia is also a consistent risk factor for incontinence. Studies aimed to maintain or improve cognitive functioning should assess change in UI as an outcome variable.

- The higher prevalence and incidence of UI, particularly stress UI, among Caucasian women, compared to Black or Asian women remains unexplained. Further studies are needed to identify additional exposures or biological factors that could explain these differences.

E. EPIDEMIOLOGY OF UI IN MEN

I. GENERAL COMMENTS

The epidemiology of UI in men has not been investigated to the same extent as for females. However, progress has been made during recent years, particularly in the reporting of population-based studies of urinary incontinence among men and more specifically, of urinary incontinence associated with prostatectomy. In addition, more reports have been published on the risk factors for the development of UI in men.

In almost all community based studies, the prevalence rates of UI continue to be reported to be less in men than in women by a 1:2 ratio. The type and age distribution of UI appear to be different between the sexes, and risk factors, although less investigated in men, seem to be different from women. It is also important not to consider UI as an isolated problem in men, but rather as a component of a multifactorial problem. Often other urogenital symptoms (LUTS) such as weak stream, hesitancy, and dribbling, or erectile dysfunction, exist.

Post-prostatectomy incontinence has been studied and reported with increasing regularity in the last few years. Since radical prostatectomy is being performed with increased frequency, and incontinence is one of the main complications of the procedure, a specific review of UI in the postprostatectomy patient population is presented in this section. In addition to epidemiological studies, we included clinical trial data on postprostatectomy incontinence.
II. PREVALENCE

Several surveys from the general population have been conducted to determine the prevalence of UI in men (Table 11). Prevalences ranging from 1 – 39% have been published. The wide span of results may be explained by the variation in the population studied, the definition of incontinence used and the methods used in the surveys. A systematic review of 21 studies reported a prevalence of UI in older men ranging from 11-34% (median = 17, pooled mean = 22%). In the same review, the prevalence of daily UI in men ranged from 2-11% (median = 4%, pooled mean = 5%) [347]. A wide definition of UI, older age, inclusion of institutionalized men, and the use of self-reporting methods tend to result in higher prevalence rates [347-348].

For any definition of UI, there is a steady increase in prevalence with increasing age (Table 12).

1. INCONTINENCE SUBTYPES

Due to differences in pathological anatomy and pathophysiology of UI in men and women, there is a different distribution in incontinence subtypes. Recent studies confirmed our previous reports of the predominance of urge incontinence (40-80%), followed by mixed forms of UI (10-30%), and stress incontinence (<10%) [376] (Table 13).

The higher percentages of the urge and mixed types of incontinence are more significant in studies involving older people. In fact, the increasing prevalence of any UI by age in men is largely due to the contribution of urge incontinence rather than stress incontinence. One study demonstrated an increasing rate of urge UI from 0.7% between age 50-59, 2.7% between 60-69 and 3.4% for 70 years and older respondents. Stress UI was steady at 0.5%, 0.5% and 0.1% for the above groups respectively [356]. On the other hand, Maral and coworkers reported increasing prevalence also of SUI with age, from 0.9% between age 35-44, to 1.2% between 45-54, 3.8% between 55-64, and 4.9% at age 65 and older [353].

Most studies report a significant fraction of other/unclassified type of urinary incontinence. One study reported that a majority of men with UI had overflow and functional types of incontinence [354], while another found constant dribbling in 7% of their respondents [373]. Terminal dribbling or postvoid dribbling is another type of leakage in men that is difficult to assign to the conventional subtypes of UI. In an Australian survey, 12% of respondents reported frequent terminal dribbling [387].

2. SEVERITY

When it comes to severity, the distribution in men follows that of the women. Estimates for severe UI in older women tend to be about twice as high as for older men [376].

3. RACE-ETHNICITY

Very few studies have looked at the impact of race or ethnicity on the prevalence of UI among men. A four-country study presented lower prevalences of reported UI among men from Korea (4%) and France (7%) than in men from Britain (14%) and Denmark (16%) [349]. On the other hand, unpublished data from the MESA study did not indicate differences in prevalence among white male respondents compared to African American respondents.

4. INCIDENCE AND REMISSION

Literature on the incidence of male UI is very scarce. The MESA study [376] found a one-year incidence rate for men older than 60 years of 9-10%. In a population-based survey in the UK among men at least 40 years of age, the one-year incidence of UI was noted to be 3.8% [364]. A review of a health organization database of males at least 65 years old revealed an UI incidence of 23.8 per 1000 person years. Malmsten [360] analysed the age of onset of UI for each age cohort. Mean starting age for all men was 63 years. The mean duration was about 8-10 years in the cohorts.

Substantial remission rates for UI in males were noted by the MESA study, higher among men (27-32%) than women (11-13%) [376]. A similarly high one-year remission rate of 39.6% was noted among British males [364].

One possible explanation for the difference in the published incidence and remission rates in men compared to women, is the predominance of urge type incontinence among men, and its close relation to overactive bladder with and without incontinence. Another factor is the close association between urge UI and prostate gland disease, infections, or bowel dysfunction, all of which are relatively amenable to treatment or may improve even without treatment.

III. POTENTIAL RISK FACTORS FOR UI

There is relatively little research concerning conditions and factors that may be associated with UI in men, and clear risk factors are more seldom scientifically documented. However, a few available studies have identified potential risk factors, which are described below.

1. AGE

As in women, increasing age is correlated with increasing prevalence of UI (Table 12). Multivariate analysis in several studies has shown that age is an independent risk factor for incontinence [349, 378,

Compared to women, however, there seems to be a more steady increase in prevalence in men with increasing age.

2. LOWER URINARY TRACT SYMPTOMS (LUTS) AND INFECTIONS

In postal and telephone surveys of community-living incontinent men, a majority has experienced a variety of other medical conditions, many of which may cause or aggravate UI. LUTS like urgency, nocturia, feeling of incomplete voiding and reduced flow are typically associated with UI [352,368, 394]. In one study, UI was reported by 15% of men without voiding symptoms, frequency or urgency and by 34% of those with such symptoms [368].

Studies have also reported that urinary tract infections and cystitis are strongly associated with male UI [356, 373], with an odds ratio of 3.7 for UI in men reporting cystitis [356] and an odds ratio of 12.5 among men with recurrent infections [354]. It should be noted that reports indicating a positive association between UTI and incontinence involved men aged older than 60 years.

Studies have also reported that urinary tract infections and cystitis are strongly associated with male UI [356, 373], with an odds ratio of 3.7 for UI in men reporting cystitis [356] and an odds ratio of 12.5 among men with recurrent infections [354]. It should be noted that reports indicating a positive association between UTI and incontinence involved men aged older than 60 years.

3. FUNCTIONAL AND COGNITIVE IMPAIRMENT, PHYSICAL ACTIVITY

Mobility problems such as use of a wheelchair or aids to walking, as well as diagnosed arthritis or rheumatism or having a fall during the last year, were significantly greater among incontinent than continent men [373, 395]. A Japanese study of community dwelling men noted that UI is more likely among men whose activities of daily living (ADL) are impaired, specifically those who are unable to change clothes and unable to walk outside, with odds ratio of 17.4 and 4.36 respectively [356]. A Canadian study found odds ratios of 1.8 and 6.4 for partially and totally immobile men aged 65+, respectively, for daily UI compared to those with normal ambulatory function. Similarly, the Silver Network Home Care project among the frail older persons in Italy showed that those with higher ADL scores (i.e., greater functional impairment) had 2-4x higher odds of having UI. A survey of nursing home residents in Wisconsin identified dementia and poor ADL as risk factors for the occurrence of UI [390]. In general, most studies find similarities between men and women (see subsection on women) for functional and cognitive impairment as risk factors for UI.

Corollary to this, the association between physical activity and UI has been studied by Kikuchi and co workers among the elderly, community-based population in Japan [391]. They found that men with middle level physical activity was associated with a lower UI prevalence compared to those with low level physical activity, with an odds ratio of 0.17-0.78. High level physical activity showed similar relations but was not statistically significant.

4. NEUROLOGICAL DISORDERS

Many specific neurological diseases may lead to UI [392]. Neurogenic detrusor overactivity is seen commonly in meningo-myelocele patients and in spinal injuries, Parkinson’s disease and multiple sclerosis. Underactive bladder dysfunction due to a cauda equina lesion or diabetes might cause overflow or a paralysed pelvic floor and hence stress incontinence. Men who have suffered a stroke were at increased risk for incontinence with an odds ratio of 7.1 [356]. A case control study of age-matched long-term stroke male survivors with controls showed a higher prevalence of UI among stroke survivors compared to controls (17% vs 9%). In addition, among UI sufferers, the stroke survivors were found to have higher frequency and more leakage than controls. In a study of 235 stroke patients, the occurrence of UI correlated with motor weakness (OR 5.4), visual defects (OR 4.8, and dysphagia (OR 4.0).

5. PROSTATECTOMY

A well known iatrogenic cause of male incontinence is prostatectomy, but we do not know the attributable risk for this factor in the population of men with UI. In a Norwegian survey of elderly men with UI almost a third had undergone prostatectomy. [394].

In a cross sectional study among men in Vienna, Schmidbauer and associates identified previous prostatectomy to be associated with UI [352].

TURP seems to be followed by an incidence of stress incontinence of about 1%. A randomized controlled trial
comparing TURP, laser prostatectomy and evaporization of the prostate for benign disease showed comparable incontinence rates immediately and up to 12 months postoperatively [396].

**Radical prostatectomy** seems to induce UI at a much higher rate than TURP. The overall prevalence of post- radical prostatectomy incontinence ranges from 2 to nearly 60% (Table 14). This wide range may be explained by many factors, including differences in study characteristics, population characteristics, study site, the definition used, and the timing of assessment of continence in relation to the surgery. The era in development of the procedure has also been found to be associated to the prevalence rates [411], as well as the various procedural modifications of the surgery (see below).

Post-prostatectomy incontinence rates elicited from symptoms reported by patients are generally 2-3x higher than those from physicians’ observations. Studies that have performed both assessments in the same population confirm this observation that doctors underestimate postprostatectomy incontinence by as much as 75% [419,422-424].

Incontinence rates after prostatectomy seem to steadily decline with time and plateaus 1 - 2 years after surgery [400, 404,407-410] (Table 15). This emphasizes the need of a long follow-up period to establish continence status postprostatectomy. An actuarial study among 647 postprostatectomy men estimated UI rate of 13% at one year and 7% at two years postsurgery [425].

The **technique of radical prostatectomy** impacts on UI rates. Modifications associated with lower UI rates include the perineal approach [416, 418] and preservation of neurovascular bundle [431-433]. Bladder neck preservation affords earlier return to continence compared with bladder neck resection, but with similar UI rates after one year [405, 434]. One study showed earlier recovery of UI after tennis racquet reconstruction and bladder neck preservation compared with bladder neck resection with puboprostatic ligament preservation, but with similar UI rates at one year [410,435]. However, continence status assessed more than 12 months after surgery showed even lower rates of UI after bladder neck preservation (11.6%) compared to resection (4.9%) in one study [410]. UI after laparoscopic procedures seems to be higher initially but approximates that of open techniques by one year [427].

Older age at time of surgery has been found to be associated with a higher prevalence of post-prostatectomy UI [398, 408, 418, 43-433], one study showed a doubled risk for every 10 years of age beginning at age 40 [406]. Another study suggested that rather than absolutely affecting final continence prevalence, elderly men need a longer time to achieve continence after surgery [407]. Two studies found no relation between age at surgery and UI [423, 436].

Other factors have been found to be associated with a higher prevalence of post-prostatectomy UI, although not consistently. Such factors include prior TURP, preoperative lower urinary tract symptoms, obesity, clinical stage, PSA, prostate volume and Gleason score [398, 432-433, 437-438]. A retrospective analysis of 156 patients who had undergone preoperative MRI of the prostate and were followed up post-prostatectomy showed that time to return to continence was associated with the variation in the shape of the prostatic apex. The prostatic apex that do not overlap with the membranous urethra was found to be significantly associated with an early return of continence [438 The 5-year cohort study of the Prostate Cancer Outcomes Study found that among prostatectomy patients, race and ethnic differences was related to urinary incontinence, with African-Americans having better recovery compared to non-hispanic whites and Hispanics [439].

Adjuvant radiotherapy has not been found to affect post-prostatectomy incontinence rates when assessed beyond 1 year [Formenti 2000, Hofmann 2003, Kundu 2004].

### IV. FACTORS OF UNCLEAR ASSOCIATION WITH UI IN MEN

A 9 year study of Janssen (377) showed increasing rates of UI with increasing BMI among the older men and women. However, multivariate analysis failed to show increased BMI (overweight and obese levels) as an independent risk factor for the development of UI.

In a study including a younger population in Australia, obesity was noted to be associated with UI with an odds ratio of 3.2 (1.2-9.0) [389]. In this study, however, being merely overweight was not associated with UI.

Several studies in the older persons have shown an association between physical activity and UI among women that is not seen among men [349, 391].

1 - continence defined as 0 pads
2 - continence defined as <= 1 pad daily
Overactive bladder (OAB) is defined as the presence of urgency and frequency (either daytime or nighttime), with or without urinary incontinence (UI) [1]. OAB is often divided into OAB without UI (OABdry) and those with OAB and UI (OABwet). To find studies looking for the prevalence of OAB a search was carried out on Medline with the strategy (((Overactive bladder.mp) or (OAB$.mp)) and ((prevalence.mp) or (incidence.mp))). The studies identified in the search were then scanned to be sure they were population based (i.e. not based on doctor attendances or similar). The references to the studies found were searched for further applicable studies. The studies often used different populations and ways of selecting samples, and the definition of OAB changed slightly, although this was standardised after the 2002 ICS standardization report. The results of these studies are summarized in the table.

The prevalence of OAB in adult males varies from 10.2% to 17.4% and in females from 7.7 to 31.3 (Table 16). Clearly different definitions, the different age groups studied and maybe cultural differences affect the rates (LE 2). OABwet was less prevalent than OABdry except for one implausible looking result. The response rate was quite low in many of these studies, and sometimes it was impossible to know the response rate (e.g. when quota sampling was used).

A common finding was that the rates increased with age, but this was not universal (LE 2). Some studies found that after adjusting for state of health then the relationship with age went away, and some found that it only applied to OABwet. Usually OAB was more prevalent in females, and this was very much more pronounced for OABwet which sometimes meant that OABdry was the same for males and females. OAB was related to general health problems and in particular diabetes. It is likely to be related to urinary problems in childhood.
Faecal Incontinence (FI) is the involuntary loss of faeces – solid or liquid. Anal Incontinence (AI) includes these events as well as the involuntary loss of flatus, which is felt by many patients to be an equally disabling disorder. The discussion below will therefore focus on the broader definition: AI. A third cause of soiling or embarrassment is anal mucoid seepage, a condition that cannot be deferred by an able sphincter and intact cognition, most often caused by an organic colonic disease or dietary sensitivity, and more rarely by faecal impaction. This is the loss of fluid, sometimes feculent, often following a normal continent defecation. This is an important condition to distinguish from true incontinence because authors that report very high prevalence rates of AI include leakage in their questionnaires and thus may include these individuals with this very common symptom. However in this case there is no detectable sphincter abnormality and it is not treatable by any of the standard therapies for true incontinence: sphincter repair, neuromuscular re-education or even faecal diversion. It is in fact why we wear underclothes.

Older reports of AI prevalence have come from single institutions, and the patients described therein have been subject to referral bias when demographics and aetiology are discussed. The accuracy of AI prevalence estimates may also be diminished by difficulty in ascertaining those figures due to the common underreporting of AI and patients’ reluctance to report symptoms or to seek treatment. It has been shown that women are more willing to report AI than men. In addition, the character (incontinence of solid faeces, diarrhoea, or flatus, or merely anal seepage) and frequency (daily versus episodic) of reported AI varies greatly in each report, and indeed between individuals. So, prevalence depends heavily on the definition of AI.

**Data Sources and Level of Evidence**

Since ICI 3, New studies were sought using Medline and EMBASE using the search terms faecal, faecal, anal, incontinence, epidemiology. In addition systematic reviews were specifically sought in Medline, EMBASE and the Cochrane Library.
Because therapeutic interventions are not the subject of this chapter, and so the epidemiology is descriptive and not derived from randomised clinical trials, the level of evidence will be at best 2, and the strongest evidence will come from systematic reviews in which there was a predefined search strategy and application of quality assessment tools that were designed specifically to minimise bias in referral or ascertainment.

II. PREVALENCE

1. ADULTS

In an effort to resolve the widely varying reported prevalence figures (Table 17), two systematic reviews of the published frequencies have been done of community dwelling adults (above age 15 in the second). A summary frequency was not calculated in the first because of the marked clinical heterogeneity between reports (Table 18). The three reports that the authors judged most free of potential biases had frequencies between 11% and 15%, though only one of these three used a validated assessment instrument [461]. The degree of disability present in these 11%-15% is not known, nor even if a portion of them had only anal seepage. These high prevalences were obtained in surveys that employed anonymous self-administered questionnaires, which may not allow objective confirmation of AI or assessment of degree of disability associated with AI. The second systematic review found a range of solid and liquid anal incontinence of 0-15.2% for solid and liquid faeces, with an average across both genders and all age groups of 4.3% [462].

2. CHILDREN

The reported prevalence of AI in children can be broadly divided into two facets: in those children born with congenital anomalies of the anus and rectum - either congenital aganglionosis (Hirschprung’s Disease) or imperforate anus - and those children without congenital anomalies. Among those children and adults who were born with defects, despite surgical correction of the defect, life long defaecation difficulties are common, occurring in roughly half of affected children [463-465]. Problems with psychological health and development because of the defaecation disorder is also common in this group, as is a generally depressed quality of life [466]. These disorders are not horribly rare, occurring in 3 to 5 per 10,000 live births [467].

Among children without congenital defects of the anal canal, bowel control has been found to be complete in one Swiss cohort in 33% by age 1 year, 75% by age two and 97% by age three. Nevertheless in this longitudinal study, a quarter of the boys and one tenth of the girls had a major period of incomplete bowel or bladder control between the ages of 6 and 18. At least annual encopresis occurred in 2-3% of these children, boys more frequently than girls [468]. In the Wisconsin Family Health Survey the prevalence of AI in children from the ages of 5 and 16 years was 12/1367 (0.88%) with the gender distribution being 7 boys and 5 girls (Wisconsin Family Health Survey: unpublished data). The common disorder for all children and then adults in this discussion is faecal retention with overflow and seepage.

III. INCIDENCE

Clinical trials have provided incidence data after a therapeutic interventions, but usually without a preliminary continence assessment. This is best seen in two Cochrane reviews of therapy for anal fissure [469-470]. AI incidence rates varied widely from 0% to 30%, to flatus only, and the duration was unspecified in the trials. Medical therapy was less likely than surgery to cause AI (0.23, 0.02-2.1), and certain operations (anal stretch) were more likely to cause AI than others (sphincterotomy) (4.2, 1.9-9.4).

IV. RISK FACTORS

1. AGE

Two systematic reviews have analyses of the association of age and anal incontinence and found age to be the most significant of all assessed associations [462,471].

2. GENDER

Most discussions of the aetiology of AI have been based upon the assumption that women, particularly for individuals under the age of 65 years, are far more at risk for AI than men. Injury to the pudendal nerve or sphincter muscle from prior obstetric trauma is described as the primary risk factor [472-474], followed by irritable bowel syndrome (a disease thought to be more prevalent in women) [475], and other aetiologies such as diabetes a distant third [476]. Yet each population based-survey of the prevalence of AI has shown a surprisingly high prevalence in males (Table 17) [459-460, 477-508]. Of the two systematic reviews that looked specifically at prevalence, only one assessed the role gender played and in that review gender was not associated with incontinence in any age group [462]. Clearly, aetiologies other than childbirth must be sought.

3. OBESITY

Three recent reports have demonstrated an increased risk of AI in obese women, a Kaiser cohort, a cross sectional survey in a specialty clinic and a case control study [508-510]. One longitudinal study found a reduction in anal leakage (again not necessarily a

direct correlate with incontinence) in women after bariatric surgery and weight loss, though other factors including dietary and activity change may have been responsible for the improvement [511].

4. CHILDBIRTH AND MODE OF DELIVERY

A meta-analysis of published reports that assessed anal sphincter integrity after vaginal delivery and correlated this with continence stated that 77%-83% (depending on parity) of anal incontinence in parous women was due to sphincter disruption [512]. Three things are implied by this conclusion: first, that incontinence in men, children, of elderly onset (or even in middle aged women) and in nulliparous women, or women having Caesarean section has a completely different cause than in women who have ever delivered vaginally. There is scant epidemiologic evidence that this is the case [513]. Second, it is implied that sphincter repair would be effective treatment for anal incontinence in almost all parous women. Yet repair of disrupted sphincter has less than a perfect track record. Even more importantly, there is a reported rapid decay in function after repair that is far too great to be explained by age alone [515-522]. Third, if direct trauma to the anal sphincter (and not intra-pelvic nerves) were the major cause of anal incontinence, then Caesarean section should be effective in preventing incontinence (Figs 6 & 7).

However a systematic review has shown that this is not the case [471]. Seventeen reports have been found eligible for inclusion in the review, encompassing 16,036 women having had 3,101 Caesarean deliveries and 12,935 vaginal births as the index event prior to anal continence assessment. None of these reports demonstrated a significant benefit of Caesarean section in the preservation of anal continence. The greater the quality of the report, the closer its Odds ration approached 1.0. There was no difference in continence preservation in women who had Cesarean section versus vaginal delivery. Among the seven best studies, the NNT is 339, i.e. 339 Caesarean section would have to be performed to prevent a single case of fecal incontinence. Surprisingly, in the only reported cohort that included nulliparous women, there is an increased risk of anal incontinence in women who have had Cesarean section [480] that approaches that of women who had a vaginal delivery (Figures 6,7,8).

Forrest plots demonstrate the meta-analyses of the 7 best studies providing data on post partum fecal incontinence (quality in this instance being defined as age and parity adjustment of data, no prior vaginal delivery in the Caesarean section cohort, and assessment a long enough time after parturition to allow for perineal healing), comparisons of elective versus emergency Cesarean section and elective Caesarean section versus vaginal delivery. Summary data are presented in Table 18.

But why doesn’t Caesarean section prevent anal incontinence, especially when associating perineal trauma with loss of bowel control is not just intuitive, but sometimes visibly obvious? Certain aspects of vaginal delivery are clearly causally related to anal incontinence: significant laceration, forceps, and some episiotomies [523-524]. However this review demonstrates that other factors need to be explored. So one must look to pregnancy and not just labour and delivery as an initiating factor. Further evidence in
Figure 6: Seven of the published studies that compare fecal incontinence rates after C-section compared to vaginal delivery that are adjusted for age, parity, primipara or prior C-section only and have adequate follow up to allow for perineal healing.

Figure 7: Studies that provide data allowing comparison of fecal incontinence rates in women having elective versus emergent C-section.

Figure 8: Studies with data that allowed comparisons of fecal incontinence rates in women have only elective C-section versus vaginal delivery.
favour of this comes from the sphincter repair literature cited above. The rapid decay in function suggests that another defect is present besides a gap in the sphincter that remains after the early effects of sphincter repair wear off. What this is is not yet known, though trauma at the pelvic inlet during pregnancy or in early labour [525] seems likely.

Indirect evidence for the possibility that injury higher in the pelvis may be related to AI in pregnant women can be found in the association of hysterectomy with AI, an association seen more prominently with abdominal hysterectomy (TAH) than vaginal hysterectomy (VH), and for flatus only [526] (Odds Ratio of TAH vs. VH for faeces: 1.2, 0.3-4.7, Odds Ratio for gas: 18.9, 1.1-327). Pelvic nerve injury during surgery is the postulated reason for this difference.

5. NURSING HOME RESIDENCE

The most prominent association with AI by far is nursing home residence. Whereas the prevalence of AI is probably around 2% to 5% for community-dwelling persons, and may rise with increasing age to greater than 10%, among nursing home residents the prevalence approaches 50% [502-504]. This is partly explained by FI being one of the most common reasons for nursing home admission. In a large survey of 18,000 Wisconsin nursing home residents, risk factors for fecal incontinence (FI) were directly observed by nursing home personnel [503]. Urinary incontinence (UI) was the greatest risk factor for FI (OR = 12.6, 11.5-13.7), followed by the loss of ability to perform daily living activities (6.0, 4.7-7.7), tube feeding (7.6, 5.6-10.4), physical restraints (3.2, 4.7-7.7), diarrhoea (3.3, 2.7-4.2), dementia (1.5, 1.4-1.7), impaired vision (1.5, 1.4-1.7), constipation (1.4, 1.3-1.6), fecal impaction (1.5, 1.1-2.1), stroke (1.3, 1.2-1.5) male gender (1.2, 1.1-1.3), age and body mass index. Inverse associations were noted with heart disease, arthritis and depression.

6. DIARRHOEA

The importance of diarrhoea of liquid stool in FI cannot be overemphasized. One case series noted that 51% of individuals with chronic diarrhoea were incontinent [458]. In the Wisconsin Family Health Survey of AI [560], 10 of the 25 subjects with FI lived in Milwaukee when the city experienced an outbreak of waterborne disease [527]. Non-infectious causes of diarrhoea must also be considered, including those initiated by leisure activities such as running [528].

7. SURGERY

AI originating from surgery would seem fairly insignificant in the general population, since prior anal surgery has not been an apparent risk factor in the larger surveys. Several operations nonetheless frequently can result in AI. Examples are midline internal sphincterotomy, lateral internal sphincterotomy, fistulectomy, fistulotomy, ileo-anal reservoir reconstruction, low anterior rectal resection, total abdominal colectomy, and ureterosigmoidostomy. The risk of lateral internal sphincterotomy for anal fissure causing AI was previously thought to be insignificant when compared to midline sphincterotomy, but a recent reappraisal of this operation has shown an AI risk may be 8% [529]. The risk of AI after fistulotomy has been reported to be as high as 18% to 52% [530]. New approaches to fissure and fistula have recently been developed specifically to lower this risk [530-531]. However incontinence after haemorrhoidectomy has also been reported to be as high as 33%, an operation in which no sphincter is divided [532]. This suggests either that division of the anoderm, not the sphincter may be affecting continence, or that the method of ascertainment used in published surveys is not accurate. Mixing urine and stool has been found to have a predictable effect on anal sphincter control, as does diarrhoea, in patients having uretero-sigmoidostomy after urinary bladder resection [493].

8. SPECIFIC NEUROLOGICAL AND OTHER DISEASES

Several specific diseases have been anecdotally associated with AI in case series, and mechanisms to explain the associations have been investigated [533]. Examples are diabetes, stroke [534-535], multiple sclerosis, Parkinson’s disease, systemic sclerosis, myotonic dystrophy, amyloidosis, spinal cord injury, perforate anus, Hirschsprung’s disease, retarded or interrupted toilet training, procidentia, and any illness causing diarrhoea (HIV, IBD, radiation, infection). Many of these conditions directly affect patient mobility and ability to perform daily living activities or they cause diarrhoea or faecal impaction.

9. OTHER FACTORS AND PROSPECTIVE ASSESSMENT OF RISK FACTORS

Because of a paucity of clinical trials that specifically address risk factors and prevention of AI, the strongest available data to identify risk come from cohorts that collected data on potential risk factors prior to the onset of incontinence. The only prospectively collected risk assessments for FI have occurred in three nursing home cohorts. Porell combined UI and FI into a single outcome variable and found many positive associations in a cohort of 60,000 nursing home residents in Massachusetts [536]. Age, African American race, cognitive and ADL impairments predicted the outcome, though specific relative risks for incidence are not presented. Chassange followed 234 previously non-FI residents in France for 10 months, during which 20% had FI episodes, but only 7.5% developed long lasting FI [537]. The others had acute episodes due to diarrhoea or impaction. The factors associated with the development of long lasting FI were urinary incontinence (UI) (2.9, 1.8-4.6), decreased mobility (1.8, 1.1-3.0), and cognitive defects:
either as seen in an MMSE score <15 (2.5, 1.4-4.4) of history of dementia (2.1, 1.2-3.5). Neither gender nor age were risk factors. Nelson reported, in a cohort of 18,000 nursing home residents in Wisconsin, a subgroup of 3,850 continent of both urine and faeces in 1992 and were assessed one year later [538]. 15% developed FI. Positive associations were seen for ADL loss (3.4, 2.4-4.5), trunk restraints (2.5, 1.7-3.6), dementia (1.7, 1.4-2.0), African American race (2.1, 1.3-3.4) and age (1.02, 1.0-1.0). UI was not investigated as a risk factor because it was felt to be a co-morbid condition.

Lastly, in a broadly based cross sectional survey, it was apparent that factors that affect an individual’s general health or physical capabilities, independent of age and gender, place that individual at greatest risk for AI [475], though all four are significantly associated with AI [460]. Among obstetrical patients age has also been a consistent association, with less consistent associations noted for chronic bronchitis (OR =6.5, 1.1-3.8), symptoms of pelvic prolapse (5.0, 3.0-8.7) and obesity (3.0, 1.0-3.4) [539].

VI. PREVENTION

This discussion is by necessity descriptive, so preventive measures are only relevant insofar as they provide insight into aetiology of incontinence. By far the most frequently applied preventive measure is Caesarean delivery, discussed above. Its lack of effectiveness in preventing anal incontinence provides a valuable insight into the relationship of pregnancy and AI – that the focus may need to be more on the pregnancy rather than the delivery and how it effects defecation afterwards. A decision analysis study suggests specific obstetrical indication for elective C. section that may be cost effective [540]. Another study related to birth trauma randomized mothers to immediate post-partum anal ultrasound with repair of occult defects in the sphincter and continence assessed in follow-up, demonstrating an improved outcome with this intervention [541].

The AHRQ recently published a monograph on prevention of incontinence, though the strategies listed for AI were therapies for existing AI, such as pelvic floor exercises and retraining, rather than established mechanisms for prevention [542].

VI. SUMMARY POINTS

- Anal and urinary incontinence commonly coexist, particularly in the elderly and in nursing home residents (LE 1).
- The prevalence of anal incontinence increases with age, but is present in all age groups and both genders varying from 1.5% in children to more than 50% in nursing home residents (LE 1).
- AI is almost as common in men as in women (LE 2).
- Mode of delivery does not seem to be a significant factor in the development of obstetric anal incontinence, i.e., AI develops after Caesarean delivery as often as after vaginal delivery (LE 2).
- Obesity is perhaps the most modifiable risk factor for AI (LE 2).
- As populations age, co-morbid disease becomes a significant component of fecal incontinence risk. Surgery, neurological diseases, and stroke are examples.
- Cognitive and ADL impairment are associated with fecal incontinence.
- More population based prevalence surveys have been published.
- More analyses comparing AI after Caesarean section and vaginal delivery have been published.
- Systematic reviews of prevalence, including the role of age and gender, Caesarean delivery and decision analyses for the application of Caesarean delivery in macrosomia have been published, providing needed aggregation of data with quality assessment of existing literature.

VII. FUTURE NEEDS

- Risk factors for AI in each age group are still poorly defined
- Prevention research, much less policy, are therefore still a great distance away.
H. EPIDEMIOLOGY OF POP

I. GENERAL COMMENTS AND DEFINITIONS

Pelvic organ prolapse (POP) refers to loss of support for uterus, bladder, colon or rectum leading to prolapse of one or more of these organs into the vagina. Prolapse is thus a continuous condition when measured by visual inspection of the vaginal wall during valsalva. For clinical purposes, the degree of POP is commonly described as above the introitus, at the introitus, or beyond the introitus with or without valsalva. The International Continence Society first developed a standardised definition for the condition of POP in 1996 [543]. The ICS Pelvic Organ Prolapse Quantification (POPQ) examination defines prolapse by measuring the descent of specific segments of the reproductive tract during valsalva strain relative to a fixed point, the hymen. The POPQ system describes the anatomic findings of pelvic organ prolapse without consideration for symptoms and bother perceived by the woman. Validation of this system has shown it to be highly reliable [544]. The stages of prolapse severity are arbitrarily defined, and there is no clear differentiation between normal anatomic variation and mild POP. For research purposes there is consensus for use of the POPQ system until further evidence might clarify the distinction between normal variation and mild prolapse [545].

Determining POP based on self-reported symptoms is difficult because of the lack of specificity and sensitivity of most symptoms attributed to pelvic organ prolapse [546] and the fact that prolapse above the level of the hymeneal ring is usually asymptomatic [547]. The only exception appears to be a sensation of bulging into the vaginal [6] which is most strongly associated with prolapse at or below the hymeneal ring [549-550]. A recent study of 110 women found that a question asking about a feeling of something bulging in or dropping out of their vagina had a sensitivity of 84% and a specificity of 94% for POP at or beyond the hymeneal ring on examination [547]. Seeing prolapse would presumably be even more specific, but is too uncommon to be useful as a definition.

While not actually population-based, the women in the trial were recruited from the community rather than from women seeking gynaecological care, and provide important information on the prevalence of POP based on pelvic examination.

The prevalence of POP based on a sensation of a mass bulging into the vagina was remarkably consistent, ranging between 5 and 10 percent. The study by Eva et al., which reported a substantially higher prevalence included in the definition of POP, pelvic heaviness or digital pressure on the perineum or in the vagina to aid with defaecation [557]. The prevalence of observed prolapse in women enrolled in the WHI trial is similar to the prevalence found in the one population-based study that also used pelvic examination [558], although the prevalence of each type of prolapse was higher in the WHI study [550]. In both studies, prolapse occurs most frequently in the anterior compartment, next most frequently in the posterior compartment, and least in the apical compartment (Table 19).

Two studies that examined prolapse by race found that Black women had the lowest prevalence and Hispanic women the highest after controlling for multiple other factors in multivariate analysis [550,556]. The study reported by Rortveit et al based on symptoms found adjusted odds ratios of 0.4 (95% CI=0.2-0.8) for Black and 1.3 (95% CI=0.8-2.2) for Hispanic women, with White women as the referent group [556] [20]. Hendrix et al reported adjusted odds ratios of 0.6 (95% CI=0.5-0.8) for Black and 1.2 (95% CI=1.0-1.5) for Hispanic women compared to White women for POP based on genital examination [551].

II. PREVALENCE OF POP

Since the 3rd ICI, several additional studies have reported the prevalence of POP in a general population [551-556]. Reports from the Women’s Health initiative (WHI) Oestrogen Plus Progesterone trial, and randomized controlled trial, have been included [551,553-554].

III. INCIDENCE

Only two studies could be located that reported the incidence of new POP. Both studies were done on sub-groups of women enrolled in the WHI Oestrogen Plus Progestin Trial. The first study of 412 women enrolled at the University of California, Davis site, used a standardised pelvic examination repeated every 2 years over 8 years [551]. The incidence of new cystocele, rectocele and uterine prolapse was 9%, 6% and 2%, respectively. Annual rates of remission from grade 1 (prolapse to above introitus) was relatively common for each type of POP (24%, 22% and 48%, respectively) but less common from grade 2 or 3 (prolapse to or beyond introitus) (9%, 3% and 0%, respectively). In a second study of 259 women post-menopausal women with a uterus were examined using the POP-Q at baseline and annually for 3 years. POP was defined as prolapse to or beyond the hymeneal ring. The incidence of new POP was 26% at 1 year and 40% at 3 years, with remission rates of 21% at 1 year and 19% at 3 years [553].

* Denominator is women with a uterus

** Stages defined as 0: no prolapse, 1: prolapse to 1 cm above hymen, 2: prolapse to between 1 cm above and 1 cm below hymen, 3: prolapse between 1 cm below hymen and 2 cm above introitus, 4: prolapse beyond 2 cm above introitus.

Note: Studies reported by Handa, Nygaard and Bradley are all subsets from study reported by Hendrix.
Several studies have reported the annual incidence of surgery for POP in the US and at least one in the UK. A longitudinal study of over 17,000 women in the U.K., age 25 to 39 at baseline, reported an annual rate of prolapse surgery of 0.16% [561]. This rate is consistent with the rate of approximately 0.2% per year reported in the US [562-563]. One US study reported an annual incidence rising with age from 0.05% in women age 30-39 to 0.5% in women age 70-79 with an estimated lifetime cumulative risk of surgery from prolapse of 7% to 11% [564]. A recent US study reported similar surgical rates: 0.07% for women 18-39, 0.24% for women age 40-59, and 0.31% for women age 60-79 [565]. Surgical rates drop substantially after age 80 [564-565]. Estimating rates of prolapse surgery has the advantage of use of hospital discharge data on procedures, which is highly accurate for the procedure performed, but less accurate for the indications for the procedures, particularly when a procedure may have more than one indication.

### IV. POTENTIAL RISK FACTORS

#### 1. BOWEL DYSFUNCTION AND PELVIC ORGAN PROLAPSE

Bowel dysfunction is highly prevalent in women and comprises a wide variety of symptoms including constipation, rectal emptying difficulties, incomplete defecation, manually assisted defecation and faecal urgency. It has been estimated that up to 27 percent of the population in industrialised countries is affected by constipation. The overall prevalence of constipation and associated symptoms in women with pelvic organ prolapse range between 20-53% depending on definition of disorders[566-568]. Neurophysiological assessments have shown that damage to the pelvic floor musculature and nerve supply can occur in women with chronic constipation [569]. Although definitions of disease differ between studies, it is widely acknowledged that bowel dysfunction is a complex condition with a multifactorial aetiology. Predisposing factors comprise low socio-economic status, pelvic floor surgery, depressive disorders, thyroid dysfunction, physical disability and inactivity, and food habits [570].

Current epidemiological evidence on the association between bowel dysfunction and pelvic organ prolapse are at odds. A number of studies suggest that women with pelvic organ prolapse are significantly more likely to experience constipation and other symptoms of bowel dysfunction [568, 571-574], whereas others show a weak or non-existent association [567, 575-577]. In a case-control study, manually assisted defaecation was present in 19.7% of women with prolapse compared to 4.4% of control subjects (p<0.001) [568]. In a randomly selected population-based study, irritable bowel syndrome and constipation were both strongly associated with pelvic organ prolapse (OR 2.9 95% CI 1.7-4.8, and OR 2.5 95% CI 1.7-3.7 respectively) [573]. Varma et al. [574], suggested that among randomly selected women, having symptomatic pelvic organ prolapse more than doubled the risk of obstructed defecation (OR 2.3 95% CI 1.5-3.7). A retrospective questionnaire based survey of women with and without prolapse concluded that constipation as a young adult was an important factor in the development of uterovaginal prolapse [571]. In a case-control study, women with prolapse were at increased risk of constipation also after adjustment for dietary fibre intake (OR 2.9, 95% CI 1.1-13.5), when compared to women without prolapse [572].

In the cross-sectional Women’s Health Initiative (WHI), cystocele and rectocele were only weakly associated with constipation (OR 1.1 95% CI 1.0-1.2) [575]. Similar weak associations between prolapse and bowel dysfunction have been observed in other large cross-sectional studies [567,576-577]. Overall severity and prevalence of bowel dysfunction has shown poor correlation with findings of pelvic organ prolapse on radiological imaging [578-580]. Also at clinical examination, increasing vaginal descent and prolapse severity, show a generally weak (or absent) association with symptoms related to bowel dysfunction [566, 581-584]. In a substudy of the WHI, no specific bowel symptom was associated with increasing loss of pelvic organ support in any vaginal compartment [577]. When considering compartment-specific pelvic floor defects, most studies suggest that increasing posterior vaginal wall defects and perineal descent are correlated more to symptoms of obstructive defecation [567, 580, 582].

#### 2. PELVIC SURGERY AND POP

Even though the notion that hysterectomy increases the risk of pelvic organ prolapse has wide acceptance, longitudinal studies confirming a temporal association are few and previous studies often do not differentiate between various types of hysterectomy. A number of cross-sectional and retrospective studies implicate hysterectomy as an independent risk factor for pelvic organ prolapse. However, due to a delay of onset, large population samples and a sufficiently long duration of follow-up are required to determine an association with adequate statistical certainty.

In a nationwide prospective cohort study, Altman et al. [585] reported that 3.2% of women with hysterectomy had pelvic organ prolapse surgery, compared with 2.0% in non-hysterectomised controls, corresponding to a risk of 1.7 (95% CI, 1.6-1.7). In this study, vaginal hysterectomy had the highest risk for subsequent prolapse surgery (HR 3.8, 95% CI, 3.1 to 4.8) in comparison to non-hysterectomised controls. These data are largely in agreement with the longitudinal
Oxford Family Planning Association study by Mant et al. [586] reporting increased overall incidence rates for prolapse surgery following hysterectomy. Although not separating various hysterectomy techniques, Mant et al. determined that the risk of prolapse following hysterectomy was 5.5 times higher (95% CI 3.1-9.7) in women whose hysterectomy was performed for prolapse as opposed to other benign conditions. A history of hysterectomy has also been shown to increase the risk of prolapse in several cross-sectional and retrospective studies [587-588].

Specific risk factors for posthysterectomy prolapse have been assessed in two case-control studies. Both Dällenbach et al. [589] and Forsgren et al. [590] showed that pelvic floor surgery before hysterectomy was the strongest risk factor for developing posthysterectomy pelvic organ prolapse (OR 7.9, 95% CI 1.3-48.2 and OR 2.8, 95% CI 1.0-7.7 respectively). The risk of prolapse repair was 4.7 times higher in women whose initial hysterectomy was indicated for prolapse [589]. Vaginal vault prolapse involves the loss of vaginal apical support and can only occur after hysterectomy [591]. Marchionni et al. reported a 4.4% overall incidence of vaginal vault prolapse after hysterectomy but in women where uterine prolapse was the indication for hysterectomy the incidence was 11.6% [592].

It has also been suggested that other pelvic surgery may predispose women to subsequent genital prolapse including: rectopexy for rectal prolapse (OR 3.1; 95% CI 1.4-6.9) [593]; gynaecological surgery in general (OR = 3.9, 95% CI 1.8-8.8) [594], and retropubic colposuspension procedures are associated with a near 30% risk of subsequent vaginal vault and posterior vaginal prolapse at long-term evaluation [595-596]. In a prospective cohort study of 374 women, the 10-year re-operation rate was 17% after traditional prolapse or incontinence surgery [597]. Having undergone pelvic organ prolapse or incontinence surgery prior to the index operation increased the risk of re-operation to 17% compared with 12% for women who underwent a first procedure (p=0.04) [597].

3. GENETIC EPIDEMIOLOGY OF UI AND POP

The aetiology of female pelvic floor disorders is widely recognised to be multifactorial, yet the complex interaction between genetic predisposition and environmental influences is poorly understood. Evidence in support of a genetic influence on pelvic floor disorders derives from studies on familial transmission of disease, studies on ethnic group diversity and twin studies.

4. FAMILIAL TRANSMISSION

A large number of studies suggest that the risk for urinary incontinence “runs in the family” [598-603]. In the Norwegian Nord-Trendelag health survey (EPINCONT), daughters of mothers with urinary incontinence had an increased risk of stress incontinence (RR 1.5, 95% CI 1.3 to 1.8), mixed incontinence (RR 1.6, 95% CI 1.2-2.0), and urgency incontinence (RR 1.8 95% CI 0.8-3.9) [600]. Although study methodology and the magnitude of the risk estimates vary, studies on familial transmission of incontinence are in agreement: having a first degree female family member with stress urinary incontinence increases the risk for an individual becoming afflicted by the same disorder [604].

There is far less evidence to support the familial transmission of pelvic organ prolapse. In a case-control study, Chiaffarino et al. [605] showed that in comparison with women whose mother or sisters reported no prolapse, the risk for prolapse was higher in women with mothers (OR 3.2 95% CI 1.1-7.6) or sisters (OR 2.4 95% CI 1.0-5.6) reporting the condition. In young women (≤45 years of age) who had been operated on for prolapse, the familial incidence of genital prolapse was about 30% [606].

It is, however, a common misunderstanding that familial aggregation of any pelvic floor disorder invariably is a result of genetic factors. Risk estimates derived from family members in most cases cannot distinguish between heritability and non-inherited (environmental) factors in the family environment. Familial environmental influences which may have a direct effect on transmission of risk for stress urinary incontinence and pelvic organ prolapse includes smoking habits, socio-economic status, care seeking behaviour, attitudes towards physical exercise, dietary and drinking habits, and toilet training.

5. ETHNIC AND RACIAL INFLUENCES

The variation of disease occurrence in groups of different racial origin yet similar environmental exposures, lend support to the presumed genetic influence on the causation of benign pelvic floor disorders. This again provides circumstantial evidence for a genetic contribution to pelvic floor disorders since most of these studies have been unable to control for heritability in relation to the complex interaction of environmental factors.

There is consistent evidence to suggest that Caucasian women are at increased risk of stress urinary incontinence when compared to African-American women [607-610]. In a consecutive analysis of women referred for gynaecological care, Caucasian race increased the risk for stress urinary incontinence by two-fold (OR 2.2. 95% CI 1.3-3.7) when compared to African-Americans [611]. Three studies report higher risk of symptoms associated with overactive bladder in African-American women when compared to Caucasians [608-609, 611].

In cross-sectional studies from the US, African-American ethnicity conferred a significantly lower risk (OR 0.4 95% CI 0.2-0.8) [573] and Asian-Americans
had a higher risk of pelvic organ prolapse when compared to Caucasians (OR 1.4 95% CI 1.1-1.9 [612]). In women presenting for routine gynaecological examination 67% of Asian-American patients had stage 2 or greater prolapse as compared to 26% of African-American and 28% of Caucasian patients [612]. In the WHI, Hispanic women had the highest risk for uterine prolapse (OR 1.2 95% CI 1.0-1.5) and African-American (OR 0.6 95% CI 0.5-0.8) the lowest when compared to Caucasians [575]. Also within racial groups, the risk may differ as shown when comparing prevalence of pelvic organ prolapse between tribes in rural Gambia [613].

6. TWIN STUDIES

By comparing monozygotic female twins with identical genotype, and dizygotic female twins who on average share 50 percent of their segregating genes, the relative proportions of phenotypic variance resulting from genetic and environmental factors can be estimated. A genetic influence is suggested if monozygotic twins are more concordant for the disease than dizygotic twins whereas evidence for environmental effects comes from monozygotic twins who are discordant for the disease.

Recent studies in twins have indeed suggested a genetic influence on the phenotype for pelvic floor disorders [614-616]. However, studies based on volunteers are liable to bias since pairs who are concordant for the disease, are more likely to participate [617]. Only recently have large-scale population based genetic epidemiological studies in twins become available which clearly suggest a genetic contribution to pelvic floor disorders while controlling for both shared and non-shared environmental risk factors [618]. For both stress urinary incontinence and pelvic organ prolapse the genetic variation in liability to develop surgically managed disease after adjusting for age and parity was estimated to be about 40%. Recognising the considerable environmental effects and that heritability estimates in twins are likely to represent the upper limit of the genetic effects, [619-620] the influence of genetic factors should not be overstated. The role of gene-by-environment interactions, i.e. that certain genes may increase the risk for pelvic floor disorders only when the individual is exposed to a specific risk factor, remains to be decided and further complicates attempts to determine the genetic effects [621].

7. CANDIDATE GENES

A number of candidate genes which may be involved in the heritability of pelvic floor disorders have been investigated. Polymorphisms of the collagen type I gene have been shown to increase the risk of stress urinary incontinence, [622] and knock-out of the nitric-oxide-syntase gene in mice results in voiding disorders [623]. Mutations in lysyl-oxidase-like-1 gene is associated with pelvic organ prolapse [624]; ATP receptor P2X3-deletion in mice increases bladder capacity and reduces urinary frequency; and polymorphisms of the endothelin-1 gene may be involved in pelvic organ prolapse [625-626]. Polymorphisms in the promoter segment of laminin gamma 1 gene increases the susceptibility for early-onset pelvic organ prolapse [627]. Other candidate genes are almost certainly waiting to be discovered and results are so far of a preliminary nature.

8. OBSTETRICAL FACTORS AND POP

The debate on the importance of mode of delivery and obstetrical events to the development of pelvic floor disorders later in life is largely unresolved. For ethical and practical reasons, randomised controlled trials to study the causal effects of vaginal versus caesarean delivery will never be performed. Observational studies will therefore most likely remain the main source of knowledge on this subject. Nonetheless it is widely accepted that childbirth is a significant risk factor for pelvic organ prolapse, presumably due to overt or occult pelvic floor tissue trauma. Controversy does, however, remain with regard to the protective effects of Caesarean section and if specific obstetrical events should be considered as risk modifiers. Due to a delayed onset of pelvic organ prolapse in relation to giving birth, studies on the subject need a long duration of follow-up as well as large study populations to be able to elucidate the possible causative events. Therefore, the majority of studies on the subject are typically designed as cross-sectional surveys or retrospective cohort or case-control studies.

Pregnancy in itself has been identified as a risk factor for stress urinary incontinence. With regard to pelvic organ prolapse, the association is less well substantiated. In a clinical case-control study, all 21 nulliparous non-pregnant women had POP-Q stage 0 or 1, whereas 47.6% of 21 nulliparous pregnant women had pelvic organ descent corresponding to stage II (p<0.001) [628]. Overall POP-Q stage was higher in the third trimester than in the first (p=0.001). Also Sze et al. [629] found that in 94 nulliparous women evaluated at the 36 week antepartum visit and six weeks postpartum, POP-Q staging increased.

A large number of studies identify childbirth as one of the strongest predictors for developing pelvic organ prolapse later in life [573, 575, 586, 588 629-633]. It is also a recurrent observation that number of deliveries is associated with the risk for prolapse. In the prospective Oxford Family Planning Association study [586], childbirth was the single strongest risk factor for developing prolapse in women under 59 years of age and the risk increased by every delivery. Similar findings derived from the WHI [575], where a parity of one conveyed an overall two-fold risk increase for prolapse compared to having no children, after which
A wide variety of risk factors for pelvic organ prolapse, other than those addressed above, have been identified in the literature. Most of these have been investigated as part of larger multivariate analyses based on cross-sectional surveys or retrospective case-control studies. Overall, the evidence for these associations are largely of level III-IV and further research is needed to disentangle the effects and interactions of environmental risk factors for prolapse.

Several somatic risk factors for pelvic organ prolapse have been identified. Generalised connective tissue disorders such as Ehlers-Danlos disease and Marfans syndrome [636-637] have been linked to an increased risk of pelvic organ prolapse. In a community-based study of prolapse in rural West Africa, chronic anaemia was the strongest risk factor for prolapse after parity and age (OR 2.1 95% CI 1.1-3.4) [613] and chronic obstructive pulmonary disorders. Skeletal abnormalities such as thoracic kyphosis, lumbar lordosis and pelvic dimension changes have been associated with an increased risk for prolapse [638-639]. Women with joint hypermobility have a significantly higher prevalence of genital (and rectal) prolapse in comparison to women with normal mobility [640-641]. Weak associations have also been shown for osteoporosis and rheumatoid arthritis [634]. Variates that did not demonstrate any significant linkage to prolapse includes body mass index [642-643], the presence of chronic obstructive pulmonary disease and diabetes mellitus [587, 643]. Pulmonary impairment has been shown to be more common in women with loss of pelvic organ support compared to those without [644].

A low educational level (OR 2.16, 95% CI 1.10-4.24) [645] and low annual income [646], are socio-economic factors which have been associated with an increased risk for pelvic organ prolapse.

In 21,449 non-hysterectomised Italian women, higher education was associated with a protective factor for uterine prolapse [635]. However, despite significant differences in educational level, smoking habits, alcohol consumption, and socio-economic indices, the prevalence of pelvic organ prolapse did not differ between Croatian urban and rural women [647]. Physically strenuous occupation have also been shown to influence the risk for pelvic organ prolapse. In a register based study of 28,000 Danish assistant nurses exposed to repetitive heavy lifting, the risk for prolapse was higher among the nurses compared to controls (OR 1.6 95% CI 1.2-2.2) [648].

Women who were labourers/factory workers had significantly more severe prolapse than other job categories (p < 0.001) in a cross-sectional study of women presenting for routine gynaecological care [646]. Also, hard physical training may increase the risk for prolapse as women attending paratrooper training, were more likely to present stage II prolapse compared to controls (RR=2.7 95% CI 1.4-5.4) [649].
Most studies have used a cross-sectional design and there is limited longitudinal data to suggest a causal relationship between symptoms of obstructed defaecation and pelvic organ prolapse or vice versa.

Posterior vaginal wall prolapse and perineal descent are the compartment specific defects most clearly associated with symptoms of obstructive defaecation.

A number of studies suggest that hysterectomy and other pelvic surgery may increase the risk for pelvic organ prolapse (LE 2).

Hysterectomy due to pelvic organ prolapse and other pelvic floor surgery are the strongest predictors of secondary pelvic floor surgery (LE 2).

Stress urinary incontinence and pelvic organ prolapse have familial transmission patterns mediated by either genetic or environmental factors (LE 2).

Stress urinary incontinence is more common in Caucasian women, and pelvic organ prolapse in Caucasian and Hispanic women when compared to African American women (LE 2).

Twin studies suggest that heritability contributes to the liability of developing pelvic floor disorders but environmental effects are substantial.

Childbirth is associated with an increased risk for pelvic organ prolapse later in life. Current evidence also suggests that increasing number of childbirths increases the risk (LE 2).

It remains undecided if caesarean section prevents the development of pelvic organ prolapse but most studies indicate that caesarean is associated with a decreased risk for subsequent pelvic floor morbidity in comparison to giving vaginal birth (LE 2).

There is a dearth in the understanding of how specific obstetrical events and the process of labour and delivery affects the risk for pelvic organ prolapse.

Life style factors and socio-economic indices appear to be associated with the risk for pelvic organ prolapse.

A number of somatic diseases and conditions have been linked to the occurrence of prolapse but the cause-effect relationship is undetermined.

The discussion here relates to UI only, as data and literature for FI and POP are very scarce. However, many of the principal arguments will be relevant to these conditions as well.

**I. GENERAL PROBLEMS IN SURVEY RESEARCH**

The well documented variation in prevalence estimates is thought to result at least in part from several confounders common to survey and epidemiological research. Herzog and Fultz[73] in a review of the prevalence and incidence of UI in community-dwelling populations, proposed that past investigations were plagued by sampling and non-response issues, by self selection and attrition, by definitional, conceptual, and measurement issues. Comprehensive reviews about measurements and methodological aspects of investigating UI are provided.[361] It is clear that there are large methodological challenges to rigorous research in this field. In general, quality of recent large studies has undoubtedly improved, but the scientific community must continue to deal with methodological challenges in order to achieve progress.

**II. DIFFERENT DEFINITIONS AND MEASUREMENT**

A major problem in research on UI has been the use of different definitions and measurements, and this might contribute to the wide range of reported prevalence estimates. The former ICS definition of UI – as a condition in which involuntary loss of urine is a social or hygienic problem and is objectively demonstrable - included objective demonstration of urine loss as one critical component. This aspect limited the ICS definition for community based epidemiological investigations, because objective demonstration of UI is difficult to achieve outside of the clinical setting, and studies which were able to include this aspect in their assessment might have produced different prevalences. In addition, a social or hygienic aspect of the definition was problematic in epidemiologic studies because it added a subjective aspect to an objectively defined condition and therefore confounded the investigation of prevalence, incidence, and risk factors. In our previous report[2] we argued for reconsideration of the definition of UI, and we emphasized that the core of the definition should be "any involuntary loss of urine". In accordance with this view, ICS changed its definition in 2001 to UI being "the complaint of any involuntary leakage of urine"[1].
The new definition makes epidemiological research easier. But three consequences should be addressed:

1. Epidemiological studies should not be based on this definition alone, and all studies should include a minimal additional data set, standard confounders, and questions specific to the aim of the study. This is discussed in the Section on Recommendations for further research.

2. The number of persons fulfilling the definition will increase. This should not be interpreted as an increase in the number potential of patients.

3. Public awareness, case finding of health care personnel, and help seeking behaviour may be affected of a new and more extensive definition.

Studies have used different severity levels and time frames for defining UI. A factor further complicating the conceptualization and measurement of UI in epidemiologic studies lies in the nature of the condition. UI is a chronic condition (or set of conditions) that often starts slowly and comes and goes for a considerable time period before it become fully established.[361] If people get used to their UI or notice it less, this can interfere with valid assessment.

Ideally self-report measures are validated by clinical evaluations. However, clinical and even urodynamical investigations should be regarded as other measures, not necessarily as gold standards, because it is known to be difficult to demonstrate all urinary symptoms in the clinical setting.

Holteledahl[212] calculated prevalence estimates using different definitions of UI for the same sample of 50 to 70 year old women. The prevalence of any self-reported leakage was 47%. Self-reported regular UI with or without objective demonstration was found for 31% of women, regular incontinence according to the former full ICS definition for 19%. Another study found prevalences of 69% and 30% for any UI and the former ICS definition, respectively [33]. The results indicate that the former ICS definition was rather restrictive.

Low response rates may further bias prevalence estimates.[361] Known differences between responders and non-responders can be compensated during the analysis. The major problems is unknown differences in response rates and other characteristics. Incontinent women may not answer (or deny UI) because of embarrassment or related handicaps. But incontinent women may also find the subject particularly relevant and therefore respond to a greater extent than continent women. At present, we do not know much about how these factors may affect the comparison between incontinent and continent women.

One paper explored the problem of underreporting incontinence and how it can be altered with the use of an introduction to the incontinence questions and probing.[79] Another paper explored the issue of selection bias in mailed surveys. The first wave had higher prevalence of incontinence than follow-up mailings, and thus individuals with UI tended to respond on the first wave.[657] In an English mailed survey on incontinence and other urinary symptoms, a sample of non-responders were traced, and those eligible were asked questions from the survey.[658] Compared with the responders, the non-responders overall showed little differences in reporting of urinary symptoms. However, non-responders >70 tended to be of poorer general health, and they reported certain urinary symptoms more frequently.

### III. SUMMARY POINTS

- The lack of epidemiological data from populations underrepresented in research limits the world wide application of the present information.
- Many investigations are plagued by sampling and non response issues, by self selection and attrition. Many early studies were obtained from sampling patients seeking care.
- A major problem is the use of different definitions of incontinence. The new ICS definition makes epidemiological research easier.
- There are large methodological challenges to research in the field of UI. Unless the scientific community deals with these issues, progress will be difficult to make.

### J. HELP SEEKING BEHAVIOUR

A majority of people with UI have not sought help,[78, 81, 333, 340, 342] and this is confirmed also in recent publications.[322, 326, 327] Reasons given by people for not seeking help include: not regarding incontinence as abnormal or serious,[78, 330] considering incontinence to be a normal part of ageing,[335] having low expectations of treatment[78, 330] and thinking they should cope on their own.[501, 497] Some studies also confirm the notion that embarrassment may be an important reason for not seeking help.[332-334] There is an association between help seeking and condition-specific factors like duration, frequency and amount, and people's perceptions of the impact of incontinence,[78, 81, 358, 359, 322] but other more personal characteristics like individual health care behaviour and attitudes may also play a role.
In a Norwegian study 4.4% of all women >20 years old in a community consulted their general practitioner for UI during a 3 year period. But mentioning the symptoms to a physician may not be enough. There are reports of doctors not responding, either by ignoring the statement of symptoms or by providing a dismissive explanation, and people interpreting a lack of response from the doctor as an indication that no treatment is available. In a study of management of incontinence in general practice, 30% of the women who had told their doctor about their symptoms perceived that they were offered no help. It is probable that many primary health care providers lack confidence in managing UI, and that this contributes to under treatment in those seeking help.

Only a small proportion of incontinent community-residing women have had surgery, medication, or exercise regimens. In addition to seeking help from the formal health care system, common responses to symptoms of illness are self-management and self-treatment behaviour. The major method of actively managing UI among community residents is the use of absorbent products.

It is obvious that millions of men and women suffer from their UI, and that for many of them good treatment options are available. However, for many persons with very mild or occasional UI it is probably adequate not to seek help from the health care system. Others are satisfied with just information and understanding about the causes and in many cases self care may be quite appropriate. A Danish study has shown that simple information and advice was adequate “treatment” for 23% of the women attending an open access incontinence clinic. A Swedish study found that among 136 women with UI, 36% wanted clinical evaluation, and only 24% subsequently started treatment.

Both epidemiological and qualitative research in this field should be encouraged in order to understand cultural, religious, and personal factors for help seeking behaviour worldwide. Specifically, other than condition-specific factors should be further explored, e.g. persons’ health care behaviour, perceptions and attitudes.

II. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

There are indications of underreporting also of FI and patients’ reluctance to report symptoms or to seek treatment. It has been shown that women are more willing to report FI than men. For POP we have no information.

III. SUMMARY POINTS

- Recent publications confirm that a majority of people with FI, UI, and POP have not sought help.
- Only a small proportion of urinary incontinent community-residing people have had surgery, medication, or exercise regimens.
- Increasing severity, increasing duration, and urge/mixed type of UI are related to consulting a health care provider.
- Associations other than condition-specific factors should be further explored in future research, e.g. persons’ health care behaviour, perceptions and attitudes.
- Health care personnel should be encouraged to approach persons at risk for FI, UI and POP. People with such symptoms should be assessed so services and treatment can be offered and targeted. The patient’s view of management, even denial, should be respected.

K. EPIDEMIOLOGY AND CLINICAL WORK: FROM RESPONDENT TO PATIENT

We have emphasised some major and important differences between epidemiology and clinical work. These differences may have several implications. A selection process is most often accomplished first by self-selection (help seeking), then a referral system, which provides specialist physicians to a patient population with higher prevalence of disease, more severe disease, and often skewed type distribution, thus obtaining test results with fewer false positives, better diagnostic accuracy, and more efficient use of resources. However, such intended and purposeful selection bias has its drawbacks. There is growing evidence that this selection process introduces bias into research and hampers our ability to generalize hospital based research back to general or primary care populations. Furthermore, it may result in recommendations and guidelines for diagnosis or therapy derived from tertiary care centres that are inappropriate at the primary care level. Often guidelines, review articles or teaching material do not take into account the varying prevalence and variation in clinical picture between community and hospital. They may also emphasise use of tests or equipment that are not appropriate or relevant for primary health care, thus leading to over utilisation of referrals. Data from hospitals or specialist level may also overestimate level of burden, costs and number of persons in need of treatment if such data are used for extrapolation.
back to community level. Therefore it is important that this Consultation uses different algorithms for initial and specialised care (see other relevant chapters).

One study provides substantial empirical evidence to support the existence of selection bias for UI.[322] The analyses were based on three populations of incontinent women: Community level (epidemiological survey), primary care level (prospective study), and secondary care level (university hospital, prospective study). The general practice patients were older and the hospital patients younger than those in the community. From community via general practice to hospital, there was an increase in duration, frequency of leakage, amount of leakage, severity and perceived impact of incontinence. Help-seeking at the primary care level was associated with increasing age and severity, and with urge symptoms and impact. Referral from general practice to hospital was only associated with (lower) age and urge symptoms.

Under the subtitle Severity and impact we have given examples of how the prevalence estimates for women change dramatically when bothersomeness and severity are considered. Taken together with selection bias, this emphasises caution when epidemiological data are used in a clinical context. It concerns “level of care” in several ways; there is a large transitional zone from healthy to diseased, there is a danger of medicalisation, and there is a danger of treating patients at a higher level than necessary. Risk factors, predictors and correlates discovered in epidemiological studies are probabilistic of nature and may not be decisive in the clinical assessment of an individual patient. In addition, the attributable risk due to some known risk factors may be statistically but not clinically significant.

The objective of the study was to estimate the current and future number of people with LUTS, including overactive bladder (OAB) and Urinary Incontinence (UI) utilising the current ICS definitions. Age- and gender-specific prevalence rates from the EPIC study[651] were applied to the worldwide over 20 year old population (4.2 billion) with males and females stratified into five-year age groups (20-24 to 80+). Projected population estimates for all worldwide regions were based on the United States Census Bureau International Database (IDB)[652].

Estimates were presented for 2008, 2013 and 2018 and are summarised in Tables 20 and 21. Table 21 summarises the estimated number of individuals with certain LUTS symptoms by year and sex in the world population and Table 22 describes the estimated number of individuals of LUTS and OAB over 10 years across the world regions.

Estimates and projections featured in this analysis were based on prevalence rates of LUTS described in the EPIC study – based primarily on a European population. The prevalence rates featured in the EPIC study are similar to other prevalence rates of LUTS that were found in others studies across other countries [653-654].

The projections in this report assume the prevalence rates of LUTS will remain throughout the year 2018 for all age and sex groups (Figure 9).

Prevalence of LUTS will also increase as other factors related to LUTS, such as obesity, increases. The estimated number for present and future years are not true numbers but are based on a projected population configured by the International Database (IDB). The IDB’s estimates and projections are drawn by Census Bureau demographers and are based on reviewed censuses, surveys, and vital statistics provided by National Statistics Offices [9]. Data on international migration and refugee movements, public health efforts, socio-political circumstances, and historical events such as natural disasters and conflict are all considered when the IDB calculates the estimates and projections (Figure 10).

It is anticipated that with the overall aging of the population the prevalence of LUTS will also increase. It has been shown that LUTS are burdensome to individuals [655-656] and the likely increase in the number of individuals experiencing. LUTS has implications on healthcare resources and overall health burden. This analysis is an estimate of the number of individuals with LUTS based on a conservative prevalence rate, and so the future number of those with certain LUTS may surpass those of this report (Table 22).

I. WORLDWIDE ESTIMATES OF CURRENT AND FUTURE INDIVIDUALS (≥20 YEARS) WITH LOWER URINARY TRACT SYMPTOMS INCLUDING URINARY INCONTINENCE AND OVERACTIVE BLADDER

In order to effectively plan health care resources it is necessary to estimate the prevalence and incidence of illnesses to know to what extent resources require to be allocated to a specific illness health care condition. This chapter has dealt with three major global problems, urinary and faecal incontinence as well as pelvic organ prolapse, that affect women and men throughout the world. At the ICI meeting in Paris data were presented regarding worldwide estimates of current and future individuals (≥20 years) with LUTS including urinary incontinence and overactive bladder [650].

Figure 9: Estimated number of individuals with UI 2008, 2013 and 2018 grouped according to gender [650].

Figure 10: Estimated number of individuals with LUTS 2008, 2013 and 2018 grouped according to gender [650].
Much biomedical research is observational and the reporting of such research is often inadequate which hampers the assessment of its strengths and weaknesses and of a study's generalisability. The STROBE (Strengthening of the Reporting of OBservational studies in Epidemiology) statement was introduced [661]. It is a checklist of items that should be addressed in articles reporting on the three main study designs of analytical epidemiology: cohort, case-control, and cross sectional studies. The use of this checklist is highly recommended.

II. SUMMARY POINTS

- The spectrum of severity of anal and urinary incontinence, as well as pelvic organ prolapse, and the symptom profile of patients referred to specialist centres do not necessarily reflect the spectrum of disease seen in the community.
- The selection and referral process may introduce bias into research and hamper the ability to generalise hospital-based research back to primary care populations.
- One should be very careful with calculating numbers of patients in need of therapy based on epidemiological data.

I. RECOMMENDATIONS FOR FURTHER RESEARCH

Much biomedical research is observational and the reporting of such research is often inadequate which hampers the assessment of its strengths and weaknesses and of a study’s generalisability. The STROBE (Strengthening of the Reporting of OBservational studies in Epidemiology) statement was introduced [661]. It is a checklist of items that should be addressed in articles reporting on the three main study designs of analytical epidemiology: cohort, case-control, and cross sectional studies. The use of this checklist is highly recommended.

I. URINARY INCONTINENCE

It is recommended that more sustained research on measurement of UI should be performed including, its
types and severity to move the research ahead. Longitudinal study designs are needed to estimate incidence of UI and describe the course of the condition and its different forms and to investigate its risk factors and possible protective factors.

There is still little knowledge with regard to prevalence, incidence, and other epidemiological data in developing countries. It is recommended that fundamental research regarding prevalence, incidence and other epidemiological data in developing countries should be encouraged, and tailored to the cultural, economic and social environment of the population under study.

Crude prevalence studies (descriptive epidemiology) from USA and Europe are abundant, and further studies should be done only with recommended and validated questionnaires or in order to combine data from the prevalence study with studies of co-factors and predictors (analytical epidemiology). Control for confounders, stratification, and multivariate techniques should be increasingly used because of the need for more advanced epidemiological analyses of risk factors and comorbidity. Strength of associations should be determined by relative risks and odds ratios, and confidence limits should be given. We have still very little knowledge of the absolute and relative importance of several risk factors, and almost no information about the attributable risk of the factors in the society.

Some potential risk and protective factors deserve more attention. For example, the role of pregnancy and childbirth in the development of UI must be studied in a fashion that links population-based methods to clinical assessment of pregnancy, delivery and the birth trauma and follows women over many years. Such a design is necessary because the effect of pregnancy and childbirth may become clear only years later when the woman is older and because the woman will not be able to report the exact nature of the tear or episiotomy, etc. There should be more emphasis on the associations between UI and specific diseases like stroke, diabetes, psychiatric disease and genital prolapse. Genetic components should be investigated.

Primary prevention is the main goal in the management of human disease. An important strategy would thus be to identify the individuals at risk, and then take measures to reduce the risk among those individuals or in certain risk groups. Based on current knowledge there are no well documented efforts that can be done in order to avoid the occurrence of UI in large populations. Primary prevention studies should be encouraged, but the epidemiological basis for choosing appropriate interventions is weak.

In surveys based on questionnaires or interviews symptoms can be registered. There are convincing data suggesting that the different types may reflect quite different pathologies and risk factors. Differentiating the types in future research might therefore prove very fruitful. Methodological work has still to be done in this area, but typical type descriptions should be included in new studies. Likewise, studies of risk factors should include important and known confounders such as age, parity, and weight.

Variations in definitions and measurement issues are fundamental and lead to problems with assessing the findings in epidemiological studies. We need to improve epidemiological studies by including variables that better characterise UI, so that more advanced and informative analyses may be conducted. It is therefore recommended that all epidemiological studies include a minimum data set (Table 23), including elements of screening question, frequency measure, quantity of urine loss, duration, type, and severity. In addition, it is recommended that validated measures of bother/quality of life and urinary symptoms other than UI should be included. We here also refer to the chapter from the committee on symptom and quality of life assessment.

In addition, it is recommended that validated measures of bother/quality of life and urinary symptoms other than UI should be included.

Table 23. Elements in a minimum data set recommended for all epidemiological studies

- Screening question for any involuntary urine loss
- Frequency measure. For example, classification into categories of none, less than once a month, one/several times a month, one/several times a week, every day/nigth, all the time
- Quantity of urine loss for a typical episode. For example, classification into categories of none, drops, small amounts, moderate amounts, much/a great deal
- Duration. For example months, years
- Type. Based on typical description; stress, urge, mixed and other
- Severity. Either by combining existing questions or by a validated index

II. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

In these areas there is a need for more epidemiological research in all areas; prevalence, incidence, and risk factors. Many of the fundamental methodological issues relevant to UI discussed above are highly relevant to the fields of FI and POP.

The committee emphasises that uniform definitions of

## REFERENCES
This aim of this report is to describe the cell and tissue physiology and biochemistry of the lower urinary tract that will help to understand the pathophysiology of the overactive bladder and lower gastrointestinal (G-I) tract and to highlight potential avenues whereby the conditions may be better managed. The report will attempt to explain the most important features of the lower urinary and G-I tracts, and describe important changes that are associated with functional disorders. It is not always possible to differentiate between primary and secondary changes to tissue that are associated with tract dysfunction but this is not necessarily important if potentially useful targeted models are identified that may be used to develop new therapeutic and other approaches to manage urinary and faecal incontinence.

Since the previous consultation [1] there has been considerable advance in our understanding of the lower urinary and G-I tract, particularly with respect to the bladder. In particular the urothelium has emerged as an important tissue in mediating lower urinary tract sensations, and the principles learnt may in the future be applied to the G-I tract. Equally, our understanding of the mode of action of some useful drugs and a greater understanding of their molecular targets has been radically altered, which should enable the development of better-targeted drugs. Figure 1 shows a diagrammatic representation of the bladder wall with some of the structures and receptors that will be described in the following sections.

Increased understanding of these tissues has also facilitated tissue-engineering approaches to develop functional implants and recent advances will be described. This report has attempted to reflect these advances. It will refer to the previous report when basic principles were described, and when some aspects were discussed in depth and re-examination might be repetitious. All referenced material is from peer-reviewed publications, most of which have appeared after the previous consultation [1].

II. THE UROTHELIUM AND SUBUROTHELIUM

1. INTRODUCTION

The previous report [1] concentrated on the structure

Figure 1: Schematic representation of the bladder wall and its principal nervous connections. The different layers are shown with some of the main pathways and receptors denoted. Positive (+) implies stimulatory and negative (−) implies inhibitory.
as well as the transport and barrier functions of the urothelium, and those factors that may alter the permeability of the membrane. In the intervening period the urothelium has been increasingly recognised also to have secretory functions that allow it to behave as a sensory and signaling structure, influencing the activity of both nerves and also underlying tissue layers. In this mode it interacts closely with the underlying suburothelial layer so that the whole structure can be regarded as a functional unit. Figure 2 shows the structure of the urothelium. Below the basal cells of the urothelium is a connective tissue layer, sometimes referred to as the lamina propria, in which is embedded a rich network of capillaries, unmyelinated and myelinated nerves and a functional syncitium of interstitial cells (myofibroblasts).

2. THE UROTHELIUM: CHANGES IN DISEASE AND BACTERIAL INFECTIONS

The urothelium consists of three layers: i) an apical (umbrella) cell layer with a very low permeability to urine and pathogens; ii) an intermediate layer; and iii) a basal layer that interacts with the extracellular matrix of the suburothelial region for structural support. The barrier is determined by: the low mobility of the aliphatic chains in phospholipid molecules (high degree of saturation, high concentrations of sphingomyelin and cholesterol) [2]; segregation of low mobility lipids into the outer leaflet of the apical membranes [3]; the presence of uroplakin proteins in the apical membrane and the presence of tight junctions between adjacent cells [4,5]. When the bladder is empty, large numbers of vesicles underlie the apical membrane. As the bladder fills, these vesicles are inserted into the apical membrane to maintain a constant relationship between the area of apical membrane and the volume of the bladder. The role of uroplakins and defects in their structure in relation to lower urinary tract anomalies remains unclear. Ablation of the uroplakin-II gene in mice [6] or loss of uroplakin expression in patients with myelomeningocele [7] led to hyperplastic growth of the urothelium and may interfere with the development of underlying smooth muscle. In addition, UPIII expression is a powerful prognostic factor in patients with upper urinary tract urothelial carcinoma [8].

Uropathogenic *Escherichia coli* (UPEC) is the main causative agent for urinary tract infections in women [9]. With animal models of cystitis UPEC have part of their pathogenic cycle as an intracellular phase within urothelial cells where replication and formation of bacterial communities occurs [10], before exiting the host cell. Invasion is facilitated by adhesive fibres - type-I pili [11]. Thus, UPEC can form hidden intracellular reservoirs of bacteria that can persist for several weeks that may be protected from antibiotics. Whilst much of the formative work has been carried out on animal models, recently intracellular bacterial communities from exfoliated urothelial cells have been detected in the urine of patients [12].

3. SECRETORY AND SIGNALING PROPERTIES OF THE UROTHELIUM/SUBUROTHELIUM

In recent years the ability of the urothelium to respond to stimuli such as stretch and osmolarity changes, and its release of various chemical factors including substance P [13], nitric oxide (NO) [14], ATP [15] and ACh [16], has been recognised. Histological studies have shown there are many sensory neurons located in the urothelial/suburothelial region that label for receptors to these factors, or contain sensory peptides. Moreover, the extent of labeling is altered in conditions that result in bladder overactivity, or in the presence of agents designed to attenuate the condition [17-20]. The proximity of these afferent nerves therefore implies that they could interact with the urothelium to detect changes in bladder fullness. Urothelial cells themselves also express sensory receptors typically found on primary afferent nerves; including P2XY receptors [21,22], TRPV1,2,4 [23,24], TRPA1 [25], TRPM8 [26], B1,2 bradykinin receptors [27], adrenergic
receptors [14,28], nerve growth factor receptors [29] and amiloride-sensitive Na⁺ channels [30-32].

One of the first stretch-released factors to be identified in the urothelium was ATP, which was released in response to stretch or hypotonic stimulation from various species [15] including humans [33]. Figure 3 shows that stretch-dependent ATP release from the bladder wall is dependent on an intact mucosa, and that release is attenuated by amiloride. The latter observation supports the hypothesis that epithelial Na⁺ channels regulate ATP release (see section VIII 2-b). It is hypothesized that purinergic receptors on sensory neurons and/or myofibroblasts are targets. P2X₃ receptors have been identified as the likely target for activation of suburothelial afferents. This suggests that P2X₃ receptors are involved in sensory activation during the filling phase, as inferred from observations of P2X₃ knockout mice, which exhibited a reduced afferent firing and micturition reflex [34,35]. The relevance of this mechanism is illustrated in figure 4, where it is observed that intravesical amiloride increases inter-micturition interval [446].

The intrinsic activity of suburothelial myofibroblasts was potentiated by P2Y receptor activation [36], most likely through the P2Y₆ subtype [37]. This suggests that there are multiple targets for urothelial-derived ATP. The release of ATP increases when damage occurs to the urothelial layer, for example, in interstitial cystitis [38] or spinal cord injury [39] and may be reduced by treatment with botulinum toxin, for example [40]. There is also a marked increase in the expression of the gap junction protein connexin26 in the urothelium [41]. The enhancement of cell-cell communication may lead to increased sensitivity and propagation of signals through the urothelium in response to stimuli. Therefore, it may be hypothesized that increased urothelial ATP is a contributing factor to afferent sensitization through enhanced activation of suburothelial nerves and/or myofibroblasts.

ACh also is released from the urothelium in response to stretch; the amount increases with age and oestrogen status [42-44]. Most likely this release is through a non-vesicular mechanism, mediated by organic cation transporter type-3 [45]. Urothelial-derived ACh, like ATP, may also have a role in promoting sensory activation. This arises from the fact that anticholinergic drugs reduce detrusor overactivity and urge during the filling phase of the bladder, when efferent nerves are not activated [46].

Hence, it can be hypothesized that anticholinergics are not acting on the muscle but elsewhere, possibly muscarinic receptors in the urothelium. Recent studies investigated the localization of muscarinic and nicotinic receptors in the human [47] and mouse [48] urothelium. All five muscarinic subtypes were expressed throughout the urothelial layers. There was specific localization of the M₂-subtype to the umbrella cells and M₁ to the basal layer, and M₃ receptors more generally distributed. M₃, but not M₂, receptor expression was reduced in human tissue from patients with idiopathic detrusor overactivity. However, it is not known if this was evident throughout the urothelium/suburothelium or confined to a specific region [49]. The mechanism by which ACh modulates these activities is still unclear. However, blockade of urothelial muscarinic receptors with atropine inhibits stretch-induced ATP release [50]. Stretch-released ACh may therefore act in a feedback mechanism to induce basolateral ATP release. Thus, the urothelium is clearly more than a barrier, demonstrating a role in modulating bladder contractile and sensory activities. The cellular transduction mechanism from the urothelium is still unclear, but elucidation of how the urothelium communicates with the detrusor and the sensory nerves could uncover potential therapeutic targets.

A network of interstitial cell-like myofibroblasts have been identified in the suburothelium that label for vimentin, are connected by gap junctions containing Cx43 (Figure 5) and are closely apposed to unmyelinated nerve endings [51,52] and label with c-kit [53]. Isolated myofibroblasts respond to exogenous ATP (via P2Y receptors) by generating nifedipine-resistant intracellular Ca²⁺ transients and a subsequent Ca²⁺-activated Cl⁻ current [36,54]. At the prevailing negative resting potential, this current generates a transient depolarization. These responses mirror spontaneous Ca²⁺ transients and inward current [36]. Thus, local release of ATP from the urothelium may be postulated to generate depolarizing Ca²⁺ waves that spread across the myofibroblasts network and thus amplify and modulate local responses to endogenous ATP. The ability of myofibroblasts to form functional networks can involve mechanisms other than via gap junctions: if two isolated cells are pushed together, each cell demonstrates enhanced responses to ATP without the obvious formation of gap junctions. Cadherin-11 has been demonstrated on myofibroblast membranes [55] and their activation by intercellular adhesion may offer a mechanism. This enhancement of response is abolished by the c-kit receptor tyrosine kinase inhibitor, glivec.

These purinergic responses are mimicked by extracellular acidosis and attenuated by capsaicin and NO donors. The latter effect is in keeping with the demonstration of NOS/guanylate cyclase activity in these cells [56]. The effect of extracellular acidosis and capsaicin is of significance as it proposes a mechanism whereby the bladder wall may respond to local ischemia – a feature of bladder filling – especially in the presence of outflow obstruction or reduced compliance [57-59].
Figure 3: ATP release from the bladder during lateral stretch. A: ATP release from a section of the bladder wall, with the mucosa removed (left-bar of pair) or retained (right-bar of pair). Wall segments were held at slack length, or stretched by 30 and 50% of the slack length. Values normalised to release at slack length with mucosa, *p<0.05. B: The effect of 1 mM amiloride on ATP release from the bladder wall – mucosa intact – under different degrees of stretch, *p<0.01.

Figure 4: The effect of intravesical amiloride on the micturition reflex in urethane-anesthetized rats. A: Typical tracings of continuous cystometry (CMG) during filling: before, during and after washout of amiloride. B: the effect of amiloride on intercontraction interval (ICI) in normal rats. C: the effect of amiloride on intercontraction interval (ICI) in rats with outflow tract obstruction, * p=0.01; ** p<0.01. From [446]
Muscarinic M<sub>2</sub> and M<sub>3</sub> receptor labeling has also been localized to suburothelial myofibroblasts and is increased in samples from idiopathic overactive bladders; an increase in M<sub>2</sub> receptor labeling was also seen in samples from patients with painful bladder syndrome [60]. Isolated myofibroblasts do not respond to exogenous muscarinic receptor agonists by a rise of intracellular [Ca<sup>2+</sup>], so the intracellular signaling mechanisms remain unknown [36].

However, these observations may be of significance as it has been demonstrated that C-fibre and Aδ-fibre afferent firing in response to bladder filling was reduced by relatively M<sub>3</sub>-selective antimuscarinics [61], or less-selective agents such as oxybutynin [62] or tolterodine [63]. The latter study was of additional interest as it demonstrated that the decrease of afferent activity persisted after desensitization of a proportion of the afferents with resiniferatoxin.

4. INTERACTIONS BETWEEN UROTHELIUM/ SUBUROTHELIUM AND DETRUSOR

Several lines of evidence indicate that the urothelium/suburothelium directly modulates detrusor function, through inhibitory and excitatory mechanisms. Using in vitro detrusor preparations the potency and the maximum contractile response to acetylcholine, but not KCl, are reduced if the urothelium is intact. The substance is unknown at present, it is diffusible but is not NO, adenosine, GABA, a cyclo-oxygenase product or mediated by the small conductance Ca<sup>2+</sup>-sensitive K<sup>+</sup>-channel [64-67]. However, whether it involves activation of a beta-adrenoreceptor or the release of a beta-agonist is controversial [65,68].

Of interest is that a similar phenomenon is present in preparations from ureter, but in this case may involve a cyclo-oxygenase product [69].

Optical imaging of transverse sections of the bladder wall shows propagating Ca<sup>2+</sup> and membrane potential waves in the suburothelial layer in response to physical stretch or very low concentrations of carbachol. After a delay these responses spread to the detrusor layer initiating activity there [70], figure 6. Optical imaging of bladder sheets, with the urothelial surface uppermost showed similar propagating waves elicited by UTP in the presence of a urothelial/suburothelium, but absent if it was removed [71]. UTP was chosen as this purine elicits excitatory responses from sub-u-rothelial myofibroblasts, but not directly from detrusor itself. Isolated strips of detrusor generate spontaneous activity, especially if the urothelium/suburothelium is intact, and such activity is also up-regulated by exogenous UTP [71].

Thus, there is evidence that a suburothelial population of myofibroblasts is an intermediate stage in the sensory response to bladder wall stimuli. It acts as a variable amplifier of the sensory response mediating signals between the urothelium and sensory afferents or the detrusor smooth muscle layer, either directly or via the activation of afferent nerve fibres [72].

Moreover, the increase of myofibroblast numbers in conditions associated with bladder overactivity [41,73] suggests it is a mechanism that may be targeted to alleviate this condition. Agents that modulate myofibroblast activity, such as glivec, also reduce spontaneous activity in the bladder [74,75].
1. CONTRACTILE MECHANISMS

Smooth muscle cells of the bladder are spindle shaped single nucleated cells organized into bundles separated by connective tissue. The thin filaments are composed of α- and β-actin, that are attached to dense bodies on the cell membrane. The thin filaments provide the binding sites for the myosin thick filaments. There are four myosin isoforms that exhibit different contractile properties—smooth muscle myosin (SM) 1A, 1B, 2A and 2B. Adult bladders are composed of approximately equal amount of SM1B and SM2B (the SM1B:SM2B ratio is ~1) [76]. SM1 produces more force than SM2; SM-A types are more slowly contracting than SM-B. In obstruction, there is a shift to more SM1A, which therefore results in slower and more forceful contractions to overcome increased resistance. A detailed description of the contractile proteins and associated intermediate filaments has been recently published [77].

An increase of the sarcoplasmic [Ca^{2+}] from a basal level of 50-100 nM is required to initiate detrusor contraction, half maximal activation is achieved at about 1 μM [78]. The source of Ca^{2+} can be extracellular, via L- and T-type Ca^{2+} channels [79,80] or from intracellular stores [81]. Release from intracellular stores may be separately mediated by activation of IP3 receptors, as it can be blocked by receptor inhibitors, or via ryanodine receptors [82]. The increase of the sarcoplasmic [Ca^{2+}] is transient and Ca^{2+} are either removed from the cell via Na+/Ca^{2+} exchange [83], or re-accumulated in the intracellular stores via a SERCA pump; the activity of the latter is modulated by intracellular proteins, such as phospholamban [84]. As with other smooth muscles, the contractile proteins are activated by phosphorylation of myosin by a myosin light chain kinase (MLCK), which in turn is activated by a Ca^{2+}-calmodulin complex. Relaxation will occur if the myosin light chain is dephosphorylated, by a myosin light chain phosphatase (MLCP), which in the pig bladder is SMPP-1M phosphatase [85]. The sensitivity of the contractile system can therefore be altered by altering the activities of MLCK or MLCP. A schematic diagram of contractile activation is shown in figure 7.

MLCK activity is decreased by itself being phosphorylated which could be achieved via a number of kinases including: CaM kinase II, mitogen-activated protein (MAP) kinase, cAMP-dependent kinase (PKA) and p21-activated kinase [86,87], although details of the pathways that modulate MLCK activity in detrusor are unclear. MLCP activity can also be reduced by phosphorylation, which would increase the Ca^{2+}-sensitivity of the contractile system. Of significance is inhibition of MLCP activity by rho-associated kinase (ROK/ROCK) [88], which in turn is activated by small G-proteins of the rho-family. In detrusor the two isoforms of ROCK (I and II) have been identified [88]. Inhibitors of ROCK activity, such as Y-27632 and HA-
1077, attenuate nerve-mediated and carbachol-activated contractions, as well as contractures in cell permeabilised preparations, but do not affect depolarization-mediated (with high [KCl]) contractures other modifying agents. The most significant K⁺ channel in detrusor is the Ca²⁺ activated large conductance K⁺ channel (BKCa). This channel has a physiological role in determining membrane potential, action potential repolarisation [107,108] and regulating contractile events [109,110]; channel opening is coupled to intracellular Ca²⁺ sparks emanating from ryanodine receptors [108]. Outward current is also modulated by Ca²⁺-current influx through L-type and T-type Ca²⁺ channels. In the former case this has been proposed as a mechanism to regulate Ca²⁺ influx into the myocyte [111], and in the latter case as a basis for spontaneous fluctuations of membrane potential [100]. Reduction of BK channel activity may contribute to myogenic bladder overactivity, as deletion of the slo-gene that encodes for the channel protein enhances muscle sensitivity to cholinergic and purinergic agonists [112], conversely injection of slo-cDNA reduced overactivity [113]. BK channel activity is regulated by phosphorylation of the pore-forming α-subunit, or associated proteins [114], and affords a mechanism whereby cAMP and cGMP, through PKC, can regulate channel function [115,116]. Conversely, the Ca²⁺-dependent phosphatase, calcineurin, decreases BKCa conductance [117] so that overall Ca²⁺ exerts a complex control of channel function – the ability to identify molecular targets for this in channel is considered in section VIII 3-c.

2. ELECTRICAL ACTIVITY AND ION CHANNELS

Detrusor smooth muscle is an electrically excitable tissue capable of generating evoked and spontaneous action potentials [86]. The upstroke phase is carried by Ca²⁺ ions, predominantly through L-type Ca²⁺ channels, and repolarisation is mediated by K⁺ efflux through several K⁺ channels [79,97]. Ca²⁺ influx through Ca²⁺ channels is sufficient to elicit further release from intracellular stores [98] and sustain contractions. T-type Ca²⁺ channels have also been described in detrusor muscle and the proportion of total inward Ca²⁺ current is increased in cells from overactive bladders [99]. Because T-type channels are activated at more negative membrane potentials it was proposed that they could contribute to increased spontaneous activity in the overactive bladder [100]. Exposure of detrusor muscle strips to low NiCl₂ concentrations, when a selective T-type channels inhibition is achieved, indeed attenuated spontaneous contractile activity [101].

A number of receptor modulators that alter detrusor contractility affect also the L-type Ca²⁺ current. Antimuscarinic agents such as propiverine, attenuate L-type Ca²⁺ current [102-104]. The effect is probably mediated via M₃ receptors as the action is blocked by 4-DAMP [104]. β-agonists also attenuate Ca²⁺ current by a cAMP/protein kinase A-dependent mechanism [105], whilst the antispasmodic agents alverine citrate reduced action potential repolarisation rate, which was interpreted as an inhibition of Ca²⁺ current inactivation, thus increasing Ca²⁺ influx [106].

Intracellular ATP-gated K⁺ channels (KATP) have also been described in detrusor smooth muscle, and channel openers hyperpolarise the cell and reduce spontaneous activity. A problem with the use of these channel modulators is that of tissue specificity, as many are as potent, if not more, in generating similar responses in vascular smooth muscle. Agents with greater uro-selectivity have been developed [118] but there has been little progress with the use of such agents to attenuate bladder overactivity.

Stretch-activated channels could serve a dual purpose in the detrusor myocyte: to permit cation influx to depolarize the cells and thus cause contraction to counter the initial stretch, and to initiate intracellular signaling cascades that may initiate cellular reconfiguration or growth [119,120]. Physical stretch of detrusor myocytes opens non-selective cation channels, depolarizes the cell and augments Ca²⁺ influx through Ca²⁺ channels [121]. Stretch also increases K⁺ conductance either through increasing BK channel activity [122] or by opening a separate TREK channel [123,124]. In view of the complex effects of mechanical stretch on channel gating the overall significance of these responses remains unclear.
3. DETRUSOR ACTIVATION AND RELAXATION

In the normal human bladder acetylcholine is the sole neurotransmitter eliciting contraction, i.e. there are no atropine resistant contractions, whilst in many pathologies associated with bladder overactivity ATP is an additional activator [125-128]. Moreover age is also associated with atropine-resistant contractions [128]. With animal bladders, except for old-world monkeys, a dual muscarinic-purinergic activation is present. When muscarinic and purinergic receptors are inactivated there is generally no recorded neurotoxin (TTX)-dependent contraction, indicating that acetylcholine and ATP are the two major neuroactivators.

Despite the fact that M2 receptors predominate over the M3 subtype, most studies conclude that the latter mediates at least 95% of contractile activation [see 129,130]. More recently, the role of M2 receptors has been re-evaluated. It has been advocated that M2 receptors exert a more significant role in certain pathological conditions (eg, denervated or hypertrophied bladders), or when the M3 receptor is desensitized [131-133], although this conclusion is not reached by all [134]. One possibility for this discrepancy is that M2-dependent actions may derive from the urothelium [136], and that this pathway becomes more significant in these pathological conditions. The question arises as to what are the functions of M2-receptors in the normal bladder and several studies indicate that they facilitate the function of other receptors, such as M3 receptors [136], or counteract the relaxant effect of β-adrenoceptor agonists [137]. However, there is little difference on overactive bladder function between the effect of more selective M1/M3-selective blockers and those with a less specific action (balanced receptor blockers), although the side-effect profiles are different [138].

The major effect of ATP on detrusor smooth muscle is through ionotropic P2X receptors, generating depolarizing non-specific cation influx, which opens L-type Ca2+ channels to permit further Ca2+ influx [139]. The potency of the non-hydrolysable ATP analogue α,β-methylene ATP (ABMA) to elicit increases of intracellular [Ca2+] was not different in nerves isolated from the urothelium [140]. Non-neuronal tetrodotoxin (TTX)-resistant contractions that occur in the detrusor have several aliases including: autonomous; intrinsic; micromotion; microtransient; non-micturition; phasic; rhythmic; spontaneous or transient activity. This activity was first reported by Sherrington in cats, as transient rises in bladder pressure seen during the filling phase [148]. Spontaneous smooth muscle contractions can also stimulate afferent fibres and generate centrally-mediated ‘reflex’ bladder contractions. These contractions, which are also referred to as non-micturition or phasic contractions, can be abolished with intravesical capsaicin without affecting smooth muscle-mediated spontaneous activity [149].

In neonatal rats, spontaneous activity, resistant to TTX, is absent at birth, increases in amplitude by week two, then changes from high-amplitude low-frequency to adult-like low-amplitude high-frequency activity by week six [70,150,151], figure 9. Micturition in neonatal rats is mediated by a somato-bladder spinal reflex pathway that is activated by the mother licking the perineum of the pup. During postnatal development, this primitive reflex is replaced by supraspinal mechanisms that control mature brain-to-bladder reflexes and voluntary voiding [152]. This developmental change in the central control of voiding occurs in concert with changes in peripheral neurotransmission and the spontaneous properties of the bladder smooth muscle [153-155]. Neurotically-evoked bladder contractions are mediated entirely by cholinergic mechanisms in bladders from one-week-old rats, but become primarily purinergic in bladders from two-week-old animals. In bladders from spinal cord transected (SCT) rats [41] and outlet-obstructed
124 bladders, there is a reemergence of high-amplitude low-frequency spontaneous activity similar to that observed in neonatal bladders.

1. The neurogenic hypothesis: reduced peripheral or central inhibition increases activation of the micturition reflex and contractions associated with detrusor overactivity [156].

2. The myogenic hypothesis: changes to the excitability and coupling of smooth muscle cells with other myocytes or interstitial cells leads to the generation of uninhibited contractions [157].

3. The urotheliogenic hypothesis: changes in the sensitivity and coupling of the suburothelial myofibroblast network leads to an enhancement of spontaneous detrusor activity [158].

4. The autonomous hypothesis: structures within the bladder wall coordinate to drive spontaneous contractions, which become enhanced in pathology [159].

5. A small leak of transmitter from motor fibres sufficient to cause small local contractions or increase tone [160].

The neurogenic hypothesis can account for neurogenic detrusor overactivity, but does not fully account for so-called sensory overactivity. However, it may well form a distinct subset of patients with detrusor overactivity because muscle samples taken from such bladder are no different from stable bladders and different from other non-neurogenic (idiopathic) overactive bladder samples [e.g. 127].

Spontaneous activity can be recorded from isolated muscle strips and several reports record an increase in samples from overactive bladders. Contractions are resistant to neurotoxins but generally labile to Ca²⁺-channel blockers or K⁺ channel openers [77]. Such activity can be recorded in isolated cells, as spontaneous changes to membrane potential and intracellular Ca²⁺. Moreover the incidence of such activity is enhanced in cells isolated from overactive bladders. The origin of such activity is not known at present. Whilst up-regulated activity in isolated cells may be present, this will not alone explain spontaneous activity in multicellular preparations. Two possibilities have been proposed for increased intercellular communication. One is that there is an increase of intercellular coupling through gap junctions. Gap junctions are composed of the connexin (Cx) family of proteins. In human detrusor, expression of the main intermuscular connexin, Cx45, is actually less in samples from idiopathically overactive bladders and this correlated with a higher gap junction resistance in such samples [161]. Other groups however, suggest that another connexin isoform, Cx43, forms gap junctions between muscle cells and expression is upregulated in overactive bladders [162,163]. However, Cx43 labels interstitial cells in the detrusor layer although their number has not been reported to increase in overactive bladder models [77]. These cells are characterized by their labelling for the tyrosine-kinase receptor protein c-kit [160] – as are the suburothelial equivalents – close apposition to muscle cells and nerves [53], and the generation of spontaneous and carbachol evoked Ca²⁺ and electrical activity [164-166]. It is postulated that rather initiate spontaneous activity in the detrusor syncitium, interstitial cells modulate its activity [167], possibly by co-ordinating activity in different muscle bundles. However, these cells could form a control point for regulation of spontaneous activity, as they are innervated by nerves that label for nitric oxide synthase [55], and also express cGMP activity [168].

The urotheliogenic hypothesis is premised on a urothelial-myofibroblast network connected by gap junctions supporting pacemaker-driven spontaneous activity where bladder pathology, due to spinal cord transection for example, leads to an upregulation of gap junctions in the urothelium and myofibroblast network. This, in turn, leads to the formation of an increasingly functional myofibroblast syncytium with focal pacemaker activity that drives spontaneous contractions. The mechanism whereby this may drive

**Figure 9: Spontaneous and evoked activity in isolated rat bladders.** A: a neonatal rat bladder showing large spontaneous contractions (arrowed) and larger contractions evoked by electrical field stimulation (EFS, 10 Hz) during the red bars. The EFS contraction, but not the spontaneous activity, was abolished by the neurotoxin, tetrodotoxin (TTX, 1 µM). B: a similar experiment in an adult rat bladder. The spontaneous activity is now of small amplitude, randomly fluctuating events. Modified from [70].
activity in the detrusor layer has been considered above (section II.3). Figure 10 shows an experiment consistent with this hypothesis. Isometric tension recorded from detrusor strips, with the urothelium removed (top) or left intact (bottom). Both respond similarly to a maximum concentration of the cholinergic agonist carbachol, but in the bottom trace not only is there significant spontaneous activity but it is up-regulated by the purine UTP, that excites suburothelial myofibroblasts, but not directly detrusor smooth muscle.

![Figure 10](image)

**Figure 10:** The influence of an intact mucosa on spontaneous activity in isolated bladder wall strips from guinea-pig bladders. A: a strip with mucosa removed; UTP and carbachol were applied as indicated by the horizontal lines. B: a similar experiment with a strip with an intact mucosa. Modified from [71]

The autonomous hypothesis takes into account the potential role of interstitial cells within the bladder wall but does not clearly indicate a specific mechanism by which spontaneous activity is driven. It most likely represents a qualitative description of a combined myogenic/urotheliogenic hypothesis. As with the urotheliogenic hypothesis spontaneous bladder contractions are enhanced by low-dose muscarinic stimulation, via M3-receptors on suburothelial myofibroblasts. Activity is modulated by ATP, substance P, nicotinic receptor agonists, noradrenaline and nitric oxide, by unspecified mechanisms [169-171].

5. TRIGONE

The bladder base consists of the trigone, the urethrovesical junction, deep detrusor, and the anterior bladder wall. The outstanding developmental and functional position of the bladder trigone has been confirmed in decades of urological research and is defined as the triangular region situated between the ureteral orifices and the bladder outlet. It has always been considered to play a crucial role in ureterovesical function, continence and micturition.

Histologically, the trigone is characterised by smaller myocytes in smaller muscle bundles than in detrusor which exhibit extensive electrical coupling via gap junctions [172,173]; it also contains a greater amount of connective tissue than detrusor.

The original, and still prevailing, concept of a functional entity of bladder base, trigone, and ureterovesical junction, was first been developed by Waldeyer [174] in the late 19th century and later refined by Tanagho [175-177]. According to this concept, the spirally-oriented ureteral muscle fibres become longitudinal, as the ureter pierces the bladder wall obliquely, travels 15-20 mm, and terminates at the ureteral orifice. Fibres from each ureter fan out over the base of the bladder to form a superficial triangular sheet of muscle that extends from the two ureteral orifices to the internal urethral meatus and, from there, further down the urethra to insert at the verumontanum. The edges of this muscular sheet, the so-called superficial trigone, are thickened between the ureteral orifices (the interureteric crest or Mercier’s bar) and between the ureters and the internal urethral meatus (Bell’s muscle). A few centimetres from the bladder, the fibromuscular sheath of Waldeyer departs from the outer muscular layers, surrounds the prevesical ureter longitudinally, and continues in the bladder as the so-called deep trigone, which is fixed at the bladder neck. The trigone is backed by outer, longitudinal and middle, circular smooth muscle layers of the detrusor. In the space between Waldeyer’s sheath and the ureter, only loose fibrous and muscular connections in the sense of a gliding plane are found. As the bladder fills, the bladder wall telescopes outward on the ureter, thereby increasing intravesical ureteral length. This facilitates passive occlusion of the ureter by the urine and warrants, like a flap valve, the basis for a reliable antireflux mechanism. This concept requires a competent vesico-ureteric anchoring, mainly provided by a strong contralateral ureteral smooth muscles blending in the shape of the interureteral ridge. Periodic contraction of this interureteric crest is thought to support the occlusive mechanism by further elongating the intravesical part of the distal ureter.

In fact, trigonal myocytes in the bladder base have recently been shown to exhibit marked spontaneous activity, which is mainly carried by Ca\(^{2+}\)-influx via membrane L-type Ca\(^{2+}\)-channels. Similar to interstitial cells, Ca\(^{2+}\)-activated Cl—channels rather than K\(^{+}\)-channels contribute to the generation of spontaneity. Extensive gap junction coupling ensures electrical propagation and provides sustained spontaneous contraction of the interureteric crest [173].
Accordingly, the trigone is thought to develop, with the ureter, from an outgrowth of the mesonephric duct, and the common mesodermal origin of the vesical neck musculature, the trigone, and the ureterovesical junction is emphasised [175]. However, recent studies challenge this concept of a common developmental origin and suggest rather that the trigone is formed predominantly from bladder muscle; and the contribution from ureteral longitudinal fibers at the lateral edges that is much more limited than previously thought [178,179].

Within the lower urinary tract, the bladder base and trigone represent an area of dual parasympathetic-muscarinic and sympathetic-adrenergic innervation. Whilst mRNA measurements, western blotting, radioligand binding assay and receptor autoradiography studies have detected only low densities of \( \alpha_1 \)-adrenoceptors in the detrusor of several species, including humans, a more consistent, and in some comparative studies, greater \( \alpha_1 \)-adrenoceptor expression was observed in the trigone and bladder neck region. The \( \alpha_1 \)-adrenoceptor seems to be the most abundant subtype in humans [180]. Reports about the proportion of adrenergic, muscarinic and other transmitter systems in the trigone are variable. Speakman et al. [181] found the maximum contraction to carbachol was no more than 50% of that elicited by phenylephrine (PE) in human tissue, but detected comparable reduction (40%) of electrically-evoked contractions by either muscarinic or \( \alpha \)-adrenergic antagonists. Templeman et al. [182] showed a maximal responsiveness to PE of only 68.7% compared to carbachol in longitudinal strips of the pig trigone, when the urothelium had been removed. Roosen et al. [183,184] found a predominant muscarinic innervation and agonist responsiveness of the superficial guinea-pig trigone, with a reduction of electrically-evoked contractions by prazosin of 41.0% compared to atropine and mean maximal contractions to PE of 67.6% relative to those of carbachol. However, the functional significance of this dual innervation is much less clear. Whilst it is widely agreed in animal experiments that adrenergic stimulation via sympathetic nerves is active during the storage phase and induces contraction of the bladder base and internal urethral smooth muscle sphincter, the role of the parasympathetic innervation is much more controversial. Some propose that cholinergic axons exert a relaxing effect on urethral and bladder neck smooth muscle via generation of nitric oxide during micturition [185]. However, strip preparations from the bladder base have been shown to contract not only to carbachol superfusion, but also to the muscarinic component of electrically-released endogenous neurotransmitters. Moreover, there is a significant adreno-muscarinic synergism in the guinea-pig bladder trigone – figure 11 - where the adrenergic pathway primarily operates through \( \text{Ca}^{2+} \)-sensitisation of the contractile machinery [183,184]. This is capable of a more than four-fold potentiation of muscarinic force activation which, in turn, seems to be a basically \( \text{Ca}^{2+} \)-dependent event. This synergistic mechanism might cause an even stronger contraction of the interureteric muscle in cases of involuntary detrusor contractions (induced by increased parasympathetic tone) and thereby prevent urinary reflux into the ureter.

If, as some suggest, the trigone takes part also in urinary outflow control, this synergy might lead to a higher closure pressure in cases of involuntary detrusor contractions and thereby prevent urinary leakage.

In general, the bladder base is thought to provide a rather stable structure against which the bladder dome can contract and relax during the micturition cycle. This might be the reason for the relatively high amount of connective tissue and the high spontaneous activity within individual myocytes. However, it is believed that during micturition the trigone may relax and cause a “funneling” effect to facilitate voiding. As in the urethra, animal experiments have shown that NO is the key relaxing factor in the bladder base [185-187]. NO effectively relaxes isolated smooth muscle preparations from the outflow region, suggesting that it may be involved in the decrease in intraurethral pressure observed at the start of normal micturition. This NO-based relaxation provides an effective mechanism to allow the bladder base and trigone to switch from a closed to open state, especially in combination with the adrenergic control of the \( \text{Ca}^{2+} \)-sensitisation of the contractile machinery.

Figure 11: Effects of muscarinic and adrenergic agonists on the guinea-pig trigone. A: isometric tension from an isolated strip exposed to carbachol (1 \( \mu \text{M} \)). During the shaded region the strip was also exposed to phenylephrine (10 \( \mu \text{M} \)). B: a similar experiment from an isolated cell loaded with the \text{Ca}^{2+} \text{ indicator Fura-2. Modified from [180].}
IV. THE URETHRA

1. INTRODUCTION

During voiding, relaxation of the bladder outlet precedes detrusor contraction and during filling the outlet is contracted. Several mechanisms contribute to these functions, mediated through urethral smooth and skeletal muscle as well as the mechanical properties of the lamina propria. Inadequate closure of the urethra during filling could contribute to stress urinary incontinence. Smooth muscle is arranged as an outer circular layer and an inner longitudinal component, contraction of the circular should maintain continence, and longitudinal muscle may shorten during micturition. In women it has been suggested that there is greater dependence on surrounding support from the pelvic organs for the intra-abdominal portion of the urethra, resulting in the maintenance of an intra-abdominal portion of the urethra and buttressing against the fixed proximal portion of urethra, in combination with pressure generated by the urethral musculature. Therefore, the smooth muscle component may be more for maintaining a continence mechanism. It has been estimated that as much as 50% of total urethral pressure in women is due to smooth muscle tone [188,189]. The urethra is innervated by both the sympathetic and parasympathetic systems. Activity in pelvic nerve parasympathetic fibres relaxes urethral smooth muscle, especially in the proximal portion, and therefore the outflow region; sympathetic fibres (T10-L2) generate contraction.

2. URETHRAL SMOOTH MUSCLE

Sympathetic control is mediated by α1 receptors, mainly the α1A/L subtype in both human and animal models [190,191]. Partial α1A/L agonists, such as Ro 115-1240, have been proposed as agents that may be used to manage stress urinary incontinence in women without significant cardiovascular side-effects [192,193], although their effectiveness remains to be demonstrated. α2 receptor agonists induce contraction in several animal models but this has not been reproduced in human preparations [180]. Urethral relaxation can be mediated via β-receptor activation, predominantly the β3 subtype. However, this mechanism is probably less important than in detrusor [180,194]. Of interest however is the observation that the β2-agonist clenbuterol also increased urethral skeletal muscle contraction raising the possibility that it may have a role in the treatment of urinary incontinence by inhibiting the detrusor contraction and augmenting external urethral sphincter activity [195,196]. Urethral relaxation during voiding is mediated by release of NO. Furthermore, prejunctional muscarinic receptors may limit noradrenaline release from sympathetic fibres, thus contributing to relaxation [197]. Muscarinic agonists generate urethral contraction, although receptor density is lower than in detrusor and clinical studies show little effect on urethral pressure [185].

NO-mediated relaxation is due to production of cGMP and activation of cGMP-dependent protein kinase, cGK. Electrical field stimulation generates relaxations that are abolished by inhibitors of NO production and are absent in mice lacking cGK [198]. The mechanism for relaxation does not seem to involve myocyte hyperpolarisation and awaits definitive evaluation [199]. CO can also exert relaxation through a rise of cGMP, which may be equivalent in magnitude to the effect of NO [200]. Derangements of the NO system have been demonstrated in several disorders associated with lower urinary tract function, such as diabetes, bladder outlet obstruction or bladder inflammation [201,202].

Sex hormones play an important role in modulating urinary tract smooth muscle function, including that from the urethra. Lack of oestrogen following menopause may contribute to decreased urethral tone, urethral integrity and incontinence, and the older literature suggested that estrogen supplementation may be beneficial [203]. However, several recent clinical studies indicate that supplemental oestrogen lowers collagen content in the periurethral connective tissue and decreases urethral closure pressure [204-206] thereby worsening the symptoms of incontinence [207-209]. Similarly, recent studies in rabbits indicate that the response of urethral pressure to α-adrenergic agonists is equivalent between control, ovariectomized and ovariectomized rabbits with oestrogen replacement [210].

Urethral smooth muscle exhibits spontaneous electrical and mechanical activity that will contribute to the overall tone exhibited by the tissue. Electrical activity occurs as bursts of spikes superimposed on a slower more rhythmic activity, and could be initiated by autonomic transmitters [211]. Two types of Ca2+- currents – L-type and T-type - have been recorded in isolated myocytes. Blockade of the former type reduced the number of spikes in each burst; the frequency within bursts was attenuated by blockade of T-type current [212]. However, both channels represent targets that may modulate spontaneous activity. The muscle cells are closely associated with interstitial cells that may be responsible for such activity, or at least modify it [165,213]. Activity in these cells results from intracellular Ca2+ release, itself triggered by Ca2+ influx, and the generation of Ca2+-activated depolarising current that generates the electrical activity. The observation that interstitial cells are closely associated with NOS-synthase containing nerves suggests that they may be intermediaries between nerves and urethral smooth muscle [214].
3. URETHRAL SKELETAL MUSCLE

The skeletal muscle of the urethra wall (rhabdosphincter) forms an incomplete ring of skeletal muscle around the urethra [215]. In human tissue three fibre types have been described; fast-twitch fatigue-sensitive, fast-twitch fatigue-resistant and slow-twitch, with the majority fatigue-resistant [216, 217]. Muscle bulk decreases with age and also with parity in women [218, 219], figure 12. Stress urinary incontinence (SUI) may be associated with a loss of muscle mass in the urethra [218, 220], due to increased apoptosis and/or denervation [221]. Alternatively, a decrease in motor nerve function may also contribute to SUI as shown in a mouse model where vaginal distension with a balloon reduced leak point pressures and the number of nerves in the urethra, without affecting muscle mass [222].

Selective inhibitors of serotonin (5-HT) and noradrenaline (NA) uptake, such as duloxetine, have been developed as potential agents for the therapeutic management of SUI [227], because 5-HT and NA terminals are present in Onuf’s nucleus that supplies the rhabdosphincter with motor nerves [228]. Analyses of current data suggest that the effect of duloxetine on alleviating USI is small, but significant [229], thus accounting for its limited use.

The striated muscle of the urethral sphincter may undergo abnormal activity resulting in urinary retention, Fowler’s syndrome [230,231]. The origin of the condition is unknown but one hypothesis is that it is due to ephaptic (i.e. direct cross-talk) electrical transmission between cells, much as can occur between nerve axons under certain conditions [232]. Neuromodulation may be effective in restoring voiding activity but there remain significant complication rates [233,234].

V. CELL PHYSIOLOGY OF NEUROACTIVE AGENTS IN THE LOWER URINARY TRACT

1. MUSCARINIC CHOLINERGIC TRANSMISSION

Acetylcholine is released not just from parasympathetic and somatic motor nerves to smooth and skeletal muscle targets respectively, but also from non-neuronal sources such as the urothelium. Muscarinic receptors are one of the main targets and are expressed throughout the lower urinary tract, nicotinic receptors are considered below. The muscarinic receptor family is divided into five subtypes based on molecular (m1-5) and pharmacological (M1-5) characteristics. Currently, the M1-4 receptors have been pharmacologically characterized, while an M5-specific compound has yet to be developed [235]. In detrusor, immunoprecipitation analyses show m2 and m3 subtypes are expressed, with m2 receptors in three- to nine-fold excess [236]. In normal human detrusor the minor M3 fraction is responsible for contractile activation, although the M2 component may modulate the overall response and become prominent in pathological bladders (see section III 3). M3 receptors are coupled to Gq/11-proteins, which importantly activate the enzyme phospholipase-C (PLC) to convert membrane phosphoinositides to the second messengers inositol trisphosphate (IP3) and diacylglycerol (DAG). IP3 in turn releases Ca2+ from intracellular stores, after binding to an IP3-receptor, to activate the contractile proteins. There is a body of experimental evidence to support the relevance of this pathway in detrusor: muscarinic agonists generate a rise of [Ca2+] independent of membrane potential and release is blocked by the IP3-receptor blockers TMB-8 [111]; and carbachol-potency is reduced by other IP3-receptor blockers such as heparin and PLC.
inhibitors [237,238]. Moreover inositol phosphate production mirrors tension generation in detrusor strips exposed to muscarinic agonists [239]. However other work casts doubt on the exclusiveness of this pathway, in part due to the relative ineffectiveness of other PLC inhibitors reducing carbachol-induced tension. It has been suggested that activation of the rho-kinase pathway by G-protein activation and of protein kinase C by DAG reduces the activity of myosin light chain phosphatase as so increases the Ca2⁺ sensitivity of the contractile proteins (see section III 1); the rise of intracellular Ca2⁺ was explained by activation of non-specific cation channels coupled to L-type Ca2⁺ channel activation [90,240-242]. Several attempts to reconcile the controversy have been attempted. Frazier et al [243] reasoned that different experimental protocols and PLC inhibitors used by different groups might partly be responsible and concluded that PLC activation was not important, whilst other have found considerable species differences in the relative importance of inositol phosphate and other pathways [244]. In addition, it must be cautioned that some of the data for these experiments rely on the use of compounds such ryanodine and cyclopiazonic acid (both Ca2⁺-store inhibitors) that have poor penetration into muscle preparations, so that a lack of effect cannot always be taken as a lack of importance for a particular pathway. M2 receptors are coupled to Gι-protein that reduces cAMP production by its influence on adenylyl cyclase activity. It has been proposed that M2 receptor activation inhibits the effect of other agonists that increase cAMP production, such as β-receptor stimulation. Recent reviews summarise the role of muscarinic-dependent pathways in the bladder and their relevance to contractile activation [130,245], and are summarized in figures 13 and 14. Muscarinic receptors are also localized on urothelial cells and myofibroblasts in the suburothelial and muscle layers (Section II.3) but where there role is less certain.

Presynaptic muscarinic receptors have also been described where it is proposed that they modulate transmitter release in either a negative (M2/4) or positive (M1 [246]) feedback mode. Knockout experiments indicate that M4, rather than M2 receptors inhibit transmitter release [247].

2. ADRENERGIC TRANSMISSION

Adrenergic receptors are predominantly found in the bladder neck and trigone regions and are activated by release of noradrenaline from sympathetic innervations to induce contraction of the smooth muscle in these regions. In the detrusor adrenergic receptors are also present that induce relaxation. There are five distinct adrenergic receptor types: α1, α2, β1, β2 and β3, with each being further divided into subtypes. The α1 subtype predominantly induces the closure of the bladder outlet through contraction of the urethral smooth muscle, while presynjucional α2-receptors modulate the release of neurotransmitters from sympathetic nerves There are also α1-receptors (α1A and α1D subtypes) expressed on the detrusor smooth muscle, but they do not appear to mediate contractile activity [185]. However, noradrenaline can affect autonomous contractions of an isolated whole bladder preparation [171]. There is also evidence that α1D receptors are present on the urothelium and may play a role in modulating reflex voiding [248].

All three β-subtypes are expressed in the detrusor smooth muscle with the β3-receptor being most highly expressed [249]. The β2 and β3-receptors can cause significant relaxation of trigonal and detrusor smooth muscle with apparent differences between species [250]. Furthermore, the effect is slightly smaller in hypertensive compared to normotensive rats [251]. There is much interest in specifically targeting β3-receptors for treatment of detrusor overactivity as it has a significant effect on reducing spontaneous detrusor contractions [252]. The β-receptor mediated relaxatory mechanism is thought to involve the rise of cAMP and modulation of large conductance Ca2⁺-activated K⁺ (BKCa) channels [253] – see figure 14. β-receptors are also found on the urothelium where their stimulation can induce release of NO and may also be involved in the release of the urothelial-derived inhibitory factor [67]. A comprehensive survey of the in vitro and in vivo actions of β-receptor modulators has been provided [180].
3. PURINERGIC TRANSMISSION

The role of ATP as an extracellular signaling molecule is now well accepted. In most mammalian species ATP is co-released with ACh from parasympathetic nerves and activates purinergic receptors to initiate detrusor contraction. This is in contrast to healthy human bladders where contraction is predominately mediated by ACh. However purinergic nerve mediated contraction is increased in a number of bladder pathologies including hypertrophy, idiopathic overactivity, interstitial cystitis, neurogenic damage and aging (Section III.3). The increase of atropine resistance in bladder disorders may be due to: increased sensitivity of detrusor cells to ATP, increased release from motor nerves, or reduced ATP hydrolysis within the neuromuscular junction. The three possibilities have been investigated using human detrusor samples from stable and overactive bladders. Only the last hypothesis was considered a possibility as ectonucleotidase activity in overactive human bladder samples was significantly reduced [254]. The purinergic P2 receptors are divided into P2X and P2Y families based on pharmacological and molecular studies [255,256]. P2X receptors are ionotropic ligand-gated non-specific cation channels while P2Y receptors are metabotropic G-protein coupled. Currently seven P2X receptors subtypes have been cloned and characterized (P2X1-7). P2X1 receptors are the predominant subtype throughout the detrusor smooth muscle (figure 14) and activation generates an inward, depolarizing current sufficient to activate L-type Ca2+ channels to generate an action potential and Ca2+ influx to initiate contraction [139].

All P2X receptors are present in cat bladder urothelium in the basal and apical layers [22]. Although the precise functional role of P2X receptors within the urothelium is still to be established, P2X2 and P2X3 may be involved in nociceptive signaling [257] and their expression has been shown to be up-regulated in painful bladder disorders including interstitial cystitis [258].

ATP released from the urothelium in response to hydrostatic pressure changes is believed to be important in bladder sensation and the initiation of micturition (section II.3).

There are eight subtypes of P2Y receptors (P2Y1,2,4,6,11-14) linked either to Gq/11 (P2Y1,2,6), Gi (P2Y12-14) or several proteins: Gq/11/Gi (P2Y4); Gq/11/Gs (P2Y11) [259,260]. P2Y receptors, although not a specific subtype, have been implicated in relaxation of smooth muscle, possibly via cAMP-dependent PKA activity [86]. P2Y1,2,4 have been identified on the urothelium [261]. Activation of P2Y receptors on urothelial cells from the rat evokes ATP release which may play a role in autocrine or paracrine signaling to modulate micturition [262]. P2Y6 receptors have also been located on sub-urothelial myofibroblasts and respond to UTP with inward currents and large, transient increases in intracellular Ca2+ [36,54]. In the cat P2Y4 receptors were detected in nerve bundles close to the urothelium and detrusor smooth muscle, however their role remains to be established although activation of P2Y receptors could alter the release of neuropeptides through increases in intracellular Ca2+ [256].

4. NITRERGIC MECHANISMS

There are three nitric oxide synthase (NOS) isoforms, encoded by separate genes, named for the tissue that they were first isolated from or the order in which the genes were cloned: neuronal NOS (nNOS) or NOS 1; inducible NOS from macrophage (iNOS) or NOS 2; and endothelial NOS (eNOS) or NOS 3. There is also a form of nNOS that has a unique leader sequence that localizes the enzyme within mitochondria.

Figure 14: A; Muscarinic, M2 and adrenergic β3 signalling pathways. These pathways influence the intracellular cAMP levels, either increasing (β3) or decreasing (M2) levels, through their influence on adenylate cyclase activity. cAMP, through a protein kinase-A (PKA) pathway, will promote relaxation by attenuating phosphorylation of the myosin light chain. B: Major ion channels in detrusor smooth muscle and their interaction. Two channels, the ionotropic P2X1 receptor and the L-type Ca2+ channel will conduct cation inward current thus depolarising the cell. The Ca2+ activated K+ channel (BKCa) will conduct outward current.
(mtNOS). Each of these enzymes can be found in every cell type of the LUT. The expression of several factors determine if there is a relaxatory effect to nitric oxide: NOS; the NO receptor, soluble guanylate cyclase (sGC); and phosphodiesterase (PDE), the enzyme that degrades cGMP, the product of sGC activity. There are eleven PDE isoforms so far identified, PDE1-5 are described in the bladder [263-265]. PDE5-selective inhibitors such as sildenafil (Viagra) and vardenafil are structural analogs of cGMP and competitively inhibit PDE. NO-donors have a rather small relaxatory effect on detrusor [266], but PDE inhibitors, such as vardenafil, relaxed pre-contracted detrusor [265], suggesting a relatively high endogenous PDE activity. These findings are corroborated by the beneficial effects of PDE5 inhibitors with LUTS, when used to treat erectile dysfunction [267]. The importance of NO-mediated mechanisms in urethral relaxation has already been highlighted (section IV.2) [268]. The cellular pathways in contraction that are mediated by NO as shown in figure 15.

Capsaicin releases nitric oxide from the urothelium [28] and therefore may have effects on nearby cells in the suburothelial region including afferent nerves and myofibroblasts [168]. Nitric oxide has also been shown to free up tight junctions and disrupt the urothelial umbrella cell permeability barrier [269]. Accordingly, upregulation of iNOS during inflammation could compromise barrier function and exacerbate the pathology.

5. NICOTINE AND NICOTINIC RECEPTORS

Transmission at parasympathetic pelvic ganglia is mediated largely by nicotinic receptors [270], but there is also evidence for the involvement of nicotinic receptors at other sites in the lower urinary tract. Nicotine may evoke release of acetylcholine from motor nerves, which itself may be upregulated by tachykinins acting via NK2 receptors [271,272]. This contractile effect of nicotine is blocked by the nicotine receptor antagonist hexamethonium. The nicotinic receptor is a pentamer of subunits and to date 17 different subunits have been identified (α1-10, β1-4, γ, δ, ε) so that there is a large variety of potential receptors. Mutation studies suggest that the α3 and β4 subunits are required for bladder function [273], which is in keeping with the pentamer structure in autonomic ganglia – (α3)2(β4)3.

Nicotinic receptor subtypes have also been localized to the urothelium, specifically for the α3, α5, α7, β3, and β4 subunits [274]. Based on experiments infusing agonists and antagonists into the bladder lumen it was proposed that these subunits form two types of nicotinic receptor, one that increases and one that decreases bladder activity. Later studies have detected a wider range of subtypes with differential distribution to various layers of the urothelium [48]. Nicotinic pathways may also have a role in alleviating the effects of bladder inflammation. With artificial models of inflammation blockade of nicotinic receptors exacerbated the effect whilst activating the receptors produced the opposite effects, possible through an involvement of the cytokine IL-6 [275,276].

6. ADENOSINE RECEPTORS

Whilst purinergic, P2, receptors have been the subject of considerable scrutiny the pyrimidine P1 receptor family has received less attention. Four subtypes have been cloned, A1, A2A, A2B and A3 and all are G protein-coupled receptors. A 1/3 receptors are negatively coupled to adenylyl cyclase activity, whilst A2 receptors are positively coupled. Adenosine relaxes bladder preparations pre-contracted by carbachol through an A2 (possibly A2B) receptor mechanism [277]. A1 receptor binding was evident in a number of smooth muscle organs except bladder [278]. However, another study using the A1 receptor agonist 2-chloroadenosine generated contractions linked to a PLC mechanism [279]. Using guinea-pig bladder preparations it has been proposed that A2-receptor

Figure 15: Nitric oxide (NO)-dependent pathways. Shown here is a scheme for a urethral smooth muscle cell where NO-dependent pathways are particularly important. NO is produced by activation of nitric oxide synthase and diffuses to a target cell, whereupon it increases cGMP production from GTP, by activation of guanylate cyclase (GC). cGMP, through a PKC pathway promotes relaxation. Muscarinic and adrenergic pathways are shown for completeness. Shown also are the sites of action of phosphodiesterase (PDE) inhibitors, sildenafil and tolafentrine.
relaxation is mediated by K<sub>ATP</sub> channel activation, through increased adenylate cyclase activity, principally involving the A<sub>2A</sub> receptor [280]. Adenosine also relaxes urethral smooth muscle, but the receptor subtype is unclear [281]. The confusion regarding the involvement of particular receptor subtypes may in part be due to the evolving knowledge regarding the specificity of different receptor subtype modulators. All four subtypes are also localized to the urothelium with some differential distribution to the different layers. Adenosine is released from the urothelium, especially when mechanically stretched and it was hypothesized that adenosine receptors may mediate increase of umbrella cell surface area under bladder stretch [282].

7. NEUROPEPTIDES

Various neuropeptides, including calcitonin gene-related peptide (CGRP), substance P, neurokinin A, vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase-activating peptide (PACAP), are released in the bladder from efferent and afferent [283] nerves and urothelial cells [284]. These peptides may also be released by noxious stimulus and promote inflammation. CGRP is an alternative product of the calcitonin gene expressed preferentially in nerve tissue. CGRP inhibits spontaneous activity and relaxes ACh-induced tension. Tachykinins (Substance P and neurokinin A) are prototypic of endogenous agonists of specific G-protein coupled receptors, termed tachykinin NK<sub>1</sub> and NK<sub>2</sub>. NK<sub>1</sub> receptors have been found in blood vessels and the urothelium of all species thus far examined, whereas their expression in muscle cells seems restricted to rats and guinea-pigs [285]. The stimulation of NK<sub>1</sub> receptors activates phospholipase C leading to inositol phosphate accumulation and is linked to smooth muscle contraction. Substance P has stimulatory effects on detrusor smooth muscle and urothelium. NK<sub>2</sub> receptors are localized on detrusor muscle of all mammalian species studied, including humans [286,287], and in the suburothelial layer in rats. The stimulation of NK<sub>2</sub> receptors is coupled to inositol phosphate accumulation and is excitatory in the bladder. In the human bladder, tachykinin receptor type NK<sub>2</sub> predominates. VIP and PACAP receptors (VPAC<sub>1/2</sub> and PAC<sub>1</sub>) are G-protein coupled receptors located on neurons and smooth muscle. They are coupled to several signal transduction pathways, including activation of adenylate cyclase and elevation of cyclic guanylate monophosphate levels in tissues [77, 288]. VIP release evokes relaxation of detrusor and urethra smooth muscle. There is indirect evidence to suggest that these various peptides can be released antidromically from afferent nerves in the bladder through different stimuli [289]. Potential stimuli for ‘efferent-release from afferents’ may be the intrinsic contractions associated with detrusor overactivity. However, whether this contributes to the enhanced spontaneous activity seen in pathology would depend on the peptide(s) released.

VI. BIOMECHANICAL PROPERTIES OF THE BLADDER WALL

1. ACTIVE AND PASSIVE CONTRACTILE PROPERTIES OF THE BLADDER WALL

The lower urinary tract is a hollow, neuromuscular system composed of four major layers: urothelium which lines the lumen; lamina propria; muscular detrusor and an outer serosal layer. The biomechanical properties of the bladder wall are principally dictated by the connective tissues of the lamina propria and the smooth muscle cells and connective tissues of the detrusor layer.

The detrusor, which comprises 60% to 70% of the thickness of the normal bladder wall, is composed of smooth muscle cells aligned in longitudinal and circumferential layers but are highly variable in cross-section, length and orientation; this orientation also changes during contraction [290]. Accordingly, the rise in luminal pressure during bladder contraction is not directly proportional to the sum of the muscle tension generated by cross-bridge formation in the myocytes. Some of the generated tension is absorbed by the connective tissues and only cells tangential to the radius of curvature of the wall contribute to force generation [291].

In principle, the different portions of the lower urinary tract need to exist between two physical states: high compliance, low wall stress, as exists in the bladder during filling; and high wall stress as exists during voiding in the bladder and in during storage in the urethra to maintain continence.

Overall wall tension results from the passive and active properties of the tissue; the former result from the viscoelastic properties of the collagen and elastin fibers in the extracellular matrices of the lamina propria and detrusor as well as the detrusor smooth muscle cells themselves. The active properties result from contraction of the component muscular structures within and surrounding the lower urinary tract and transmission of the resultant force through the extracellular and intracellular tissues. Whether the high compliance state is merely an absence of contraction of the muscular components or is contributed by active relaxation is a subject of increasing debate.

The translation of changes in wall tension to an increase or decrease of intraluminal pressure will also depend on the geometry of the system, i.e. the shape, intravesical volume and wall thickness. It is important to remember that whilst intraluminal pressure changes are the driving force for fluid movements in the lower urinary tract, the relationship with wall tension is highly dependent on geometrical factors.
2. COMPLIANT PROPERTIES OF THE BLADDER AND BLADDER WALL

There exists some inconsistency regarding the use of various terms to describe the relationship between distending or compressive forces and the resulting deformation. The stiffness, $k$, of a body is the ratio of an applied force to the resulting change of dimension; the inverse parameter is compliance and is a measure of the ‘distensibility’ of a system. In three dimensional terms pressures and volumes are substituted for force and distension, e.g. bladder compliance ($C$) is the ratio of change to bladder volume, $V$, per change to unit intravesical pressure, $P$, i.e. $C = \Delta V / \Delta P$. Generally, the elastic (Young’s) modulus, $E$, is not the same as stiffness; $E$ is a property of the constituent material, stiffness is an extensive property, i.e. a property dependent on the material and the geometrical shape of the body. Here compliance and stiffness will be used.

In principle, it is difficult to state a standard value for compliance for several reasons: bladder capacity increases with age whereas intravesical pressures do not vary as much; intravesical pressure itself is a function of bladder volume (see below) and thus compliance would vary as the bladder fills. Furthermore, it must be emphasised that compliance is a steady-state property so that measurements should only be made when any stress-relaxation has fully subsided. Several approaches have been attempted to account for these confounding factors. A normalization factor has been introduced in urodynamic studies to correct for values calculated in different size bladders [292,293]. Ex vivo, non-linear pressure-volume relationships have been transformed into linear stress-strain relationships to correct for different initial bladder volumes [294], when more direct comparisons can be made with data from tissue strips [294,295], figure 16.

Outflow tract obstruction in human and animal models has variable effects on bladder and isolated strip compliance. With shorter periods of obstruction compliance does not seem to alter [296], whilst after more extensive periods compliance may either decrease [297-300] or increase [294,295,301]. Most likely the different effects result from the severity and duration of the obstruction, with the bladder progressing from a hypertrophied low compliance state to a high compliance state that may mark end-stage failure [302]. The physiological consequences of this progression of function need to be considered. A decreased compliance will mean that intravesical pressures should rise more for a given amount of filling and if maintained can contribute to upper tract damage [303]. One consequence of a greater compliance will be that detrusor contractions will be less effective in raising pressure and thus make voiding more difficult [289]. It is thus important to determine which physical properties of the bladder wall determine changes to the compliance of the bladder.

3. BIOMECHANICAL PROPERTIES OF LOWER URINARY TRACT TISSUES AND COLLAGEN SUBTYPES

The passive properties of LUT tissues will depend on the respective properties of the muscular and extracellular components and the respective proportions of each [291,304]. The most significant extracellular components in this context are collagen and elastin; of the former collagen types I and III have the most influence on mechanical properties [305].

In obstructed bladders collagen type-I and type-III content rises in the lamina propria, but particularly in the detrusor muscle layer, with an increased ratio of type-III to type-I reported in some [306-309]. Such increases of collagen may be accompanied by reduction of elastin gene expression [310]. Collagen

*Figure 16: Bladder pressure-volume and derived tension-length relationships. A: ex vivo pressure-volume relationships for three different bladders from fetal sheep: red and blue symbols, obstructed bladders; black symbols, unobstructed control. B: derived tension-circumference plots from the data in part A. Tension was calculated according to Laplace’s Law (see text for details) and circumference was calculated from bladder volume assuming a spherical shape. forms large fibers and predominates in tissues with high tensile strength, whilst collagen III, forming smaller fibers, imparts increased flexibility to tissues and an ability to rearrange during bladder filling [311]. This may be of particular importance to bladders undergoing hypertrophy with a large increase of muscle mass. Collagen synthesis by cells is upregulated by physical stretch, which may provide the basic stimulus in bladder outflow obstruction [312] and may be determined by an increased release of basic fibroblast growth factor from the urothelium [313]. During bladder development the collagen III:I ratio shows an inverse relation to compliance [314]; however other geometrical factors, as mentioned above, will also determine compliance so that changing collagen ratio per se is only one factor among many. The biomechanical properties of the bladder wall will depend not just on the quantity and type of collagen, but also on its packing arrangement, and much work is required to determine the inter-relationship of these factors in determining overall tissue compliance. Figure 17 illustrates information that may be obtained by X-ray analysis on collagen packing arrangement.

**Figure 17**: Collagen visualisation in whole tissue and formation of glycation end-products. A: wide angle X-ray diffraction pattern of hydrated rat tendon. Meridional reflections are from helical layers in the longitudinal axis of the collagen molecules; equatorial reflections from lateral packing of collagen molecules. B: the reactions of non-reducing sugars, such as glucose (shown here in open-chain configuration as in aqueous solution), with amine groups, such as lysine, on protein molecules (R). The initial steps involve production of a Schiff base (a functional group that contains a carbon-nitrogen double bond with the nitrogen atom connected to an aryl or alkyl group) and an Amadori rearrangement product. Such products can then combine causing cross-linking between protein molecules leading to disorganization of protein structure. Environmental and other factors can have significant effects on the passive properties of the bladder. For example oestrogen deprivation reduced the smooth muscle, and increased the collagen content of the bladder wall [210]. The aduction (combination) of sugar to protein without the action of an enzyme (glycation or non-enzymic glycosylation) is associated with diabetes and ageing and a significant factor in damage to extracellular and cellular proteins by promoting cross-linking and aggregation. Figure 17 shows the first steps whereby a reducing sugar, such as glucose, reacts with a basic residue on a protein to form a Schiff base and Amadori product. The subsequent interactions of these products generates cross-linking between adjacent protein chains and a loss of integrity and function. This formation of advanced glycation end-products increases the stiffness of tissues [315]. However several studies have shown that bladder compliance actually increases in animal models of diabetes [316,317] so that the exact relation of this condition and the formation of advanced glycation products remains unclear.

Stress-relaxation is a feature of the whole bladder and isolated muscle strips. It is a visco-elastic phenomenon that manifests itself as a partial reduction of stress (pressure or tension) after a rapid change of strain (volume or length). Physiologically this is advantageous to the filling bladder as it enables steady-state changes of pressure to be minimized during filling. Practically it means that if a bladder is rapidly filled then changes to intravesical pressure may be greater than during slow-fill and give the impression that compliance is less than it actually is. Compliance is a steady-state measurement and changes to pressure or tension should only be made when any stress-relaxation has finished. Stress-relaxation may reside from a rearrangement of the cellular and extracellular elements in a muscle component, although isolated cells also show the same phenomenon indicating that internal rearrangement of cytoskeletal elements must also occur [318]. In the over-compliant obstructed bladder the extent of stress-relaxation diminishes in the same proportion as steady-state stiffness [295]. Because the proportion of extracellular material increases in these bladders this suggests that the phenomenon may reside in both the cellular and extracellular components.

Detrusor muscle also undergoes a phenomenon of strain-softening: this is a reduction of steady-state stiffness on stretch to a new length, distinct from viscoelastic behavior [319,320]. Different stress-strain relationships are illustrated in figure 18. When the muscle is relaxed the process is irreversible, possibly due to cross-link breakages and can take many minutes, even hours, to develop. However, when active force is generated the process is reversible as new cross-bridges are made. Thus the passive
4. PROPERTIES OF THE PELVIC FLOOR AND APPARATUS.

Some studies have indicated down-regulation of oestrogen receptors in tissue samples of women with stress urinary incontinence (SUI) [330]. However, greater cross-linking of fibres was observed in these SI women, which would decrease the Ca²⁺-sensitivity of the contractile apparatus.

5. THE ACTIVE PROPERTIES OF MUSCLE IN THE LOWER URINARY TRACT

The role that intracellular Ca²⁺ plays in activating the contractile machinery was also considered previously and is up-dated in the section on the cell physiology of detrusor smooth muscle (III.3; V.I).

a) Length-tension relationships

All smooth muscles exhibit a bell-shaped dependence for active force on its initial resting length, i.e. there is an optimum resting length, L₀, at which active force is maximal. However, this length-tension curve extends over a greater range of initial lengths than does striated muscle. This is particularly true of detrusor where passive extension much beyond L₀ does not greatly reduce force [333]; human detrusor exhibits similar curves to those from animal preparations [334]. This has obvious physiological advantage whereby large changes in bladder circumference will still permit adequate force development by individual myocytes. Changes to tissue length are reflected in changes to cell length, so that these curves reflect accurately the length-dependence of contractions from individual myocytes [335,336]. There is evidence that length-tension relations are shifted rightwards, i.e. to longer lengths, in samples from some overactive bladders [337], but when normalized to L₀ curves do not vary much between control and pathological organs [338].

b) The contractile state

There is divergence of opinion whether absolute force (normalized to cross-section area) varies in samples from normal and pathological bladders. This is an important issue as it is important to know if conditions such as detrusor underactivity or overactivity are mirrored by changes to the contractile state of detrusor muscle. Alternatively they may be due to others causes such as alteration (total or proportional) to the amount of muscle in a bladder sample, the extent of functional innervation, or the physical properties of the extracellular matrix. Therefore, in this respect care must be exercised in the interpretation of experimental data, as contractile responses evoked agents such as muscarinic receptor agonists may give different responses compared to nerve-mediated responses. In the latter, a reduction of force may be due to denervation rather than muscle failure. To measure the relative extent of denervation compared to contractile
failure one method is to calculate the ratio of tension evoked by nerve-mediated stimulation and an agonist such as carbachol. A reduction of the ratio would imply denervation [339]. Animal models of bladder hypertrophy due to obstruction suggest some contractile failure [295,340,341], but not in all cases [294] and it may be hypothesised that failure is a feature of later growth when a decompensated, more compliant bladder is generated by obstruction. With human detrusor there is little evidence that agonist-induced force is different in detrusor from normal and overactive bladders [127]. There have not been systematic studies of the contractile state of detrusor samples from underactive human bladders. Perhaps the most interesting task in this context is to determine the basis of the condition described as detrusor hyperactivity with impaired contractile function – a symptomatic condition [342] that describes bladder overactivity with incomplete emptying. It is ascribed to a reduction of detrusor contractility [342,343] although this is a description based on urodynamic measurements rather than one derived from principles of muscle mechanics.

6. TENSION AND PRESSURE

Contraction of the muscle component of a hollow system such as the lower urinary tract generates a wall tension (stress) that manifests itself as a change of internal pressure, i.e. energy per unit volume, and by Pascal’s principle is everywhere the same in a static system. The quantitative relationship between pressure, \( P \), and wall tension, \( T \), is not linear but governed by Laplace’s Law, which for a uniform cylinder or radius, \( r \), and wall thickness, \( d \), is given by:

\[
P = \frac{2Td}{r}
\]

Thus a large radius sphere generating the same unit wall tension as a smaller sphere will undergo a smaller pressure change. This can lead to confusion when changes of pressure, regardless of the size of the vessel, are equated linearly to changes of wall tension and muscle performance. Two situations exemplify the need to understand the inter-relationship between pressure and wall tension: i) changes to internal pressure by passively filling the bladder; ii) calculation of active wall tension from internal pressure changes. The first situation [294] shows that when pressure-volume relationships are generated during bladder filling the plots are non-linear and are crucially dependent on the volumes used to fill the bladder. When normalised to wall tension versus changes to bladder radius the plots are linearised, enabling the compliance or stiffness to be calculated (compliance here is change of radius required to generate a unit change of wall tension). The second approach, to estimate active contractile properties of the bladder from pressure changes has been attempted from urodynamic measurements [344] and has been used to compare contractile properties of the bladder in patients with different pathologies [345]. However, this approach is really only useful when the pressure changes manifest wall tension changes alone and not when the energy in the fluid volume is being used to move fluid – i.e. when the pressure is generated isovolumically [346]. Furthermore, changes to contractility can then only be evaluated when muscle length (approximated by bladder radius) is constant, otherwise changes to the length-tension relationship will have occurred to confound the active tension estimations. Figure 19 shows calculations of pressure - left - for a bladder contracting isometrically (constant volume) at two different volumes during development of wall tension. The larger volume bladder develops pressure. Shown also is the change of pressure during the development of wall tension when a bladder is emptying, or remaining at constant volume. In the

![Figure 19: Contraction and pressure changes in a hollow organ. A: tension is developed in a unit element of the wall of a spherical organ as a function of time (dotted line). The solid lines show that consequent change of isovolumic pressure at two volumes, 200 and 400 ml. For the same amount of tension developed, the internal pressures are different. B: Pressures developed in a spherical organ due to the same change to tension as in part A. For the brown curves, volume (dotted line) remains constant; for the green curves volume reduces as the organ empties. Note again the different pressure profiles.](image-url)
latter case more pressure develops as the bladder empties, because the radius is reducing as a function of time. The other extrapolation drawn from muscle mechanics is to estimate changes to the force-velocity relationship from pressure-flow studies. Again a superficial resemblance exists between the two relationships but often calculations fail to recognize the non-linear relationship between force and pressure, and also between velocity and flow, is the cross-sectional area through which the flow occurs is not constant. Attempts to review the various paradigms that relate urodynamic to muscle dynamical properties have been made [347-350], and further hydrodynamic analyses of the lower urinary tract are awaited.

text

VII. THE LOWER GASTRO-INTESTINAL TRACT

1. THE NORMAL PHYSIOLOGY OF THE RECTUM AND ANUS

The ano-rectum is a functional structure that maintains faecal continence and also facilitates defaecation, when appropriate. The structure is shown in figure 20. Continence is maintained by maintaining an adequate rectal capacity at pressures less than that required to overcome the resistance offered by a competent anal sphincter, analogous to the condition in the lower urinary tract. Anal sphincter competence is due to a combination of internal sphincter tonic contraction, augmented by voluntary control via the external sphincter [351]. The anal sphincter mechanism may be helped by a sling effect of the puborectalis muscle around the anal canal, and the magnitude of the anorectal angle correlates with the severity of incontinence [352]. Faecal incontinence is increased in patients where the muscle has been divided; however, results from procedures that generate an acute anorectal angle are inconclusive [353]. Rectal compliance is maintained on filling by a reflex decrease of tone. The ano-rectum contains the necessary systems of receptors, neural networks and pacemaker cells to maintain the filling and emptying functions, assisted with external autonomic and somatic control.

The rectum is normally empty, but fills as faecal material accumulates in the descending and sigmoid colon, and is pushed forward through occasional peristaltic waves (mass movements). Volume of first sensation is up to 70-90 ml, urgency develops above about 200 ml [354,355]. A recto-anal sampling reflex [356] occurs on rectal distension that lowers pressures [357-359] in the anal canal allowing the contents to approach the mucosa, whilst the external sphincter remains contracted. The considerable sensory innervation of this region can distinguish between the gaseous (flatus) or solid state of the material. If defaecation is inappropriate contents are returned to the rectum, assisted by an increase of rectal compliance and inhibition of descending pathways. Such a sampling reflex can normally occur four to ten times per hour [360]. With larger volumes in the rectum, defaecation can be voluntarily deferred by contraction of the external sphincter and puborectalis (Figure 21).

If defaecation is appropriate intra-abdominal and intra-rectal pressures are raised to overcome sphincter resistance; the process is assisted by reflex relaxations of the internal and external sphincters, as well as the puborectalis. An increase of the anorectal angle also facilitates the process; brought about by taking up a sitting or squatting position and puborectalis relaxation. Upon completion, the internal sphincter and puborectalis transiently contract and restore the anorectal angle.

Continence is therefore maintained by a number of factors:

- effective anal sphincters and an acute anorectal angle to provide a proper barrier
- a suitably large, compliant and evacuable reservoir
- intact sensation in the ano-rectum
- proper consistency of the faeces

The most common cause of incontinence is damage to, or dysfunction of, the external and internal anal sphincters or their nerve supply. In addition, damage to sensory nerves that detect stools in the rectum will derange the reflexes that maintain continence. Damage may occur during childbirth, pelvic tumours, haemorrhoid surgery or neurodegenerative conditions. A decrease of rectal compliance can occur following radiation treatment or inflammatory bowel disease. Other manifestations of pelvic floor dysfunction such as rectal prolapse, rectocoele or weakness of pelvic floor muscles will all increase the likelihood of faecal incontinence.

2. INNERVATION

Parasympathetic innervation to the rectum and anal canal, via the pelvic plexus, originates mainly from sacral segments S1-S4 (pelvic splanchnic nerves).
the sympathetic supply is from T11,12 and L1,2. These fibres have the usual antagonistic effect on function with parasympathetic fibres increasing peristalsis and secretions. Somatic fibres to the external sphincter and pelvic floor muscles originate from Onuf's nucleus in S2-S4 and run in the pudendal nerve. Somatic and visceral afferents also arise from the ano-rectum: somatic fibres accompany the pudendal nerves and visceral afferents the parasympathetic and sympathetic efferents. The target for the postganglionic fibres can be the enteric nerve plexi that lie between the smooth muscle layers or the smooth muscle cells. Moreover there is increasing evidence that interstitial cells of Cajal (ICC – see below) are the main target for excitatory and inhibitory motor neurones that modulate smooth muscle contractility. The density of neurones in the myenteric and submucosal plexi declines towards the distal rectum and into the anus, but do not disappear together [362,363]. However, the variability of neuronal ganglia is variable along the ano-rectum and between patients and thus renders difficult the generation of criteria to neuronal deficits akin to intestinal neuronal dysplasia [364]. The use of botulinum toxin A is increasing advocated to manage various spastic conditions in the gastrointestinal tract [365,366], but as with its use in the lower urinary tract, its mode of action is unclear, although it has been postulated to diminish sympathetic activity [367]

Hirschsprung's disease is a developmental disorder of the enteric nervous system, characterised by an absence of ganglion cells resulting in functional obstruction. The aganglisation begins at the anus and continues proximally. The absence of ganglion cells results in an increase of extrinsic innervation, in particular adrenergic innervation, resulting in an increase of muscle tone and a functional obstruction. This pathology may be exacerbated by increased myogenic tone and loss of inhibitory control mediated through ICC [368,369]. The genetic basis of the disease has been investigated, and one hypothesis is that it is a failure of neural crest cells to migrate. A number of mutations have been identified including the proto-oncogene RET, an associated protein EDNRB, as well as various endothelin-receptor genes [370-372].

3. SMOOTH MUSCLE TISSUES

The rectum. The rectum is composed of outer, longitudinal and inner, circular layers of smooth muscle, as in proximal regions of the G-I tract, and generate phasic rhythms at 10-20 per hour [373]. The circular muscle develops little intrinsic tone, in contrast to that developed by the longitudinal muscle layer. Relaxation is induced by both alpha- and beta-receptor agonists with the latter generating more long-lasting responses [374]. Experiments with isolated strips show that nerve-mediated contractions are mediated by cholinergic (M3) and non-cholinergic components, with little sympathetic, adrenergic activation [375]. The non-cholinergic fraction is importantly mediated by tachykinins acting on NK2 receptors. The sympathetic supply to the rectum exerts an inhibitory influence, as cutting the thoraco-lumbar supply reduces motility of the rectum [376,377], which may by a presynaptic effect on excitatory nerves analogous to their action in lower urinary tract. In addition, the rectum receives a nitricergic innervation that relaxes the smooth muscle, as evidenced in preparations from human and animal sources [378,379]. 5-HT receptors

Figure 21: Components of faecal continence and defaecation. A: the conditions required for faecal continence. These include: appropriate muscle function in the anus and rectum to maintain a closed outlet and compliant reservoir; appropriate structural features; and proper consistency of the faeces. B: The stages in (deferred) defaecation.
also mediate smooth muscle tone and peristalsis throughout the gastrointestinal tract. In human and canine rectum preparations relaxation is also mediated via 5HT4 receptors [380-382]. This is of interest because 5HT4 receptor-agonists might be used as modulators of rectal tone as they have uses in the management of gastro-intestinal disorders [383], although reported cardiac side-effects have resulted in agents such as cisapride being withdrawn from the North American market [384]. More recent prokinetic receptor agonists (eg ATI-7505) may have fewer cardiac side-effects and so may prove safer alternatives [385].

The anal canal. The longitudinal smooth muscle layer of the rectum extends into the anal canal, to form a conjoint longitudinal coat, whilst the circular layer forms the internal anal sphincter. The responses to autonomic transmitters differ from the rectum whereby the anal sphincter muscle is relaxed by muscarinic and β-adrenoceptor agonists and contracts to α-adrenoceptor agonists. The longitudinal muscle contacts to both α- and β-adrenoceptor agonists [386]. The response to adrenoceptor agonists reflects the predominant effect of extrinsic sympathetic fibres in maintaining control of the anal sphincter [387]. Parasympathetic fibres have been suggested to modulate sympathetic nervous activity [388]. Nitric fibres offer the predominant relaxatory tone and may exert their effect via the enteric nerve system (below) [389]. Oral intake of the NO precursor L-arginine had no effect on anal pressures [390], but topical application of L-arginine paste to anal fissure did ameliorate the condition [391]. The different responses along the anorectum may in part be due to the variation of receptor populations in this region [392]. Angiotensin II (AT) has been proposed as an important mediator of tone in the anal sphincter and ACE-inhibitors as well as AT1 receptor antagonists reduce internal anal sphincter pressures [393-395].

The distribution of receptor subtypes in the anorectum is of interest because of the desirability of developing more tissue selective agents to modulate muscle function. β3-receptor subtypes have been demonstrated throughout the gastrointestinal tract in both human and animal preparations [396,397], and this may provide a role for receptor modulators as is being advocated in the lower urinary tract. Muscarinic responses are predominantly mediated by M3 subtype receptors.

There has been considerable interest in the role of the rho-kinase system in maintaining and modulating tone in the anal sphincter [398], and has been proposed as a potential therapeutic target [399]. This pathway may be involved in the relaxatory effect of the PDE5 inhibitor, sildenafil on precontracted anal smooth muscle [400,401]. Such pathways may be useful in the management of anal fissure, but an understanding of this mechanism will also be valuable in the investigation of the basis of faecal incontinence.

4. INTERSTITIAL CELLS

Interstitial cells of Cajal (ICC) accompany the enteric nerve plexuses that run between the successive smooth muscle layers of the gastrointestinal tract: IC- MY in the longitudinal layer as they are associated with the myenteric plexus; and IC-SM in the circular muscle layer. They form an extensive network through connections via gap junctions, and also form similar junctions with adjacent smooth muscle cells. ICC are believed to be pacemaker cells in the gastrointestinal tract as evidenced by spontaneous electrical signals arising from ICC and propagating to smooth muscle cells [402-405]. ICCs are probably the target for neuroeffector nerves from the autonomic and enteric systems supplying the gastrointestinal tract, rather than the smooth muscle cells themselves [406]. Rhythmic electrical activities in ICCs varies in cells from different sites in the gastrointestinal tract; however most are mediated by transient increases of the intracellular [Ca2+] arising from intracellular stores that subsequently open Ca2+-dependent ion channels to generate transient depolarisations [407]. The particular roles of intracellular Ca-stores, including the endoplasmic reticulum and mitochondria, vary in cells from different sites. ICCs express a surface marker to a receptor tyrosine kinase, kit, that not only acts as a characterising feature of the cell but is also vital for cell function.

Within the anorectum ICCs have been identified but their distribution is heterogeneous. In the rectum there were dense networks in the myenteric and submucosal layers, whereas in the anal sphincter they were confined to regions around the muscle bundles [408]. In the rectum ICCs have been shown to be the target of relaxatory nitric fibres, as heterozygous kit knock-out mice, as well as those deficient in nitric oxide synthase demonstrate impaired relaxation [409]. Others have suggested that ICC may not be responsible for all aspects of anal tone, rather that they determine intrinsic tone of the tissue. However, more complex reflexes, such as the recto-anal reflex (RAR; i.e. relaxation of the internal anal sphincter in response to anal stretch) may be more independent of ICC [410]. Furthermore, the latter study showed that different sources of NO mediated different functions – endothelial NOS regulated basal tone and neuronal NOS mediated the RAR and relaxation mediated by electrical stimulation of nitric fibres. Thus the precise inter-relationship between ICCs, smooth muscle cells and NOS-dependent muscular tone in the ano-rectum remains to be clarified.

5. FUTURE DIRECTIONS

There is still an incomplete knowledge of the factors
that regulate the contractile state of the smooth and skeletal muscles of the ano-rectum, as well as the role of the enteric and extrinsic nerve supplies, along with the interstitial cells that seem to mediate between nerves and smooth muscle. Much data obtained from studies of obstructive conditions can shed light on these control system and be used to understand better failure of continence mechanisms. Furthermore, the cellular biology that underlies sensation in the ano-rectum, as a basis of sampling reflexes for example, is little understood. However, several studies have shown that a subset of patients with faecal incontinence demonstrates an increase of urgency that may underlie the condition [411-413]. An interesting aspect is whether the emerging field of lower urinary tract sensation may be applied to the analogous situation in the ano-rectum.

VIII. NOVEL MOLECULAR TARGETS

1. INTRODUCTION

The previous sections have described recent advances in the multiplicity of mechanisms that regulate lower urinary tract function, and that may undergo changes associated with pathological changes to function. Various signal transduction mechanisms have been implicated in these controls that may make suitable targets for manipulation of function. According to the most recent classification [414], signal transduction mechanisms have been sub-classified into seven categories, namely.

- 7TM (seven-transmembrane helix) metabotropic receptors of the G protein-coupled superfamily;
- Transmitter-gated channels;
- Ion channels;
- Catalytic receptors;
- Nuclear receptors;
- Transporters;
- Enzymes.

This report will highlight several examples from the first and third categories as sources of novel targets for the treatments of urinary incontinence. The following terminology and definitions are derived from the most recent classification, “Guide to Receptors and Channels, 3rd Edition [414]. Emphasis in this section will be on targets covered less comprehensively above.

2. METABOTROPIC RECEPTORS

a) Acetylcholine-Muscarinic receptors

Among the many 7TM (metabotropic) receptors, muscarinic receptors are the most important for urinary bladder contraction, and currently for treatment of the overactive bladder.

The urinary bladder is profusely supplied with autonomic nerve fibers, which form a dense plexus among the detrusor smooth muscle cells. The majority of these nerves are excitatory cholinergic and contain acetyl cholinesterase [415]. Whilst they occur in profusion throughout the muscle coat of the bladder, some muscle bundles are more richly innervated than others. Thus, normal human detrusor contraction is mediated almost exclusively through muscarinic receptor stimulation by released acetylcholine, and responses are completely abolished by atropine [416]. Detrusor strips from normal human bladders produce little response to single stimuli and require repetitive activation of the intrinsic nerves to induce a response.

Molecular cloning studies have revealed five distinct genes for muscarinic ACh receptors in rats and humans, and five receptor subtypes (m1-5) correspond to these gene products [416] – see also section V.1. Muscarinic receptors are coupled to G-proteins; M1, M3 and M5 preferentially couple by Gq to phosphoinositide hydrolysis and diacylglycerol production, and M2 and M4 couple to Gi and inhibit adenylate cyclase activity. The abundance and roles of the various receptors have been considered above (Sections III and V).

Desensitization of muscarinic acetylcholine receptors is one mechanism that may cause detrusor smooth muscle to become less sensitive to incoming stimuli. This is mediated by phosphorylation of the muscarinic acetylcholine receptor by guanosine phosphate binding G-protein coupled receptor kinase (GRK) [417-419], and m2 and m3 GRK2 mRNAs have been described. Protein expression of GRK2 in normal bladder detrusor is significantly higher in obstructed bladder detrusor in patients with benign prostatic hyperplasia [419]. Failure of the desensitizing mechanism may therefore contribute to detrusor overactivity with bladder outlet obstruction.

Non-neuronal acetylcholine release is also described, from the bladder urothelium, or the suburothelial space, although its function in unknown (see also section II). The non-neuronal acetylcholine release is increased by stretch, is increased with age [420] and may contribute to pathogenesis of overactive bladder.

b) Adrenergic beta-receptors

During urine storage, sympathetic nerve activity to the lower urinary tract is important: with both relaxation of bladder smooth muscle, via adrenergic ß-receptors, and contraction of urethral smooth muscle via adrenergic ß1-receptors [421] - (see also section V.2). There are three ß-receptor subtypes, ß1, ß2, and ß3, and gene expression of ß3 receptors and relaxation of human detrusor via the same receptors has been recently reported [249,422-424]. Several ß3-agonists (KUC-7483, YM-178, FK-175) have been developed, and are undergoing clinical trials.
The beta-adrenoceptor is a Gs-protein-coupled receptor and activation elevates smooth muscle camp, which may trigger relaxation of smooth muscle. Downstream effectors activated via a cAMP-dependent mechanism(s) include plasma membrane K+ channels, such as the large-conductance, Ca2+-activated K+ (BKCa) channel. ß-adrenoceptor-mediated relaxant mechanisms also include cAMP-independent signaling pathways, suggested by several pharmacological and electrophysiological studies. In airway smooth muscle, direct activation of the BKCa channel by Gs-α is a mechanism by which stimulation of β2-adrenoceptors elicits muscle relaxation independently of the elevation of cAMP [425]. The α3 adrenoceptor is recognized as an attractive target for drug discovery, as activation of β1 or β2-receptors can have undesirable side effects such as tachycardia or muscle tremors. Consequently, recent efforts have been directed toward the design of selective β3 agonists [145]. GW427353, a novel agonist, evokes bladder relaxation and facilitates bladder storage mechanisms in the dog [146]. The β3 agonist CL-316243 increases urine storage in SHRs [147].

**c) Endothelin**

The three isoforms of the 21-amino-acid peptide endothelin (ET-1, ENSG00000078401, ET-2 (ENSG00000127129) and ET-3 (ENSG00000124205) mediate their actions via the 7TM receptors ETA and ETB [426]. Non-selective peptide (e.g. TAK044, pA2 8.4) and non-peptide (e.g. bosentan, pA2 6.0–7.2; SB209670, pA2 9.4) antagonists can block both ETA and ETB receptors. The predominant role of ETA receptors in the contractile effects of ETs in the detrusor has been confirmed by several other investigators in animal, as well as in human bladders [427,428]. Features of ETA and ETB receptors are summarised in Table 1.

In human detrusor, ET-1-induced contractions are mediated mainly by the ETA receptor and not by the ETB receptor. RT-PCR revealed positive amplification of the ETA, but not ETB, receptor mRNA fragments [429]. This is in contrast to findings in guinea pig bladder, where both ETA and ETB receptors contributed to ET-induced contraction [430]. The functional role of ETs in the detrusor has not been established. The slow onset of the contractile effects seems to preclude direct participation in bladder emptying. It has been suggested that ETs may be involved in regulation of detrusor muscle tone by a direct effect [430]. However in the rat bladder ET-1 potentiates the contractions evoked by both transmural nerve stimulation and applications of ATP at peptide concentrations 10-fold below those needed to produce an increase in bladder tone [427]. This suggests a modulatory effect on detrusor neurotransmission. The selective ET-A antagonist LU 302146 acts on the atropine-resistant component of efferent detrusor activation since additional administration of atropine almost completely abolished detrusor contraction. This observation raises the possibility that ET-receptor antagonists might be beneficial in patients with neurogenic bladder dysfunction or in patients with functional or anatomical BOO [431].

**Table 1. Endothelin receptors. The values in parentheses for the selective antagonists are pKi values**
ET-1 and ET<sub>A</sub> receptors might be involved in the generation of premicturition contractions in BOO rats, and endothelin ET<sub>A</sub> receptor antagonists, such as YM598, may have ameliorating effects in patients with bladder overactivity associated with BOO [432]. ET<sub>A</sub> receptor inhibition could be an effective treatment for neurogenic bladder overactivity in pathological conditions such as SCI [433]. ET<sub>A</sub> receptors play an important role in the lower urinary tract contraction, and that the selective endothelin ET<sub>A</sub> receptor antagonist YM598 has ameliorating effects on various urinary dysfunctions, including benign prostatic hyperplasia [434].

d) GABA<sub>B</sub>

Functional GABA<sub>B</sub> receptors are formed from the heterodimerization of two similar 7TM subunits termed GABA<sub>B1</sub> ENSG00000168760: GABA<sub>B2</sub> ENSG00000136928. Principal transduction is via G<sub>i/o</sub>. Selective agonists are 3-APPA, 3-APMPA (CGP 35024,), (R)-(−)-baclofen, and CGP44532, and selective antagonists are CGP62349, CGP55845, SCH50911, 2-hydroxy-s-(−)-saclofen and CGP35348.

Detrusor overactivity may be controlled by modulating the afferent input from the bladder and the excitability of the sacral reflex centre and suggests a novel method to treat obstructive bladder patients with oral gabapentin [435]. Fourteen of 31 patients with refractory OAB and nocturia improved with oral gabapentin. Gabapentin was generally well tolerated and can be considered in selective patients when conventional modalities have failed [436].

e) Glutamate metabotropic receptors

There are two major classes of glutamate receptors, the ionotropic receptors which form ligand-gated cation channels [437] and the metabotropic receptors (mGluRs) which are a family of G-protein coupled receptors activating distinct signal transduction pathways in neurons [438]. The former includes n-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-l-isoxazole-4-propionic acid (AMPA), and kainite receptors, which have been revealed to play essential roles in the control of micturition reflexes [439,440]. The latter, mGluRs are constituted of eight groups on the basis of sequence homology, transduction mechanism and agonist pharmacology, and less is yet known about the functional roles in the lower urinary tract. These studies examined whether the group I mGluRs (ie, mGluR1 and mGluR5) participated in the micturition reflex of decerebrate, unanesthetised mice. Glutamate is involved in many CNS functions, and drugs acting on the different glutamate receptors may affect not only micturition [441, 442].

Female wild-type C57BL/6 mice and mGluR1 knockout mice under decerebrate, unanesthetised conditions were used for in vivo cystometry with 6-methyl-2-(phenylethynyl)pyridine (MPEP, 0.3-30 mg/kg i.p.), a selective mGluR5 antagonist. Inter-micturition interval (IMI) was measured during continuous infusion cystometrograms. Blocking mGluR1, mGluR5 or both increased bladder capacity and mGluR1 and mGluR5 additively interacted to transmit afferent signals from the bladder (figure 22). Thus, a group I mGluR antagonist, which blocks both mGluR1 and mGluR5, would exert a beneficial effect more potently than a drug targeted at either mGluR1 or mGluR5 alone. Therefore, these may be promising drugs to treat storage dysfunctions, including detrusor overactivity and urgency urinary incontinence [443].

f) Prostanoid receptors

Prostanoid receptors are activated by the endogenous ligands prostaglandin (PG) D<sub>2</sub> (D), PGE<sub>2</sub> (E), PGF<sub>2α</sub> (F), PGH<sub>2</sub> (H), prostacyclin [PGI2 (l)] and thromboxane A<sub>2</sub> (TX). Measurement of the potency of PGI<sub>2</sub> and TXA<sub>2</sub> is hampered by their instability in physiological salt solution; they are often replaced by cicaprost and U46619, respectively, in receptor characterization studies. Prostanoid actions are mediated by specific receptors on cell membranes, including DP, EP, IP, and TP receptors that preferentially respond to PGD<sub>2</sub>, PGE<sub>2</sub>, PGF<sub>2</sub>, PGI<sub>2</sub>, and TXA<sub>2</sub>, respectively. The EP receptor itself is subdivided into four subtypes: EP<sub>1</sub>, EP<sub>2</sub>, EP<sub>3</sub> and EP<sub>4</sub> (table 2) [444, 445].

The signaling pathways vary. For example, TP receptors signal via G<sub>q</sub> protein, activating IP<sub>3</sub>/diacylglycerol pathways, but also other G-proteins may be involved. EP<sub>1</sub> receptors signal via IP<sub>3</sub> generation and increased cell Ca<sup>2+</sup>; activation of EP<sub>2</sub> and EP<sub>4</sub> leads to an increase in cAMP; and EP<sub>3</sub> activation inhibits cAMP generation via a pertussis toxin-sensitive G<sub>i</sub>-coupled mechanism and may also signal via the small G-protein, rho. Prostanoids may affect excitation-contraction coupling in the detrusor in two ways, directly by effects on the smooth muscle, and/or indirectly via effects on neurotransmission.

The prostanoid receptor most important for detrusor function has not been established. Mice lacking EP<sub>1</sub> receptors had normal cystometry, but did not react to intravesical PGE<sub>2</sub> instillation, which caused detrusor overactivity in wild-type controls. Obstruction of EP<sub>1</sub> receptor-knockout mice did not prevent the resulting increase in bladder weight but prevented the increase in spontaneous contractile activity (non-voiding contractions) seen in wild-type controls [231]. Prostaglandin E<sub>2</sub> enhances the micturition reflex through C-fiber afferents via EP<sub>1</sub>. Therefore, EP<sub>1</sub> selective antagonists may improve bladder storage function [446]. However, EP receptor distribution and the implications for bladder mucosa function are not fully understood. EP<sub>2</sub> and EP<sub>4</sub> mRNA are over-expressed in the urothelium of obstructed human urinary bladder compared to non-obstructed bladder.
Figure 22: Modulation of mGlu receptor activity and continuous infusion cystometry. A: effect of 6-methyl-2-(phenylethynyl)pyridine (MPEP, 30 mg/kg i.p.), a selective mGluR5 antagonist, on bladder activity during continuous infusion (30 µl/min) in a decerebrate, unanesthetized mouse. The dose increased the inter-micturition interval approximately 26% of the baseline value in this animal without a suppression of micturition pressure. B: the time-course of the effect of MPEP (0.3, 3 and 30 mg/kg i.p.) or vehicle on inter-micturition interval (IMI) in decerebrate, unanesthetized wild type mice. C: the time-course of the effect of MPEP (30 mg/kg i.p.) or vehicle on IMI in decerebrate, unanesthetized mGluR1 knockout mice. The peak increase of IMI was similar to that in wild-types. M Takeda, unpublished data

This overexpression significantly correlated with International Prostate Symptom Scores (IPSS), especially the storage IPSS component [447]. Hence, in contrast to the previous mouse data, EP2 and EP4 could be promising receptor subtypes for the treatment of overactive bladder [446].

3. ION-CHANNELS

a) Calcium (voltage-gated)-channels

Calcium (Ca\(^{2+}\)) channels are voltage-gated ion channels present in the membrane of most excitable cells and form hetero-oligomeric complexes. The \(\alpha_1\) subunit is pore-forming and provides the extracellular binding sites for practically all agonists and antagonists. The ten cloned \(\alpha\)-subunits can be grouped into three families:

- a) the high-voltage activated dihydropyridine-sensitive (L-type, CaV1.x) channels;
- b) the high-voltage activated dihydropyridine-insensitive (CaV2.x) channels and
- c) the low-voltage-activated (T-type, CaV3.x) channels.

Each \(\alpha_1\) subunit has four homologous repeats (I–IV), each repeat having six transmembrane domains and a pore-forming region between transmembrane domains S5 and S6. Gating is thought to be associated with the membrane-spanning S4 segment, which contains highly conserved positive charges. Many of the \(\alpha_1\)-subunit genes give rise to alternatively spliced products. At least for high-voltage activated channels, it is likely that native channels comprise co-assemblies of \(\alpha_1\), \(\beta\) and \(\gamma_2\)-\(\delta\) subunits. The \(\gamma\) subunits have not been proven to associate with channels other than \(\alpha_1S\). The \(\alpha_2\)-\(\gamma_1\) and \(\alpha_2\)-\(\gamma_2\) subunits bind gabapentin and pregabalin.

Activation of detrusor muscle, both through muscarinic receptor and NANC pathways, seems to require both influx of extracellular Ca\(^{2+}\) through Ca\(^{2+}\) channels and mobilization of intracellular Ca\(^{2+}\) [448,449]. The importance of each mechanism may vary between species and also with respect to the transmitter studied.

b) Epithelial Na\(^{+}\) channels (ENaC)

Epithelial Na\(^{+}\) channels (ENaC) are responsible for sodium reabsorption by the epithelium lining the distal part of the kidney tubule, and fulfill similar functional roles in some other tissues such as the alveolar epithelium and the distal colon. This reabsorption of Na\(^{+}\) is regulated by aldosterone, vasopressin and glucocorticoids, and is one of the essential mechanisms in the regulation of sodium balance, blood volume and blood pressure.

The degenerin epithelial Na\(^{+}\) channel (ENaC) family has been proposed as a transducer of sensory stimuli in several species [450-453]. These ENaCs seem to be mechanosensitive (MS) according to many findings. In the rabbit urinary bladder, ENaC changes its Na\(^{+}\) transporter properties after changes of hydrostatic pressure [451]. ENaC in the renal pelvic epithelium of rats participates in the activation of afferent renal MS neurons by increased renal pelvic pressure [31]. Thus, ENaCs are likely to be involved in MS transduction in the bladder, and may be related to the pathophysiology of changes in sensory nerve function by upregulation of ENaCs in the bladder epithelial cells or afferent nerve terminal. ENaC is expressed in the mammalian urinary bladder and it has been proposed that amiloride-sensitive Na\(^{+}\) transport across the apical membrane of the mammalian urinary bladder epithelium is mediated primarily by ENaC [454].

1. ENaC in human urinary bladder:

The \(\alpha\)-, \(\beta\)-, and \(\gamma\)-subunit ENaC proteins and mRNA are clearly expressed in human bladder epithelium with and without BOO. The quantified ENaC mRNA expression correlates significantly with the storage symptom score (figure 4).

2. ENaC in rat and rabbit urinary bladder:

Intravesical infusion of amiloride (1 mM) significantly reduces the frequency of reflex voiding during bladder filling, increases bladder capacity, with no effect on the amplitude of micturition pressure. Stretch (50%) induced significant increase in ATP release from whole layer bladder strips, but only a slight increase in muscular layer strips without epithelium. Amiloride (1 mM) significantly suppressed stretch-evoked ATP release from bladder epithelium [455,456]. cAMP stimulates the insertion of new Na\(^{+}\) channels into the apical membrane of the rabbit bladder epithelium [457].

c) Potassium channels: The 6TM family: Maxi-K channel

Potassium channels are fundamental regulators of excitability. They control the cell membrane potential, the frequency and the shape of the action potential, and the secretion of hormones and neurotransmitters. Their activity may be regulated by transmembrane voltage, Ca\(^{2+}\) and neurotransmitters (and the signalling pathways they stimulate). They consist of a primary pore-forming \(\alpha\)-subunit often associated with auxiliary regulatory subunits. The three main families are the 2TM (two transmembrane domain), 4TM and 6TM families.

The 6TM family of K channels comprises the voltage-gated Kv subfamilies, the KCNQ subfamily, the EAG subfamily (which includes HERG channels), the Ca\(^{2+}\)-activated s/o subfamily (actually with 7TM) and the Ca\(^{2+}\)-activated SK subfamily. As for the 2TM family, the pore-forming \(\alpha\)-subunits form tetramers and heteromeric channels may be formed within subfamilies (e.g. Kv1.1 with Kv1.2; KCNQ2 with KCNQ3).
Large-conductance, voltage- and Ca$^{2+}$-activated K$^+$ (Maxi K, or BK$_{Ca}$) channels regulate the resting potential and repolarization of the action potential, and play a critical role in modulating contractile tone of smooth muscle, including the detrusor [107,458], and neuronal processes. Not only BK$_{Ca}$ channels, but also small-conductance (SK$_{Ca}$) channels, are regulators of excitability in detrusor smooth muscle. Ca$^{2+}$ entry through voltage-dependent Ca$^{2+}$ channels activates both BK$_{Ca}$ and SK$_{Ca}$ channels, but Ca$^{2+}$ release (Ca$^{2+}$ sparks) through ryanodine receptors activates only BK$_{Ca}$ channels [459, 460]. Thus, BK$_{Ca}$ channels are more important in counteracting enhanced spontaneous mechanical activity with urinary bladder smooth muscle stretch. Phasic contractions of human detrusor, due to transmitter release, are dependent on calcium entry through L-type Ca$^{2+}$ channels and BK$_{Ca}$ channels have a very significant role in reducing both cholinergic- and purinergic-induced contractility [112]. Thus, Ca$^{2+}$-dependent K$^+$ channels could contribute to pathologies such as overactive detrusor and represent attractive pharmacological targets for decreasing phasic contractions of detrusor smooth muscle in OAB [461]. The selective antagonist for BK$_{Ca}$ channels, NS-8, decreased the discharge rate of the afferent pelvic nerve on bladder filling in rats [122]. Thus, NS-8 might have the potential for treating patients with urinary frequency and incontinence.

The importance of the BK$_{Ca}$ channel is also demonstrated by the observation that local h-slo cDNA (i.e., the BK$_{Ca}$ channel) injection ameliorated detrusor overactivity in a rat model of partial urinary outlet obstruction [113]. It was proposed that expression of h-slo in rat bladder functionally antagonized the increased contractility normally observed in obstructed animals, and thereby improved detrusor overactivity and also indicated a potential utility of gene therapy for urinary incontinence. Consistent with increased urinary bladder contractility caused by the absence of BK$_{Ca}$ currents, slo(-/-) mice demonstrate a marked elevation in urinary frequency [462]. BK$_{Ca}$ channels consist of distinct α and β-subunits. Whereas only one α-subunit has been identified until now, four putative β-subunit types have been cloned. The existence of BK$_{Ca}$ α- and β-1-subunits in human urinary bladder (both in the mucosal layer and the detrusor) have been demonstrated with a combination of genetic and immunohistochemical methods. The expression level of BK$_{Ca}$ channels in the detrusor muscle and the mucosal layer decreased in BOO bladders compared with controls, consistent with the possibility that they have a pivotal role in the generation of OAB induced by bladder outlet obstruction [463] (figure 23).
A novel BKCa channel blocker, A-272651, represents one of the first small molecules that could be used to characterise BKCa channels in physiological and pathological states [464]. No other K+ channel opener seems to have passed the proof of concept stage, and there is at present no convincing evidence showing that K+ channel opening is a useful principle for treatment of detrusor overactivity [465]. The safety and tolerability of escalating doses of hMaxi-K, a gene transfer product of the human Maxi-K (BKCa) channel, were confirmed by clinical and laboratory tests in 11 patients with moderate to severe erectile dysfunction. hMaxi-K gene transfer is potentially a viable approach to the treatment of erectile dysfunction and other smooth muscle diseases with targeted access [466].

d) Transient receptor potential (TRP) cation channels

The TRP superfamily of cation channels, whose founder member is the Drosophila Trp channel, can be divided, in mammals, into six families; TRPC, TRPM, TRPV, TRPA, TRPP and TRPML based on amino acid homologies. TRP subunits contain six putative transmembrane domains and assemble as homo- or hetero-tetramers to form cation selective channels with varied permeation properties. The TRPC ('Canonical') and TRPM ('Melastatin') subfamilies consist of seven and eight different channels, respectively (i.e., TRPC1-7 and TRPM1-8). The TRPV ('Vanilloid') subfamily comprises six members (TRPV1-6) whereas the TRPA (Ankyrin) subfamily has only one mammalian member (TRPA1). The TRPP ('Polycystin') and TRPML ('Mucolipin') families are not fully characterised. Established, or potential, physiological functions of the individual members of the TRP families are discussed in detail in the recommended reviews and are only briefly mentioned here [467,468].

The importance of stretch-evoked ATP release from urothelium, and the subsequent activation of afferents has been described above (section II). The nature of the mechnosensitive (MS) processes responsible for ATP release is unclear but ENaCs and TRP ion channels are candidates [469]. With respect to TRP channels several have been identified, and many also have thermosensing properties [470].

Among several thermosensing TRP channels, TRPA1, TRPM8, TRPV1, and TRPV4 are candidates of molecular targets of the novel treatments for urinary incontinence (table 3) [471]. TRPA1 may be a candidate for an MS channel, with cold-sensing capability [472,473]. In addition to activation by mechanical stimuli, TRPA1 is also a cold receptor: activation is initiated when the temperature is decreased to 17°C [474]. Intravesical infusion of ice water elicits uninhibited contraction of bladder in infants and patients with neurogenic bladder and it is reasonable to assume that TRPA1 is involved in the bladder-cooling reflex and should provide a further treatment target [475].

• TRPA1 and TRPM8 in the rat and the human urinary bladder:

Whole mount double-staining demonstrates expression of TRPA1 on the CGRP-reactive sensory nerve termini, but not on mucosa of the bladder (figure 24) and is much greater in the obstructed bladder. Expression of mRNA and protein of TRPA1 and TRPM8 were confirmed by quantitative RT-PCR and immunohistochemistry. During cystometry, 0.6 mM trans-cinnamaldehyde (CA; an agonist of TRPA1) decreased the pressure threshold (PT), inter-micturition interval (IMI) and micturition pressure (figure 25) – similar results were obtained with AITC: allyl-isothiocyanate. The effects on PT and IMI were completely reversible. Desensitization of C-fibres by capsaicin significantly attenuated the effects of 0.6 mM CA on PT and IMI (p=0.022, 0.002). These results, couple to the fact that TRPA1 expression is increased in the obstructed bladder, suggest that both TRPA1 and TRPM8 may contribute to the pathophysiology of OAB [476,477].

e) ER stress

In bladder outlet obstruction (BOO), mechanical stress and ischemia/hypoxia are implicated in structural and functional alterations to the urinary bladder. In other organs, mechanical stress and hypoxia trigger a

C: the expression of TRPA1 and TRPM8 mRNA in the human bladder mucosa (muc), detrusor muscle (musc) and prostate (pros). D: the expression of TRPA1 mRNA was significantly higher in the mucosa of BOO (bladder outlet obstruction) than non-obstructed human bladder, but not in the muscle layer, nor in the prostate, p<0.01. M Takeda, unpublished data
particular response, the endoplasmic reticulum (ER) stress response. ER stress is defined as accumulation of unfolded or misfolded proteins in the ER, which induces a coordinated adaptive program called unfolded protein response (UPR). UPR alleviates ER stress by suppression of protein synthesis, facilitation of protein folding via induction of ER chaperones, including a 78 kDa glucose-regulated protein (GRP78) and reinforced degradation of unfolded proteins. If the stress is beyond capacity of the adaptive machinery, however, cells undergo apoptosis via several mechanisms including induction of CCAAT/enhancer-binding protein-homologous protein (CHOP) [478].

Hence, the involvement of ER stress in the damage of the bladder caused by BOO has been examined. An experimental model of BOO was established in rats by complete ligature of the urethra for 24 h, and bladders were subjected to Northern blot analysis and assessment of apoptosis. Isolated urinary bladders and bladder-derived smooth muscle cells (BSMCs) were also exposed to mechanical strain and hypoxia and used for analyses. To examine the involvement of ER stress in bladder damage, effects of a chemical chaperone, 4-phenylbutyrate (4-PBA), were evaluated in vitro and in vivo. Outlet obstruction for 24 hours induced expression of ER stress markers, GRP78 and CHOP, in the bladder, and was associated with induction of markers for mechanical stress (cyclooxygenases 2) and hypoxia (vascular endothelial growth factor and glyceraldehyde-3-phosphate dehydrogenase). When isolated bladders and BSMCs were subjected to mechanical strain, induction of GRP78 and CHOP was not observed. In contrast, when BSMCs were exposed to hypoxic stress caused by CoCl₂ or thenoyltrifluoroacetone (TTFA), substantial up-regulation of GRP78 and CHOP was observed, suggesting involvement of hypoxia in the induction of ER stress (figure 26). In bladders subjected to BOO, the number of TUNEL-positive cells increased in the epithelial cells and BSMCs. Similarly, treatment with TTFA or CoCl₂ induced apoptosis of BSMCs, and 4-PBA significantly attenuated ER stress and apoptosis triggered by these agents. Furthermore, in vivo administration with 4-PBA significantly reduced apoptosis in the bladder subjected to BOO [479].

Figure 26: Induction of apoptosis in cultured detrusor smooth muscle cells (DSMCs) by hypoxic stress and BOO and attenuation by molecular chaperones. A: Upper panels. DSMCs were exposed to 500 mM TTFA (thenoyltrifluoroacetone) for eight-hours and observed by phase-contrast microscopy. Lower panels. Induction of apoptosis in the bladder by BOO. Control bladders and bladders subjected to BOO for 24 hours were examined by DAPI staining (4',6-diamidino-2-phenylindole staining) and terminal deoxynucleotidyl transferase-mediated dUTP nick-end labelling assay (TUNEL), to count apoptotic cells. B: Induction of apoptosis in the bladder by BOO. Control bladders and bladders subjected to BOO for 24 h were examined histologically by 4',6-diamidino-2-phenylindole staining (DAPI) and terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling assay (TUNEL). C. The effect of 4-phenylbutyrate (4-PBA) on the apoptosis of the urinary bladder induced by BOO. Rats were administered daily with either ethanol vehicle or 4-PBA (120 mg/kg, i.p.) for three-days and subjected to BOO. Histological analyses were performed using hematoxylineosin (HE) and DAPI staining, and TUNEL assay. All data are means±SE (n=4). The values represent the percentage of cells undergoing apoptosis. M Takeda, unpublished data.
These results suggest that outlet obstruction caused ER stress via hypoxic stress in the bladder and that hypoxia-triggered ER stress may be involved in the induction of apoptosis. ER stress may therefore trigger BOO-induced detrusor overactivity, or OAB. Hence, chemical chaperons such as 4-PBA might be a novel pharmacotherapy for prevention of BOO-induced bladder dysfunction, or urinary incontinence (figure 27).

![Figure 27: Hypothesis of the possible implication of BOO, hypoxia-induced ER stress and urinary bladder injury. The possibility of novel pharmacotherapy for BOO-induced bladder injury or dysfunction by attenuation of BOO-induced apoptosis in the bladder by chemical chaperones such as 4-PBA.]

1. INTRODUCTION

Translational research must maintain two key components:

- A direct pathway to impacting on patient care
- An ethical responsibility to improve on current treatment

Tissue engineering is now at a stage where research is moving out of the laboratory and into the clinical arena and now demands that financial and well as scientific imperatives must be considered. A recent estimate for the development of a new tissue engineered device is in excess of €10MM, with a time span of not less than five years [480]; the NIH spent $643 million on stem cell research in 2006. The evolution of organ replacement therapy through cell culture and implantation has attracted considerable attention from both the medical profession and the media. Progress must be closely monitored to ensure that the driving forces of the commercial requirements of stakeholders balance the necessary clinical objectives.

Several groups have produced innovative and progressive work and in the last twenty years there has been a move from predictions of success to a more considered approach. The progression has been evident with an increasing understanding of the complexity of the problem. Technology has developed to allow various means of producing a pure cell culture – including better understanding of selective media, and fluorescent-activated cell sorting. An increasing number of abstracts at major urological conferences in recent years further testifies to the proximity of clinical application.

2. INJECTABLE THERAPY

This work is a step away from the production of a functional and implantable graft. Its strengths include no requirement for the use of a scaffold and the final functional outcome is largely dependant on the host's regenerative abilities.

Animal model work suggests that in the case of stem cell therapy there is cellular differentiation, and in the example of sphincteric replacement this may lead to cells with characteristics of smooth and skeletal muscle. Some data claim a clinical cure rate approaching 90% with these therapies [481], and in addition measurable parameters such as maximum urethral closing pressure can be improved with injection of stem cells [482]. Histological evidence for the generation of muscle fibres is also evident [483]. In a randomized control trial comparing the treatment against conventional injectables the use of stem cells fared far better. But there is a need for multicentre trials before such a treatment could become accepted as a standard [484].

3. TISSUE REPLACEMENT

a) Urethra

There have been attempts at urethral regeneration – most commonly by implantation of a matrix to stimulate regeneration. Acellular bladder collagen has been used to replace tissue in an animal model [485]. Success was improved by initial epidermal seeding – the cells of which disappeared six months after grafting. Growth and subsequent blood supply may be improved by adding growth factors, such as VEGF, and cell selection [486]. It appears that ex vivo urethral regeneration has, hitherto been unsuccessful. However, a clinical trial using tissue engineered buccal mucosa demonstrates that in a near three-year follow up series there is promise: there is a 100% initial graft
take, with two out of five patients requiring either
partial or total graft excision; the remainder having
patent urethras but have required instrumentation
[487]. Bigger groups of patients have had small
intestine submucosa (SIS) implanted as a graft for
the treatment of urethral stricture disease and
demonstrate a success rate of up to 85% with this
technique – the poorest outcomes with reconstruction
of the penile urethra [488,489]. Seeded tubular
constructs have been used with success in preclinical
studies and this is an area that awaits further
development. However, one must compare the
potential success, against conventional treatment, or
even the culture of single layer grafts, and consider
the resource implications of such a treatment strategy.
Recent data suggest that there may be a less invasive
approach to establishing urothelial cultures. Multi-
layered cultures of urothelial cells were established
from bladder washings from 29 patients [490]. Using
careful cell selection and culture techniques it is
possible that grafts could be created in this way.

b) Bladder

The complexities of generating a tissue-engineered
urothelium have been widely acknowledged. In order
to survive, imbibition and inosculation will not be
sufficient – the graft must have an adequate vascular
supply. Furthermore, for functional success the smooth
muscle must be controlled i.e. with a functional
innervation. The generation of a seeded co-cultured
cellular construct continues to be a major research
directive. Alternatives have been trialled, such as the
urothelial-lined uterus [491], but have not yet reached
a stage of clinical application. The issue of graft
nutrition appears to be helped considerably by
wrapping the graft in omentum. Such grafts appear
to show reasonable in vitro characteristics [492], as
well as improvement in some clinical parameters such
as compliance and capacity [493]. The questions
relating to the sensory status of the construct and the
voiding function remain open. Data have shown the
phenotypic similarities of cultured cells to their native
counterparts [494], although this has not yet translated
into in vivo success. However, a recent improvement
appears with the use of dynamic cell culture [495].
Other components may be developed with the use of
further stem cell technology, in conjunction with
stromal cells. The scaffold in turn can be considered
as 3 components:

- Support mechanism for cells
- Nutrient supply for cells
- Functional control of cells

a) Support mechanism for cells

Many potential scaffolds have been trialled. Options
include the creation of a layer of urothelium; which is
then seeded as a new lining and incorporated as part
of another organ in augmentation. Examples have
included bowel and uterine covered segments used
to expand bladders [490]. It is likely that different
organs and, perhaps different disease states, will
require different scaffolds. With developing technology
and understanding of the interaction of the scaffold and
cells there is a necessity to explore this area. Improved
biocompatible (CO alkene) polymers have increased
cellular activity [500]. Mechanical properties have not
been widely investigated. However, the growth of cells
may be influenced by the physical properties of a
scaffold, more than previously realised, and factors
such as the elastic modulus may be important in
generating optimal cell growth [501]. Cells cultured on
a dynamic bioreactor, that stretched and relaxed the
culture plate, improved the contractility of the resultant
cells. Those cultured on a static plate showed no
measurable contractility whilst preconditioned cells
showed tetanic and twitch responses between 1 and
4 weeks of culture [495]. In addition work is constantly
aiming to find alternative scaffolds including the amnion
(although this has not been tested for urological
application) as alternatives to decellularised bladder
matrix and SIS [502].

b) Nutrient supply for cells

The culture of cells ex vivo has led to a number of
solutions for providing cell nutrition. Bioreactor
technology has become an area of subspecialist
development in its own right. It appears that problems
arise with removal from the bioreactor and
implantation, and the difficulties in establishing and in
vivo nutrient supply. Baumert et al have pursued the
possibility of early transition of the construct to an
‘omental bioreactor’ for neo-ureters – with seeded
constructs being placed intra-abdominally and wrapped in omentum. Animal data suggest that this may be a successful strategy for final culturing - with the generation of a vascularised multilayered, terminally differentiated graft [492,503]. Other factors, such as pretreatment of scaffolds with growth factors, may also have both a direct effect on nutrient availability and utilisation leading to enhanced cell growth [486,504]. The possibility of growth factors stimulating specific co-culture of a capillary network have also to be considered [505].

c) Functional control of cells

There are two aspects to this: firstly, the differentiation of cells. Factors that may influence this have been mentioned but included either stimulation of cells (such as stretch for muscle cells [495]), or the use of selective media. The generation of the correct cell line is vital and forms part of the functional control. Secondly, the generation of a mechanism that will allow functional control of the final graft. The ideal will be to include sensory responses from the graft – a tissue engineered substitution cystoplasty would be completely insensate, making control difficult except by timed voiding. The motor control of an implant is also important. This does not appear to be an issue for the injectable therapies discussed earlier but may be for free grafts. Histology from animal work with such implants suggests that there is a degree of neural ingrowth at the periphery of grafts when harvested [506], however there is no specific reference to the voiding function of these grafts. Indeed the continuation of this work suggests that contractile function may only be seen in cells that have been cultured in a dynamic environment [494] – with very poor contraction seen in cells not treated in this way.

5. CONCLUSION

Current work in this field is impressive and fast moving. It is now evident that with the involvement of commercial interest the huge financial investment will be expected to generate return. The focus of this work must remain our consumer – the patient. Outcomes must be at least as good as currently available treatments in order to gain recognition and credibility and no commercial pressure should be allowed to compromise this. The complexities and interaction of different graft components have highlighted many difficulties to progress. The increased application of stem cell work and an understanding of host-regenerative strategies may overcome some of these obstacles. Dynamic culture and the further development of bioreactor technology also hold hope for further development.

It is clear that none of these therapies could be advocated outside a trial setting and that data regarding each patient needs to be carefully followed up and preserved in the interests of long term results.

X. RECOMMENDATIONS FOR LOWER URINARY TRACT AND LOWER GASTRO-INTESTINAL TRACT RESEARCH

1. Integrate data from reductionist experiments to formulate better systems-based approaches in the investigation of the pathology of the LUT and LGIT.

2. Generate improved experimental approaches to investigate the pathophysiology of the LUT and LGIT by:
   • the development of characterised animals models
   • use of human tissue from well-characterised patient groups.

3. Encourage greater emphasis on basic research into our understanding of tissues receiving relatively little attention: i.e. the lower gastrointestinal tract; the bladder neck and urethra.

4. Generate a more multidisciplinary approach to investigate the function of the lower urinary tract through collaborations between biological, physical and mathematical sciences.

5. Increase interaction between higher education institutions (HEIs), industry and medical centres to encourage translational approaches to research.

6. Bring about a greater emphasis on the importance of research to medical trainees through:
   • establishing research training as a core component of medical training
   • increased access to support funds, especially scholarships and personal awards
   • organisation of focussed multidisciplinary research meetings, either stand-alone or as part of larger conferences
   • greater interaction between medical centres and HEIs

7. Increase emphasis on research into lower urinary tract and gastro-intestinal tract in HEIs through:
   • greater representation on grant-funding agencies
   • encouragement of submission to high impact-factor journals and recognition of research published in specialty journals
   • more integrated teaching and training opportunities

This chapter deals with individual components regulating the neural control of the urinary bladder. This chapter has been completely remodeled and updated with the focus on factors and processes involved in the two models of operation of the bladder: storage and elimination. There has been significant new information since the last consultation in a number of fields:

- The urothelium and its roles in sensor and transducer functions including interactions with other cell types within the bladder wall ('sensory web')
- The location and properties of bladder afferents including factors involved in regulating afferent sensitization
- The neural control of the pelvic floor muscle and pharmacology of urethral and anal sphincters (focusing on monoamine pathways)
- Efferent pathways to the urinary bladder
- Abnormalities in bladder function including mechanisms underlying co-morbid disorders associated with bladder pain syndrome and incontinence

The next sections deal with the current understanding of brainstem neuronal networks, which regulate lower urinary tract function (1-4). The importance is reflected in the current advances in functional brain imaging (both positron emission topography or PET and functional magnetic resonance imaging or fMRI). These advances have had a major impact on understanding CNS control of the human bladder. This section has been completely revised to also include the recent advances in understanding of bidirectional brain-gut interactions in addition to discussion of homeostatic function and neural mechanisms underlying fecal and anal continence.

This book attempts to use Levels of Evidence throughout. The Oxford Centre for Evidence Based Medicine has laid down guidelines that apply to Levels of Therapeutic Interventions and Grades of Recommendations to Patients; the existence of dispute regarding each major conclusion should be documented. However this advice does not really apply to the basic sciences, where randomized controlled trials are not a common format of investigation, and acute studies with internal controls are more common.

Within this chapter we intend to be selective and report scientific evidence that has appropriate controls and achieves statistical significance. Other categories of evidence, e.g. uncontrolled studies, anecdotal information, hypothesis or speculation will be referred to as such.

Of some importance in this field are species differences, and efforts have been made to make it very clear when each new topic is introduced in which species the observation was made with special emphasis as to the extent comparable data exists for humans.

In this report, we intend to indicate whether the conclusions are based on (A) peer-reviewed papers in reputable journals (B) evidence in book chapters or reviews, and (C) Abstracts: abstracts will only be mentioned if they refer to a systematic study with good statistical methodology.
There is evidence that a number of functional pain syndromes are associated with changes in the epithelial layer. Alterations of bladder urothelium at the molecular and structural levels have been reported in both patients and animals modeled for various bladder disorders. It is likely that many therapies currently used in the treatment of bladder disease may target urothelial receptors and/or their release mechanisms.

1. INTRODUCTION TO THE ANATOMY AND BARRIER FUNCTION OF THE UROTHELIUM

The urothelium is the epithelial lining of the lower urinary tract between the renal pelvis and the urinary bladder. Urothelium is composed of at least three layers: a basal cell layer attached to a basement membrane, an intermediate layer, and a superficial or apical layer composed of large hexagonal cells (diameters of 25-250 µm) known as ‘umbrella cells’ [5, 6] (Figure 1). The umbrella cells are interconnected by tight junctions (which are composed of multiple proteins such as the claudins) and are covered on their apical surface (nearly 70-80%) by crystalline proteins called uroplakins that assemble into hexagonal plaques [7-10]. Uroplakins and other urothelial cellular differentiation markers, such as cytokeratin 20, are not expressed in the stratified epithelium of the urethra. In some species, the umbrella cells and perhaps also the intermediate cells have projections to the basement membrane [5].

The ability of the bladder to maintain the barrier function, despite large alterations in urine volume and increases in pressure during bladder filling and emptying, is dependent on several features of the umbrella cell layer. These features include tight-junction complexes that reduce the movement of ions and solutes between cells and specialized lipid molecules and uroplakin proteins in the apical membrane, which reduce the permeability of the cells to small molecules (water, urea, protons) [5,11]. The apical surface of the urothelium is also covered with a sulfated polysaccharide glycosaminoglycan (GAG) or mucin layer that is thought to act as a nonspecific anti-adherence factor and as a defense mechanism against infection [12-14]. In addition, during bladder filling the umbrella cells become flat and squamous and this shape change is accompanied by vesicular traffic (i.e. exocytosis/endocytosis), adding membrane to the apical surface thereby increasing overall urinary bladder surface area [7,15,16]. There is evidence that this stretch-induced exocytosis is dependent on activation of epidermal growth factor receptor (EGFR) [17,18]. These processes allow the bladder to accommodate increasing volumes of urine during filling without compromising the barrier function. Exocytosis/endocytosis (vesicular recycling) may also play an important role in modulating the release of a number of neurotransmitters/mediators as well as regulation of the function of many receptors and ion channels in urothelial cells [19,20].

2. RESPONSE OF THE UROTHELIUM TO INJURY

Basal cells, which are thought to be precursors for other cell types, normally exhibit a low (3-6 month) turnover rate, in fact the slowest turnover of any mammalian epithelial cells [7,21]. It has been shown that neither urine-derived factors nor cyclic mechanical changes contribute to urothelial proliferation and differentiation; however accelerated proliferation can occur in pathology. For example, using a model (protamine sulfate) that selectively damages the umbrella cell layer, it has been shown that the urothelium rapidly undergoes both functional and structural changes in order to restore the barrier in response to injury [22]. The initiation of urothelial proliferation is thought to involve up-regulation of growth factors such as fibroblast growth factor and nerve growth factor (NGF) [23,24].

Figure 1: Ultrastructural features of umbrella cell apical membrane. Left panel: Scanning electron micrograph (high magnification) of apical surface of rabbit umbrella cell layer (hinges “H” marked with arrows). Right panel, high power view of tight junctions. (from Apodaca, 2004; Truschel et al., 1999).
Though the urothelium maintains a tight barrier to ion and solute flux, a number of local factors such as tissue pH, mechanical or chemical trauma, or bacterial infection can modulate the barrier function of the urothelium [7,25]. Other conditions such as bladder pain syndrome/interstitial cystitis (BPS/IC) or spinal cord injury are also associated with changes in urothelial barrier [26,27]. When the barrier is compromised, water, urea and toxic substances can pass into the underlying tissue (neural/muscle layers) resulting in urgency, frequency and pain during bladder filling and voiding. In some pathological conditions the disruption of the urothelial barrier is associated with ultrastructural changes and alterations in the levels of chemical mediators such as nitric oxide (NO) and adenosine triphosphate (ATP) that may alter epithelial function and/or integrity. Disruption of urothelial barrier integrity has also been linked to the expression of substances such as antiproliferative factor (APF), which also slows urothelial cell growth [28-30]. APF, a frizzled 8 protein detected in the urine of patients with BPS/IC, is secreted by bladder epithelial cells obtained from these patients. Treatment of urothelial cells from normal patients with purified APF decreases the expression of adhesion and tight junction proteins.

Urinary tract infections produced by uropathogenic Escherichia coli (UPEC) are initiated by bacterial adherence to uroplakin proteins on the apical surface of umbrella cells [25,31] (Figure 2). The UPEC express filamentous adhesive organelles (type 1 pili) that mediate both bacterial attachment and invasion of the urothelial cells. Internalization of UPEC in the umbrella cells and formation of intracellular colonies (biofilm-like pods) of UPEC in umbrella cells has been implicated in the mechanism of chronic urinary tract infections.

Disruption of urothelial function can also be induced by more remote pathological conditions that influence neural or hormonal mechanisms. For example, spinal cord transection in rats leads to a rapid alteration in the urothelial barrier including ultrastructural changes and increased permeability [26]. The changes are blocked by pretreatment with a ganglionic blocking agent, suggesting an involvement of efferent autonomic pathways in the acute effects of spinal cord injury on bladder urothelium. Other types of urothelial-neural interactions are also likely, based on the recent reports that various stimuli induce urothelial cells to release chemical mediators that can in turn modulate the activity of afferent nerves [5,20]. This has raised the possibility that the urothelium may have a role in sensory mechanisms in the urinary tract.

In summary, modification of the urothelium and/or loss of epithelial integrity in a number of pathological conditions can result in passage of toxic/irritating urinary constituents through the urothelium or release of neuroactive substances from the urothelium leading to changes in the properties of sensory nerves and in turn sensory symptoms such as urinary frequency and urgency. Thus chemical communication between the nervous system and the urothelial cells may play an important role in the generation of urinary bladder dysfunction.

3. UROTHELIAL HETEROGENEITY

Studies (comparing a number of species) have shown that the major part of the urinary tract is lined with a fully differentiated urothelium [9]. Findings in cultured cells reveal a distinct difference in morphology of ureteral and bladder urothelial cells, supporting a difference in cell lineage. There seems to be no apparent difference between the urothelium of the trigone compared to the detrusor, in contrast to cells from the proximal urethra [9,32]. In this region, there is a transition from urothelium to a stratified or columnar epithelium accompanied by a lack of urothelial-specific differentiation markers. Taken together, present evidence suggests at least 3 urothelial lineages: 1) those of the ureter/renal pelvis, 2) detrusor/trigone and 3) bladder neck/proximal urethra [33]. The functional significance of these findings has yet to be determined.

4. ROLES FOR UROTHELIAL CELLS IN VISCERAL SENSATION

While urothelial cells are often viewed as bystanders in the process of visceral sensation, recent evidence has supported the view that these cells function as primary transducers of some physical and chemical stimuli and are able to communicate with underlying cells including bladder nerves, smooth muscle and inflammatory cells (Figure 3).

There are at least 3 lines of evidence that suggest that
Figure 3: Hypothetical model depicting possible interactions between bladder afferent and efferent nerves, urothelial cells, smooth muscle and myofibroblasts. Stimulation of urothelial receptors and channels can release mediators that target bladder nerves and other cell types; urothelial cells can also be targets for neurotransmitters released from nerves or other cell types. Urothelial cells can be activated by either autocrine (i.e. autoregulation) or paracrine (release from nearby nerves or other cells) mechanisms. Abbreviations: ACh, acetylcholine; AdR, adrenergic receptor; BR, bradykinin receptor; H+, proton, MR, muscarinic receptor; NE, norepinephrine; NGF, nerve growth factor; NR, neurokinin receptor; NicR, nicotinic receptor; NO, nitric oxide; P2R, purinergic 2 receptor unidentified subtype; P2X and P2Y, purinergic receptors; PG, prostaglandin; SP, substance P; Trk-A, receptor tyrosine kinase A, high affinity receptor for nerve growth factor; TRPs, transient potential channels.
urothelial cells participate in the detection of both physical and chemical stimuli. First, bladder nerves (afferent and efferent) are localized in close proximity, and some within, the urothelium [20, 34-36]. A second line of evidence suggesting that urothelial cells play a role in sensory function is the expression of numerous receptors/ion channels similar to that found in both nociceptors and mechanoreceptors. And finally, these cells secrete a number of transmitters or mediators capable of modulating, activating or inhibiting sensory neurons.

**a) Urothelial-Neuronal Signaling**

Recent studies have shown that both afferent and autonomic efferent nerves are located in close proximity to the urothelium. Peptidergic, P2X- and TRPV1- immunoreactive nerve fibers presumed to arise from afferent neurons in the lumbosacral dorsal root ganglia are distributed throughout the urinary bladder musculature as well as in a plexus beneath and extending into the urothelium [20,34]. (Figure 4) In humans with neurogenetic detrusor overactivity intavesical administration of resiniferatoxin, a C-fiber afferent neurotoxin, reduces the density of TRPV1 and P2X3 immunoreactive suburothelial nerves, indicating that these are sensory nerves [37,36]. In addition, immunohistochemical studies have also revealed both adrenergic (tyrosine hydroxylase) positive as well as cholinergic (choline acetyltransferase, ChAT) positive nerves in close proximity to the urothelium [35].

A network of cells with morphologic characteristics similar to those of myofibroblasts or interstitial cells is also detected in the suburothelial space of the bladder in both humans and animals [39-41]. These cells, which are extensively linked by gap junctions and have close contacts with nerves, can respond to neurotransmitters, such as ATP released from nerves or urothelial cells, suggesting that they could act as intermediaries in urothelial-nerve interactions [40-42]. Thus the anatomic substrates for bidirectional urothelial-neural communication exist within the urinary bladder.

**b) Involvement of the Urothelium in “Sensing” Chemical and Mechanical Stimuli**

The involvement of urothelial function in sensory signaling is suggested by the finding that urothelial cells express various receptors that are linked to mechanor or nociceptive sensations. Examples of neuronal “sensor molecules” (receptors / ion channels) that have been identified in urothelium include receptors for purines (P2X1-7 and P2Y1,2,4) adenosine (A1, A2a, A2b and A3), norepinephrine (α and β), acetylcholine (muscarinic and nicotinic), protease-activated receptors (PARs), amiloride- and mechanosensitive epithelial sodium channels (ENaC), bradykinin (B1 and B2), neurotrophins (p75, trkA, EGF family ErbB1-3), corticotropin releasing factor (CRF1 and CRF2), estrogens (Erα and ERβ), endothelins and various TRP channels (TRPV1, TRPV2, TRPV4, TRPM8 and TRPA1) [34, 43-51]. The expression of these various receptors enable the urothelium to respond to a number of “sensory inputs" from a variety of sources. These inputs include increased stretch during bladder filling, soluble factors (many found in the urine) such as epidermal growth factor (EGF), or chemical mediators/ peptides/ transmitters such as substance P, calcitonin gene-related peptide (CGRP), corticotropin releasing factor (CRF), acetylcholine, adenosine or norepinephrine released from nerves, inflammatory cells and even blood vessels [5, 19, 20, 52, 53].

Various stimuli can lead to secretion of numerous chemical substances such as neurotrophins, peptides, ATP, acetylcholine, prostaglandins, prostacyclin, nitric oxide (NO) and cytokines that are capable of modulating, activating or inhibiting sensory neurons. [19, 20]. For example, urothelial-derived NO can be released in response to mechanical as well as chemical stimulation and may either facilitate or inhibit the activity of bladder afferent nerves [20, 54]. Release of various factors from the urothelium can also modulate the spontaneous activity of the underlying smooth muscle [42, 55].

The mechanism underlying release of chemical mediators from the urothelium, including whether all sensory “inputs” stimulate membrane turnover (i.e. vesicular exocytosis) is not well understood. What little is known about the roles and dynamics of membrane-bound cytoplasmic vesicles in urothelial cell physiology is derived from measurements of membrane capacitance and microscopy of fixed tissues and cells. For example, there is evidence that once released, ATP can act as an important autocrine mediator, which can induce membrane turnover as well as enhance both stretch induced exocytosis and

![Figure 4](image-url): Confocal image of the urothelium depicts afferent nerve fibers (red) located in close proximity to basal (green) urothelial cells.
endocytosis [56]. Alterations in membrane turnover can not only increase apical surface area (as described above) but also regulate the number and function of receptors and channels at the cell surface.

1. PURINERGIC RECEPTORS

Since the first report of distension-evoked ATP release from the urothelium there is now abundant evidence supporting a role for urothelially-derived release of ATP in autocrine and paracrine signaling within the lower urinary tract. ATP is released from both the apical and basolateral urothelial surfaces in response to bladder stretch and can act on P2X2 and P2X3 urothelial receptors to stimulate stretch-induced exocytosis [56]. (Figure 5) The expression of both P2X and P2Y receptors in nerve fibers and myofibroblasts in close proximity to the bladder lumen and the sensitivity of these cells to ATP suggests that basolateral ATP release from the urothelium may also influence function of myofibroblasts and bladder nerves [57, 58]; The amiloride-sensitive apical sodium channel, ENaC, may be involved in mechanotransduction by controlling basolateral release of ATP [59]. In addition, intercellular communication mediated by gap junctions in myofibroblasts could provide a mechanism for long-distance spread of signals from the urothelium to the detrusor muscle [42]. Adenosine is also produced and released by the urothelium, and may play important roles in modulating sensory afferent function and smooth muscle contraction [60].

2. TRP CHANNELS

The ability of capsaicin to evoke NO release from rat urothelium, reported in 1998, provided the first, albeit indirect, demonstration that TRPV1 channels are expressed in urothelial cells and that urothelial cells and afferent nerves, which also express these channels, share a number of common properties [61]. This ion-channel protein is activated by capsaicin, as well as to moderate heat, protons and lipid metabolites such as anandamide (an endogenous ligand of both cannabinoid and vanilloids receptors) [62, 63] TRPV1-positive nerves are in close contact with urothelial cells [64, 65]. Activation of urothelial cells with capsaicin or resiniferatoxin can increase intracellular calcium and evoke transmitter (nitric oxide, NO or ATP) release. Similar to that in sensory neurons, urothelial-response to vanilloids are enhanced by low pH, blocked by TRPV1 antagonists and eliminated in TRPV1 null mice [66]. In afferent neurons, TRPV1 is thought to integrate/amplify the response to various stimuli and to play an essential role in the development of inflammation-induced hyperalgesia. It seems likely that urothelial-TRPV1 might participate in a similar manner, in the detection of irritant stimuli following bladder inflammation or infection.

Though TRPV1-null mice are anatomically normal, they exhibit a number of alterations in bladder function, including a reduction in stretch-evoked and hypotonic-evoked ATP release and stretch-evoked increase in membrane capacitance [66]. In addition, TRPV1 knockout mice have a higher frequency of low-amplitude, non-voiding bladder contractions suggesting the possibility of a small but ongoing role for TRPV1 in normal urine storage function. These relatively benign changes may result from TRPV1 expression not only in afferent nerves that form close contacts with bladder epithelial (urothelial) cells but also in urothelial cells themselves. (Figure 6) These findings demonstrate that the functional significance of TRPV1 in the bladder extends beyond pain sensation to include participation in normal voiding function, and is essential for mechanically evoked purinergic signaling by the urothelium.

3. ADDITIONAL TRP CHANNELS

Much less is known about the involvement of other TRPs in bladder function or disease. TRPV4 which is a nonselective cation channel activated by a number of stimuli including heat, shear stress, changes in osmolarity and lipid ligands is expressed mainly within the epithelium of the urinary bladder [67]. While a definitive role for TRPV4 in bladder function has not been established, there is evidence that null mice exhibit impaired voiding responses and, intravesical instillation of a TRPV4 agonist in the rat triggers a novel voiding reflex which could regulate the late phase of micturition [68, 69]. In addition, in the awake ewe, TRPV4 may also be involved in a urethra to bladder reflex, proposed to facilitate bladder emptying [70]. Another member of the TRP family, TRPA1 (characterized as a thermoreceptor activated by noxious cold), is expressed in C-fiber afferents as well as urothelium and agonists to this channel induce bladder hyperreflexia [71]. Of interest is the finding that hydrogen sulfide, which may be formed during infection/inflammation, is an activator of TRPA1 [72].
4. ACETYLCHOLINE AND THE UROTHELIUM

There is evidence that the urothelium expresses the full complement of muscarinic receptors as well as enzymes necessary for the synthesis and release (except vesicular choline transporter) of acetylcholine. [53, 74]. Further, the urothelium is able to release acetylcholine following both chemical and mechanical stimulation [53]. Once released, urothelial-derived acetylcholine is likely to exert effects via a number of sites including smooth muscle, nerves as well as urothelial associated-muscarinic or nicotinic receptors, the latter that could contribute to feedback mechanisms modifying urothelial function. In addition, stimulation of urothelial-cholinergic receptors elicits release of mediators such as nitric oxide as well as ATP, which could alter bladder sensation by stimulating nearby sensory afferent nerves [73, 75, 76].

Thus, targeting muscarinic receptors and/or urothelial release mechanisms may play an important role in the treatment for a number of bladder disorders. In this regard, recent evidence suggests that botulinum toxins prevent the release of transmitters from the urothelium, which may suggest urothelial-released mediators contribute to sensory urgency [77].

5. CLINICAL SIGNIFICANCE OF THE SENSORY WEB

Defects in urothelial sensor molecules and urothelial-cell signaling are likely to contribute to the pathophysiology of bladder diseases. For example, a number of bladder conditions (BPS/IC, spinal cord injury (SCI), chemically-induced cystitis) are associated with augmented release of urothelial-derived ATP, which is likely to result in altered sensations or changes in bladder reflexes induced by excitation of purinergic receptors on nearby sensory fibers [9, 10, 47, 73].

ATP can also act in an autocrine manner that would act to facilitate its own release from urothelial cells [10]. Once released, ATP can alter the threshold for activation of ion channels such as TRPV1. This novel mechanism, which likely reflects activation of intracellular protein kinases and phosphorylation of the TRPV1 channel, represents a means by which large amounts of ATP released from damaged or sensitized cells, in response to injury or inflammation, could trigger the sensation of pain. Changes in epithelial signaling/barrier function would not be unique to the urinary bladder. For example, airway epithelia in asthmatic patients as well as keratinocytes in certain types of skin diseases also exhibit a number of similar abnormalities and compromised repair processes [78-80]. This is particularly relevant given the high incidence of associated diseases that can include both visceral and somatic conditions, many of which exhibit a shared loss of epithelial barrier function. Taken together, epithelial cells can respond to a number of challenges (including environmental pollutants and mediators released from nerves or nearby inflammatory cells) resulting in altered expression and/or sensitivity of various receptor/channels as well as changes in release of mediators, all of which could impact function.

II. AFFERENT NEURONES

There have been a number of new developments in this area since the last consultation as a result of the introduction of in vitro preparations, knockout animals and an increasing influence of molecular techniques. Up until recently most experiments have taken place on cats and rats, but several studies have been reported in mice and guinea-pigs, mainly using in vitro preparations. These involve recordings from the pelvic or hypogastric (lumbar splanchnic) nerves at peripheral sites near the bladder; hence the conduction velocities of the single units, which provided information relevant to the degree of myelination, have not been measured. These preparations have however been able to increase the knowledge of the location of afferent endings within the bladder wall and some of the physiological/pharmacological properties in relation to synaptic transmission at these nerve endings. Drugs that are toxic in the whole animal have also been used in isolated preparations, and some authors have used drugs to minimise the smooth muscle movements and the generation of inflammatory mediators; the latter are useful in the analysis, but may give rise to differences in the properties studied either in vivo or in vitro in the absence of such agents.

1. PROPERTIES OF BLADDER AFFERENT NEURONS

Afferent axons in the pelvic, hypogastric (lumbar splanchnic) and pudendal nerves transmit information...
from the lower urinary tract to the lumbosacral spinal cord [81-83] and studies in several species including cats, rats and mice have shown some similarities in properties.

The most sensitive afferents are excited by a physiological increase in volume and by detrusor contractions: it is believed that these low threshold afferents have small myelinated axons, are A-delta fibres (which are larger in diameter and conduct action potentials more rapidly than C-fibres) and that their endings are located in the detrusor smooth muscle. They have been called ‘in series tension receptors’ (84) because they are excited by bladder wall tension caused either by distension or by contraction, and neurons with this range of conduction velocities are less likely to contain peptides.

There have been a number of systematic studies recently in mice and guinea pigs that have provided detailed information about the classes of receptors in the pelvic and hypogastric nerves (Figure 7). In the mouse, it seems there may be at least four classes of mechanosensitive afferents, which include myelinated and unmyelinated fibres, and distributed in the serosa, muscle and urothelial layers of the organ; one class has mechanosensitive endings in both the muscle and urothelial layers. The lumbar splanchnic nerves contain principally serosal and muscular afferents whereas all four classes of afferents are present in the pelvic nerve (63% of which are muscular afferents) [85]. Another study found endings in the urothelium and in the muscle layers, as well as stretch-insensitive afferents and chemosensitive afferents [86]. The small myelinated afferents are involved in two processes: (a) sensing bladder volume, and (b) reinforcing reflex function by monitoring the contractile state of the detrusor. In particular these afferents, which form the most sensitive distension receptors, are most probably responsible for the sensation of fullness, and mediate the normal micturition reflex that involves a spinobulbospinal pathway that passes through the brainstem.

The unmyelinated afferents contain peptides and most appear to terminate within the lamina propria and within the transitional epithelium itself. Many of these afferents discharge within the higher range of physiological bladder volumes, and are not usually sensitive to detrusor contraction, possibly because only the former causes stretch of the urinary epithelium. The C-fibres in the urothelium and lamina propria contain peptides such as substance P and CGRP, which is a characteristic of one subgroup of afferent C-fibres. These and other C-fibre afferents may mediate the spinal C-fibre micturition reflex seen following cord transection in the cat [87]. It is not

---

Figure 7: Tension-mucosal mechanoreceptors. (A) Response of tension-mucosal mechanoreceptors to fast 3 mm stretch at 1000 µm’s, held for 10s. (B) Response of the same unit to mucosal stroking with a 0.1 mN von Frey hair (five strokes, indicated by asterisks). (C) Activation of the same tension-mucosal unit by mannitol (1 M) applied to its receptor field in the mucosa.
clear whether they also contribute to normal voiding in this species, but there is increasing evidence that they may be involved in normal bladder control in rats and mice. In rats and mice, these high threshold units respond to a range of intravesical pressures that overlap with the sensitivity of the low threshold units, so that these together cover the spectrum of pressures and volumes seen physiologically, and these may contribute to spinal automatic micturition mediated by the sacral cord.

A third group of unmyelinated bladder afferent axons does not respond to normal distending volumes but only become active during chemical irritation of the bladder, including high osmolality and high potassium solutions and during inflammation, when they behave like the high volume sensing C-fibres. These have been demonstrated in cats and rats, and are usually called ‘silent afferents’ (meaning that the last group do not respond to normal distensions, but can become mechanosensitive in inflamed or over-distended tissues). Thus it would be unwise to infer function simply on the basis of conduction velocity. This group of afferents also appears to be sensitive to ATP.

Ultrastructural studies of nerves in the human bladder have found only unmyelinated nerves in the urothelial and immediate suburothelial layer, the first small myelinated nerves appearing only close to the smooth muscle layers [88]. Whether or not the suburothelial nerves become myelinated as they pass towards the serosal surface cannot be ascertained from this study but it would be inadvisable to make deductions about the relative number of C and A-delta fibres in the human based on these observations. Table 1 shows the properties of afferent fibres, classified according to their volume thresholds.

2. UROTHELIAL AFFERENTS

Reference has already been made to the presence of CGRP-containing afferent endings that branch beneath and within the lamina propria, and within the urothelium itself. These axon collaterals can release neurotransmitters on to the various tissues in the lining of the bladder, including blood vessels, smooth muscle, urothelium, connective tissue cells, mast cells and other neurones. In addition there is evidence in the human bladder that intramural neurones receive axonal contacts from axon collaterals that contain the peptides characteristic of primary afferents (see the section on ganglia, and on integrative physiology).

The plexus of afferent nerves is thickest in the neck of the bladder and in the initial portion of the urethra, and it becomes progressively less dense in the adjacent regions. It does not extend beyond the equatorial region, and therefore the lamina propria of the cranial region of the bladder has no afferent axons. In contrast, the afferent innervation of the musculature is more diffuse, and appears uniform throughout the bladder. CGRP-immunofluorescence in urothelial afferent axons is enhanced in the surviving axons 5 days after contralateral denervation, a change which may be an early sign of regeneration of these axons [89]. In the human bladder, CGRP together with Substance P and NKA occur only infrequently in nerves in the muscle but are moderately frequent in the suburothelial layer. Also in the human there appears to be another population of CGRP-containing fibres that co-localize with NPY and galanin and some of these synapse on intramural ganglia within the bladder [90-93]. There is also recent evidence that nerves cross the basal lamina and enter the basal layers of the human urothelium [89]. Table 2 shows the properties of afferent nerve endings in different locations.

3. SENSITIVITY OF AFFERENT ENDINGS

The term afferent sensitivity refers to the gain of the afferent signal, i.e. the number of impulses that are fired by an afferent ending at any level of distension. Sensitizing mediators are able to increase the size of

Table 1. Properties of low and high threshold afferents from the bladder in cat, rat, mouse and guinea pig
the sensory signal (the frequency of impulse traffic) at a given level of distension, so the sensations that occur at a particular rate of firing in an afferent occur at lower bladder volumes if the afferent endings have been sensitized. (Figure 8).

The sensitivity of afferent endings may be influenced by the release of mediators from different cell types, including possibly the urothelium, myofibroblasts, nerve endings, smooth muscle, mast cells and other connective tissue cells. It is likely that many or all of these can release ATP, and some may release other mediators including nitric oxide, tachykinins (Substance P, Neurokinin A, Neurokinin B), growth factors (Nerve Growth Factor [NGF], Brain Derived Neurotrophic Factor [BDNF] and others) and other endogenous mediators such as nociceptin.

The similarity of the properties of the urothelial cells and the C-fibre afferents suggests that the most likely contender for a sensory cell may be a urothelial cell, but it is clear that the afferent endings themselves respond to a variety of stimuli, and that surrounding cells may simply enhance the gain of the transducer. The following paragraphs refer to some of the mediators that can sensitize bladder afferents.

a) ATP and P2X3 Receptors

Recent studies of mice have shown the P2X2/3 receptor, is present in small sensory neurones innervating the bladder, and that the effects of bladder distension on these sensory endings is markedly attenuated if the gene for the P2X3 receptor is deleted. Knockout mice that do not express this receptor exhibit
a marked urinary bladder hyporeflexia, characterized by decreased voiding frequency and increased bladder capacity, but normal bladder pressures [94, 95]. In addition, they have reduced pain-related behaviour in response to injection of ATP or formalin, and lose the rapidly desensitizing ATP-induced currents in their dorsal root ganglion neurons; they also have a reduction in the sustained ATP-induced currents in nodose ganglion neurons. Immunohistochemical studies localize P2X3 to nerve fibres innervating the urinary bladder of wild-type mice, and show that loss of P2X3 does not alter sensory neuron innervation density. Thus, P2X3 is critical for peripheral afferent pathways controlling urinary bladder volume reflexes, which take place at physiological volumes and pressures. Antagonists to P2X3 may therefore have therapeutic potential in the treatment of disorders of urine storage and voiding such as overactive bladder. In one recent study it was observed that humans with detrusor overactivity treated with botulinum toxin showed decreased levels of P2X3 and TRPV1 receptors in the bladder biopsies [96].

Some groups of bladder afferents appear to be sensitive to the release of ATP from the urothelium or other cells. In the last few years, the sensitivity of bladder afferents to ATP and mechanical stimuli has been studied intensively in the rat and mouse using protocols designed to avoid sensitization of the afferents [97-99]. In the rat, 90% of bladder afferent neurons gave persistent electrical responses to the P2X agonist α-β-methylene ATP that were inhibited by the P2X antagonist 2',3'-O-trinitrophenyl-ATP (TNP-ATP) which suggests that pelvic nerve afferents from the rat bladder express predominantly P2X (2/3) heteromeric receptors. In the mouse, Rong et al [99] found that the majority of the low threshold and nearly all the high threshold receptors were sensitized by α-β-methylene ATP, i.e. there was a reduction in the threshold and an increased peak activity during distensions. In addition some of the 'silent' afferents became mechanosensitive. The absence of sensitization in P2X3 knockout mice indicated that the responses were mediated by the P2X3 receptor. However there is a recent in vitro study in the guinea-pig that suggests that one group of afferents, the low threshold 'in series' tension receptors in detrusor muscle, are not sensitive to ATP [86].

b) Nitric Oxide

Nitric oxide (NO) is an important mediator that can be released from urothelium and from adjacent neurones. The detrusor however is not very sensitive to ATP [86].

NO may be involved in the control of afferent sensitivity, and we now know that NO may increase the activity of capsaicin-sensitive nerves within the bladder wall after spinal cord injury [101]. Basal release of nitric oxide has not been detected in the urothelium of the normal cat; however it is released in cats with feline interstitial cystitis [102], and from normal cats after the addition of agonists. Nitric oxide release from neurones depends on the enzyme nitric oxide synthase (NOS) and increased expression of neuronal NOS in bladder afferent and spinal neurones occurs following cord injury [103], and in bladder afferents following chronic bladder irritation with cyclophosphamide. There is also evidence that nitric oxide can inhibit the function of primary afferent neurones [104, 105]. This inhibitory effect may occur in the normal bladder because intravesical administration of a solution of oxyhemoglobin, a nitric oxide scavenger, induced bladder overactivity in the conscious rat [106]. The effect of oxyhemoglobin was reduced by pretreatment with ZD6169, a drug that suppresses capsaicin-sensitive bladder afferents, suggesting that oxyhemoglobin enhances afferent excitability.

Knockout mice that do not have neuronal NOS appear to have normal function in the lower urinary tract [107], and knockout animals that do not have inducible NOS do not show major abnormalities. However, the latter appear to need iNOS in the response to urinary obstruction [108].

c) Tachykinins: Substance P, Neurokinin A and Neurokinin B

The tachykinins are a group of neuropeptides that includes substance P and neurokinin A (which are produced by the same gene), and neurokinin B. They are found in small diameter afferent neurones, particularly within the C-fibre population, and may be released, along with other peptides, by afferent endings when these become active, e.g. during the axon reflex in skin. A similar event occurs in the bladder and is associated with the phenomenon of neurogenic inflammation. These peptides cause vasodilatation and an increase in capillary permeability, and are algesic agents.

In addition some tachykinins can sensitize sensory nerve endings. This view is based on (a) autoradiographic studies that show the disappearance of NK-2 receptors in the lamina propria in capsaicin-treated rats that are deficient in sensory nerves [109], (b) on studies in which afferents or dorsal root ganglia can be made hypersensitive using a NKA-analogue and other intravesical chemical stimuli such as high [K+] and high osmolality [110-112], and (c) the demonstration that the development of hypersensitivity to a number of sensitizing agents including high [K+] can be blocked by an NK-2 receptor antagonist [113, 114]. More recently it has been shown that rat dorsal root ganglion neurones are excited by NK2 agonists, but are inhibited by NK-3 agonists [115]. This NK2 action...
is on L- and N-type Ca\(^{2+}\) channels, whereas the NK-3 action is only on the L-type channels. Both of these effects are blocked by inhibition of protein kinase C.

d) TRP (Transient Receptor Potential) Receptors

Ion channels that act as receptors because they are responsible for transient receptor potentials (TRP) generally work by opening non-specific ion channels. Some are sensitive to capsaicin and other vanilloids (TRPV), while others are associated with other mediators, including cinnamaldehyde (TRPA1) and Melastatin (TRPM). TRP channels are opened by a variety of physical and chemical stimuli including heat, cold, mechanical stress, voltage, hydrogen ion concentration and osmolality, as well as by specific ligands, such as capsaicin, melastatin and trans-cinnamaldehyde. The nerve endings that contain these channels are therefore often polymodal in their properties, one of the characteristics of non-myelinated sensory endings, and also in other cell types, including the urothelium. TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1 have been described in different parts of the urogenital tract, and TRPV1 (the vanilloid receptor) has received special attention, particularly in relation to its role in bladder sensation [116].

The TRPV1 receptor is a cation channel expressed by nociceptive neurones and can also [117, 118] be activated by protons or temperature greater than 43 degrees C [119, 120]. Within the bladder, it may be that it is activated naturally by low pH, but such changes (e.g. in metabolic acidosis) are not usually associated with bladder pain. The expression of the TRPV1 receptor in sensory neurones is regulated by Nerve Growth Factor (NGF), and stimulation of the TRPV1 receptor with capsaicin causes the release of CGRP [121]. Capsaicin and resiniferatoxin act on unmyelinated afferent fibres throughout the body, but it is also clear that capsaicin can act on the urothelium by binding to TRPV1 receptors. Capsazepine is a blocker of this receptor and it has been found that nitric oxide (NO) release and the increase in intracellular Ca\(^{2+}\) induced by capsaicin are blocked by this antagonist. In addition to capsaicin and resiniferatoxin, a new agonist, piperine, has been shown to activate TRPV1 receptors and produce bladder hyperactivity and activity of sensory nerves in this organ in the rat [117, 118]. Several groups have searched for endogenous ligands for the TRPV1 receptors, and anandamide, palmitoylethanolamide and nociceptin are three compounds that deserve a mention, although much more work needs to be done to elucidate their exact roles. Anandamide and palmitoylethanolamide (PEA) are endogenous cannabinoids (acting on CB-1 and CB-2 receptors respectively) that also are agonists of TRPV1 receptors [122, 123] and may act on peripheral perivascular sensory terminals in a manner that is antagonized by the capsaicin antagonist capsazepine. These agents can also cause the release of CGRP and Substance P by increasing intracellular Ca\(^{2+}\), and have other actions, such as activation of G-proteins [124]. Both anandamide and PEA have been found to attenuate bladder hyper-reflexia induced by intra-vesical NGF [125-127]. The TRPV1 receptor seems to be important for normal bladder function and for excitation of low threshold distension-sensitive afferents in mice [128, 129] (Figure 9).

• Other TRP Receptors

The bladder-cooling reflex (induced by instillation of intravesical cold saline and termed the ice water test) is believed to be triggered by menthol-sensitive cold receptors in the bladder wall. Recently, this test has been used to distinguish sensory symptoms in patients with bladder pain syndrome and overactive disorders [130]. Because pain elicited in BPS patients was not accompanied by reflex detrusor contractions, this test may be of particular interest since the response of afferent nerves to cold (and to menthol) depends on a particular TRP receptor subgroup, TRPM8. In experiments in the guinea-pig bladder, the afferent nerves innervating the organ have been shown to express TRPM8, and the bladder cooling reflex is enhanced in the presence of menthol [131].

The TRPA1 channel is also expressed in dorsal root ganglion cells that innervate the rat bladder. Trans-cinnamaldehyde or allyl isothiocyanate, agonists of this receptor, cause bladder hyperreflexia and appear to act through C fibres that might be mechanoreceptive or nociceptive [132].

e) ORL Receptors

Nociceptin/orphanin FQ, another endogenous ligand that binds with the opioid receptor-like 1 receptor (ORL1 receptor, now also known as the 4th category of opioid receptors, OP4) has been shown to have naloxone resistant inhibitory effects on the micturition reflex. These actions are mediated at several sites including the capsaicin sensitive nerves in the bladder, and a central supraspinal site [133]. Nociceptin produces a long-lasting protection against capsaicin-induced desensitization of TRPV1 in afferent nerves, such that a chemoceptive micturition reflex could be repeatedly evoked by topical capsaicin in nociceptin-pretreated rats. This is in sharp contrast to the effects of nociceptin on the local response to capsaicin, which corresponds to the release of peptides from capsaicin-sensitive afferent neurons. Topical application of nociceptin onto the bladder serosa evokes a tachykinin-mediated contraction [133]. These results suggest that the afferent and ‘effenter’ functions of capsaicin-sensitive primary afferent neurons in the rat bladder are differentiated by nociceptin, and that nociceptin has a significant action on afferent sensitivity.
In humans nociceptin elicits a strong acute inhibitory effect on the micturition reflex in patients with a neurogenic bladder [134]). This was in contrast to the placebo, and led to the conclusion that nociceptin and other orphan peptide receptor agonists may be useful in future as drugs for the treatment of neurogenic urinary incontinence.

Local administration of kappa-opioid receptor agonists by intra-arterial injection attenuated the responses of pelvic nerve afferents to high pressure distension of the urinary bladder [135]. These agonists had essentially the same effects whether the bladder was inflamed or not. The conclusion was that the ability of kappa opioid agonists to attenuate the responses of afferents to large bladder distensions indicated a potential use for peripherally acting kappa opioid receptor agonists in the control of urinary bladder pain.

f) Neurotrophins

1. NERVE GROWTH FACTOR

(NGF; neurotrophin-1), the first of a group of growth factors called neurotrophins, is produced in larger quantities in humans with detrusor overactivity [136], BPS/IC and bladder cancer [137], in rats with inflamed bladders [138], spinal cord injury or chemically induced cystitis [139] or bladder outlet obstruction [140], in diabetic rats [141] and a number of other states. This protein is known to sensitize myelinated and unmyelinated afferents from the bladder [142, 143] and it is involved in the production of referred pain in bladder inflammation [144]. It also appears to stimulate the expression of the vanilloid receptor TRPV1 [121], and there is a suggestion that increased NGF levels resulting from intrathecal injection of NGF can induce a decrease in A-type K⁺ current density in the afferent pathway that may influence the emergence of bladder overactivity [145].

Recent studies in an animal model for BPS/IC termed feline interstitial cystitis (FIC) in which TRPV1 responses to capsaicin were measured in lumbo-sacral dorsal root ganglion neurones have suggested that affected neurones are increased in size and exhibit exaggerated responses to capsaicin that may be associated with enhanced activity of endogenous protein kinase C [146]. A further study from the same group suggested that the abnormal activity of afferent neurones from cats with feline interstitial cystitis may be due to changes in the behavior of K⁺ currents which are restricted to capsaicin-sensitive neurones [147].

2. BRAIN DERIVED NEUROTROPHIC FACTOR (BDNF)

levels in the urinary bladder and some other epithelia are higher than those found in the brain or skin [148]. In situ hybridization experiments showed that BDNF mRNA was made by visceral epithelial cells, in several types of smooth muscle, and in neurons of the myenteric plexus. However the receptors from BDNF (trkB and p75[NTR]) are not present on the urothelium but are present in neurons of the peripheral nervous system. Hence it is thought that in the bladder this neurotrophin is produced by the urothelium and can act on the afferent nerves. The mRNAs for NGF, BDNF and neurotrophin-3 all increase within 2 hours of bladder inflammation in the rat, and this increases expression may contribute to sensory and reflex hyperactivity [138]. Inflammation of the colon also appears to induce up-regulation of CGRP and TrkB (suggesting an involvement of BDNF) in bladder afferent neurons, and suggests that there may be cross sensitization of bladder afferent pathways by colonic inflammation [149]. In spinal cord injury there is also an increase in BDNF and galanin in the dorsal root ganglia and spinal segments below the lesion; interestingly NGF expression was reduced below the level of the lesion [150].

Figure 9: Stimulus-response profile of low threshold, LT (A) and high threshold, HT (B) bladder afferents. Note that the LT afferents have a blunted response profile in the TRPV1 -/- mice compared to wildtype (P<0.001, 2-way ANOVA and Bonferroni test). The response profile of HT afferents is unchanged (from Daly et al., 2007).
**NGF and TTX-Resistant Na⁺ Channels**

Sensitization of afferents appears to be an important mechanism that leads to reflex hyperexcitability, and a number of studies have linked the tetrodotoxin (TTX)-resistant sodium channel, sometimes known as Nav1.8 to this process. A number of sensitizing agents including NGF are known to induce increased expression of this membrane channel; this appears to be sufficient to change the properties of afferents so as to lower the threshold for firing of bladder (lower volume threshold for voiding) and induce spontaneous and burst firing (overactive contractions, urgency) [142]. TTX-resistant Na channels (Nav1.8 and Nav1.9) have been found in SP/CGRP immunoreactive small DRG giving rise to C-fibers supplying the bladder [151, 152]; these also express the trkA receptor, which binds NGF and is necessary for its action. Plasticity of TTX-sensitive and TTX-resistant Na⁺ channels (Nav 1.8 and Nav 1.9) occurs in these neurones after spinal cord injury, and a decreased expression of Nav 1.8 channel immunoreactivity and a small increase in Nav 1.9 channel immunoreactivity in bladder DRG neurons can be observed [153, 154].

The dependence of the sensitization of these afferent neurones and the occurrence of overactivity on NGF and its actions on the Nav 1.8 channels has been shown in experiments using immunoneutralization of NGF or antisense oligonucleotide treatment to reduce the expression of these channels in sensory neurons [151, 155]. More recently studies on ralfinamide, a drug that interferes with TTX-resistant sodium channels, indicate that this drug reduces inflammatory and neuropathic pain as well as bladder overactivity in rats. The ability of ralfinamide to reduce capsaicin-induced hyperexcitability and tonic activity of rat afferent neurones appears to be due to its action as a sodium channel antagonist [156].

In clinical studies the local anaesthetic lidocaine and the oral Na⁺ channel blocker, mexiletine, which operate by reducing excitability in sensitized neurones have been used to treat urge incontinence and hyper-reflexic conditions [157-162] with variable degrees of success.

4. **SPINAL CORD**

This section is concerned with the central projections of the primary afferent neurons. Axonal tracing experiments have been performed in many animal species [163, 164] and have localized the segmental distribution and spinal termination of afferent pathways in the pelvic, hypogastric and pudendal nerves. The primary afferent cell bodies of the pelvic and pudendal nerves are contained in lower lumbar and sacral dorsal root ganglia depending on species; whereas afferent innervation in the hypogastric arises in the rostral lumbar dorsal root ganglia. The central axons of the dorsal root ganglion neurons carry the sensory information from the lower urinary tract to second order neurons in the spinal cord.

Trans-ganglionic transport of axonal tracers has identified the spinal projections and terminal fields of visceral and somatic primary afferent neurones. The dorsal commissure (DCM), superficial dorsal horn and sacral parasympathetic nucleus (SPN) all contain interneurons with rostral projections that are activated during noxious [165, 166] or non-noxious stimulation [167] of the rat bladder and the urethra. These neurones are the site of origin of ascending pathways that project to various structures in the brainstem via spinal pathways that include the dorso-lateral funiculus [168, 169]. In humans spinal tractotomies for intractable pelvic pain provide the only insight available as to the organization of spinal pathways involved in bladder control in man [170].

Visceral afferent fibers of the pelvic [171] and pudendal [163] nerves enter the cord and travel rostrocaudally within Lissauer’s tract, and transversely around the dorsal horn via the lateral (LCP) and medial collateral pathways (MCP) to reach the deeper layers of the spinal cord. Within the spinal gray matter, the LCP and MCP provide a dense innervation to laminae I, V, and VII and the dorsal commissure. Muscle and cutaneous afferents in the pudendal nerve terminate in different regions of the cord.

**Afferents from the Urethra, Bowel and Genital Organs**

Studies have demonstrated that electrical stimulation of urethral afferent fibers when the bladder is full can evoke strong detrusor contractions sufficient for voiding in intact cats [172, 173] as well as acute spinalized cats [174]. Similarly, using minimally invasive methods to apply electrical stimulation within the proximal urethra via a catheter-mounted electrode, it has been shown that reflex bladder contractions can be generated in humans with complete paraplegia but these do not seem to produce efficient voiding can be evoked in chronic SCI cats by stimulation of an excitatory pudendal to bladder spinal reflex [176].

The excitability of the micturition reflex can be influenced by other sacral afferent pathways [177], including facilitatory effects resulting from stimulation of urethral afferents, and inhibition of bladder activity by stimulation of the dorsal nerve of the clitoris in keeping with known interactions from the vagina and colon [178]. Stimulation of urethral afferents by fluid flowing through the urethra can facilitate the micturition reflex; however contraction of the urethral sphincter resulted in inhibition of bladder motility [179].

Excitability of spinal neurons receiving afferent input from the bladder can also be modulated by input from other pelvic structures such as the colon [175, 180, 181]. This convergence of sensory information from a number of pelvic organs can occur at the level of the
spinal cord. In addition, the expansion of primary axon terminals within the spinal cord can also play a role in altering bladder reflexes. For example, it has been shown that expression of a number of peptides including CGRP, VIP as well as PACAP is altered in primary afferent terminals and may correlate with changes in bladder function following SCI [182-184].

Glutamate is an important excitatory transmitter in the afferent limb of the micturition reflex and mediates its effects by means of both NMDA and nonNMDA receptors. This conclusion is based on studies of C-fos expression and the transmission of afferent activity rostrally, and the depressive effects of both NMDA and nonNMDA glutamatergic receptor antagonists [185, 186].

Bladder afferent neurons contain a number of peptidergic neurotransmitters, and the central distribution of bladder afferent terminals and peptidergic immunoreactive fibers is quite similar. There has been considerable interest in the role of tachykinins in the micturition reflex [187] and in nociception. Intrathecal treatment of adult rats with intrathecal capsicain can result in a reversible block of the micturition reflex [188]. Further, while normal micturition is not altered following ablation of NK1-R expressing SC neurons using SSP-saporin, the response to a noicceptive stimulus was significantly reduced. These and other studies [188, 189] suggest that substance P and its receptors may play a part in transmission of bladder nociceptive responses at the first synapse in the micturition reflex.

5. SPINAL CORD GLIAL CELLS AND MODULATION OF PELVIC AFFERENTS

a) Anatomy and Function of CNS Glia

The nervous systems of animals are generally composed of two cell types: neurons, which propagate electrical currents and function as the signaling moieties of the nervous system, and glia, the functions of which are far less understood [190]. Central nervous system (CNS) glia, (which greatly outnumber the neuronal component [191, 192]), comprise ependymal cells, oligodendrocytes, astrocytes and microglia.

Astrocytes, (similar to neurons and oligodendrocytes) are ectodermal in origin. Two distinct types are described based on their morphology: fibrous astrocytes, which have long thin processes and are commonly found in white matter, and protoplasmic astrocytes, which have short thick processes and are typically found in grey matter. In the reactive state, protoplasmic astrocytic processes become more pronounced [193].

Astrocytes contribute to the regulation of the microenvironment in which neurons develop and function, maintaining a tight control on local ion (notably K⁺) and pH homeostasis. In addition, they are involved in the clearance of synaptically-released neurotransmitters, such as glutamate and GABA [194]. These multifunctional cells are key players in the ‘tripartite synapse’, which is composed of pre- and post-synaptic membranes and extra-synaptic astrocytic contacts; they have the potential to modify synaptic transmission and plasticity [195].

Microglia are considered to have a mesodermal origin and to enter the brain during the neonatal period; they are commonly considered to function as the resident macrophages of the CNS and are more abundant in grey than white matter. In the normal brain and spinal cord, they have a ramified morphology; when activated, such as when there is damage to the CNS, they rapidly retract their processes and migrate toward the site of injury, where they turn into macrophages and remove the debris [193].

While astrocytes and microglia present as two very different types of glial cell, it is now becoming increasingly known that they have functional similarities. Recent evidence has shown that spinal cord activation of either of the two cell types may be involved in both the development and maintenance of central sensitization in various chronic pain conditions. Thus, both astrocytes and microglia are attracting wide interest in the pain field [196].

b) Modulation of Neuronal Signaling by Spinal Cord Glia

At the level of the spinal cord (the first relay site in the transmission of nociceptive information from the periphery to the brain [197], dorsal horn glia may be activated by chemicals released from primary afferent terminals such as the neurotransmitters: SP, CGRP, NO, purinergic agents, glutamate, opioid peptides, and the chemokines: fractalkine or neuractin. Activation may result in altered cell morphology, changes in receptor expression, or release of factors by astrocytes and microglia, which in turn can lead to changes in neuronal function and ultimately influence pain transmission [198]. There is evidence that microglia may mediate the activation of astrocytes seen in both somatic and visceral pain pathologies—the ‘neuropathic pain triad’ [199]. Generally, microglial activation is transient, while astrocytic activation is much longer-lasting. However, activation of either of the two cell types promotes pain [196, 200].

While most reports on the contribution of glia to pain, study somatic rather than visceral forms of chronic pain, there is now increasing evidence pointing to a role for glia as key modulators during inflammatory pain. Microglia probably play a pivotal role in the initiation phase, while astrocytes are likely to contribute to the maintenance of the persistent pain state. There are reports in non-acute [201, 202] and acute [202] models of colonic irritation of altered glial cell morphology, in segments L6-S1 of the spinal cord.
In addition, in the naturally occurring chronic model of bladder pain syndrome/interstitial cystitis (BPS/IC) seen in the cat, a pronounced upregulation in immunointensity of astrocytic intermediate filament glial fibrillary acidic protein (GFAP) in dorsal horn regions which receive pelvic afferent input [202], has been reported. Preliminary findings from functional studies using primary cultures of astrocytes (Figure 10) isolated from lumbo-sacral region of cats with BPS/IC and normal cats (Hanna-Mitchell, Buffingtonm and Birder; unpublished data), point to significant differences in the physiology of astrocytes in regions of the spinal cord receiving pelvic afferent input following this pathology.

Together these findings indicate a pronounced activation of spinal cord astrocytes in animal models for BPS, which may plan an important role in the pain syndrome and open up new potential approaches for drug intervention.

**III. NEURAL CONTROL OF FEMALE PELVIC FLOOR MUSCLES AND RHABDOSPHINCTERS**

1. STRUCTURAL ELEMENTS OF THE PELVIC FLOOR

The pelvic floor [203] in women is a bowl-shaped structure comprised of bone, muscle, and connective tissue. The rim of the bowl is formed by the bones of the pelvic girdle (sacrum, ileum, ischium, and pubis). The “inside and bottom” of the bowl is lined with striated muscle: the iliococcygeus and pubococcygeus (which together comprise the levator ani) as well as the coccygeus, and puborectalis muscles. The muscles are attached to the bone and to each other with various connective tissue supports. These 3 components, bone, muscle, and connective tissue provide support of the pelvic viscera (i.e. rectum, vagina, and bladder) but also allow for excretory and sexual function.

The viscera, as well as striated muscles that serve as true sphincters - urethral and anal rhabdosphincters - are attached to the pelvic floor muscles and each other by connective tissue but do not attach directly to bone. In addition to the urethral and anal rhabdosphincters, striated perineal muscles associated with the viscera include the urethrovaginal sphincter, the compressor urethrae muscle, the ischiocavernosus, and bulbospongiosus muscles [203-205]. In contrast to the levator ani muscles described above, the rhabdospincter and perineal muscles embryologically develop from the cloaca with a 2 week delay in striated muscular differentiation compared to the levator ani and other skeletal muscles [206, 207] and are completely separated from the levator ani muscles by connective tissue [204].

2. INNERVATION OF THE FEMALE LEVATOR ANI MUSCLES

The levator ani muscle of the pelvic floor is innervated by the levator ani nerve in human (Figure 11) [208], squirrel monkey [209-211], dog [212], cat (Karicheti and Thor, unpublished observations), and rat [213]. The levator ani nerve primarily arises from sacral spinal roots (e.g. S3-S5 in humans) and travels along the intrapelvic face of the levator ani muscle with a high degree of variability in branching patterns [208]. In humans, there is some controversy whether or not the pudendal nerve also innervates the levator ani muscle [214, 215]. This is not the case in other species (rat, cat, dog, squirrel monkey) where hodological studies show a marked loss of levator ani muscle mass and a decrease in levator ani myocyte diameter following transection of the levator ani nerve [211, 213] but no change in levator ani muscle mass or myocyte diameter following pudendal neurectomy [211, 213], 2) the existence of only a single motor endplate zone at the point of levator ani nerve insertion into the levator ani muscles [211, 213], 3) absence of contractions of levator ani muscles upon electrical stimulation of pudendal nerve efferent fibers (Thor and Karicheti, unpublished observations) and 4) phenotypically distinctive motor neuron labeling following application of nerve tracers to the pudendal and levator ani nerves [212, 216-221], respectively. All of these divergent techniques support the conclusion that only the levator ani nerve innervates the levator ani muscles with no significant contribution from the pudendal nerve in non-human species.

In consideration of the vast phenotypic differences between rhabdospincter pudendal motor neurons in Onuf’s nucleus and levator ani motor neurons (Figure 11 and Table 3), the likelihood of pudendal
Figure 11: A) Illustration of the course of the levator ani nerve in a left hemipelvis, sagittal view (arrow points to levator ani nerve). Abbreviations: S, Sacrum; S1-S5, sacral foramina; Cm, coccygeal muscle; LAN, levator ani nerve; IS, ischial spine; ICm, iliococcygeal muscle; Olm, obturator internal muscle; PCm, pubococcygeal muscle; PRm, puborectal muscle; ATLA, arcus tendinous levator ani; C, coccyx; V, vagina; U, urethra; R, rectum (from Barber, 2002). B-E) Photomicrographs of a single transverse section of sacral spinal cord from a squirrel monkey with pubocaudalis muscle injected with cholera toxin B (CTB) and the anal rhabdosphincter injected with fast blue. B) Bright field illumination shows cytoarchitecture of gray and white matter; white box indicates area shown in high power in panels D and E. C) Epifluorescent illumination showing CTB-labeled (bright green) levator ani motor neurons; white box indicates area shown in high power in panels D and E. D) High power photomicrograph of boxed area in panels B and C using epifluorescent illumination to show CTB-labeled levator ani motor neurons. Note large α and small γ CTB-labeled motor neurons; also CTB-labeled processes extending from levator ani motor neurons into Onuf’s nucleus (dashed circle) and the ventrolateral funiculus. E) Same area and section as panel D viewed with epifluorescent illumination to show fast blue-labeled (bright blue) anal sphincter motor neurons in Onuf’s nucleus (dashed circle). Close apposition between CTB-labeled levator ani motor neuron processes and fast blue-labeled rhabdosphincter motor neurons were observed (from Pierce, 2005).
motor neurons innervating the levator ani muscle in humans seems very small. Similarly, the distinct embryological origins of levator ani muscles versus rhabdosphincter and perineal muscles (the latter originating from the cloaca [206, 207]), as well as a separate “compartmentalization” of the rhabdosphincter and perineal muscles by connective tissue [204], are parsimonious with distinctive “special somatic” motor innervation by the pudendal versus typical skeletal motor innervation by the levator ani nerve. Possibly, the confusing morass of small muscles (puborectalis, compressor urethrae, urethrovaginal sphincter, urethral and anal rhabdosphincter, ischiocavernosus, bulbocavernosus), blood vessels, connective tissues, and nerves in the perineal region makes dissection, identification, and nomenclature of specific nerve branches and muscles difficult in cadavers.

Indeed, this morass has led to confusion regarding even the nomenclature of the muscles themselves [204, 205] and, without extreme care, a contribution of the pudendal nerve to levator ani muscle innervation might be confused. Alternatively, there may be true species differences between humans and other mammals in regards to a minor pudendal nerve contribution to minor levator ani muscles (e.g. puborectalis). However, the ability to conduct precise experimental manipulations in animals provides a clear conclusion that the pudendal nerve does not innervate the major muscles of the pelvic floor, i.e. iliococcygeus, pubococcygeus, or coccygeus muscles to a significant degree.

The positioning of the levator ani nerve on the intrapelvic surface of the muscles may expose it to damage as the fetal head passes through the birth canal [208]. This positioning also puts it in a favorable position to be activated when current is applied with a St. Mark’s electrode placed in the rectum. The positioning of the levator ani nerve, close to the ischial spine, also risks entrapment by sutures used for various suspension surgeries for pelvic organ prolapse (POP) and may account for dyspareunia, pelvic pain, and/or recurrent prolapse [222] associated with such surgery. Finally, since the ischial spine is used as a landmark for needle placement when applying a transvaginal “pudendal nerve” block [223], the possibility that this procedure also anesthetizes the levator ani nerve and pelvic floor muscles must be considered. These complicating factors of historically-accepted clinical concepts may explain why a possible innervation of the levator ani muscle by the pudendal nerve in humans remains controversial.

a) Levator Ani Motor Neurons and Sensory Innervation

Retrograde tracing studies involving injection of cholera
toxin B (CTB) into the levator ani muscle and fast blue into the anal rhabdosphincter muscle of squirrel monkeys [217] show that levator ani motor neurons are located in the sacral ventral horn (Figure 11 B-E) in a longitudinal column. In contrast to the very dense packing of sphincter motor neurons in Onuf’s nucleus [216, 218-221], the levator ani motor neurons are more diffusely distributed. Furthermore in contrast to the uniform intermediate size of pudendal motor neurons, levator ani motor neurons (Figure 11D) show a bimodal distribution of large neurons (presumably α motor neurons) and small neurons (presumably γ motor neurons). These 2 sizes of motor neurons are in keeping with the presence of muscle spindles (whose intrafusal muscle fibers are innervated by γ motor neurons) in levator ani muscle [224, 225] and the absence of muscle spindles in rhabdosphincter muscle [224, 226-230]; consequently levator ani may exhibit la (muscle spindle) evoked monosynaptic stretch reflexes, whereas the EUS does not [231-234].

Levator ani motor neuron processes (dendrites or axon collaterals) project into two important areas in the sacral spinal cord [217]. The first, medial lamina VI, is a region where primary afferent fibers from muscle spindle and Golgi tendon organs terminate [235, 236]. This again suggests an important role for stretch-activated contraction of levator ani muscles. Importantly, the second projection of levator ani motor neurons is to Onuf’s nucleus (Figure 11D-E), which contains rhabdosphincter motor neurons. These levator ani motor neuron processes form close appositions with sphincter motor neurons in both monkey [217] and rat (Thor, unpublished observations).

Presumably, these appositions reflect a neuroanatomical substrate for coordination of the rhabdosphincter and the pelvic floor muscles during micturition and defecation. Whether these projections are dendrites designed to receive common afferent input to levator ani and rhabdosphincter motor neurons, or if they are axon collaterals transmitting information from levator ani motor neurons to rhabdosphincter motor neurons to coordinate contractions is not known and will require electron microscopic or electrophysiological analysis to be resolved.

Dual-labeling immunohistochemistry combined with cholera toxin-B (CTB) tracing studies of the levator ani muscles of squirrel monkeys has shown that there are approximately 4 times as many afferent neurons versus motor neurons labeled following injection of tracer into the levator ani muscle [210]. About 7 of the neurons were large, myelinated (i.e. RT-97 neurofilament positive) that did not contain the peptide transmitter CGRP, binding sites for isolectin-B4 (IB-4), or the growth factor receptor, TrkA, immunoreactivity. Of the remaining small RT97 negative neurons, approximately 50% contained CGRP, IB-4 binding sites, and TrkA. It is tempting to speculate that the large, myelinated afferent neurons signal proprioceptive information from muscle spindle and Golgi tendon organs, while the small peptidergic, IB-4, TrkA positive neurons signal nociceptive information. A possible role for the large sensory neurons, in addition to control of levator ani contractility, may involve regulation of bladder reflex pathways during on-going levator ani contractile activity; while the small peptidergic fibers may play a role in detrusor overactivity associated with pelvic floor trauma or nerve entrapment by sutures during suspension surgeries, in addition to classical sensation of muscle nociception.

Transganglionic transport of CTB from the primary afferent cell body to their synaptic terminals in the spinal cord was only seen in medial lamina VI of the lumbosacral spinal cord, an area of termination for large, myelinated proprioceptive terminals [235, 236]. Since many of the CTB-labeled primary afferent neurons were positive for CGRP, IB-4, and TrkA, the absence of transganglionic CTB labeling in the superficial dorsal horn is likely due to an inability of small primary afferent neurons to transport CTB rather than a true absence of levator ani nociceptive terminals in the region. Experiments with a tracer (e.g. horseradish Peroxidase, HRP) that is transported to nociceptive spinal terminals should be done to confirm this.

In contrast to the rhabdosphincters [224, 226-230], levator ani muscles have been shown to contain muscle spindles [224] and evidence has been presented that they contain Golgi tendon organs [225].

b) Role of the Levator Ani Innervation in Pelvic Organ Prolapse in Monkeys

Because the pelvic floor is responsible for providing support of the viscera, and because one might expect contraction of pelvic floor muscles to be necessary for adequate support, damage to the levator ani innervation and subsequent muscle flaccidity might be expected to promote pelvic organ prolapse (POP). To test this expectation, the levator ani muscles were bilaterally denervated in 7 squirrel monkeys [209], which is a species that shows age and parity correlated POP similar to humans [237]. Surprisingly, these monkeys showed no POP following this procedure for 2-3 years after surgery, despite showing statistically significant decreases in levator ani muscle mass and myocyte diameter. However, a slight increase in bladder and cervical descent with abdominal pressure was seen on MRI evaluation compared to nulliparous controls. Of possible significance was the finding that, after a single birth, 2 of 4 bilateral levator ani neurectomy animals showed POP, which is unusual. A larger study is needed to confirm whether levator ani nerve damage may accelerate parity-related POP. Thus, these experiments indicate that, in the absence
of childbirth, the pelvic floor muscle plays a minor role in providing visceral support and suggests that the connective tissue plays the major role. Possibly after stretching of the pelvic connective tissue accompanying childbirth, the muscle plays a compensatory role. In support of this possibility, it was shown that levator ani muscle mass and myocyte diameter in monkeys with naturally occurring POP was equal to or greater than measurements in age-, parity-, and weight-matched monkeys without POP [209, 238], suggesting that the levator ani muscle attempts to prevent visceral descent by working harder, which induces hypertrophy.

3. INNERVATION OF URETHRAL AND ANAL RHABDOSPINCTERS

At the level of the pelvic floor, the urethra and rectum are surrounded by intimately associated bands of striated muscle fibers; the urethral and anal rhabdosphincters, respectively. The muscles do not have “dedicated” attachments to skeletal structures and thus act as a true sphincters (i.e. contraction produces virtually no movement except constriction of the lumen). In addition, there are small, thin bands of striated muscle (compressor urethra, urethrovaginal sphincter, bulbocavernosus, and ischiocavernosus) that surround the urethra, vagina, and/or rectum and have connective tissue attachments to the perineal body [203].

Extensive studies of the urethral rhabdosphincter, anal rhabdosphincter, bulbocavernosus, and ischiocavernosus muscles have shown that these muscles are innervated by the pudendal nerve [208, 216, 218-221, 239, 240], which originates from the sacral roots and passes along the lateral surface of the internal obturator and coccygeus muscles, through Alcock’s canal, to eventually approach these muscles laterally from the extrapelvic surface of the pelvic floor. The specific innervation of the smaller bands of muscles attached to the perineal body has not been characterized.

The nerve fascicles [241], as well as the motor nerve terminals and end plates [242] of the urethral rhabdosphincter, are preferentially located along the lateral aspects of the urethra in rat. Overlap, or crossing of the midline, between the left and right pudendal nerve terminal fields has been described in monkeys [243]. The urethral rhabdosphincter of both men and women contain neuronal nitric oxide synthase (nNOS) which is contained in a subpopulation (43%) of the muscle fibers, as well as nerve fibers, with concentration at the neuromuscular junction [244-246]. Additionally, nNOS has been localized to pudendal motor neurons which innervate the rhabdosphincter [247, 248]. nNOS is responsible for producing the transmitter nitric oxide. While NO is known to increase cGMP levels in many types of smooth muscle; its role in control of striated muscle and neuromuscular junction function is not well established [249]. An NO donor has been shown to reduce urethral pressures at the level of the rhabdosphincter [250], but it is difficult to conclude if the effect is on smooth or striated muscle.

Some evidence suggesting that the rhabdosphincter receives a “triple innervation” from somatic, parasympathetic, and sympathetic nerves [251] was based on anatomical studies that showed these fibers within the portion of the urethra that contains striated muscle fibers. However, this suggestion has been disputed by subsequent studies [252] that showed no physiological effects of autonomic nerve stimulation on striated sphincter function and showed that the autonomic fibers are only “passing through” the outer layer of striated muscle to reach the inner layers of smooth muscle.

a) Urethral and Anal Rhabdosphincter Motor Neurons and Sensory Innervation

Extensive hodological studies locate pudendal motor neurons that innervate the urethral and anal rhabdosphincters (and bulbocavernousus and ischiocavernosus) muscles along the lateral border of the sacral ventral horn in Onuf’s nucleus (Figure 11E) in man [253] monkey [218, 254], dog [212], cat [219, 220], hamster [255] and guinea pig [256]. Studies in cats [219], monkey [218], and man [253] show that within Onuf’s nucleus, urethral rhabdosphinctor motor neurons occupy a ventrolateral position and anal rhabdosphinctor motor neurons occupy a dorsomedial position within the confines of Onuf’s nucleus.

However in other species, urethral and anal sphincter motor neurons are located in separate nuclei. In rat[216], anal sphincter (and bulbospongiosus) motor neurons are located medially in the ventral horn, just ventrolaterally to the central canal; while the urethral sphincter (and ischiocavernosus) motor neurons are located in the same region as others species, i.e. along the lateral edge of the ventral horn. In the domestic pig [257] and Mongolian gerbil [258], anal sphincter (and bulbospongiosus) motor neurons are located just dorsolateral to the central canal.

Sphincter motor neurons are exceptionally different from motor neurons that innervate other striated (i.e. skeletal) muscles. They are densely packed within the confines of Onuf’s nucleus and exhibit tightly-bundled dendrites that run rostrocaudally within the confines of the nucleus, and transversely into the lateral funiculus, dorsally towards the sacral parasympathetic nucleus, and dorsomedially towards the central canal [219, 259]. This is similar to dendritic projections of bladder preganglionic neurons [260] and very different from that of limb motor neurons, suggesting that EUS motor neurons and preganglionic neurons receive inputs from similar regions of the spinal cord. It has been suggested that the dense
packing and dendritic bundling of sphincter motor neurons may be related to their special sphencteric function and may facilitate simultaneous activation of all sphincter motor units. Recurrent axon collaterals [259] in the absence of recurrent inhibition [232, 261] suggests a recurrent facilitation that may also reinforce simultaneous activation. Because the rhabdosphincters are not attached to bone, efficient closure of the sphincter requires symmetrical contraction of all motor units simultaneously, i.e. partial contraction in one part of the “circle” would be defeated by relaxation in another region, like squeezing a balloon only on one side. It has been suggested that the arrangement of somatic motor nerve terminals bilaterally at dorsolateral and ventrolateral positions in the urethra provide symmetrical activation and force generation [242].

In addition to their unique morphology, rhabdosphincter motor neurons are also physiologically distinctive from skeletal muscle motor neurons in that they do not exhibit significant monosynaptic inputs [232], Renshaw cell inhibition [232], nor crossed disynaptic inhibition [261]. The passive membrane properties (e.g. high input resistance, low rheobase, short after-hyperpolarization, membrane bistability, non-linear responses to depolarizing current injection, which was recently reviewed [262]) are uniquely conducive to simultaneous, prolonged, tonic activity, in keeping with the anatomical and functional properties described above.

While various studies have characterized primary afferent neurons of the pudendal nerve [216, 219, 263], it is difficult to specifically characterize the sensory innervation of the sphincters per se since the pudendal nerve innervates many visceral structures (e.g. urethra, genitalia, rectum, vagina) in addition to rhabdosphincters. However, the absence of labeling of the largest sensory neurons in sacral dorsal root ganglia following application of tracers to the pudendal nerve suggests that the sensory innervation of the rhabdosphincters does not contain large fiber sensory endings such as muscle spindles, Golgi tendon organs, or Pacinian corpuscles. Furthermore, multiple investigators using various techniques have not found muscle spindles or Golgi tendon organs in the rhabdosphincters themselves, nor have they found evidence of the large myelinated nerve fibers (i.e. Type Ia and Ib) associated with muscle spindle and Golgi tendon organs in the pudendal nerve [224, 226-230]. This is consistent with the absence of small γ motor neuron axons (which innervate muscle spindles) in the pudendal nerve [228] and the absence of rhabdosphincter connections to bone by tendons.

Local injection of HRP targeted to the urethral and anal rhabdosphincters [219] produced labeling of the spinal terminals of primary afferent neurons in lateral and medial lamina I, the intermediate gray matter, and the dorsal commissure gray matter. Since the HRP likely spread beyond striated muscle fibers into other tissues of the urethra and rectum, it is possible that this afferent labeling is associated with the viscera and not necessarily the striated muscle fibers. However, since no labeling was seen in large diameter primary afferent neurons nor in terminals in medial lamina VI, an area where large diameter myelinated fibers of muscle spindle and Golgi tendon organs nerves terminate [235, 236] it is again reasonable to conclude that the rhabdosphincters are not significantly innervated by large myelinated nerve fibers typically associated with other striated muscle.

b) Segmental Activation of Urethral and Anal Rhabdosphincters

Rhabdosphincter motor neurons can be activated via segmental [231-233, 264, 265] and descending pathways [232, 264, 267]. The segmental inputs can be activated by stretch receptors and nociceptors in the bladder or urethra or genitalia [268-271]. Electrophysiological studies [231, 233, 234, 264, 265, 272] show that stimulation of either pelvic nerve or pudendal nerve afferent fibers can activate polysynaptic spinal segmental reflexes that can be recorded at a latency of about 10 msec from electrodes placed on pudendal nerve efferent fibers or inserted directly into the urethral or anal rhabdosphincter muscles.

Previously, the afferent inputs from the urinary bladder have been emphasized as being of primary importance for activation of the segmental reflex by pelvic nerve stimulation and is often referred to as the “guarding reflex” or “continence reflex”. However, recent studies are placing greater emphasis on urethral afferent fibers [269, 271, 273] mediating spinal reflex activation of the urethral rhabdosphincter. It is tempting to speculate that the guarding reflex is actually activated more vigorously by urethral afferent fibers if urine inadvertently begins to pass through the bladder neck and into the proximal urethra, with a requirement for a rapid closure of the more distal urethral sphincter (i.e. guarding against urine loss) compared to simple bladder distension or increases in intravesical pressure.

The greater importance of urethral afferent fibers is also suggested by experiments where bladder afferent fibers are electrically stimulated. For example, [233] were unable to evoke pudendal nerve firing with electrical stimulation of pelvic nerve fibers close to the bladder in a high number of cats but were able to evoke firing with placement of electrodes more centrally on the pelvic nerve. In our lab (Karicetti and Thor, unpublished observations), we have also found that stimulating nerve bundles close to the bladder is often ineffective in producing a spinal reflex to the urethral rhabdosphincter and/or pudendal nerve, while in the same animals it is possible to consistently evoke a reflex by moving centrally on the pelvic nerve, which would include fibers from the urethra. Since the more
Figure 12: Activation of a ‘Spinal, Urine-Storage-Reflex, Inhibitory Center’ (SUSRIC) and reduction of inhibition by 5-HT1A receptor stimulation. A-C) Averaged tracings (10 sweeps each) of evoked potentials recorded from the urethral rhabdosphincter (URS EMG, top traces) and the hypogastric nerve (HN, bottom traces) resulting from paired pulses of electrical stimulation (1 V, 0.05 msec, 0.5 Hz) of pelvic nerve (PN) afferent fibers (arrows) with a delay of 100 msec between first and second stimuli in each trace, in chloralose-anesthetized female cats. A) Control. Note that the evoked potentials elicited by the first stimulus (i.e. ‘condition’ stimulus) recorded at 10 msec on the URS and 60 msec on the HN are much larger than the evoked potentials elicited by the second stimulus (i.e. ‘test’ stimulus). (The evoked potentials resulting from the test stimulus are denoted by an *). B) After administration of the 5-HT1A receptor agonist, 8-OH-DPAT, note that there is a small increase in the condition URS EMG evoked potential but a remarkably larger increase in the test URS EMG evoked potential (*), indicating that the inhibition of the URS EMG test potential by the conditioning stimulus is reduced. Also note that 8-OH-DPAT had no influence on the inhibition of the HN evoked potential. C) Subsequent administration of WAY100635, a 5-HT1A receptor antagonist after 8-OH-DPAT restores the inhibition. Note that the inhibition of the test pulse by the conditioning pulse has been restored to control values. D) Graph showing the relationship between the amplitude of the URS EMG test evoked potential (expressed as a percentage of the amplitude of the conditioning evoked potential) versus the condition-test (C-T) interval (i.e. time between first and second of the paired pulse stimulations) during the control period (blue squares, n=12), following 8-OH-DPAT (red triangles, n=8), and subsequent WAY 100635 (green circles, n=8). Remarkably, 8-OH-DPAT produced no change in the paired pulse inhibition of the HN evoked potential.
Figure 12: (Ctd) Importantly, acute spinal transection at the T10 level produced only a small decrease in the paired pulse inhibition, indicating that inhibition is mediated by a spinal network. No effects of 8-OH-DPAT on the paired pulse inhibition were seen in animals following acute T10 spinalization, indicating that the 5HT1A receptors responsible for diminishing the paired pulse inhibition are located supraspinally. E-F) Tracings of URS EMG potentials evoked by repetitive stimulation of the pelvic nerve (PEL) at a frequency of 5-Hz for 10 sec. at 1 V, 0.05 msec pulse. E) Note that during the control period that the amplitude of the second and subsequent PEL-URS evoked potentials are considerably reduced compared to the first potential. F) Note that after 8-OH-DPAT that the amplitude of the second and subsequent potentials are much less reduced (from Thor, 2008).
central electrode placement would also activate colonic and genital afferent fibers, additional experiments are needed to specifically compare urethral versus bladder versus colonic pelvic afferent fibers in evoking the “guarding reflex”.

Electrical stimulation of pudendal afferent fibers also evokes a spinal reflex activation of the rhabdosphincter [233, 274]. Since some urethral afferent fibers (as well as rectal, genital, and cutaneous afferent fibers) also travel in the pudendal nerve, it is possible that the spinal urethral rhabdosphincter activation by pudendal afferent stimulation is also a manifestation of the “guarding reflex”.

4. SPINAL URINE-STORAGE-REFLEX INHIBITORY CENTER (SUSRIC)

While electrical stimulation of pelvic and pudendal afferent fibers can activate urethral sphincter motor neurons via a spinal reflex, these same stimuli also produce an inhibition of urethral sphincter motor neurons in cats. In early studies of McMahon et al., [233] an inhibition of pudendal nerve spontaneous activity occurred for a period of 50 - 1,000 msec following pelvic nerve stimulation.

Recently, this inhibitory effect has been characterized using electrical stimulation of pelvic (PEL) and pudendal (PUD) nerve afferent fibers and recording of evoked potentials with urethral rhabdosphincter (URS) EMG electrodes (i.e. PEL-URS and PUD-URS reflexes, respectively) in cats [275]. In addition to recording these somatic motor urine storage reflexes, electrodes were also placed on the hypogastric (HgN) nerve (i.e. PEL-HgN and PUD-HgN reflexes, respectively) to record sympathetic urine storage reflexes. Both the somatic and sympathetic urine storage reflexes are reliably evoked when the frequency of PEL or PUD stimulation is below 1 Hz (Figure 12A-C). However, when the frequency is raised to 5 Hz or higher, the amplitudes of the reflexes immediately drop (Figure 12E). This is not a “rundown” phenomenon because the reflex drop occurs immediately after the first stimulus (i.e. upon application of the second impulse in a given frequency’s series of pulses). This suggested that the first stimulus was activating an inhibitory circuit that blocked the second and subsequent stimuli’s ability to evoke the reflex (Figure 13).

The activation of an inhibitory circuit was shown in anesthetized cats [275] using a paired-pulse or condition-test paradigm, where the first stimulus of a pair (i.e. the condition pulse) precedes the second stimulus of the pair (i.e. the test pulse) by incremental times (i.e. 10, 20, 50, 100, 200, 500, 1,000 msec). This paradigm showed that when a second (i.e. paired or test stimuli) stimulus was applied to the PEL and/or PUD nerve 50 - 500 msec after the first stimulus, the reflexes evoked by the second stimulus were reliably inhibited (Figure 12A,D). The paired pulse inhibition was maximal (2nd stimulus evoked potential was < 20% of the 1st stimulus evoked potential) at paired intervals of 50 - 100 msec and gradually disappeared at paired intervals of 1,000 msec or more (Figure 12B,D). A possible clinical correlation of SUSRIC...
activation may be the elegant demonstration that conditioning stimuli applied to the dorsal nerve of the penis (i.e. pudendal nerve afferent fibers) inhibited urethral rhabdosphincter contractions reflexively evoked by magnetic stimulation of the spinal cord at intervals of 20 - 100 msec [276].

The threshold stimulus intensity for evoking inhibition in cats was the same as the threshold stimulus intensity for evoking the reflex, suggesting the same, or similar sized, fibers activate both the reflex and SUSRIC. Inhibition of both the PEL - URS EMG and PEL - HgN evoked potentials showed similar intensity-response characteristics. The inhibition could be evoked by homologous (PEL after PEL and PUD after PUD) or heterologous (PUD after PEL or vice-versa) pulse pairing. Furthermore, stimulation of PEL afferent fibers close to the bladder, which did not evoke a URS reflex, also produced inhibition of the PEL - URS reflex evoked by an electrode placed more centrally on the PEL nerve that did evoke a PEL - URS reflex. This indicates that the inhibition is not due to refractoriness of the rhabdosphincter motor neurons.

The paired pulse inhibition was slightly reduced (10-15%) but otherwise similar after acute spinal transection at T10, indicating that the inhibitory circuit is located within the same segment as the PEL - URS reflex pathway (i.e. sacral cord). (Since L5 spinalization interrupts the PEL - HgN reflex, which precludes testing for its inhibition, we cannot speculate on the location of the inhibitory circuit for the PEL - HgN reflex except that it is caudal to T10.) Since this inhibitory center is located in the spinal cord, and inhibits both the somatic and sympathetic storage reflexes evoked by either PEL or PUD stimulation, the name, "spinal, urine-storage-reflex, inhibitory center" (SUSRIC), is suggested.

The two nerves that are effective for activating the SUSRIC, the pelvic and pudendal nerves, have spinal terminals that densely project to the dorsal gray commissure region of the sacral spinal cord [219, 277]. This is also an area that contains inhibitory GABAergic and glycnergic neurons that are thought to mediate urethral rhabdosphincter inhibition during micturition [278, 279]. Because pelvic and pudendal nerves densely innervate this same region of the spinal cord, it is tempting to speculate that these GABAergic and glycnergic neurons are also the inhibitory cellular substrate of SUSRIC. Requirement of multiple, parallel inputs to SUSRIC from pelvic nerve axons (e.g. bladder afferent fibers), pudendal nerve axons (urethral afferent neurons), and descending axons from the pontine micturition center might be valuable to prevent sphincter relaxation unless all 3 systems "agreed" that micturition should proceed. On the other hand, redundant inputs might also be valuable to ensure initiation and maintenance urethral sphincter inhibition until micturition is complete and all urine has flowed out of the bladder and completely through the urethra prior to urethral closure. Experiments to test this model are needed.

In addition to its physiological role, overactivity of SUSRIC may be involved in the pathology of stress urinary incontinence, while under activity may be involved in bladder-sphincter dyssynergia or retentive urinary dysfunction such as Fowler's syndrome [280].

• 5-HT1A Receptor Regulation of SUSRIC

Administration of the 5-HT1A receptor agonist, 8-hydroxy-dipropylaminotetraline, 8-OH-DPAT, significantly reduced the paired pulse inhibition of the SUSRIC to 20% of control in spinal intact animals (Figure 12A-D) [275]. The 8-OH-DPAT-induced reduction in paired pulse inhibition was reversed by WAY100,635, a highly selective 5-HT1A receptor antagonist, which confirms the role of 5-HT1A receptors in suppressing SUSRIC. 8-OH-DPAT also enhanced the ability of the PEL - URS reflex to follow high frequency (i.e. 2 - 10 Hz) stimulation (Figure 12E-F). Importantly, 8-OH-DPAT reduced the inhibition in spinal cord intact cats but not in animals with an acute T10 spinal transection, indicating that 5-HT1A receptors are working supraspinally, probably to inhibit a descending excitatory input to SUSRIC (i.e. disfacilitation of the inhibitory center).

Previous urodynamic studies in anesthetized cats [281-283] support the supraspinal location of 5-HT1A receptors that facilitate urethral rhabdosphincter activity. This support stems from urodynamic studies that showed a remarkable enhancement of spontaneous urethral rhabdosphincter EMG activity in the chloralose-anesthetized cat irritated bladder model when the spinal cord is intact [283] but not when the spinal cord is transected, even after spinal bladder reflexes have emerged following spinal shock [281, 282]. In other words, it is proposed that 8-OH-DPAT's enhancement of urethral rhabdosphincter activity results from stimulation of supraspinal 5-HT1A receptors, which subsequently results in a reduction of SUSRIC-mediated inhibition of rhabdosphincter motor neurons, i.e. excitation results from disinhibition (Figure 13).

a) Supraspinal Activation of Rhabdosphincters and Pelvic Floor Muscles

Supraspinal activation of urethral and anal rhabdosphincter motor neurons includes voluntary inputs (i.e. corticospinal [254]), as well as involuntary reflexic inputs (e.g. during coughing, sneezing, vomiting) presumably from nucleus retroambiguus in the caudal medulla [267, 284-286]. Nucleus retroambiguus also innervates the pelvic floor muscle [285, 286], as well as the abdominal muscles; consist
with a role in raising intra-abdominal pressure during Valsalva maneuvers. Generally, the pelvic floor and rhabdosphincter muscles are activated as a functional unit when voluntarily contracted. However, differences in activation between the rhabdosphincter and the pelvic floor muscles have been documented [287], indicating distinct CNS control systems and innervation. Clinical EMG recordings show that even during sleep, activity can be recorded from specific rhabdosphincter motor units [288].

Rhabdosphincter motor neurons are unique among somatic motor neurons in receiving input from the paraventricular hypothalamus [286], although the function of this input has not been determined. In addition, their input from brainstem serotonergic and noradrenergic neurons is among the most dense in the spinal cord [289-292]. Finally, rhabdosphincter motor neurons also receive input from the “L region” of the pons that might be important for maintaining continence, since a lesion in this area produced continuous incontinence in a cat [293].

1. **Relative Contribution from Levator Ani Nerve, Pudendal Nerve, and Hypogastric Nerve in Continence Mechanisms During Sneezing in Rats and Cats**

Analysis of the urethral closure mechanisms during sneeze-induced stress conditions in anesthetized female rats and cats has revealed that pressure increases in the middle portion of the urethra are mediated by reflex contractions of the rhabdosphincter as well as the pelvic floor muscles [294, 295]. Transection of the pudendal nerves reduced sneeze-induced urethral reflex responses by 67% and transecting the nerves to the ilioococygeus and pubococcygeus muscles reduced urethral reflex responses by an additional 25%.

Transecting the hypogastric nerves and visceral branches of the pelvic nerves did not affect the urethral reflexes indicating that sneeze-evoked urethral reflexes in normal rats were not mediated by these autonomic pathways. However, hypogastric nerve transection in conscious, chronic spinal cord injured, female rats reduced urethral baseline pressure, reduced postvoid residual urine volumes, reduced maximal voiding pressure, and increased voiding efficiency. This indicates that sympathetic pathways to the bladder neck and proximal urethra contribute to urethral pressure and functional outlet obstruction and voiding dysfunction after spinal cord injury in unanesthetized animals [296].

2. **Neurochemical Anatomy of Urethral Rhabdosphincter Motor Neurons**

In addition to their unique morphology, neurophysiology, and supraspinal inputs, rhabdosphincter motor neurons in Onuf’s nucleus also exhibit a plethora of unique and highly diverse neurotransmitter inputs, receptors, ion channels, and growth factors (Table 3). While many of the markers listed in Table 3 are likely involved in rhabdosphincter control, it is dangerous to assume a role in rhabdosphincter control based strictly on anatomical association with Onuf’s nucleus, since some motor neurons in Onuf’s nucleus innervate the ischiocavernous and bulbospongiosus muscles and thus may be involved in control of sexual function. The following section will offer some guidance regarding which transmitter and receptor systems are involved in control of rhabdosphincter function.

### 5. Pharmacology of Urethral and Anal Rhabdosphincters

The excitatory amino acid neurotransmitter, glutamate, mediates initiation of action potentials in rhabdosphincter motor neurons (and subsequent rapid contraction of the muscle) by binding to NMDA and AMPA receptors. Both spinal reflex activation and supraspinal activation of the rhabdosphincter are sensitive to NMDA and AMPA receptor antagonists [297-299]. Thus it is useful to think of these transmitters as part of the “hardwired” reflex circuitry that is involved in all or none activation of consistent and reliable storage reflexes, as compared to monoamines and peptide transmitters (see below), that play a role as modulators of the reflexes, increasing or decreasing the gain of the reflexes transmitted by the excitatory amino acids.

The inhibitory amino acids glycine, acting through strychnine-sensitive ionotropic receptors [279, 300], and GABA, acting through both GABA-A (ionotropic) and GABA-B receptors (metabotropic) [257, 301, 302] are thought to be major inhibitory transmitters regulating rhabdosphincter activity. Clinical studies have indicated that systemic [303] and intrathecal [304, 305] administration of the GABA-B agonist, baclofen, may reduce bladder-sphincter dyssynergia in some neurogenic bladder patients. However, because of the ubiquity of glycine and GABA in mediating inhibition of multiple systems, pharmacological studies linking either of these transmitters (or any other inhibitory transmitter) to the inhibition of rhabdosphincter activity during voiding are not definitive.

In addition to amino acid transmitters, the monoamine transmitters (serotonin and norepinephrine) are also important in modulating rhabdosphincter motor neuron activity [306]. It was the preferential association of norepinephrine and serotonin terminals [289-292] that led to extensive studies of noradrenergic and serotonergic control of rhabdosphincter function and eventual clinical studies of duloxetine, a norepinephrine and serotonin reuptake inhibitor, as a treatment for stress urinary incontinence [270, 307-311]. Elegant studies in humans using magnetic stimulation of brain and sacral nerve roots [312] have indicated that duloxetine increases the excitability of rhabdosphincter
motor neurons to both supraspinal and segmental inputs and to double urethral pressure responses to sacral nerve root magnetic stimulation. Importantly, duloxetine’s ability to increase urethral rhabdosphincter activity did not interfere with the inhibition of sphincter activity during voiding (i.e. bladder-sphincter synergy was well-maintained). Similar clinical results have been seen with S,S-reboxetine, a selective norepinephrine reuptake inhibitor [313, 314]. This approach of increasing synaptic levels of serotonin and/or norepinephrine is logical since, it has been shown that noradrenergic and serotonergic terminals associated with rhabdosphincter motor neurons show an age-dependent decrease in density in rats [315] that might explain the increased incidence of stress incontinence with aging.

Multiple adrenergic receptor subtypes play a role in control of the rhabdosphincter, and the results with norepinephrine reuptake inhibitors indicate that these receptors can be activated by endogenous norepinephrine in anesthetized cats [272]. Strong evidence exists that α1 adrenoceptors excite rhabdosphincter motor neurons [272, 316, 317]. Patch clamp studies [318] have shown a direct depolarizing effect of norepinephrine on rhabdosphincter motor neurons (Figure 14D) that can be blocked by the α1 adrenoceptor antagonist, prazosin. Similar conclusions regarding the excitatory effects of α1 adrenoceptors on rhabdosphincter neurons have been reached in clinical studies [317] where decreases in rhabdosphincter activity were seen after administration of prazosin to human subjects. On the other hand, strong evidence exists that α2 adrenoceptor stimulation has the opposite effect, i.e. inhibition, of rhabdosphincter activity [272, 319]. Importantly, the innervation of the urethral and anal smooth muscle (i.e. the hypogastric nerve) shows similar adrenergic pharmacology - an enhancement of activity by α1 adrenoceptors [272, 316, 320] and inhibition of activity by α2 adrenoceptors [272, 316, 321].

Multiple subtypes of serotonin (5-hydroxytryptamine, 5-HT) receptors are also involved in modulating rhabdosphincter motor neuron excitability. Strong evidence exists that 5-HT2 receptors can excite sphincter motor neurons [274]. Indeed duloxetine’s facilitatory effects on rhabdosphincter activity in anesthetized cats are mediated in part through activation of 5-HT2 receptors [270]. Both 5-HT2A and 5-HT2C receptor agonists increase rhabdosphincter EMG activity in dogs, guinea pigs, and rats [322, 323]. Recent in vitro rat spinal cord slice patch clamp studies show that part of this effect may be directly on rhabdosphincter motor neurons, as opposed to interneurons [318], since 5-HT induces a direct depolarization of rhabdosphincter motor neurons (Figure 14E). Interestingly, substance P, a peptide transmitter that is co-localized with 5-HT in raphe spinal nerve terminals, also produces direct depolarization of rhabdosphincter motor neurons in rat spinal cord slices [324], and thyrotropin releasing hormone (TRH), another peptide transmitter co-localized with 5-HT in nerve terminals, induces excitation of rat sphincter activity [325, 326] in vivo.

A peculiar finding regarding 5-HT2 receptor-induced activity of pelvic nerve-evoked rhabdosphincter reflexes in chloralose-anesthetized cats is that the effect is highly reproducible when the spinal cord is isolated (i.e. acute T11 transection), but it is highly variable and statistically insignificant when the spinal cord is intact [274]. This suggests that supraspinal 5-HT2 receptors have an opposing, inhibitory, effect that counteracts their spinal, excitatory, effect. Whether this phenomenon is an artifact of anesthesia and/or is specific to cats is important to determine.

Immunohistochemical and molecular studies in humans and dogs [322] have shown that 5-HT2A, 5-HT2B, and 5-HT2C receptor subtypes are associated with Onuf’s nucleus motor neurons. In addition, 5-HT2C receptor mRNA has been localized to anal sphincter motor neurons in the rat [327]. On the other hand, another immunohistochemistry study with retrograde labeling of urethral rhabdosphincter motor neurons and ischiocavernous motor neurons in rats indicates that the 5-HT5A receptor is associated with the former, while the 5-HT2A receptor is preferentially associated with the latter [328].

As described in the previous section on the SUSNRC, supraspinal 5-HT1A receptor stimulation enhances rhabdosphincter activity in cats [275, 281-283]. Importantly, the excitatory effects of 5-HT1A receptor agonists on the rhabdosphincter can still be “over ridden” by inhibitory mechanisms during voiding, i.e. bladder-sphincter synergy remains despite 8-OH- DPAT-induced enhancement of rhabdosphincter activity [275, 281-283].

The effect of 5-HT1A receptors on rhabdosphincter activity in rats is more complicated. Firstly, rats do not show an inhibition of rhabdosphincter activity during voiding like cats and humans but, instead, show a high frequency bursting (or “phasic firing”) of rhabdosphincter EMG activity during micturition [329]. This bursting is actually necessary for efficient voiding in rats presumably by creating a “pumping” action through the urethra. When the spinal cord is transected, this bursting disappears and rats present with urinary retention. Although the bursting is not seen in anesthetized spinal rats at any time [329], in conscious spinal rats, the rhabdosphincter EMG bursting gradually returns in some animals across a period of 6 weeks [330]. Interestingly, 5-HT1A receptor stimulation can unmask the bursting rhabdosphincter EMG activity in the anesthetized spinal rat [282, 331]. Chang et al [331] further showed that the center responsible for bursting activity in spinal rats was located between the T11 and L4 spinal segments. In
Figure 14: Monoaminergic modulation of sphincter motor neurons recorded using patch clamp electrophysiology. A-C) Visual identification of rat urethral sphincter motor neurons. A. Retrograde labeling of dorsolateral nucleus (DLN) motor neurons was accomplished by fluorescent dye injections into the urethral sphincter (adult), or the ischiorectal fossa (neonate). Dye was transported through the motor branch of the pudendal nerve to the lumbar spinal cord. B. Composite fluorescence and low-light image showing DiI-labeled DLN neurons in the ventral horn of an adult rat lumbar spinal cord section. The dotted line denotes the grey/white matter boundary, and the dorsal surface is oriented toward the top of the page. C. Enlarged neurons from B with a patch-clamp electrode schematic to demonstrate electrophysiological recordings from DLN neurons. Calibration bars are 80 µm (B) and 20 µm (C). D-E) Either norepinephrine (NE) or serotonin (5-HT) was bath applied to rat lumbar spinal cord slices containing DiI-labeled dorsolateral nucleus neurons. D. NE (1 µM) produced a reversible depolarization and action potential firing. E. 5-HT (10 µM) also produced a reversible depolarization and action potential firing (from Burgard, 2008).
the studies of Gu et al [282], 5-HT1A receptor stimulation had no influence on the asynchronous rhabdosphincter activity that precedes, and follows, micturition-associated bursting, it only re-organized the activity into the bursting or phasic characteristics that accompany micturition.

Another aspect of 5-HT1A receptor function in rats can be seen from studies of pelvic nerve-to-rhabdosphincter reflex potentiation. Early studies showed that this reflex can be potentiated by prolonged, low frequency electrical stimulation of the pelvic nerve and by bladder distention [332-334]. Subsequent studies showed that the potentiation involved a 5-HT1A receptor-based link [335].

An interesting and possibly important comparison between drug effects on rhabdosphincter activity in cats and rats is also shown with κ2 opioid receptors. In cats, the κ opioid receptor agonist, ethylketocyclazocine, selectively inhibits spinal rhabdosphincter reflexes [234]. In rats, it was found that a κ2 opioid receptor agonist inhibits the rhabdosphincter bursting pattern associated with micturition, leading to decreased voiding efficiency [336]. In these studies, κ opioid receptor stimulation had no influence on the asynchronous rhabdosphincter activity that precedes and follows micturition-associated bursting.

Thus there may be parallels between excitation of rhabdosphincter reflexes in cats with enhancement of rhabdosphincter bursting activity in rats on one hand (5-HT1A receptor-mediated), and inhibition of rhabdosphincter motor neurons in cats and suppression of bursting activity in rats on the other hand (κ opioid receptor-mediated). The fact that asynchronous rhabdosphincter activity in rat was not affected by either 5-HT1A or κ opioid receptor stimulation highlights differences in the organization of the asynchronous (spinal) and micturition associated-bursting (supraspinal) reflex control in rats.

Another possible parallel for exploration of rhabdosphincter function in rats might lie in comparing the above spinal micturition-associated rhabdosphincter bursting center with the spinal ejaculation center in rats: both centers are located in the mid-lumbar spinal cord [331, 337, 338], both centers exhibit “bursting” [329, 339]; 5-HT1A receptor agonists can facilitate both activities [340-342], κ opioid receptor agonists inhibit both activities [336, 343]. Of course it must be appreciated that differences between the two “bursting centers” exist (i.e. the former activates rhabdosphincter motor neurons while the latter activates bulbospongious motor neurons, the former has a period of 6 Hz while the latter has a period of 0.5 Hz).

Future Pelvic Floor Research Needs

The controversy regarding a contribution of the pudendal nerve to the innervation of the levator ani muscles should be addressed. As a first step, agreements regarding nomenclature should be established in regards to which muscles actually comprise the levator ani (i.e. should the definition include only the pubococcygeus, iliococcygeus, and coccygeus muscles or should it include the puborectalis, urethralis, urethrovaginal sphincter, the compressor urethrae; etc.). Careful characterization of these various muscles based on physiological criteria such as embryological origin, skeletal sites of origin and insertion, compartmentalization imposed by connective tissue boundaries, myofiber phenotype, and sensory structures (e.g. Golgi tendon organs and muscle spindles) is likely to provide insight into which types of motor neurons (i.e. alpha, gamma, or “special somatic”) innervate each muscle and which nerve carries their motor axons. Resolving this controversy is important for a number of reasons: surgical guidance, understanding iatrogenic pathologies, and understanding physiological and pharmacological control of the individual muscles.

A second important area regards the reflex control of the levator ani muscles and viscerosomatic interactions between pelvic floor muscles and pelvic viscera. While visceral and somatic reflex control of the rhabdosphincters has been extensively studied, studies of levator ani muscle reflexes are few. Understanding whether there are spinal reflex connections between, for example, bladder afferent fibers and levator ani motor neurons would further our understanding of contience control. Similarly, understanding anatomical connections between rhabdosphincter and levator ani muscles are important. Determining whether the cholera toxin B-labeled processes of levator ani motor neurons located in Onuf's nucleus (Figure 11 D-E) are dendrites or axonal collaterals may provide important insight into understanding physiological coordination between the pelvic floor and rhabdosphincters. Finally, understanding the role of levator ani primary afferent fibers in controlling lower urinary tract and bowel function might explain indirect bladder symptoms that might be induced by pelvic floor injury or suspension surgeries, as well as physiological controls of levator ani muscles over excretory function and vice-versa. The abundant small diameter peptidergic afferent fibers innervating pelvic floor muscle might also play a role in the etiology of chronic pelvic pain syndrome or interstitial cystitis; two conditions for which a frank pathological cause has not been determined.

A third important area for study is the relative importance of bladder afferent fibers versus urethral / bladder neck afferent fibers in eliciting the “guarding” or “continence” reflex. This is important since there are phenotypic differences between these two groups of afferent neurons in regards to neurotransmitter and ion channel phenotypes [344] that might be exploited to independently control urine storage and voiding dysfunction.
IV. EFFERENT PATHWAYS TO THE BLADDER

The motor arm of the lower urinary tract drives bladder contraction during voiding and the outlet contraction required for urine storage. In this section, spinal and peripheral elements contributing to the motor activity of the bladder is described, while the equivalent structures for the bladder outlet are discussed in section III.

1. PREGANGLIONIC NEURONS

Parasympathetic preganglionic neurons are located in the lateral part of the sacral intermediolateral gray matter in a region termed the sacral parasympathetic nucleus (SPN) and are small, fusiform-shaped cells which send dendrites into lateral lamina I of the dorsal horn, the lateral funiculus and medially into the dorsal grey commissure (DGC). Bladder pre-ganglionic motor neurons are located in the S1-S3 in the cat [361], dog [362] and monkey [363]. In cat these motor neurons are located ventrolaterally in the intermediolateral column, with cells innervating the colon lying dorsomedial. The guinea pig is similar; retrograde labelling following bladder wall injections reveals neurons bilaterally in the ventrolateral part of the intermediolateral column at S1 [256]. The rat is different, as preganglionic motor neurons are located at L6-S1 [364]; unilateral ventral root rhizotomy at the L5 level in the rat decreases peak cystometric pressures [365].

The parasympathetic preganglionic neurones project through the ventral spinal roots to the major pelvic ganglion [366-368], releasing the excitatory transmitter, acetylcholine. They are divided functionally into tonic and phasic types. In some species they also release opioid peptide transmitters and express nitric oxide synthase [369]; there is also evidence of involvement of pituitary adenylate cyclase activating peptide (PACAP), a peptide present in visceral afferent neurones, and of prostaglandins within the spinal cord [370]. The DGC also contains a group of interneurones, which are likely to be active during micturition [371, 372]. These DGC interneurones may influence the function of the parasympathetic preganglionic neurons [279, 371, 372].

At spinal levels L1–L2, both the intermediolateral horn and the DGC contain sympathetic preganglionic neurones whose axons project to the major pelvic ganglion. With ageing, there is selective attrition of preganglionic sympathetic neurones in L1–L2, which project to the pelvic ganglion, with reductions in the extent of the dendritic arbor of remaining cells [366, 367].

In man the preganglionic parasympathetic motor nerves to the bladder (and other pelvic organs, the rectum and descending colon) course through the pelvic nerves from the sacral anterior roots S2-S4. Stimulating these roots with implanted electrodes designed principally for bladder emptying in spinal cord injury [373] elicits two principal responses at S3; at low levels of stimulation, the external urethral sphincter, external anal sphincter and pelvic floor muscles are contracted. At high levels of stimulation, parasympathetic activation contracts the detrusor muscle, leading to efficient emptying of the bladder when the sphincter muscle relaxes [374]. Attempts to use extracorporeal magnetic stimulation to achieve the same effect [375] have shown insufficient power to activate the small parasympathetic neurons at the level of the lumbar-sacral roots [376].

2. GANGLIA

The peripheral ganglia convey the autonomic innervation to the lower urinary tract and reproductive organs, along with a substantial part of the extrinsic motor innervation of the lower bowel. There are substantial species differences in organization and neurochemistry of pelvic ganglion cells and their spinal inputs. Large mammals have a plexus of pelvic and intramural ganglia, containing both sympathetic and parasympathetic neurons. The guinea pig is intermediate in complexity, with separate posterior and anterior plexuses innervating different pelvic organs. In the rat and mouse, the pelvic plexus consists of the major pelvic ganglia (MPG) and a number of small accessory ganglia. In the rat there are two major pelvic ganglia and small accessory ganglia, with less cytological complexity and almost no intramural ganglia.

The preganglionic input releases acetylcholine, which acts on nicotinic receptors. Patients with megacystis-microcolon-intestinal-hypoperistalsis syndrome (MMHIS) [377] have reduced or no alpha-3 nicotinic receptor subunit [378]. Selective gene knockout mice lacking the alpha-3 nicotinic receptor subunit alone or the beta-2 and beta-4 subunits in combination [379], develop severe bladder distension soon after birth, and later overflow incontinence. The detrusor muscle in these animals contracts in response to field stimulation or muscarinic agonists, but not nicotinic agonists [380], indicating the potential importance of alpha-3, beta-2, and beta-4 nicotinic receptor components in control of voiding, but not their functional location.

Within the pelvic plexus there is topographical representation of the pelvic organs. In the female dog, neurons supplying different pelvic organs are located in separate ganglia, which possess a distinctive composition of neurone types and different preganglionic supply [381]. Neurons retrogradely labelled from the urinary bladder mainly occur in ganglia located at the vesico-ureteric junction. They comprise catecholaminergic calbindin neurons and noncatecholaminergic neurons containing calbindin or NOS, with relatively sparse pericellular varicose nerve fibres.
In male mice [382], the major pelvic ganglia are close to the dorsal surface of the prostate gland. Their main inputs are the pelvic nerves, and the hypogastric nerve from the inferior mesenteric ganglion. The major outputs are the penile (cavernous) nerve and the supply to the urogenital organs. Tyrosine hydroxylase (TH) is expressed by one-third of neurons, almost all co-expressing dopamine beta hydroxylase (DBH). Numerous TH axons are present in the hypogastric nerve, but very few in the pelvic nerve, supporting a primarily sympathetic origin. Non-neuronal cells containing TH are also present, resembling small, intensely fluorescent (SIF) cells observed in many other autonomic ganglia [382]. Neurons immunostained for choline acetyl transferase (ChAT) have a complementary distribution to noradrenergic neurons. About half of the cholinergic ganglion cells contain VIP, distributed throughout most of the ganglion, with a cluster near the origin of the penile nerve [382]. Neurones with NPY are numerous and apparently randomly distributed throughout the ganglion, with marked variation between mouse strains. All noradrenergic neurons contain NPY, but many NPY neurons are not noradrenergic. Many of the cholinergic NPY neurons also contain VIP. ChAT is seen in varicose axon terminals closely associated with ganglion neurons. Neither NPY nor VIP are present in preganglionic terminals, except for a small number of individual neurones. The latter may arise from viscerofugal neurones in the myenteric plexus of the lower bowel [383].

Autonomic ganglia are also found in the vicinity of the bladder neck, trigone, proximal urethra and prostate. They receive noradrenergic and cholinergic excitatory innervation and non-cholinergic, non-noradrenergic inhibitory innervation [384]. Knowledge of this distribution allows strategic planning for surgical dissection (Figure 15). In ureteric reimplantation, several branches of the pelvic plexus travel to the ureterovesical junction and surround the distal ureter as a fine network in the human. The main neural elements are located 1.5 to 2 cm. dorsal and cranial to the bladder trigone, and dorsal and medial to the ureter in both female and male cadavers [385]. In the context of hysterectomy, cadaveric dissections show pelvic autonomic nerves are at greatest risk during sacrouterine dissection [386], corresponding with observed innervation density [387]. In addition pathophysiological processes such as ageing can influence the pelvic ganglia, for example the postganglionic sympathetic neurones in the major pelvic ganglion of rats [388, 389]. In the proximal female urethra, virtually all of the NOS immunoreactive cells also contain the carbon monoxide-synthesising enzyme, haem-oxygenase- (HO-) 2, but of the HO-2 positive cells, 25% did not show NOS immunoreactivity [390].

The bladder wall itself contains intramural ganglia, and small clusters of autonomic ganglion cells are present in the adventitial connective tissue and among the detrusor muscle bundles. There is species variation in the extent of intramural innervation of the bladder; ganglia are present in many species such as the guinea pig [383], while the rat bladder contains the post-synaptic innervation alone [391]. The ganglia are found throughout the bladder wall and vary considerably in size [91, 392]. They show immunoreactivity to vasoactive intestinal polypeptide (VIP), nitric oxide synthase (NOS), neuropeptide Y (NPY) and galanin (Gal) in varying amounts. However, they do not contain enkephalin (ENK), substance P (SP), calcitonin gene-related peptide (CGRP) or soma-
tostatin (Som) [90], suggesting that cell bodies of sensory neurones are not located in the intramural ganglia. Postganglionic sympathetic nerves, identified with antibodies to TH and NPY, also synapse on these neurones. Nicotinic receptors have been identified on intramural nerve cell bodies within the bladder [380]. α1-adrenergic facilitatory receptors in bladder parasympathetic ganglia (393).

The endothelins (ET-1, ET-2 and ET-3) mediate various biological effects through two receptor subtypes ET-A and ET-B. Electrostimulation of the sacral roots responsible for bladder contraction in the pig leads to detrusor activation with consecutive rise in bladder pressure, which can be partly inhibited by an ET-A receptor antagonist, probably by influencing the atropine-resistant component of efferent detrusor contractions of detrusor muscle strips [394]. Both ET receptors are widely distributed in the urinary tract. ET-1 modulates bladder function [395], eliciting potent and long-lasting contractions. It is synthesized locally and may be a paracrine mediator of detrusor contraction [397]. The predominant receptor sub-type in the bladder dome is ET-A [398].

3. TERMINAL NERVE FIBRES

The majority of nerves running in the detrusor stain positively for acetylcholinesterase and for vesicular acetylcholine transferase (VACHt) [392, 399] and are thought to be parasympathetic. Putative postganglionic sympathetic fibres immunoreactive for TH or NPY are rare in the detrusor, although they are moderately frequent in the suburothelium [92]. Nonetheless, presynaptic α1-adrenergic facilitatory receptors are present on efferent parasympathetic nerve terminals in the bladder wall [400, 401]. The parasympathetic efferents release acetylcholine to stimulate muscarinic receptors. However, the presence of additional substances allows immunohistochemical subclassification of nerve fibres, and raises the question as to whether additional transmitters other than ACh have a role in normal micturition function or disease pathophysiology. Many nerve fibres contain NPY and VIP, while some contain NOS or Gal. In the human bladder, markers for sensory nerves (SP, CGRP and neurokinin A) occur infrequently in nerves running in the detrusor, in contrast to the suburothelial layer [90-93]. In the mouse bladder, noradrenergic axons form a sparse supply in the trigone muscle, are quite rare in the detrusor muscle and are absent from the mucosa [382]. Cholinergic axons are prevalent in muscle and mucosa, with similar relative prevalence of co-localised peptides in the two regions. In the muscle of the trigone, the most common axons also contain both VIP and NPY. In the detrusor muscle, the most common axon type varied for the two strains studied. Noradrenergic / NPY axons provide a dense supply to blood vessels, in common with the other pelvic organs. Many vessels also have a sparse supply of VIP axons [382]. Cholinergic nerves are also present in the suburothelium; most of them in addition contain NPY and some contain NOS [92].

Smooth muscle cells in the bladder are grouped into fascicles, several of which make up a muscle bundle. They receive a dense innervation, which runs in line with the axis of the fascicle and is derived from coarse nerve trunks in the connective tissue around the fascicles and bundles. This innervation mediates the widespread co-ordinated detrusor contraction accompanying voiding. The anatomical relationship between the preterminal innervation and the muscle fascicles has been described in a serial sectioning study in the human bladder [402]. The nerve supply is distributed by a series of dichotomous branchings, illustrated schematically in Figure 16. Adjacent to the muscle bundles, 1 or 2 primary nerve trunks run parallel to the long axis of the bundle. These give rise to circumferential peribundle branches. Both the longitudinal and circumferential trunks give off transverse interfascicular branches, entering the bundle perpendicular to its long axis, approximately at the midpoint of the bundle. Within the bundle they give axial interfascicular branches running along the long axis within and closely adjacent to individual fascicles, ending in the preterminal and terminal varicose intrafascicular axial innervation.

4. DESCENDING AND SPINAL SEGMENTAL INFLUENCES ON SPINAL AUTONOMIC CENTRES

In the spinal cord, several transmitters mediate the effects of modulatory pathways that influence the onward progression of efferent activity from the SPN. Ascending and descending connections contribute to micturition reflex control, in many cases involving excitatory and inhibitory spinal interneurones between sacral and lumbar spinal segments. In a rat model of neurogenic bladder dysfunction (autoimmune encephalomyelitis), an exaggerated descending excitatory control arises at the spinal segmental level, which gives rise to detrusor overactivity [403].

Some animals with autoimmune encephalomyelitis develop detrusor areflexia rather than overactivity; in these animals, the excitatory control is probably dominated by segmental inhibition, mediated primarily by glycine receptor activation. Spinal shock in rats induces an alteration of glycine/glutamate concentration ratio [404]. A change in the ratio of excitation and inhibition was also observed in humans suffering from spasticity and pain [405]. Ageing affects many synaptic inputs [368]. This balance of inputs, and the potential plasticity of neuronal circuits, is crucial in understanding pathophysiological processes; following injury to spinal roots, plasticity can create new reflex circuits, including a somatic–CNS–bladder reflex, whereby scratching the skin in specific dermatomes may elicit bladder contractions [406-408].
Glutamate  Glutamate is present in the terminals of primary afferent neurons in the spinal cord along with interneurons and fibres originating in the medulla oblongata. In general, glutamatergic neurons tend to be excitatory, contrasting with generally inhibitory effects of glycinergic neurons; however, excitatory/inhibitory effects of transmitters can be reversed by the nature of the post-synaptic neuron. Thus, glutamatergic neurons can indirectly have an inhibitory effect if an inhibitory neuron is interposed before the ultimate target [409]. With ageing, there is a decrease in the density of glutamatergic synaptic inputs, which may influence urinary tract function [368]. Glutamate acts on spinal neurons through a variety of receptor subtypes. These include NMDA receptors, which are important in controlling polysynaptic reflex pathways at the lumbosacral levels. The NMDAR1 glutamatergic receptor sub-unit is present in the spinal cord of male rats, and is expressed in the SPN. Glutamate is present in the dorsal root ganglion cells supplying the bladder [410], and the NMDAR1 sub-unit is also present in L6 dorsal root ganglion cells of the rat [411]. In female rats, intrathecal injection of an NMDA receptor antagonist decreases bladder contraction pressure [412]. NMDAR1 receptors may be activated by glutamate released by afferents from peripheral and supraspinal origins to elicit bladder contractions [413].

Glycine/ gamma amine butyric acid  Glycinergic and GABAAergic interneurones have a major role in neural control processes mediating LUT function [414]. Glycinergic/GABAAergic projections to the lumbosacral cord inhibit the micturition reflex and also inhibit glutamatergic neurons [404]. Rectal distention prolongs the interval, decreases the amplitude and shortens the duration of bladder contractions in rats; this effect is not seen after simultaneous intrathecal injection of low dose strychnine (a selective glycine-receptor antagonist) and bicuculline (GABA-A receptor antagonist), suggesting that the inhibitory rectovesical reflex involves glycinerigic and GABAergic mechanisms in the lumbosacral spinal cord, which may be synergistic [415].

Serotonin  Spinal reflex circuits involved in voiding function have a dense serotonergic innervation [416] (Figure 17). Immunocytochemical studies in rats, cats and primates show that lumbo-sacral sympathetic and parasympathetic autonomic nuclei receive serotonergic inputs from the raphe nuclei [291, 292, 417, 418]. Activation of the central serotonergic system can suppress voiding by inhibiting the parasympathetic excitatory input to the urinary bladder, and 5-HT elicits a prolonged activation of thoracic sympathetic preganglionic neurons. Stimulation of the raphe nuclei in the cat inhibits reflex bladder activity [419-421].

HT₁A and 5-HT₂ receptors are present in the SPN. However, in different species serotonin (5-hydroxy tryptamine, 5-HT) may have varying functions in the central nervous control of bladder activity [416]. For example, activation of 5-HT₁A receptors mediates inhibitory effects on 1, parasympathetic preganglionic neurons (PGN), 2, spinal interneurons (INT) that provide an inhibitory input to sphincter multineurons (MN) and 3, raphe neurons in the brain stem. The transmitter released by inhibitory interneurons has not been identified. Activation of 5-HT₁A and 5-HT₃ receptors also inhibits afferent input passing from the bladder to the brain. Blockade of 5-HT₁A autoreceptors in raphe neurons would increase raphe neuron firing and enhance serotonergic control of spinal reflex mechanisms. This effect would promote urine storage by enhancing sphincter activity and depressing bladder activity. From de Groat W.C., 2002.

Adrenergic

Descending catecholaminergic neurones are primarily located in the upper medulla or pons [315] (Figure 18). In clinical use, non-selective α₁-adrenergic antagonists influence urine flow and storage phase lower urinary tract symptoms; the two effects probably occur by different mechanisms, and both central or peripheral locations may be responsible [400]. Reflex bladder activity is modulated by at least two spinal α₁-adrenergic mechanisms.

Firstly, there is inhibitory control of reflex bladder contractions, probably by modulation of afferent processing. Secondly, there is excitatory modulation of the amplitude of bladder contractions due to regulation of the descending glutamatergic limb of the spinobulbospinal bladder reflex pathway [427, 428]. α₁A- adrenoceptors comprise 70% and α₁B-adrenoceptors comprise 30% of the α₁-adrenergic receptors in the rat lumbar spinal cord [429], while α₁D-adrenoceptors do not appear to have a significant role [428].

Substance P

Substance P-containing terminals are closely apposed to both sympathetic and parasympathetic preganglionic neurones projecting to the major pelvic ganglion [430]. Substance P-containing afferents in the pelvic nerve terminate in the outer laminae of the dorsal horn and in the region of the SPN and DGC [364, 431]. Substance P is also located in intraspinal neurones located in the dorsal horn [432] or DGC [433]. In young adult rats, substance P in the ventral horn is almost exclusively co-localized with serotonin and derived from descending axons of medullary neurones [430, 434, 435].

Notably, substance P is often co-localized with 5-HT in axon terminals in the lumbosacral spinal cord [436]. Functionally, substance P affects micturition reflex activity [437]; intrathecal administration of Substance P at spinal levels L₅–S₁ induces bladder contraction [438]. Substance P also increases the firing rate of sympathetic preganglionic neurones [439]. Studies in the rat show that substance P levels decline with ageing in both the dorsal and ventral regions of the lumbosacral cord [440, 441]. Substance P-immunoreactive innervation of the dorsolateral nucleus (supplying the EUS) is not obviously altered with ageing [442].
5. NEURAL TRAFFIC

Low frequency (10 Hz) stimulation of the pudendal nerve elicits a continence-like response, by decreasing parasympathetic outflow in the pelvic nerve and increasing sympathetic outflow in the hypogastric nerve, thus inhibiting the bladder and activating the external urethral sphincter. Stimulation of both genital and anal sensory branches in the pudendal nerve results in bladder inhibition. If low frequency stimulation is applied during a bladder contraction the bladder pressure decreases and the activity of the external sphincter increases. When the pudendal nerve is stimulated at higher frequency in the cat (intact or after spinal transection), the response is fundamentally different [444]. Following spinal transection, pudendal nerve stimulation at 33 Hz elicits bladder contraction synergically with reduction in external urinary sphincter activity, provided the bladder contains more than a threshold volume. Indeed, efficient post stimulus voiding can be induced by intermittent high frequency pudendal nerve stimulation [425]. Such activity may be influenced by various peripheral receptors, exemplified by menthol (TRPM8) [445].

6. PELVIC ORGAN INTERACTIONS AT THE EFFERENT NEURAL LEVEL

a) Bladder and Outlet

Neural coordination of physiological and behavioral functions depends on convergence within the nervous system of information from relevant areas, and convergence could result in collateral effects of pathology in one organ affecting function elsewhere. There is extensive convergence of pelvic organ input [446, 447] at the levels of the spinal cord, dorsal column nuclei, solitary nucleus, medullary reticular formation, and thalamus [448]. Convergent processing underpins the coherent functioning of systems controlled by efferent outflows diverging from a common starting point, as exemplified by the synergic co-ordination of bladder and urethra required for normal voiding. The fundamental role of supraspinal mechanisms in lower urinary tract synergy is well recognized. However, synergic lower urinary tract function may also be a feature of the peripheral innervation, independent of CNS co-ordination. In the female minipig, pre-ganglionic pelvic nerve stimulation evokes a pressure increase in the bladder and a pressure decrease in the urethra [449]. It remains to be determined whether this observation reflects coherent activation of separate motorneurones (excitatory to the bladder, inhibitory to the outlet), or whether postganglionic motorneurones send branches which supply both bladder and urethra. In the latter arrangement, release of different neuromuscular transmitters from branches of the same motoneurone, or interposition of an additional intermediary cell would be required. The former is circumstantially supported by the observed co-localization of acetylcholine- and nitric oxide-related enzymes [450].

b) Bladder and Bowel / Uterus

Clinicians are familiar with the detrimental effect of bowel disorders on lower urinary tract activity. Physiologically, the efferent limb of the micturition reflex is inhibited by afferent input from the rectum [451]; thus, rectal distention inhibits bladder activity via glycinergic and GABAergic mechanisms in rats [415]. Dual labeling studies show that many neurones in Barrington’s nucleus supply both colon and bladder, with smaller populations supplying the two organs separately (Figure 19; 20). At the level of the major pelvic ganglion, double-labeled cells are relatively infrequent, but processes of colonic-retrograde-labeled cells often surround cell bodies of equivalent cells for the bladder. Dual-labeled cells in the spinal cord are rare [452].

The pelvic organs are supplied by sensory and autonomic fibers in the hypogastric nerve [453]. Inflammation of the uterine horn or colon gives rise to inflammation in the bladder, an effect that can be eliminated by sectioning the hypogastric nerve [454]. Bladder overactivity induced by inflammation is
Figure 19: A, Fluorescent micrographs of sections at the level of (A1) the major pelvic ganglion, (A2, B1, B2 and C1) the lumbosacral spinal cord and (C2) Barrington’s nucleus of rats injected with PRV-Beta-GAL in the bladder and PRV-GFP in the colon and having different survival times. The viscera, tracer and survival time are indicated in each photomicrograph. BD, bladder. CO, colon. A1. Separate labeling from both viruses is apparent in the MPG at 48 hours. A2. In the same case, only occasional cells are labeled in the spinal cord. B1. Substantial labeling from both organs is visible in the preganglionic parasympathetic column of the spinal cord and most cells are singly labeled from either the colon or the bladder. The arrow points to a rare double-labelled neuron. B2. Bladder- and colon-related neurons in close proximity. Processes from the colon-related neuron (arrow heads) are apposed to the bladder-related neuron. C1. Increasing survival time results in greater number of double-labelled cells (arrows). In most double labeled cells PRV-Beta-GAL label from the bladder is surrounded by PRV-GFP label from the colon. C2. Section from Barrington’s nucleus from the same case as C1 indicating that only a few cells are transsynaptically labeled from the bladder and none from the colon at the survival time. Arrow heads point to the surface of the fourth ventricle and stars indicate the location of trigeminal mesencephalic neurons. Calibration bars: 50 µm A1 and A2, 30 µm B2 and C1, 50 µm B2, 50 µm C2. From Rouzade-Dominguez, M., et al. 2003.

influenced by estradiol, probably mediated through effects on the sympathetic nervous control of the bladder [455]. There are several potential mechanisms by which neural input could contribute to emergence of inflammation in neighbouring organs [454] (Figure 21):

1. Axon reflexes occurring in hypogastric sensory nerves that branch to supply more than one pelvic organ. Though such branching has not yet been specifically identified, a small proportion of single afferent fibres may branch to supply the colon and bladder [456].

2. A dorsal root reflex; hypogastric afferents from the inflamed organ could, via a spinal interneuron, sensitize and antidromically activate other hypogastric afferents from an uninfamed organ, exemplified by sensitization of a population of spinal neurons responding only to bladder input with chronic colonic inflammation [457].

3. Input from the inflamed organ (via the hypogastric nerve) activates neurons in the dorsal horn that activate postganglionic neurons in the pelvic ganglion via thoracolumbar preganglionic neurons.

4. A spinal mechanism could be mediated by intraspinal connections to lumbar sacral preganglionic neurons (as seen for gynaecological organs [458]).

5. A suprasacral mechanism could be mediated through the brain stem [452, 459, 460].

7. EFFERENT INHIBITION

The possibility of bladder inhibition by the CNS can be inferred from various experimental observations [461]. The sympathetic nervous system mediates inhibition of ganglionic transmission to the bladder. Isolated whole bladders manifest spontaneous contractile activity [118, 461-465], suggesting the possibility of active neural inhibition of the bladder during urine storage. In the decentralised bladder, following transection of sympathetic input, addition of the ganglion blocking agent hexamethonium leads to an increase in spontaneous bladder activity, likewise suggesting that a peripheral reflex inhibits the bladder during urine storage [461]. Rat brainstem/spinal cord/bladder preparations or neonatal spinal cord/bladder preparations show tonic inhibition, arising at L6-S1 and involving a peripheral ganglionic synapse [465-467]. Clearly, efferent inhibition of the bladder will facilitate urine storage.

In the neonatal rat, considerable activity arises in the bladder wall when inputs from the lumbar sacral spinal cord are disrupted [465]. Selective spinal cord and root lesions indicate that intrinsic bladder activity of the neonatal rat is tonically inhibited by parasympathetic efferent outflow [465]. This path is additional to the predominant cholinergic preganglionic efferents mediating the main voiding reflexes. The functional difference in the two sets of cholinergic ventral root efferents may result from differing synaptic targets, since both are blocked by the nicotinic antagonist hexamethonium [465]. Thus, inhibitory efferents must synapse with noncholinergic inhibitory neurons in the major pelvic ganglia, in contrast to excitatory efferents synapsing with the cholinergic detrusor innervation.

In addition to efferent input, local reflexes may contribute to the inhibition of detrusor activity, probably driven by interstitial cells [468], so that peripheral autonomous activity increases as a result of bladder distension [462, 469]. This has been proposed to signify the presence of a regional regulatory influence [470] and a peripheral “pacemaker” [471] and various mechanisms for the propagation of activity within the bladder wall [464]. In the clinical context, processes affecting peripheral innervation would then predispose to emergence of inappropriate detrusor activity during urine storage (through loss of inhibitory fibres), associated with inefficient bladder emptying (through loss of excitatory fibres).

8. PERIPHERAL EXCITATORY MECHANISMS

Agonist exposure appears to elicit contraction by two different mechanisms, comprising a component derived from direct stimulation of the muscle cell (‘classical’ efferent), and a separate component which is more phasic, responsible for the obvious pressure fluctuations. The latter ‘intrinsic’ mechanism may involve an intermediary cell type [472]. Optical imaging and calcium-/ voltage-sensitive dyes in whole rat bladder preparations have detected electrical activity moving in a co-ordinated manner from localized regions over the entire bladder [473, 474]. The isolated whole bladder shows regionalized responses when exposed to cholinergic/muscarinic agonists [463, 465, 472, 475, 476]. Dynamic migrating localities of contraction and elongation, give rise to a complex mix of micromotion phenomena, including micro-contractions, microstretches and propagating waves. Several species show differences in contractile activity according to the region of the bladder from which a muscle strip is taken. Different effects are seen according to stage of development- spontaneous activity is not apparent in bladder strips from neonatal rats [401], but subsequently emerges, so that at one month, high-frequency spontaneous contractions occur in conjunction with high-amplitude, low frequency contractions.

The likely functional significance of peripheral excitatory mechanisms is exemplified by the rodent neonate voiding reflex, which is induced by parental stimulation of the perineum, prior to establishment of mature control by the higher micturition centres [401, 465]. The physiological role of such activity in the adult is not known, but could include; 1. Optimization of the bladder wall configuration for volume contained,
Figure 21: Five compatible mechanisms by which hypogastric nerve fibres can contribute to the process of inflammatory induction between organs. A. Branching sensory afferents. B. Dorsal root reflex. C. Multisynaptic route involving sensory afferents from the inflamed organ to the T-13/L1 segment of the cord followed by output from preganglionic fibres in the T13/L1 segment to postganglionic in the pelvic ganglion that innervate the uninflamed organ. D. Multisynaptic route involving sensory afferents from the inflamed organ to the T13/L1 segment of the cord followed by output from preganglionic fibres in the L6-S2 segments to postganglionic fibres in the pelvic ganglion that innervate the uninflamed organ. E. Multisynaptic route involving sensory afferents from the inflamed organ to the T-13/L1 segment of the cord followed by output from preganglionic fibres in the L6-S2 segments to postganglionic fibres in the pelvic ganglion that innervate the uninflamed organ. In this case the multisynaptic route includes ascending connections from spinal cord to brain and descending connections from brain to L6-S2. From Winnard, K.P. et al. 2006.
to ensure efficient voiding regardless of volume [477].
2. Stimulation of ‘in series’ receptors for signaling bladder volume [476].
3. A mechanistic component of accommodation during filling, a counterintuitive suggestion supported by the observation that accommodation in the colon involves synchronous contraction and relaxation [478].
4. Servoassistance of voiding for maintenance of contraction [479].

The potential importance of peripheral functional structures may explain the recognition that nerve growth factor can contribute to overactive bladder problems [480].

V. MIDBRAIN-BRAINSTEM CONTROL OF BLADDER FUNCTION

With the direct role of both limbs of the autonomic nervous system in regulating filling and voiding of the bladder, the involvement of brainstem circuitry is paramount in normal bladder function. The brainstem is involved in reflexes controlling filling, storing and emptying of the bladder. Clinical cases of lesions within specific brainstem regions, most notably the pons, can result in either bladder continence or incontinence problems. This section will review the current understanding of brainstem neuronal networks that influence the parasympathetic and sympathetic motor outflows destined for the detrusor and smooth muscle of the urethral sphincter.

1. AFFERENT PATHWAYS TO THE BRAINSTEM

Sensations of bladder fullness are conveyed to the spinal cord by the pelvic and hypogastric nerves, while input from the bladder neck and urethra is carried in the pudendal and hypogastric nerves. Afferents arising from the bladder and urethra are mechanoreceptive (Aβ fibres) and nociceptive (C fibres). The most important afferents for initiating micturition are those passing in the pelvic nerves, whose fibres terminate in discrete regions of the lateral aspect of the dorsal horn of the lumbar and sacral spinal cord (see [481, 482, 483] for reviews). Many of these dorsal horn neurones make spinal connections that mediate segmentally organised reflex responses. However, a proportion of the spinal interneurones send ascending projections to the brain. These afferents are involved in transmitting sensory information to the cerebral cortex and can trigger micturition mediated by neural circuitry within the brainstem.

Ascending fibres from dorsal horn neurones receiving afferent input from the bladder terminate in the gracile nucleus and the central aspect of the periaqueductal grey (PAG; Figure 22); the latter has been described as a most dense spinal innervation [483, 484], perhaps emphasizing its essential role. The gracile nucleus relays information regarding nociception to the thalamus and cortex. Those PAG neurones receiving direct spinal inputs project to multiple sites including the pontine micturition centre (PMC) and the thalamus for onward relay to the cerebral cortex [483]. Although these data are based on animal species, the pivotal role of the PAG and PMC has been confirmed in man using positron emission tomography [485, 486] and functional magnetic imaging [487] with and without a full bladder (see Figure 23). Indeed, the PAG projections to the PMC originate from its lateral aspects [488]. Since the spinal projections relaying bladder distension target the central PAG there is the possibility of some integration prior to onward transmission to the PMC. This is likely to include integration of descending information from higher brain regions such as the limbic system and cerebral cortex [483], which provide contextual information concerning the appropriateness for micturition. Recently, the parabrachial nucleus appears activated during bladder contraction and may also receive afferent inputs directly from the spinal cord or via other central structures (Fig 23).

2. DEFINING BRAINSTEM CIRCUITRY REGULATING BLADDER FUNCTION

It is evident from recent reviews [481, 482] that most regions of the brainstem involved in controlling bladder function are known. However, as is evident in figure 4 of de Groat’s (2006) review, it remains unclear how these central nervous structure are connected up (see Figures 23 & 24). Are there, for example, brainstem pathways running in parallel and/or series that drive the preganglionic motoneurones? A method of revealing key brainstem regions regulating end organ function that has the ability to address this is transneuronal retrograde labelling using pseudorabies virus (PRV). Both the bladder wall and urethra of the rat have been injected with PRV. This has resulted in similar regions of the brainstem being labelled, which supports the close coordination of detrusor and urethral muscle function as suggested previously [481]. The brainstem regions labelled included Barrington’s nucleus (the pontine micturition centre), midline raphe (magnus and obscurus), locus coeruleus (A6), subcoeruleus, A5, reticularis gigantocellularis and nucleus paragigantocellularis [489, 490] but also in neonatal rats only the prepositus hypoglossal nucleus and lateral vestibular nucleus [489]. In addition, the PAG was labelled (Figure 22). Recent work has also indicated a role for the medial parabrachial nucleus (Figure 22). Whilst this provides information concerning the major players within the brainstem, the PRV technique does not imply precise information about connectivity. For example, are all these brainstem regions connected in parallel to the spinal interneurones and / or pre-ganglionic neurones or are some positioned in series? Are reciprocal connections between these nuclei present? Much of this information remains unknown but seems important if one is to understand the way in which the brain controls bladder storage and emptying and how one obtains reversible switching between these essential
Figure 22: Schematic representation of the described sensory and motor pathways regulating bladder function in animals. Of note are roles for gracile nuclei in transmitting afferent information from the spinal cord to the thalamus and cortex; the pontine storage centre activated during bladder filling, the lateral parabrachial nucleus (as a sensory integration centre) and the rostral ventromedial medulla as a centre important during voiding. For further details and all references see text.

Figure 23: Consistent with animal studies, regions of the human brain, imaged using positron emission tomography including aspects of the midbrain (periaqueductal gray, the dorsal mesencephalic reticular formation) and brainstem (dorsolateral pontine tegmentum-pontine micturition center and dorsolateral pontine reticular formation-pontine storage centre) are evident when the bladder is filled. (From Kavis et al., 2005).
functions. Most anatomical, electrophysiological and imaging studies to date have concentrated on the PMC as this appears pivotal regarding bladder function in both animals and man.

3. THE PONTINE MICTURITION CENTER (PMC)

In the rat, the PMC is just dorsomedial to A6 [293, 491] whereas in the cat it appears to be within A6 extending ventromedial into the mesencephalic tract of the trigeminal nerve [266]. It is these regions that are termed Barrington’s nucleus- a region named after Barrington, who in 1925 was the first to describe this pontine control centre for micturition in the cat (Figure 22). In man, comparable regions in the pons can be imaged and found activated when the bladder is full (see Figure 23; [486]).

a) Barrington’s nucleus: is it the master of ceremonies for bladder emptying

Based on the finding that its activation (electrical or chemical stimulation) in rats and cats relaxes urethral sphincters and initiates bladder contractions [293, 492, 493], it seems reasonable to propose a dominant role for the PMC in micturition. Moreover, lesions localised to this pontine region in animals abolish micturition and cause urine retention [293]. Similarly, a PMC lesion (on the right hand side) resulted in urinary retention in man [494]. Thus, the PMC would appear to play a major point of convergence of numerous pro- and anti micturition drivers. Thus, it may be a major integrating centre and, indeed, possible ‘command’ centre for initiating and orchestrating the act of bladder emptying.

b) How is the PMC connected up?

The inputs to, and outputs from, the PMC are considered below:

1. INPUTS: As described above, the lateral aspects of the PAG send information regarding the degree of bladder distension. These inputs are powerful and can trigger micturition as evidenced by the finding that chemical stimulation of ventrolateral PAG can cause voiding [488]. Recently, Kuipers et al. [495] have examined the afferent inputs to the PMC using conventional anterograde and retrograde tracing techniques. In addition to the PAG (ventrolateral and dorsomedial aspects) inputs arose from: ventromedial pontomesulcillary terminal field (Figure 22); medial preoptic area, posterior hypothalamus (perifornical region). It is unclear as to the exact function of the pontomesulcillary terminal field, although Holstege believes this is a diffuse input providing a ‘general level-setting’ of PMC neuronal activity [496]. This might be interpreted as a potential mechanism for establishing a neuronal set-point or threshold beyond which micturition occurs. The medial pre-optic region may well provide inhibition and this may be important during sleep and/or sexual activity to suppress micturition [266, 483, 497], although the previous work by Gjone demonstrated that micturition could be evoked following activation of this region [498], which is inconsistent with an exclusive inhibitory role. The posterior hypothalamic region is involved in fight or flight (defense response). Its connection to the PAG may account for the urination reported in conscious animals during a defense response, since regions of the PAG can also evoke the defense response [499] and, via PMC, could also initiate urination [500].

The study by Kuipers et al. [495] in the cat failed to confirm the numerous central nervous afferent inputs to the PMC described by Valentino et al. in the rat [501]; these included the Kolliker Fuse nucleus, raphe, nucleus tractus solitarius, parabrachial nucleus, nucleus paragigantocellularis and the cuneiform nucleus. Whether a species difference can explain this seems unlikely. Certainly the regions labelled by Valentino et al. [501] map more closely to data obtained using PRV injected into the bladder wall or urethra (see [489, 490, 502]) as described above. With this said, it is likely that many of the nuclei that project to the PMC also connect to each other but this needs confirming using localised injections of neuronal retrograde and anterograde tracers.

2. OUTPUTS: During micturition the PMC exerts simultaneous excitatory influences on parasympathetic outflows that cause bladder contraction and complete emptying but inhibition of sympathetic preganglionic to relax the urethral sphincter. It is, therefore, entirely appropriate that within the PMC there are bulbospinal neurones (Figure 24): PMC sends direct projections to parasympathetic preganglionic motoneurones innervating the bladder [503]. The latter authors provided ultrastructural evidence of asymmetric (excitatory) synaptic contacts on sacral parasympathetic preganglionic neurones originating from the PMC. Moreover, single neurones have been recorded extracellularly from Barrington’s nucleus in cats (i.e. medial to the mesencephalic tract of the trigeminal nerve) and found to have sparsely projecting axons based on antidromic invasion testing from the dorsolateral funiculus of the first sacral segment [504-506]. An involvement of glutamate as the main neurotransmitter in this pathway has been described [507]. Such a pathway would explain bladder contraction. Urethral relaxation requires an inhibition of somatic motoneurones and this appears to be mediated from PMC projections onto inhibitory interneurones located in the intermediolateral cell column at the sacral segmental level [278]. Both glycine and gamma amino butyric acid are thought to play a role here [279, 508].

c) On-switching micturition: a role for the PMC

With the PMC being essentially a pre-motor (parasympathetic/sympathetic) micturition nucleus, it should fulfil certain criteria if it is involved in the initiation
of bladder contraction and sphincter relaxation. For example, neurones should project to the spinal cord, fire ahead of a bladder contraction and fire continuously with each bladder contraction. Previous studies have found pontine units that fired in phase with bladder contraction [509, 510], but whether these connected to the spinal cord directly was not tested. However, subsequent single unit recordings by Sasaki [504, 505] and Sugaya et al. [506] provide convincing evidence that many PMC neurones do project to the spinal cord. Studies have shown that feline spinally projecting neurones (as demonstrated using the antidromic collision test) located in Barrington’s nucleus discharged in phase with bladder contractions (Figure 25). Many had firing patterns not different to those recorded from bladder afferents. But this is not always the case. Indeed, some of these units fired prior to the onset of bladder contraction consistent with a role in initiating bladder contractions (Figure 25). Whilst the proof of causality is always a difficult one, these neurones do make excellent candidates for driving/initiating bladder contraction. Indeed, many were also shown to be synaptically activated (orthodromically) following electrical stimulation of the spinal cord [506] raising the possibility of bladder afferent input, which may assist in providing positive-feedback and additional excitatory drive to both sustain and possibly amplify firing during micturition. The latter of course should be taken cautiously as it is not clear whether the spinal input demonstrated originated from bladder mecanoreceptors. Physiological stimulation of the bladder mecanoreceptors themselves, rather than electrical stimulation of the spinal descending afferents, would be necessary to confirm this.

The issue of whether the PMC is the only pre-motor micturition initiating region is addressed by Sugaya et al. [506]. From their recordings, units localised to the rostral medial medulla (reticularis gigantocellularis and magnocellularis) could also be activated antidromically from the spinal cord (L1) and also fired in or out of phase with bladder contractions (Figures 22, 23 & 25). These units included those that fired just before and/or with bladder contractions as well as firing in between bladder contractions. Interestingly, many of these rostral medial medullary units responded at short latency (2 to 3 ms) following stimulation of the PMC, supporting direct orthodromic activation. Thus, Sugaya et al. [506] proposed two descending pathways from the PMC for initiating micturition: one direct to the parasympathetic preganglionic neurones and the other via the medial reticular formation. Incidentally, the study also showed that these medullary units could be orthodromically activated from L1 indicating the potential for bladder mechanosensitive afferent drive to these neurones, although no direct proof for this was given that this spinal input originated from the bladder wall.

A question arises as to whether the spinally projecting PMC and rostral medial medullary neurones are actually defined pre-parasympathetic versus pre-sympathetic neurones? Said differently, does a single unit project to both autonomic preganglionic neuronal types in the spinal cord (see [508, 511]). This relates to the current understanding that during micturition the bladder contracts (parasympathetic activation) but relaxes the urethral sphincter (somatic inhibition). No data exist for this presently. However, in the nucleus tractus solitarius located in the dorsomedial medulla, a similar issue exists. Here, neurones receive mecanoreceptor sensory inputs from arterial baroreceptors activated by increases in blood pressure, which when activated mediate simultaneous excitation of cardiac parasympathetic motor outflow but inhibition of vasomotor sympathetic activity, thereby reducing cardiac output and peripheral resistance respectively that together lower arterial pressure to normal levels. Simms et al. [512] recently reported that the cardiac parasympathetic limb was activated at a
higher pressure threshold compared to the sympathoinhibition. It was surmised that output neurones within NTS are dedicated and already destined for either the parasympathetic or sympathetic networks [512]. Thus, a similar organization may exist within the PMC and could be teased apart by differences in the bladder pressures threshold necessary for bladder contraction versus urethral relaxation. Moreover, each autonomic limb of the baroreceptor reflex could be modulated differentially (e.g. [513-515]).

4. BLADDER ‘FILLING’ NEURONES IN THE PMC AND MEDIAL RETICULAR FORMATION: WHAT’S THEIR ROLE?

Within both the vicinity of the PMC and medial reticular formation, neurones were encountered that fired during the interval between bladder contractions but were silent during contractions. These were termed type 2 neurones by Sugaya et al. [506] and ‘inverse neurones’ by Sasaki et al. [516]. Many of these neuronal types had spinal projections (e.g. 26/35 type 2 neurones of Sugaya et al. [506]) but some could not be antidromically back fired. Although the latter is not definitive proof that these cells do not project spinaly, the data are suggestive that they form a group of interneurones.

So, what is the function of these spinally and non-spinally projecting inverse neurones? Considering those with spinal projections, these cells might provide excitatory drive to sympathetic pre-ganglionics destined for the detrusor muscle to bring about active relaxation, via \( \beta_2/3 \)-adrenoceptor stimulation. In regard to the non-spinally projecting neurones that fire out of phase with bladder contractions, these may be involved in ensuring that the neurones which are active during bladder contractions that project spinally to the parasympathetic preganglionic neurones remain silent during filling via local inhibitory connections. If so, one might predict that they contain GABA or glycine as an inhibitory neurotransmitter.

Future studies could consider difference in neuronal phenotype spinally and non-spinally projecting neurones by juxtacellular labelling and post-hoc immunocytochemistry or in situ hybridisation to identify their neurochemical content (glutamergic versus GABAergic, for example) as elegantly performed by others in the cardio respiratory regions of the medulla [517, 518]. Equally, the non-spinally projecting PMC neurones that fired in phase with bladder contractions could provide a source of synaptic inhibition to prevent neurones involved in bladder relaxation from firing prematurely.
5. OFF-SWITCHING MICTURITION – THE PONTINE CONTINENCE CENTRE (PCC)

As Sasaki (2004) points out [505], since the majority of units recorded from Barrington’s nucleus (60/76) continued to fire after the onset of bladder relaxation and that almost all inverse neurones do not start to fire until after relaxation is well underway (Fig 25), there must be a separate region for ‘off-switching’ bladder contractions and for relaxing the detrusor muscle. Simultaneously the urethral sphincter should constrict to allow filling and prevent incontinence. For these functions, the pontine continence centre or PCC is considered. This region was also termed the L region being distinct from the M region designated to be the PMC (see [519]).

**Where is the PCC, what types of neurones exist and what are their connections?**

The PCC is located in the dorsolateral pontine tegmentum (Figure 22). Neuroanatomical evidence indicates that PCC neurones do not project to spinal regions influencing detrusor muscle. Rather, projections appear to be limited to Onuf’s nucleus in the sacral cord. This nucleus contains the urethral sphincter motoneurones, suggesting that PCC drives their contraction. Perhaps some of the PCC neurones therefore have a defined pre-motor autonomic function as discussed above in the context of the arterial baroreceptor reflex. However, activation of PCC can stop micturition contractions [520]. Importantly, 78% of PCC neurones fire during the relaxation phase of bladder contractions (Figure 25) and the onset of their firing can be prior to the initiation of bladder relaxation [521].

Indeed, this would make sense if their prime function is to close the urethral sphincter. Another potential role is in off-switching micturition. One argument against this is that there appear to be no connections between the PCC and PMC, although a small number of PCC units could be either ortho- or anti-dromically activated from the PMC using electrical stimulation [506], which does not necessarily indicate the origin of the input or axon terminal. Others believe that the PMC and PCC act independently [520].

However, evidence supporting a role in off-switching micturition is that lesions within PCC cause incontinence, excessive detrusor activity, an inability to store urine and relaxation of the urethral sphincter. Further, activation of the PCC stops micturition, excites the pelvic floor musculature and contracts the urethral sphincter [278, 520]. Whether the PCC is actively involved in off-switching micturition to allow filling and storage and how it does this are questions requiring future experimental consideration. An area that may play a role in regulating micturition is the periaqueductal grey or PAG.

6. THE PERIAQUEDUCTAL GREY (PAG): IS THIS AN ESSENTIAL REGION FOR SUPPRESSING THE MICTURITION REFLEX?

The PAG is often referred to as a relay between ascending bladder afferent information and PMC activation of sacral parasympathetic preganglionic motoneurones. The present evidence suggests that the PAG is not just a simple ‘relay’. As mentioned above, afferents of sacral origin terminate in central regions of the PAG but that onward transmission to the PMC originates from more lateral aspects [484, 488, 490, 502]. Therefore, some form of ‘neural integration’ within the PAG is very likely. Chemical stimulation of the ventrolateral PAG can trigger micturition together with defensive behaviours (see [522]) but equally inhibition of micturition can be evoked by stimulation of rostral dorsal and caudal ventral PAG regions as well as areas ventral to the PAG (e.g. dorsal mesencephalic reticular formation and nucleus reticularis pontis oralis; [523]). Lesions within the PAG abolish the micturition reflex in the pre-collicular decerebrate cat [524] but studies in human also report bladder overactivity [525]. Matsuura, Downie et al. (2000) have shown that micturition evoked by chemical stimulation of the ventrolateral PAG is mediated by Barrington’s nucleus in the urethane anaesthetized rat. Moreover, these same authors were able to obtain coordinated sphincter activation from the PAG (with bladder contraction) as well as sphincter activation without bladder contraction at different sites within the PAG. This suggests the PAG is involved in both voiding and storage functions. This proposal is consistent with single unit recording from the PAG: Liu et al. [523] recorded from 84 micturition-related PAG neurones of which the majority were storage neurones (i.e. fired during bladder filling; 58%; Figure 25). Further, PET imaging revealed PAG regions becoming active during urinary retention in man [485]. However, close examination of the recording sites in Liu et al. study [523] reveals that the majority of neurones (68 of the 84) were located ventral to the lateral/ventrolateral PAG (in which 16 were recorded) in the dorsal mesencephalic reticular formation and nucleus reticularis pontis oralis. Nevertheless, based on the prominence of storage neurones in this region the idea that it plays a role in both urinary filling and suppression of the micturition reflex was advanced by Liu et al. [523]. They also proposed that micturition neurones may reciprocally depress the storage neurones. If true, this makes this part of the midbrain important in terms of providing a command locus for on- and off- switching micturition. In support of this was the observation of diverse firing patterns of the neurones including augmenting and decrementing [523]. Such firing patterns have been ascribed roles as ‘phase-switching neurones’ in the respiratory network [526], and could well play a role
in the transition between storage and voiding. Some of the midbrain cells recorded by Liu et al. [523] also fired across voiding/filling or filling/voiding transitions (Figure 25); this again supports the possible role in switching again akin to the brainstem respiratory network [526] between filling and emptying of the bladder. With the well established connections of the PAG that include orbital and pre-frontal cortex, amygdale, pre-optic region of the hypothalamus [500], it is proposed that the PAG may form a site for the integration of information from both higher centres, such as cortex, and bladder distension afferent inputs. With this said, the PAG is a clear contender for decision making about when to void or not, which it could execute via connections to PMC and PCC respectively.

7. NEUROTRANSMITTERS & MODULATORS WITHIN BRAINSTEM NETWORKS CONTROLLING BLADDER FUNCTION

There is not the scope in this review to provide a thorough detailed coverage of all transmitters and modulators affecting brainstem regulation of the urinary bladder. For recent reviews see: [481, 482]. These latter reviews highlight the importance of classical transmitters (glutamate, GABA and glycine) and non-NMDA, NMDA, GABA_A and glycine receptors within the brainstem (and PMC) for regulating bladder capacity and micturition (see also: [297, 492]). Important observations include that both NMDA and non-NMDA receptors within the brainstem are important for micturition [527] and that the PMC is under tonic inhibitory tone mediated by GABA_A receptors [492]. This prompts the question as to where and how this inhibitory tone is generated. Possibilities could be the PAG or higher centres, such as pre-optic hypothalamic structures, for example. Below is a brief account of two important and clinically relevant transmitter systems affecting bladder function via effects within the brainstem.

a) Serotonin

Many transmitter systems have been investigated by drug applications into the brain ventricles. Whilst this determines whether or not a modulating system has an effect on micturition it is difficult to assess where this might be exerted. In their review [528], Burgard et al. emphasise that serotonin appears to affect nervous control of bladder function at multiple levels including sensory processing of bladder wall afferents within the dorsal horn of the spinal cord and at the level of the spinal motoneurones. In all cases this appeared to be inhibitory on detrusor muscle activity but excitatory on urethral sphincter. A model proposed, was that 5-HT_1A receptors were located on the terminals of sensory afferent fibres to depress neurotransmitter release. Similarly, Ito et al. [529] have described a predominance of an inhibitory effect evoked from the midline raphe system extending from the pons to medulla on micturition in cats. Where this effect is mediated (i.e. supra-brainstem, pons or spinal cord) is unclear. Moreover, 79 raphe neurones were recorded in which their firing was related to bladder pressure with 66% related to storage [529]. These data support a role of the raphe system in suppressing micturition and facilitating external urethral sphincter activity in cats, which is consistent with earlier studies identifying a central inhibitory role for 5-HT_1A receptors [283]. In stark contrast, this does not seem to be the case in the rat where 5-HT_1A system facilitates micturition [530].

b) Dopamine

In Parkinson’s disease, where there is a reduction in dopamine availability, the bladder is hyperactive (409). Yoshimura et al. [531] discovered that D_1 and D_5 receptors acting within supraspinal sites are inhibitory to micturition whereas other dopamine receptor subtypes were facilitatory. This is an important finding given the major clinical and psychological problems of incontinence.

• Looking towards the horizon

A number of pertinent questions regarding brainstem mechanisms regulating detrusor and urethral muscle have evolved. First, the issue of the neuronal mechanisms underpinning the switching from storage to voiding but also off-switching detrusor activity at the end of voiding remain unclear. Most brainstem neurones relating to bladder voiding/filling appear to show firing that is either in or out of phase with bladder contractions (as indexed by increases in bladder pressure). Whether this neuronal firing is a cause or consequence of the bladder contractions is unclear. Therefore, future studies could address the issue of the origin of neuronal activity (whether coincident with bladder contraction or relaxation) in terms of that generated centrally versus that which is dependent on sensory afferent mechanoreceptor feedback for midbrain and brainstem regions. Second, and a related issue, is following the volitional command to void, which lower brain structures execute this demand? Is this in the brainstem or midbrain (PAG) or higher centres? Based on the evidence presented here, a most likely candidate appears to be the PAG/dorsal mesencephalic reticular formation. This structure appears to have the right neuronal connections in terms of both ascending spinal afferent inputs and outputs to pontine micturition centres. In addition, it receives inputs from higher centres. Third, switching between voiding-filling-voiding has to be coordinated with the corresponding control of the urethral sphincters. This means there has to be cross talk between detrusor and sphincter neural circuits. Whilst evidence was discussed for a spinal inhibitory mechanism within the sacral cord, no such cross connectivity was found between PMC and PCC regions but there remains a possibility that some cross talk may exist in the PAG/dorsal mesencephalic reticular formation. Fourth, is whether there are within
the PMC/PCC (or PAG) neurones that are dedicated
to the sympathetic or parasympathetic nervous system
that exist as pre-motor autonomic neurones. It was
discussed above that such organisation exists for
brainstem control of the baroreceptor reflex in
regulating arterial pressure. Finally, some technical
issues. Most studies inflate the bladder and work on
spontaneous isovolumetric contractions. This is clearly
not physiological as the bladder does not void. This
will affect detrusor muscle mechanoreceptor afferent
feedback as well as afferent feed back from the urinary
tract. The bladder volume/pressure always remains
above the micturition threshold, again non-physio-
logical. Many of the early experimental studies were
based on the cat. Typically this was decerebrate
raising the issue of how this relates to the conscious
intact animal where higher centres are intact and
known to regulate micturition. It is clear that more
recent studies have ventured to the rat and most
recently man. One wonders how compatible the
regions regulating bladder function is between species
and whether the connectivity and neuronal
mechanisms are preserved or different. A good
example is the opposing effects of 5-HT1a receptors
in cats (inhibit micturition) versus rat (pro-micturition;
for references see above). This is an important issue
in terms of translating work from cat/rat to man. Whilst
serotonin seems to be inhibitory to detrusor muscle
activity in cat this is not the case in rat. Thus, the idea
that modulation of the descending serotonergic system
as a potential treatment strategy for incontinence in
human [528] will need further validation. However, it
is notable that areas identified as key brainstem sites
for micturition in animal models do relate to regions
identified in man using fMRI [486]. Finally, a universally
agreed consensus needs to be defined as to how to
correlate symptoms with smaller, more discrete
lesions at particular brain sites. However this “lesion”
literature is really quite sparse, presumably mainly
because if bladder symptoms occurred as a result of
a cerebral lesion the clinical picture was usually
dominated by a variety of other neurological deficits
and furthermore such bladder symptoms that there
were would not have been of interest to the majority
of neurologists. Initially the lesion studies were based
on observations made in life correlated with post
mortem or pathological specimens, but with
increasingly better means of imaging it was possible
to correlate symptoms with smaller, more discrete
abnormalities.

From what was written, the importance of the frontal
cortex and pons was clearly recognized and there
are a number of case histories of patients reported with
lesions at either site. Subsequent functional brain
imaging studies confirmed the clinically based findings
and then greatly extended our understanding of the
complex cortical and subcortical networks involved
in sensing bladder filling and activating appropriate
voiding. In fact the few further cases of “cortical
bladders” described since the emergence of functional
imaging findings have reported lesions at sites that
previously would probably not have been recognized
as being important in “lesion” evidence presented
here and summarized in Table 4. In fact functional
imaging and lesion studies should be regarded as
complementary because, functional brain imaging
provides information about regional activation of grey
matter, whereas lesions may give information about
damage to white-matter connecting pathways. The
lesion literature also improves our understanding of
patients’ complaints. Most of the functional imaging
studies to be reviewed were carried out using either
positron emission tomography (PET) or functional
magnetic resonance imaging (fMRI). Both provide
indirect measures of regional blood flow, assumed to
be related to local neuronal activity, but their temporal
resolutions are quite different: several minutes for
PET versus a few seconds for fMRI. For this reason
PET is good for measuring long-lasting states of a
system, while fMRI is better for following relatively
fast events. Experimental paradigms are therefore
quite different for the 2 techniques.

2. ROLE AND IMPORTANCE OF CEREBRAL
CONTROL OF VOIDING

In order to understand the cerebral control of voiding
it is helpful first to examine what would happen if there
were no such control. Provided brainstem and midbrain
are intact, micturition is organized in 2 phases, storage

VI. CORTEX AND BRAINSTEM
CONTROL OF BLADDER FUNCTION

1. BACKGROUND

The aim of this section is to present a synthesis of the
human literature and review what this tells us about
brain regions mediating specific aspects of human
bladder behaviour.

Prior to the advent of functional brain imaging
techniques, our knowledge of the cerebral and
brainstem areas involved in the control of micturition
was based on a small number of carefully observed
clinical cases: patients presenting with specific bladder
symptoms who were found by investigation to have
lesions at particular brain sites. However this “lesion”
literature is really quite sparse, presumably mainly
because if bladder symptoms occurred as a result of
a cerebral lesion the clinical picture was usually
dominated by a variety of other neurological deficits
and furthermore such bladder symptoms that there
were would not have been of interest to the majority
of neurologists. Initially the lesion studies were based
on observations made in life correlated with post
mortem or pathological specimens, but with
increasingly better means of imaging it was possible
to correlate symptoms with smaller, more discrete
abnormalities.

From what was written, the importance of the frontal
cortex and pons was clearly recognized and there
are a number of case histories of patients reported with
lesions at either site. Subsequent functional brain
imaging studies confirmed the clinically based findings
and then greatly extended our understanding of the
complex cortical and subcortical networks involved
in sensing bladder filling and activating appropriate
voiding. In fact the few further cases of “cortical
bladders” described since the emergence of functional
imaging findings have reported lesions at sites that
previously would probably not have been recognized
as being important in “lesion” evidence presented
here and summarized in Table 4. In fact functional
imaging and lesion studies should be regarded as
complementary because, functional brain imaging
provides information about regional activation of grey
matter, whereas lesions may give information about
damage to white-matter connecting pathways. The
lesion literature also improves our understanding of
patients’ complaints. Most of the functional imaging
studies to be reviewed were carried out using either
positron emission tomography (PET) or functional
magnetic resonance imaging (fMRI). Both provide
indirect measures of regional blood flow, assumed to
be related to local neuronal activity, but their temporal
resolutions are quite different: several minutes for
PET versus a few seconds for fMRI. For this reason
PET is good for measuring long-lasting states of a
system, while fMRI is better for following relatively
fast events. Experimental paradigms are therefore
quite different for the 2 techniques.

2. ROLE AND IMPORTANCE OF CEREBRAL
CONTROL OF VOIDING

In order to understand the cerebral control of voiding
it is helpful first to examine what would happen if there
were no such control. Provided brainstem and midbrain
are intact, micturition is organized in 2 phases, storage
and voiding, governed by reflexes involving the brainstem and spinal cord. During storage the urethral sphincter mechanism contracts tonically, preventing urine leakage, while the detrusor remains relaxed, so as to avoid developing a pressure that would expel urine. Urethral contraction is maintained by sacral reflexes known collectively as the ‘guarding reflex’; detrusor relaxation is ensured by absence of excitatory parasympathetic input as well as active sympathetic inhibition provided by spinal reflexes (2).

During voiding the urethral sphincter relaxes, facilitating urine flow, and the detrusor contracts so as to expel urine. This coordinated relaxation and contraction of urethra and bladder respectively is driven by a long-loop spinobulbospinal reflex (2), shown schematically in Figure 26. As the bladder fills, increasingly strong bladder afferents travel via synapses in the sacral cord to the brainstem and midbrain, where they synapse in the central periaqueductal gray (PAG). If the afferent signals exceed a trigger level, efferent fibres in the more lateral PAG are excited and they in turn excite the pontine micturition centre (PMC). Efferent signals from the PMC descend to the sacral cord, where they excite an indirect inhibitory pathway via the nucleus of Onuf that leads to sphincter relaxation [535] and an excitatory pathway to the bladder that leads to detrusor contraction; thus voiding occurs. In the absence of higher control, the reflex system just described would lead to involuntary bladder emptying (i.e. incontinence) whenever the bladder volume reached a critical level. However human behaviour relating to bladder function is fundamentally different from that of other species because in modern-day society we void in a controlled fashion, preferably in privacy. Embarrassment with inappropriate voiding and feelings of shame about incontinence are deeply embedded in human behaviour. Voiding at a socially acceptable time and place is only achieved by maintaining strict voluntary control of the voiding reflex.

The decision to void is based on a combination of factors, including one’s emotional state, an appreciation of the social environment and the afferent (sensory)

Table 4. Effect on bladder behavior of pathological changes in key brain regions.
signals arising from the bladder. Knowledge of the extent to which one’s bladder content is comfortable and ‘safe’ is central in this process. Thus, voluntary control of the bladder and urethra has two important aspects, namely registration of bladder filling sensations and manipulation of the firing of the voiding reflex. The PAG – the most rostral part of the reflex pathway shown in Figure 26 – appears to have a pivotal role in both aspects. On the one hand it receives bladder afferents [535] and transmits them to higher brain centres and into the realm of conscious sensation. On the other hand it receives projections from many higher centres and controls the primary input to the PMC [536]. During bladder filling, such higher brain centres can suppress any excitatory signal from the PAG to the PMC and prevent voiding or incontinence. Then, when voiding is consciously desired, they can allow the PAG, and thus the PMC, to be excited.

Thus, during the storage phase, the net effect of higher (voluntary) control is tonic suppression of the voiding reflex. This suppression can be interrupted to allow voiding to occur if appropriate: i.e. if it is necessary (bladder volume is adequate), socially acceptable, and judged to be safe.

3. CORTICAL AND SUBCORTICAL CENTRES INVOLVED IN BLADDER CONTROL. EVIDENCE FROM OBSERVATIONS OF LESIONS AND FROM FUNCTIONAL BRAIN IMAGING IN HUMANS

a) Frontal Lobes

Although Andrew and Nathan (1) were not the first to describe disturbances of micturition resulting from a variety of causes of frontal lobe pathology, their celebrated paper reporting the syndrome of frequency, urgency (and in some patients faecal) incontinence causing distress to the patient, is regarded as seminal in the field. Their description of these patients cannot be improved upon.

“The patients described here were not demented, indifferent or lacking in social awareness; they were much upset and embarrassed by these symptoms. The acts of micturition and defecation occur in a normal manner; what is disturbed by this frontal lesion is the higher control of these acts. The lesion causes frequency and extreme urgency of micturition when the patient is awake, incontinence when asleep. The sensation of gradual awareness of increasing fullness of the bladder and the sensation that micturition is imminent, are impaired. When the syndrome is less pronounced, the sensation underlying the desire to micturate is absent, whereas the sensation that micturition is imminent still occurs. Then the patient is waylaid by a sudden awareness that he is about to pass urine; when neither sensation is experienced, the patient is amazed to find that he has passed urine. The threshold of the micturition reflex is much lowered. In the most complete form of the syndrome, the patient cannot inhibit the detrusor contraction of the micturition reflex; he is thus forced to empty his bladder as soon as the reflex occurs. When the syndrome is less pronounced, the patient can make a conscious effort to stop the act of micturition, and he may or he may not succeed. The lowering of the micturition reflex threshold may account for the fact that the patient

![Figure 26: The voiding reflex. The lines on the right (green) show bladder afferent activity ascending to the PAG during storage. Note there is no direct afferent input into the PMC. On the left (blue), lines show activation of the PMC by the PAG, with descending activity to the sacral cord from where the parasympathetic innervation to the detrusor arises. An inhibitory synapse onto the motor innervation of the sphincter (Onuf’s nucleus) results in relaxation of the striated sphincter muscle and thus synergistic detrusor sphincter activity. Note that higher brain regions control the voiding reflex almost exclusively via the periaqueductal grey (PAG), apart from a connection via the hypothalamus.](image-url)
does not feel the normal gradual filling of the bladder that underlies the desire to micturate; but it cannot account for the unawareness of the sensations arising from the activity of pelvic and perineal muscles or of the sensation that urine is passing.*

The cases of leucotomy in Andrew and Nathan’s series were regarded as most useful for localizing the lesion causing the syndrome. The significant plane of the lesion was that lying immediately anterior to the tips of the ventricles and the genu of the corpus callosum. Such lesions involved grey matter, in particular the superomedial part of the frontal lobe (see Figure 27); but they caused a permanent disorder of the control of micturition and of defecation only when they involved some of the white matter lateral to the anterior horns of the lateral ventricle. Lesions that did not affect this white matter caused only transient disordered control of micturition. Correspondingly, Andrew and Nathan’s Figure 10A suggests that most of the critical lesion area was in this white matter (Figure 27).

Subsequently the same features were observed in 7 patients out of a series of 50 consecutive frontal tumours [537]. In an analysis of patients with acute hemispheric strokes the occurrence of disturbance of micturition was found to be more common in frontal than occipital lobe lesions and there was an association with hemiparesis [538]. In 3 cases, Andrew and Nathan observed that lesions in similar areas to those discussed above led to urinary retention rather than incontinence (Table 4). Three further cases of frontal lesions with urinary retention have been reported. Successful treatment brought recovery of bladder function [539, 540].

Imaging studies, both PET [485, 541-544], and fMRI [545-548], are in agreement that, during bladder filling, storage and withholding of urine, there is activity in the right inferior frontal or dorsolateral prefrontal cortex, perhaps extending into the lateral part of the superior frontal cortex (Figure 28A,B). There is some right-sided predominance. In contrast there is little evidence for activation of the medial parts of the frontal cortex during storage. One PET study showed medial frontal activity during sacral nerve stimulation [548], but this is difficult to interpret; another study that showed medial frontal activity during filling [549] employed SPECT imaging, which has poor spatial resolution. An fMRI study showed abnormally weak activation in medial prefrontal cortex in subjects with urge incontinence [547], and further analysis revealed that bladder filling tends to provoke deactivation in this region [550]. Regardless, there is little overlap with the superomedial frontal region described by Andrew and Nathan (1), except in part of the anterior cingulate gyrus (ACG; see Figure 29). These observations are consistent with the concept that functional imaging reveals grey-matter activation or deactivation, while lesions may damage critical links in white-matter connecting pathways as well as grey-matter regions.

Neuroanatomical observations indicate that there is a strong and direct connection from medial prefrontal cortex to PAG [536]. It is tempting to postulate that this pathway is responsible for tonic PAG suppression of the voiding reflex, thus maintaining the storage phase. White-matter lesions in this pathway would then allow involuntary excitation of the voiding reflex, with resulting incontinence. It would appear from this account that bilateral lesions would be required to cause incontinence, yet in practice a lesion on one side seems to be sufficient. Andrew and Nathan’s suggestion – that this is because a unilateral lesion is likely to involve the fibres connecting one side with the other [551] – is difficult to follow.

Voiding has not been studied directly by fMRI, but there are 3 PET studies of voiding [535, 542, 543] and one fMRI study of simulated voiding [552]. All identify activation of the right inferior frontal gyrus (dorsolateral prefrontal cortex) and in the medial prefrontal cortex or nearby ACG (see next section).

b) Anterior Cingulate Gyrus (ACG)

The anterior cingulate is an extensive area with parts serving varied functions. The cases of aneurysm in Andrew and Nathan’s series of frontal lobe pathologies were thought to have involved the anterior end of the cingulate gyrus (1) (Figure 29, cyan circle). Incontinence was observed as part of a complex behavioural disorder following bilateral infarction of the anterior cingulate gyri [553]. A recent report of a patient in whom a glioma in the right posterior ACG and supplementary motor area was resected described how she experienced urgency incontinence and loss of bladder sensation following surgery [533].

Many functional imaging studies have observed ACG responses – activation or occasionally deactivation – to bladder filling, storage or withholding [485, 541, 542, 544, 547, 549]. The reported locations form a trail extending from dorsal to ventral ACG, suggesting that different parts of the ACG respond to the very varied experimental paradigms that were used (Figure 29). There is a cluster of activations near the anterior area identified from lesion studies by Dr Nathan (personal communication), confirming that this part of the brain is indeed critical for control of micturition. Response of the dorsal ACG to bladder filling is abnormally pronounced in patients with urge incontinence, even in the absence of any detrusor contraction [547, 550], suggesting that it is involved both in recruitment of accessory pathways (to help avoid loss of control of the bladder) and in the sensation of urgency that accompanies this situation. Imaging studies of voiding [541-543] and simulated voiding [552] have all revealed ACG involvement.

c) Insula

Given what we now know from functional imaging
Figure 27 A, B and C: Location of white matter lesions causing persisting incontinence (red: based on Andrew and Nathan’s Figures 10 A, B and C (1)); and of grey matter lesions causing incontinence (cyan: personal communication to CJF from Dr Nathan).

Figure 28A: Locations of peaks of activation reported as right inferior frontal or lateral prefrontal cortex, during bladder filling, storage and withholding of urine. Locations of peaks more than 20 mm from the midline are projected onto right lateral surface of brain. Note some overlap with insula shown in Figure 30.

Figure 28B: Medial prefrontal area activated in a few studies during withholding of urine. Locations of peak activation less than 20 mm from the midline are projected onto the midline plane.

experiments about the importance of the insula in processing afferent activity from the bladder (see Figure 30) it is remarkable that there have not been more reported cases of bladder dysfunction from lesions at that site. Possibly the bilateral nature of insular connections, even though there is some right-sided predominance, protects against a drastic effect of insular lesions. One patient in whom a glioma affecting the inferior frontal gyrus and the insula was excised experienced incontinence without loss of bladder sensation [533].

Imaging studies during storage or withholding of urine show that regions reported as insula form a cluster near the expected location of that structure (Figure 30) [541-544, 547, 549, 554]. There is some overlap with the lateral frontal activations reported above and shown in Figure 28A. In the figure right and left sides are projected on the same brain surface, masking any right-sided predominance, and the insula is about 20 mm deeper than the brain surface shown. In healthy subjects, insular activation becomes stronger with increasing filling of the bladder, consistent with its postulated role in bladder sensation [555]. In normal elderly, this insular response to bladder filling decreases with age, consistent with age-associated loss of sensation. However, insula activity cannot by itself be responsible for conscious desire to void or urgency, because these sensations are lost following extensive frontal lesions [551], suggesting that integrity of connecting pathways between insula and frontal cortex is essential for conscious sensation. The insula was activated in only one [543] out of four imaging studies of real or imagined voiding, suggesting that it is not strongly involved in this phase of micturition.

d) Periaqueductal Grey (PAG)

A single case history describes a young man presenting with urinary retention in whom the only abnormality found was a small, presumed inflammatory lesion in the PAG [532]. Presumably in other cases the clinical picture was dominated by other symptoms and deficits that were more striking to a neurologist.

Given the spatial resolution of PET and fMRI (a few mm), it might be expected to be difficult to distinguish small but functionally different areas in the brainstem and midbrain. In fact however the brainstem/midbrain activations reported during the storage and voiding phases seem to cluster in 3 distinct regions (Figure 31), one of them being the PAG. PAG response to bladder filling is reported in 3 studies [485, 544, 547]. This response may reflect increased afferent signals arriving at the PAG (Figure 26) or increased inhibitory activity from the medial prefrontal cortex (MPFC), needed to prevent triggering of the voiding reflex (see Figure 32). The PAG responded to imagined voiding in one fMRI study [552], but not to real voiding.

e) Hypothalamus

Lesions at this site as a cause of bladder symptoms are rare but 3 cases of pituitary tumours, extending upwards into the hypothalamus have been described with urgency incontinence or retention, weight loss, psychiatric disturbance and bitemporal field restriction [534]. Other instances include gliomas involving the hypothalamus [551] or vascular disturbances of the anterior hypothalamus. Andrew and Nathan also reported five patients with bladder symptoms appearing after a ruptured cerebral aneurysm and speculated that the site of lesion responsible was the anterior hypothalamus [556].

Animal observations suggest that the anterior and caudal hypothalamus have monosynaptic connections with the PAG and PMC [536]. Correspondingly, two human brain imaging reports suggest response to bladder filling in a region near the caudal hypothalamus [485, 555], and one near the preoptic area [547]. It has

Figure 30: Locations of activation peaks reported as insula, during bladder filling, storage and withholding of urine, projected onto right lateral surface of brain. Note overlap with areas shown in Fig 28A.

Figure 31: Brainstem areas activated during storage or voiding, projected onto the midline plane.
been suggested that these connections allow the hypothalamus to inhibit voiding unless the situation is judged to be safe.

f) Pons

The demonstration by Barrington [557] in the cat that a centre existed at the level of the pons necessary for activation of micturition, provided the background for recognizing a comparable centre in humans and the early report of the association of difficulty with micturition with posterior fossa tumours [558]. Later histories of individual cases of discrete pontine lesions [559, 560, 561], [494] and reports of difficulties with micturition or retention as a feature of brainstem gliomas in children [562, 563] or vascular lesions [564], confirmed the likely existence of a comparable centre in humans. Studies using MRI to visualize the precise location of the responsible lesions, sited this in the dorsolateral pons, including the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and locus coeruleus [564]. Lesions in this location are frequently associated with disturbances of consciousness and respiration and bladder symptoms may therefore be overlooked. The commonest clinical association of urinary retention arising from a pontine lesion is an internuclear ophthalmoplegia or disorder of eye movements.

Functional imaging experiments have shown a cluster of activations near the postulated location of this pontine micturition centre (PMC), Figure 31. There are 3 reports of PMC activation during voiding [541-543] and – surprisingly – one in response to bladder filling [555]. However, excitation during bladder filling might be inhibitory rather than excitatory, a distinction that cannot be made by functional imaging.

A few studies suggest activation of the postulated pontine L-region or continence centre (Figure 31), somewhat ventral, lateral and/or caudal to the PMC (Figure 26): during storage [485], during failed attempt to void [541, 542], during imagined voiding [554], and during imaginary inhibition of voiding [552]. However, not all these studies recognized the L-region as such.

g) Other Regions

The regions discussed in sections 3.1 to 3.6 are reasonably well established since they are observed in lesion, imaging and (in some cases) animal studies. In particular, the triad insula/ACG/prefrontal cortex is well known from studies of other aspects of brain function [565]. Other regions relevant to bladder control however have been revealed only by functional imaging. They include parts of parietal and frontoparietal cortices, posterior cortex (precuneus, posterior cingulate cortex), putamen, caudate, parts of the limbic system (hippocampal complex, amygdala), and various parts of the cerebellum. Rarely seen in functional imaging experiments is activity in the basal ganglia, yet dopamine pathways are thought to have a profound inhibitory effect on the PMC in health, which is lost in Parkinson’s Disease.

4. WORKING MODEL OF BRAIN/BLADDER CONTROL

The diagram in Figure 32 shows what are currently thought to be the principal areas and connections involved in bladder control, with the more important connections identified by thicker lines. This scheme is hypothetical but offers, at this point in time, a framework based on evidence from the clinical reports of the effects of “lesions”, the regions shown to be activated in the PET imaging experiments (Figure 33) and the results currently emerging from functional MRI and connectivity studies.

The PMC is the final efferent brain nucleus involved in bladder control – when activated there follows coordinated sphincter relaxation and detrusor contraction, resulting in voiding. However the PMC has been shown to have only a few central connections (Figures 26 and 32) namely, from the hypothalamus and from the PAG. The PAG is now recognized as having a central role in mediating the influences of higher function on the PMC and so achieving voiding at brain- rather than bladder-determined volumes. To perform this role the PAG receives afferent input via the sacral roots conveying “bladder fullness” information, as well multiple inputs from higher centres including the

Figure 32 A: preliminary conceptual framework, based on current evidence, suggesting a scheme for the connections between various forebrain and brainstem structures that are involved in the control of the bladder and the sphincter in humans. Arrows show probable directions of connectivity but do not preclude connections in the opposite direction. PAG = periaqueductal grey; PMC = pontine micturition centre. Reproduced, with permission (2), based on the work of (4).
prefrontal cortex, ACG, insula and hypothalamus and also probably the basal ganglia and cerebellum. The insula (the right in particular) has been shown to respond in a way that suggests it is responsible for mapping and processing bladder as well as other visceral sensations and is sometimes referred to as the “sensory cortex of the autonomic nervous system”.

The ACG monitors stress and conflict and generates appropriate autonomic arousal. It may also determine how much attention is paid to signals from the bladder and how one reacts to them. The medial prefrontal cortex (MPFC) has a role in response selection and so may be involved in evaluating afferent activity. The MPFC is crucial for decision-making in an emotional and social context and is thus evidentially important in controlling micturition. It is close to the anterior cingulate region revealed by lesion studies and functional imaging (Figure 29) and has strong and direct connections with the PAG, suggesting that it may be responsible for maintaining the tonic suppression of the voiding reflex during the storage phase, which normally is only relaxed when the decision to void has been made. This decision is conveyed back to the PAG, which correspondingly excites or inhibits the PMC (Figure 34).

Figure 33: Brain areas involved in the regulation of urine storage. A meta-analysis of positron-emission tomography and functional MRI studies that investigated which brain areas are involved in the regulation of micturition reveals that the thalamus, the insula, the prefrontal cortex, the anterior cingulate, the periaqueductal grey (PAG), the pons, the medulla and the supplementary motor area (SMA) are activated during the urinary storage. Reproduced with permission from (3).

Figure 34: A preliminary working model of lower urinary tract control by higher brain centres. A: During storage, ascending afferents (yellow) synapse on the midbrain periaqueductal grey (PAG); they are relayed via the thalamus (TH) to the dorsal anterior cingulate gyrus (ACG: responsible for monitoring and warning) and to the right insula (RI: responsible for sensations such as desire to void) and lateral prefrontal cortex (LPFC); in the storage phase they pass to the medial prefrontal cortex (MPFC, red arrow) where the decision to void or not is made; in this phase the decision is not to void, and this situation is maintained by chronic inhibition of the PAG via a long pathway (red arrows) from the MPFC; consequently the pontine micturition centre (PMC) is also suppressed, and voiding does not occur. B: When the decision to void is made, the MPFC relaxes its inhibition of the PAG (green arrow) and the hypothalamus (H) also provides a ‘safe’ signal; consequently the PAG excites the PMC which in turn sends descending motor output (green arrow) to the sacral spinal cord that ultimately relaxes the urethral sphincter and contracts the detrusor, so that voiding occurs.
VII. ABNORMAL LOWER URINARY TRACT FUNCTION

Dysfunction of neural control may underpin a wide range of clinical urinary tract problems. On the afferent side, neural dysfunction will alter reflex activity and influence sensation, which can either be enhanced, reduced or altered (e.g. with the emergence of pain instead of usual bladder filling sensations). On the efferent side, motor activity within the components of the lower urinary tract (bladder and outlet) can be increased, reduced or uncoordinated. The following is not a comprehensive description of the entire scope of this complex arena, but focuses on key issues relevant in the clinical context.

1. ABNORMALITIES INVOLVING INFLAMMATION

• Bladder Pain Syndrome / Interstitial Cystitis (BPS/IC)

Although no consensus has been reached on the fundamental causes of Bladder pain syndrome/Interstitial Cystitis (BPS/IC), existing data suggest 3 pathophysiological mechanisms: epithelial dysfunction, mast cell activation, and neurogenic inflammation [566].

1. MAST CELL ACTIVATION – Mast cells may be activated by a number of mechanisms within the bladder wall. Increased permeability with influx of potassium ions may lead to sensory nerve up-regulation resulting in mast cell activation. Vasoactive, nociceptive and pro-inflammatory molecules released from mast cells can produce neuronal sensitisation and secretion of neurotransmitters that further stimulate mast cells. Mast cell – neuronal interactions may therefore provoke a vicious cycle in BPS/IC, contributing to the painful symptoms of the disease [567].

2. NEUROGENIC INFLAMMATION – The close physical relationship between the C fibres and mast cells is of particular importance, as substance P (SP) released from the nerve fibres degranulates mast cells. During degranulation, the mast cells release a multitude of proinflammatory agents including nerve growth factor (NGF), tumour necrosis factor-α (TNF-α), histamine, heparin, proteases, interleukins, serotonin and others. This induces an inflammatory response in the form of vasodilatation (redness) and plasma protein extravasation (oedema). Additionally, newly released nerve growth factor (NGF) stimulates a further increase in the number of afferent fibres, thus increasing the potential for further releases of SP and the transmission of nociceptive impulses. Neuroinflammatory models of cystitis result in increased levels of TNF-alpha, SP and NGF production in the bladder, paralleling the hypothesized neuro-inflammatory etiology of IC [568].

During mammalian development, NGF is required for the survival and growth of several populations of neurons. There is evidence to suggest that it also plays a role in the ongoing regulation of neural function, as well as inflammation and pain [569].

In the urinary tract, NGF is produced by the bladder, smooth muscle and urothelium, and levels of NGF increase in response to interstitial cystitis. In one study, patients with BPS/IC were found to have elevated levels of neurotrophic factors in their urine, including neurotrophin-3, nerve growth factor and glial cell line-derived neurotrophic factor [570]. This finding is consistent with the observation of increased NGF mRNA and protein in bladder biopsies from patients with BPS/IC compared with controls [571].

Intravesical NGF is known to sensitize bladder afferent fibres [142], and sequestration of NGF can reduce inflammation associated with chemical cystitis in a rat model [572]. Blockade of NGF using either endogenous antibody or antibody against the NGF receptor, or a fusion protein that prevents interaction between NGF and its receptor, prevents neural plasticity and bladder overactivity in experimental models of these conditions [143, 573].

Other substances including neurotrophins, prostaglandins, and tachykinins may also contribute to altered afferent excitability [574]. The potential relevance of these changes has been demonstrated in cats diagnosed with feline interstitial cystitis (FIC) (which demonstrates nearly all the characteristics and symptoms of human BPS/IC), in which capsaicin sensitive neurons are larger, with dorsal root ganglia that exhibit increased excitability and slower desensitisation to capsaicin, suggesting changes in the properties of the primary afferent neurons [146, 147], a finding that may be associated with tendency of NGF to stimulate TRPV1 expression.

2. INVOLVING ABNORMAL URINE STORAGE

a) Overactive Bladder / Detrusor Overactivity

Detrusor overactivity can arise in neuropathic conditions, secondary to bladder outlet obstruction or idiopathically. Several observations on structural and functional properties of the bladder have been made in individuals with detrusor overactivity:

• Patchy denervation is present within the bladder wall, while sensory neurones and parasympathetic ganglion cells are enlarged

• Exaggerated spontaneous myogenic activity can be seen in isolated detrusor muscle strips, with increased incidence of fused tetanic contractions

• Muscle strips also show altered responsiveness to nervous and pharmacological stimuli
• Characteristic changes in smooth muscle ultrastructure have been described.

Smooth muscle strips dissected from the bladder in detrusor overactivity often show altered responses to nerve stimulation and to various agonists. For example, in obstructed overactive bladders there is reduced contractile response to intrinsic nerve stimulation, along with supersensitivity to muscarinic agonists and potassium solutions [575-578]. Among neuropathic conditions, spina bifida is associated with supersensitivity to cholinergic agonists and potassium solutions, but there is no change in the sensitivity to intrinsic nerve stimulation [579]. In spinal cord injury, there is no reduction in sensitivity to electrical field stimulation, but the maximum force generated by each milligram of bladder tissue is significantly reduced [92]. In idiopathic detrusor overactivity, bladder strips show supersensitivity to potassium, but not to muscarinic agonists, and there is a reduced contractile response to intrinsic nerve stimulation [580]. Where functional denervation is present, there appears to be an increase in spontaneous contractile activity and presence of fused tetanic contractions, a feature more typical of well-coupled smooth muscles [581, 582]. A common ultra-structural feature of the overactive detrusor is the emergence of protrusion junctions and ultra-close abutments between the smooth muscle cells [583]. Overall, the cells may be better coupled electrically in detrusor overactivity, perhaps allowing spontaneous activity to propagate over a wider area. Bladder biopsies from overactive detrusor show a patchy denervation; some muscle bundles may be completely denervated, whilst neighbouring ones appear normal and in other areas sparser innervation is also seen [92, 579, 580, 584]. A similar pattern is seen in animal models [576, 585]. Overall, these observations suggest that response to loss of local innervation by the smooth muscle cell may explain the altered behaviour of the bladder in detrusor overactivity [575, 586].

Preclinical studies in animal models of OAB / detrusor overactivity contribute further to our understanding of the importance of neural control in this condition. The main models relevant to OAB include (i) instillation of irritative agents into the bladder during cystometry, (ii) partial bladder outflow obstruction, (iii) the spontaneously hypertensive rat, (iv) spinal cord injury, and other CNS lesions similar to those responsible for bladder dysfunction in humans [587]. Irritative agents are employed in animals to evoke a painful or irritant response, in particular through C-fibres. Both acetic acid and citric acid have been used, although the latter probably represents a better model since it is less irritant and therefore less likely to invoke an acute inflammatory response. Both agents have been shown to increase bladder contractile activity, decrease bladder capacity and reduce bladder compliance, while micturition pressure remains normal or is increased, suggesting that this model may contribute to understanding of increased bladder sensory activity, as may occur during the symptom of urgency. These effects are due to stimulation of nociceptive afferent fibres, confirmed through demonstration of increased c-fos expression in rat spinal cord and in regions of the periaqueductal grey [372, 588], an effect that can be eradicated by desensitization of TRPV1 receptors on the sensory neurones following pre-treatment with resiniferatoxin [589].

Partial bladder outflow obstruction has been achieved through application of urethral ligatures or a constricting ring that results in partial urethral occlusion, mimicking the obstruction seen in men with BPH who often develop secondry OAB [577]. The animals develop cystometric features such as increased bladder capacity and non-voiding bladder contractions, with associated histological features (muscle hypertrophy, patchy denervation and enlarged sensory neurones and parasympathetic ganglia) and detrusor functional features (spontaneous myogenic activity and altered response to stimuli) reminiscent of the human condition [586]. Afferent plasticity in animals with bladder outflow obstruction involves NGF, the content of which is increased in obstructed bladders prior to the enlargement of bladder neurones and the development of urinary frequency [590]. The relevance of NGF in the response to obstruction in animals is suggested by the finding that rats immunized with mouse NGF in order to develop autoantibodies do not develop neural plasticity and urinary frequency in response to obstruction [591]. While neuronal changes are evident in the obstructed model, further observations appear to indicate that the overactive phenotype in obstructed rats derives from a combination of increased propensity to localized muscle contraction, together with a tendency towards wider propagation of this activity in an organ that may have developed greater autonomy from central control as a result of the neuronal changes [592]. In this context, the relevance of peripheral contractile modules appear to emerge as the functional units of detrusor activity [477].

The spontaneously hypertensive rat (SHR) is a genetic model of hypertension, which is also known to exhibit abnormal bladder function; in particular, SHRs have been shown to have reduced bladder capacity and voided volume, increased urinary frequency and increased occurrence of non-voiding contractions, associated with altered detrusor innervation and physiological response [450]. Again, increased bladder smooth muscle NGF levels appear to be associated with these changes [593]. The bladders of SHRs also show increased levels of calcitonin gene-related peptide immunoreactive fibres (presumably afferent) with increased size of neuronal cross-sectional area profiles for bladder afferents in the L6–S1 dorsal root.
ganglia as well as the major pelvic ganglia [594]. The potential importance of the afferent innervation in this model can be highlighted by the finding that intrathecal application of antisense oligonucleotide against the tetrodotoxin-resistant sodium channel (Nav1.8) reduces bladder hyperactivity [595].

Spinal cord injury (SCI) in animals has been shown to result in changes in lower urinary tract function similar to those seen in humans [596]. Recovery of bladder function from the initial areflexia after SCI in animal models is dependent in part on plasticity of bladder afferent pathways and the unmasking of reflexes triggered by the normally silent capsaicin-sensitive C-fibre bladder afferent neurons, resulting in cystometric changes akin to those seen in neurogenic detrusor overactivity [596]. Studies in rats indicate that the increased excitability in the C-fibres is associated with an increase in the expression of sodium channels from a high-threshold TTX-resistant type to a low-threshold TTX-sensitive type [597].

Other animal models of CNS lesions associated with bladder dysfunction have also been developed. For example, a model of Parkinsonism secondary to 6-hydroxydopamine injection into the substantia nigra pars compacta in rats has been developed, confirming the relevance of D1/D5 dopaminergic stimulation in improving bladder capacity [531]. Furthermore, a model of bladder overactivity associated with cerebral infarction due to occlusion of the middle cerebral artery in rats has been shown to lead to significant ischaemia within the putamen and cerebral cortex, confirming the importance of these areas in the control of micturition [598]. In this latter model, a role for glutamatergic and dopaminergic stimulation in the development of bladder dysfunction has been demonstrated [598, 599]. These findings are consistent with the observation that anterior brain lesions in humans are more likely to be associated with incontinence than posterior, occipital lesions [600].

Additional evidence for the importance of emergent C-fibre contribution to afferent signalling in OAB and detrusor overactivity can be found in experimental clinical studies. For example, patients with various idiopathic and neurogenic bladder dysfunctions have reduced current perception threshold to direct bladder stimulation [601] and urethral stimulation [602] at frequencies that selectively stimulate C-fibres, indicating increased excitability in the C-fibre afferents in these patients. Similarly, ice water instillation (which excites C-fibres) into the bladder can trigger involuntary detrusor contraction in patients with neurogenic detrusor overactivity [603]. In addition, the efficacy of capsaicin and resiniferatoxin in the treatment of patients with both idiopathic and neurogenic detrusor overactivity confirms the role of C-fibres and the afferent limb of the micturition reflex in bladder storage conditions [604]. While the hyper-excitable C-fibres appear to be the conduit for the abnormal sensory signals from the overactive bladder, the origin of the sensations probably lies in the bladder wall itself, either in uncoordinated asynchronous localized detrusor contractile activity [476, 605] which may lead to urgency with negligible associated pressure rise within the bladder, or in a more co-ordinated propagation of autonomous contractile activity via emergent gap junctions providing more syncytial characteristics to the overactive detrusor [583].

b) Stress Urinary Incontinence

Stress urinary incontinence (SUI) is characterized by reduced outflow resistance during urinary storage due to weakness in the urethral sphincter mechanism. It is often associated with weakness of the pelvic floor and urethral musculature, but peripheral nerve dysfunction is also implicated, in particular pudendal nerve damage following childbirth in women [606]. Animal models have contributed to understanding of the importance of the peripheral innervation of the urethra in SUI, with development of disease models association with pudendal nerve crush and vaginal distension initiating neuropraxic nerve injury in rats [607] and mice [608]. The role of pharmacological neuromodulation in the treatment of SUI has shown that urethral function and therefore incontinence can be improved by augmenting somatic neuronal discharge using the serotonergic (5HT) and noradrenergic (NE) reuptake inhibitor duloxetine, which is thought to act in the sacral spinal cord at Onuf’s nucleus, the pudendal somatic motor nucleus of the spinal cord which is densely innervated by SHT and NE terminals [307, 609]. More recent data on the effect of the selective noradrenergic reuptake inhibitor, [S,S]-reboxetine in the treatment of SUI, indicate that the serotonergic activity of duloxetine may be redundant and that effects are dependent solely on noradrenergic reuptake inhibition [610, 611].

3. INVOLVING ABNORMAL VOIDING

- Bladder Outflow Obstruction

Bladder outflow obstruction (BOO) is typically associated with prostatic enlargement in men, although it is also seen in women following surgery for stress urinary incontinence and in children secondary to proximal urethral valves. Bladder overactivity is seen in many patients with BOO, and this storage dysfunction together with the associated neuronal changes has been described above. The voiding dysfunction per se seen in patients with BOO is caused by a combination of both passive and dynamic obstruction of the proximal urethra and, in some patients, by detrusor decompensation resulting in a deterioration in the contractile function of the bladder during voiding.

During obstructed voiding, the bladder is subject to high pressures required to expel urine through a region of high resistance. These pressures compromise detrusor
blood flow during voiding leading to periods of ischaemia and hypoxia, followed by reperfusion [612]. Recurrent cycles of ischaemia and reperfusion result in progressive neuronal damage in the bladder wall, an effect that has been seen in animal models of obstruction and bladder distension, as well as in an in vitro model in which detrusor muscle is intermittently exposed to hypoxic glycopenic perfusate followed by oxygenated glucose-containing perfusate [384, 613]. This neuronal damage initially has a patchy appearance, when it seems to be related to the development of an overactive phenotype in pigs [586]. With time, however, bladder denervation with incomplete voiding and chronic retention can develop, and this is associated with a more generalized detrusor denervation and reduced contractile response to neuronal stimulation in organ bath studies [614].

4. CO-MORBID DISORDERS

The significance of neural control mechanism in lower urinary tract dysfunction is further implied by a number of comorbid conditions that have been associated with BPS/IC and incontinence.

Patients with BPS/IC and SUI are more likely to report depressive symptoms. Findings on two validated depression measures indicate that patients with interstitial cystitis report significantly greater depressive symptomatology than healthy controls, although less than 20% notice moderate or severe depressive symptoms. This finding is consistent with the observation that patients with chronic pain experience a higher level of depressive symptoms than healthy controls and other chronically ill populations. Patients report low mood (56%), fatigue (63%), difficulty concentrating (49%), insomnia or excessive daytime sleepiness (49%) and are 3 to 4 times more likely to report suicidal thoughts than the general population [615]. The association of IC/PBS [616] and incontinence [617] with depression has been corroborated in other studies, although a more recent study suggests that, after multivariate adjustment for the influence of other urogenital symptoms, only the symptom of nocturia remains significantly associated with depression [618].

BPS/IC has also been associated with other chronic pain conditions, especially fibromyalgia [616, 619-621]. An association has also been shown for child abuse [616, 622]. Based on recent improvements in understanding of pain processing pathways in the central nervous system, and in particular the role of limbic structures, especially the anterior cingulate cortex, hippocampus and amygdala, in chronic and affective pain perception, a condition termed limbic associated pelvic pain has been proposed to explain the concurrence of these various chronic pain conditions. This limbic dysfunction is manifest both as an increased sensitivity to nociceptive afferents from pelvic organs, and as an abnormal efferent innervation of pelvic musculature, which undergoes tonic contraction as a result of limbic efferent stimulation, generating a further sensation of pain. The nociceptive afferents from these pelvic organs then follow the medial pain pathway back to the sensitized, hypervigilant limbic system. Chronic stimulation of the limbic system by pelvic pain afferents again produces an efferent contraction of the pelvic muscles, thus perpetuating the cycle [622].

VIII. BRAIN-GUT INTERACTIONS

The bidirectional interactions between different hindgut organs (urinary bladder, rectum) show both similarities and differences. The primary function of both organs is to store waste products, and to empty them in accordance with a) the state of filling as well as b) the overall state of the organism, and environmental and social constraints. While the former is accomplished by a series of hierarchal reflexes, the latter is accomplished by modulatory input from the brain to change the gain of these reflexes. While spinal and supraspinal reflexes are involved in both the regulation of bladder and rectal emptying, peripheral reflexes contained within the enteric nervous system are unique to the colorectum, while supraspinal reflexes involving the periaqueductal grey and Barrington’s nucleus (or pontine micturition center) appear to play a more prominent role in bladder emptying. Conscious perception of the state of these organs is the end result of various afferent inputs to the insular cortex, including visceral afferents, and inputs from cognitive and emotional arousal circuits. Based on this model, modulation of both emptying and perception of peripheral events in both health and disease can occur at multiple levels, and by various mechanisms. It is proposed that while peripheral changes in the end organ by inflammatory processes may play the primary role in organic disorders, central changes in modulatory circuits may play the primary role in so called functional disorders, like irritable bowel syndrome and bladder pain syndrome/interstitial cystitis (BPS/IC).

1. BACKGROUND

Functions required for the elimination of waste products are coordinated with each other, with the body’s needs and with appropriate behaviors. This integration is accomplished at different levels of the neuroaxis, from the lumbar spinal cord (reflex functions; bladder – rectal integration) to pontine nuclei such as Barrington’s nucleus (integration of bladder and rectal function with other information about the state of the organism) to the periaqueductal grey (PAG) and to cortical regions (insula, anterior cingulate cortex, ACC). The PAG and BN receive inputs from cortical and emotional brain circuits, integrating pelvic visceral function with voluntary behavior and with the emotional state of
the organism. Symptoms affecting several pelvic viscera, such as incontinence and chronic pain and discomfort related to the distal colon/rectum (irritable bowel syndrome, IBS) and to the urinary bladder (BPS/IC) often co-exist.

This section on bidirectional brain distal gut interactions tries to put rectal sensations and continence mechanisms into the larger context of regulation of homeostatic function, and highlights the differences and similarities in neural mechanisms underlying fecal and urinary continence mechanisms. The approach of providing a general framework to understand how the nervous system, in particular the human brain, processes and modulates visceral afferent input arising from two viscera derived from the embryological hindgut is useful to understand the comorbidity of fecal and urinary incontinence, and of BPS/IC and IBS.

**a) The concept of homeostatic emotions**

We humans uniquely experience feelings from each of the tissues of our bodies, including the viscera concerned with storage and evacuation of bodily waste (anorectum and the urinary bladder), because evolution has produced brain mechanisms in humans for the conscious perception of an image of the physiological condition of our bodies.

The classical term *interoception*, formerly used only to refer to visceral sensation, has been re-defined, to refer to the sense of the physiological condition of the body. Recent neuroanatomical findings indicate that all of the feelings from our bodies reflect its physiological condition and can be viewed as *homeostatic emotions*.

This includes not only visceral sensations such as hunger and thirst, but also a range of other sensations including rectal or urinary fullness, urge and pain. Like all emotions, these comprise both a (conscious) feeling and a motivation and motor response. While the anterior insula has been identified as an important neurobiological substrate involved in the conscious perception of feelings and sensations from our viscera, a set of brain circuits referred to as the emotional motor system [623] is involved in the mediation of the motor response to such visceral input.

**b) Homeostatic emotions drive behavior**

Sensory inputs that relate the body’s physiological condition, or homeostatic afferents, drive the homeostatic mechanisms that promote survival. The primordial means of regulating the evacuation of stool and urine in all vertebrates is motivated behavior, so the pathways that guide homeostatic sensory input to motivational processes must be ancient. Such behavioral motivation (and the accompanying autonomic and somatic motor changes required for the evacuation of waste products) is generated in non-humanoid mammals by a signal to the forebrain from the main homeostatic afferent integration site in the brainstem, the parabrachial nucleus (PBN).

As proposed by Craig, [624] evolution produced a new direct (spino-thalamo cortical) pathway in humans to the forebrain that surmounts the primal pathway and which generates both an affective motivation and a sensation in the limbic motor and sensory cortices (Figure 35A). The basic homeostatic (interoceptive) feelings or modalities include abdominal fullness as well as fecal and urinary urge. These feelings are the human percepts of distinct “homeostatic emotions” that directly relate to the body’s needs.

---

**Figure 35A** : Ascending projections of homeostatic afferents: Organization of interoceptive pathways. Small diameter afferents that travel with sympathetic and with parasympathetic efferent’s provide input to lamina I and NTS, respectively. In mammals, the activity of both types of afferents is integrated in the PBN, which projects to insular cortex. In non-human and human primates, a direct projection from lamina I and from the NTS exist to ventromedial thalamic nuclei (Vmpo and VMb, respectively). Neurons in these nuclei project in a topographical fashion to the mid/posterior insula. In humans, this cortical image of the homeostatic state of the organism if re-represented in the anterior insula on the same side of the brain. These representations provide the substrate for a subjective evaluation of interoceptive state.
The concept of homeostatic emotions, regardless of the valence of the emotion, is consistent with the reported activation of similar brain regions (insula, dACC) by a variety of both pleasant and unpleasant stimuli (reviewed in Vogt, 2005 [625]).

2. ORGANIZATION OF HOMEOSTATIC REFLEXES: PROCESSING OF PELVIC VISCERAL INFORMATION WITHIN HIERARCHICAL ORGANIZED HOMEOSTATIC REFLEXES

a) Enteric reflexes within the Enteric Nervous System

The hierarchal organization of homeostatic reflexes within the central neuroaxis, and which are pertinent to both anorectum and urinary bladder is shown in Figure 35B. A fundamental difference in the regulation of the distal gut and the urinary bladder is the prominent role of the enteric nervous system (ENS) as the primary reflex circuit mediating both filling and emptying of the distal colon. The ENS, which is considered the third division of the ANS [626], is made up of two ganglionated plexus situated between the different muscle layers of the gut (myenteric plexus) and the mucosa (submucosal plexus). Even in the absence of any central input, these enteric (or intrinsic) reflexes can generate proximal to distal propulsion of colonic contents (peristaltic reflex), and relaxation of the internal anal sphincter [627]. While the enteric reflex circuitry within the anorectum is unique to fecal continence, the spinal and supraspinal reflexes mediated by extrinsic afferents overlap considerably for bladder and rectum.

b) Lamina I afferents provide input to spinal and supraspinal reflexes.

The small-diameter afferent fibers that innervate the pelvic viscera course peripherally with sympathetic and parasympathetic nerves (e.g. splanchnic, pelvic, vagus), and with somatic nerves (e.g. pudendal). Many innervate the mesenteric ganglia and play a role in the communication between the central nervous system and the ganglionated plexus of the ENS. Many of these extrinsic afferents respond to chemical and mechanical stimuli over a broad range of thresholds and response slopes, so that they might be considered to represent a broad continuum of response properties. However, they can also be regarded as separable into different classes, including low-threshold, high-threshold (nociceptive), “silent” (unresponsive unless inflamed), and thermosensitive (primarily warm) [628, 629]. These classes may correspond to different functional roles and different subjective feelings. Within the gut, there are also several distinct anatomical patterns of innervation, with some fibers ending within the longitudinal muscle sheets, others ending within the enteric ganglia (intraganglionic laminar endings, IGLEs), [630] and others in close proximity to enterochromaffin [631] or to mast cells [632].

c) Spinal and supraspinal reflexes

The lamina I neurons that receive the small-diameter fiber inputs have projections within the spinal cord and brainstem (Figure 36A). In the spinal cord, their only major projection is to the sympathetic cell column of the thoracolumbar spinal cord, where autonomic preganglionic output neurons are located. In the brainstem, they project exclusively to the recognized homeostatic integration sites (e.g. caudal and rostral ventrolateral medulla, catecholamine cell groups A1-2 and A5-7, Barrington’s nucleus (“pontine micturition center”, PMC), PBN, periaqueductal gray [PAG]), which also receive parasympathetic afferent activity by way of the NTS and which are heavily interconnected with the hypothalamus and the amygdala complex (including the bed nucleus stria terminalis, BNST). The NTS that receives small-diameter fibers from parasympathetic nerves similarly projects to all of these sites. These spinal and bulbar
projections from lamina I and from the NTS provide the substrate for the hierarchical, modality-selective somato-autonomic reflexes activated by spinal small-diameter afferents that are crucial for homeostatic control of all tissues of the body [633].

Traditionally, the pontine regulation of the pelvic viscera had been considered specific for the urinary bladder and was accordingly referred to as the pontine micturition center (PMC). However, more recent work in rodents has clearly established a role of this pontine nucleus (Barrington’s nucleus, BN) as the anatomical substrate for the co-regulation of both bladder and rectosigmoid with central arousal circuits (via projections to the locus coeruleus) and with forebrain function [634] (Figure 37). Efferent projections from BN to the dorsal motor nucleus of the vagus (DMV) and to the sacral parasymathetic nucleus give this nucleus a unique role in the regulation of both upper and lower GI function through the two divisions of the parasympathetic nervous system [634]. Efferent projections from BN to the noradrenergic locus coeruleus are an important pathway by which afferent signals from both pelvic viscera can activate central arousal mechanisms, and hyperresponsiveness of these arousal circuits have been implicated in central pain amplification in functional visceral disorders such as IBS and PBS/IC [635]. The forebrain connections from the BN make this brain region ideally positioned to coordinate the activity of both pelvic viscera with behaviors that are appropriate for evacuation. Valentino et al. demonstrated evidence for the existence of 3 types of neuronal populations in BN, one of which is synaptically linked to both the bladder and the colon, and the other two populations which are specifically linked to either viscera [460, 452]. The authors concluded that these neuroanatomical substrates may underlie the central coordination of bladder and colon function and, in pathological states, may play a role in disorders characterized by a co-existence of bladder and colon symptoms.
Figure 37: Role of Barrington’s nucleus in the co-regulation of pelvic viscera. A, Barrington’s nucleus (or “pontine micturition center”, PMC) is in a unique strategic position to co-regulate upper and lower gastrointestinal function via vagal and sacral parasympathetic projections, and to influence higher brain functions via projections to cortical and emotional circuits. Close interactions with the noradrenergic locus coeruleus mediate the effect of pelvic visceral afferent input on emotional arousal circuits (ascending noradrenergic projections) as well as on descending pain modulation (descending noradrenergic projections). B, Afferent projections to Barrington’s nucleus as identified by retrograde and anterograde tracing studies. Different cell groups within Barrington’s nucleus receive either converging input from both pelvic viscera, or selective input from either bladder or rectum. BN receives descending projections from the periaqueductal grey (PAG), the lateral hypothalamus (LH), the bed nucleus striae terminalis (BNST), the medial preoptic nucleus (MPO) and cortical regions, including the ACC. From Valentino et al. [634]
d) Spino-thalamic input to interoceptive cortex

In sub-primates, ascending lamina I homeostatic afferent activity is integrated mainly in several brainstem sites (A1, PBN, PAG), which then provide an integrated signal to behavioral control regions in the forebrain. In primates, however, there is a novel, additional lamina I STT projection to a specific thalamo-cortical relay nucleus (VMPo) in posterolateral thalamus, which in turn projects to a discrete portion of dorsal posterior insular cortex (Fig. 35) [636]. This interoceptive cortex contains modality-selective representations of all afferent activity from lamina I (i.e., sympathetic afferent input) and from the NTS (i.e., parasympathetic input). In monkeys, this pathway is just visible, but in humans, it is greatly enlarged. Many functional imaging studies in primates confirm role of the insular cortex in pain, hunger, thirst, temperature, itch, muscle sensation, sensual touch, and cardiorespiratory activity, (reviewed in Craig, 2002 [636]), and it can be regarded as primary sensory cortex for the physiological condition of the body in primates. By contrast, in sub-primates the insular cortex appears to have a primordial role in modulating brainstem homeostatic integration (in PBN and other sites) and shows convergent, non-selective responses to homeostatic afferent inputs. The differences in the neuroanatomy of the insular cortex and its subregions have potentially important implications for the pathophysiology of IBS and BPS/IC. The modulation of visceral afferent input reaching the posterior insula is modulated by emotional arousal circuits and by cognitive input at the levels of the mid and anterior insula, respectively [624].

e) Spino thalamic input to limbic behavioral motor cortex

The ascending homeostatic afferent lamina I pathway in primates and humans also provides a direct thalamo-cortical pathway (by way of MDvc in medial thalamus) that activates the dACC (Fig. 35). In sub-primates, the dACC receives only integrated homeostatic input from the brainstem [636, 637]. On the basis of functional imaging and lesion studies in humans, the dACC can be directly associated with the affective aspect of visceral and somatic pain (unpleasantness), and with volition, behavioral motivation, as well as autonomic and motor responses [636,637,638,639,640]. Its interconnections with PFC regions, insular, and ventral striatal regions, along with its strong descending projections to the brainstem, particularly the PAG and the BN, strongly support the idea that it can be regarded generally as the limbic behavioral motor cortex, just as the insula can be regarded as the limbic sensory cortex [625-641].

3. CONSCIOUS PERCEPTION OF INPUT FROM THE BODY AS ASPECTS OF HOMEOSTASIS

Pain or discomfort from the pelvic viscera is often regarded as a distinct feeling, but from the perspective laid out above, pain can be viewed as another homeostatic feeling. It has characteristics exactly comparable to other feelings from the body. Pain normally originates with a change in the condition of the tissues of the body, a physiological imbalance that automatic (subconscious) homeostatic systems alone cannot rectify. It comprises both a sensation and an affective behavioral drive with accompanying autonomic adjustments. Depending on conditions, pain can be unpleasant (as usual) or pleasant (such as when it relieves an intense itch). Pain also generates characteristic reflexive motor patterns as do experimental gut and bladder stimuli. The behavioral motivation of pain is normally correlated with the intensity of the sensory input, but this can vary under different behavioral, autonomic and emotional conditions, so that pain can become intolerable or it can disappear, similar to any other homeostatic emotion (e.g., hunger). The modulation of the motivational aspect of a homeostatic emotion like pain can occur via inhibitory or excitatory prefrontal influences on brain circuits involving the dACC [640-642,643].

Viewing rectal or urinary urge and pain as homeostatic emotions provides a ready explanation of the interactions of these feelings from the body, including “gut feelings,” with other homeostatic conditions (including blood pressure, level of arousal, mood and affect) because homeostasis is an integrated, dynamic process. This conceptual perspective also provides a firm basis for explaining the interactions of pain and non-painful visceral discomfort with emotional status, emotional arousal or attention (i.e., the psychological dimension of pain), and it unifies the different conditions that can cause different types of pain/discomfort from different tissues under a common homeostatic function – the maintenance of the integrity of the body. All animals respond with emotional behavior to stimuli that in humans cause a feeling of pain [644]. An example relevant to preclinical studies in visceral pain mechanisms is the so called visceromotor reflex seen in response to colorectal or urinary bladder distension in rodents [645]. In primates, novel thalamo-cortical projections have emerged from this basic homeostatic system that provides direct pathways to encephalized cortical mechanisms for highly resolved sensations and motivations. In humans, these novel pathways are further elaborated, re-represented, and integrated with other forebrain emotional components in the anterior insula and in the orbitofrontal cortex (the fronto-insular region) (Figures 35A, B).

The concept of homeostatic emotions has considerable implications for the study of mechanisms underlying visceral pain and autonomic dysregulation in patients with symptom based (or “functional”) disorders of the GI and urinary tract. In the majority of these patients, primary symptoms (urgency, sensation of fullness, pain) are directly related to the altered perception of homeostatic feelings associated with the intestine,
rectum or urinary bladder (visceral hypersensitivity). Since rodents, the animals most commonly used in experiments to model these disorders, do not have the forebrain structures to generate the same conscious emotional feelings of humans, findings obtained in such animals (using so-called pseudo-affective reflex responses) may reflect primarily the phylogenetically shared enteric, spinal and brainstem components of homeostatic pathways (e.g. reflexes), but may provide little or no insight into the uniquely human experience of abdominal pain and discomfort, nor to the modulatory cortical influences related to this experience.

The VMpo also has a collateral influence to a portion of sensorimotor cortex (area 3a) that is intercalated between the primary somatosensory area and the primary motor area. Similarly, vagal afferent activation occurs in the lateral portion of area 3a of the primary sensorimotor region by way of the NTS and VMb. These projections can be associated with cortical control of the reflex actions of skeletal muscle in response to homeostatic afferent inputs, a role subsumed under the term “viscero-somatic” integration.

The forebrain interoceptive representation of the body’s condition in the dorsal posterior insula is successively re-represented in the middle insula and then in the right (non-dominant) anterior insula (636). Functional imaging data show that the right anterior insula is associated with subjective awareness of homeostatic emotions (e.g. visceral and somatic painful and non-painful sensations, temperature, sexual arousal, hunger, and thirst) as well as all emotions (e.g. anger, fear, disgust). This region is intimately interconnected with the dACC, which is co-active in such studies. Thus, viewing feelings from the body as homeostatic emotions enables neuroanatomical explanations of interactions with other homeostatic functions and with emotions at the level of the forebrain. Finally, recent evidence showing asymmetry in the sympathetic and parasympathetic afferent re-representations and control mechanisms in the left and right insula/orbitofrontal cortex and ACC seems to accord with the psychophysiological evidence for the forebrain asymmetry of positive and negative emotions [646]. In this context, it is of considerable interest that studies of central representation of both bladder [482] and rectal distensions [635] have repeatedly shown activation of the right ventrolateral PFC.

4. DESCENDING MODULATION OF HOMEOSTATIC REFLEXES AND FEELINGS

Lamina I neurons not only receive input via somatic and visceral afferents, but also receive descending (facilitatory and inhibitory) modulation directly from brainstem pre-autonomic sources, including serotonergic nuclei within the rostral ventral medulla and the noradrenergic pontine locus coeruleus complex (Figure 36). Indeed, lamina I and the spinal autonomic columns are the only regions in the spinal cord that receive descending modulation from the hypothalamus. Thus, the activity of lamina I neurons that ultimately produces the various feelings from the body is modulated by various tonic and phasically active, descending inhibitory and facilitatory pathways [647,648,649], whose primary purpose is control of homeostatic integration [650,651]. As pointed out by Mason [651,652,653], these serotonergic descending pathways from the PAG and ventromedial medulla are not only involved in descending pain modulation, but play a prominent role in various homeostatic functions including micturition and continence.

Recent evidence (in mice) suggests that the gain of the spino-bulbo-spinal reflex loops originating from neurokinin 1-receptor-containing lamina I neurons is not constant but can be modulated by peripheral primary afferent inputs from inflamed tissue or damaged nerves, [654] adapting the homeostatic response to the overall state of the organism. Thus, since the descending forebrain control of these pre-autonomic brainstem regions originates in brain networks associated with attention, emotion generation (i.e. the limbic system) and emotion regulation (PFC), these anatomic connections provide the basis for corticolimbic modulation of the afferent activity associated with feelings from the body, including pain and discomfort, at the spinal level as well as at the brainstem and forebrain levels (Figure 36).

5. BRAIN CIRCUITS ACTIVATED BY ACUTE VISCERAL STIMULI: EVIDENCE FROM FUNCTIONAL BRAIN IMAGING STUDIES IN HUMANS

Visceral sensations, including discomfort, hunger, fullness, early satiety, nausea, bloating or abdominal pain in humans are a subjective, conscious experience, that result from the modulation of homeostatic feelings by cognitive (attention, expectation), emotional (arousal, anxiety) and motivational factors, as well as memories of past experiences. Thus, the conscious experience is an image of the homeostatic state of the body represented in the insular cortex (Figure 35) and is further modified by these cortical and limbic inputs. In principal, altered perception of visceral stimuli could result from activity changes in visceral afferent signal processing areas alone (reflecting increased visceral afferent input to the brain from the gut), from alterations in distinct but overlapping pain modulation circuits (“central pain amplification”), or from variable combinations of these two overlapping circuitries [655,656,657] (Figure 37).

a) Activation of Regions involved in Homeostatic Emotions in Studies of the Human Brain-Gut Axis

Studies published during the past 5 years using widely
different experimental paradigms have confirmed the consistent activation of the central homeostatic afferent network consistent with the robust activation of homeostatic afferent pathways despite varying experimental paradigms and analysis techniques [658,659,660,661,662,663]. On the other hand, the variable activations of PFC and limbic regions, and the seemingly contradictory results on sex differences in reported studies is reflective of the fact that experimental paradigms and analysis techniques varied, and that the majority of these studies did not take into account cognitive and emotional aspects of pain modulation.

b) Modulation of Homeostatic Afferent Network Matrix by Cognitive and Emotional Stimuli

The brain has multiple ways to modulate the perception of afferent information and this modulation is influenced by the environmental context, the emotional state of the individual (e.g. fear, anxiety, or anger), cognitive factors (e.g. expectation, attention), or memories of previous sensory events (conditioned responses) (Figure 37A). Considerable progress has been made both on a preclinical and, more recently, on a clinical level to identify brain regions, circuits and mechanisms which play a role in the facilitation and inhibition of the subjective pain experience [649-664]. Both clinical and preclinical studies support a role for right orbitofrontal and right ventrolateral PFC in mediating inhibition of emotional and pain responses (reviewed in Lieberman et al. 2004 [643]) and for dorsolateral PFC in pain modulation [642-665].

- Cognitive Modulation

Attention. Aziz’s group (666) examined the modulatory role of attention on the brain responses to non-painful visceral (esophageal) distension in 7 healthy volunteers (6 males). Brain responses to phasic visual and esophageal stimuli were presented simultaneously while subjects were asked to focus their attention on either the esophageal or the visual stimulus (selective attention) or both (divided attention). Selective attention on the esophageal stimulus was associated with activation of sensory (somatosensory cortex) and cognitive (dACC) networks, while selective attention on the visual stimulus activated the visual cortex. During the divided attention task, more brain regions in the sensory and cognitive domains were activated to process esophageal stimuli, in comparison to those processing visual stimuli. These findings emphasize the importance of attentional processes in the modulation of sensory information from the body and the relative biological importance placed on visceral sensation, compared to other sensory modalities.

Expectation. A variety of studies in the somatic pain literature have evaluated brain responses to the expectation of an aversive stimulus [662-667, 668, 669,670]. These studies suggest that the brain can either up- or down-regulate sensory and limbic brain regions based on previous experience, familiarity with the stimulus and expected intensity [668]. Several early studies have shown some evidence of activation of the homeostatic afferent network during conditioned anticipation of a visceral stimulus [662-667]. Berman et al. studied the brain fMRI BOLD response to anticipated (cue condition) and delivered mild and moderate rectal distension in 12 healthy women and 14 female IBS patients [671]. Distension increased activity in the homeostatic brain regions and decreased activity in the infragluteal cingulate. As in previous studies comparing IBS patients and control subjects, the increases were more extensive in the IBS patients, with significant differences in midcingulate and dorsal brainstem. During cued anticipation of distension, activity decreased in the insula, dACC, amygdala and dorsal brainstem in healthy women, but not in IBS patients, consistent with a top-down modulation of homeostatic afferent networks by cortical regions. Three self-rated measures of negative affect during scanning were higher in IBS patients than healthy women (P < 0.001), and the anticipatory BOLD decreases in bilateral dorsal brainstem, centered in the pontine LCC, were inversely correlated with all three measures. The amplitude of anticipatory decrease in the LCC was associated with greater activation by subsequent distension in right orbitofrontal cortex and bilateral supragenual ACC – regions previously implicated in corticolimbic inhibition. When the cue was followed by a sham distension (e.g. no change in distension pressure from the resting pressure of 5 mmHg occurred), only IBS patients showed activation of the insula cortex, and this activation was limited to the more anterior portions of the insula. These findings are consistent with top-down modulation of the anterior insula by PFC influences, and with an enhanced top-down facilitation in IBS patients. In summary, these findings suggest that in healthy women, the brain decreases activity within the homeostatic brain matrix in expectation of a certain, inescapable pelvic pain stimulus. A failure to generate this down-regulation in IBS patients, and an inappropriate activation of the anterior insula during a sham distension, may be related to differences in cortically-mediated coping styles, emotional factors and linked arousal systems.

Yaguez et al. [672] studied brain responses during different phases of visceral aversive conditioning in 8 healthy volunteers (5 males) using fMRI. The authors used a classical conditioning paradigm in which different colored circles were used as conditioned stimuli and were paired with painful esophageal distension (learning phase), airpuff to the wrist or nothing. Brain responses during the learning phase
In summary, numerous studies have supported the hypothesis of changes in brain network connectivity. An analysis examining the covariation of these brain regions, as well as preliminary results from an effective connectivity modeling approach to the data, revealed that components of this network can be modulated differentially by top-down corticolimbic influences. These findings emphasize the importance of cognitive influences, such as expectation and memory recall in top-down modulation of brain regions involved in the processing of homeostatic information from the body.

**Hypervigilance.** Several lines of evidence indicate that IBS patients and other functional disorders have hypervigilance for symptom-relevant sensations [673]. Repeated exposure to experimental visceral stimuli can lead to decreased hypervigilance and, therefore, discomfort. In a longitudinal study of IBS patients exposed to 6 sessions of rectal inflations over a 1-year period, we examined regional cerebral blood flow to the inflations and anticipation of inflations using H215O-PET at the first and last session [674]. Subjective ratings of the rectal inflations normalized over the 12 months of the study, while IBS symptom severity did not, indicating decreased vigilance independent of changes in perceived disease activity. In response to rectal distension, stable activation of regions of the homeostatic afferent network (including thalamus and anterior insula) was observed over the 12-month period, while activity in limbic, paralimbic and pontine regions decreased. During the anticipation condition, there were significant decreases in dACC, amygdala, and dorsal brainstem (perhaps involving the LCC) activation at 12 months. One way to interpret these findings is that brain regions processing the feeling and the motivational dimension of the homeostatic emotion were affected differentially by the habituation process: while insula activation remained constant, dACC activity progressively decreased.

An analysis examining the covariation of these brain regions, as well as preliminary results from an effective connectivity modeling approach to the data, supported the hypothesis of changes in a network including the hypothalamus, amygdala, and dorsal brainstem. The fact that components of this network can be modulated differentially by top-down corticolimbic influences has important implications for a better understanding of symptom generation/modulation in functional GI disorders.

**c) Modulation of Homeostatic Emotions by Descending Modulation**

Since the beginning of the 20th century it has been known that the brain can tonically inhibit spinal cord excitability, thereby regulating the amount of peripheral sensory information reaching the central nervous system. More recent evidence has demonstrated the activity of both pain inhibitory and facilitatory mechanisms which can tonically and phasically regulate spinal cord excitability [647,648,649]. While top-down tonic pain inhibition modulation appears to predominate in healthy individuals during basal conditions, an up-regulation of descending pain facilitatory systems has been demonstrated in the maintenance of hyperalgesia in animal models of peripheral nerve injury [654]. An alteration in the balance between inhibitory and facilitatory pain modulatory systems has been proposed as a possible mechanism underlying chronic pain syndromes such as fibromyalgia [676] and IBS [677,678].

Zambreanu and coworkers were the first to demonstrate the activation of brainstem regions in the context of central sensitization in healthy human volunteers [679]. Using 3T fMRI, they compared whole brain responses, including the brainstem, to punctuate mechanical stimulation in an area of secondary hyperalgesia (induced by heat/capsaicin sensitization model) or in a control area. They found greater activation during stimulation of the hyperalgesic region in several cortical regions, including posterior insula, ACC and posterior cingulate cortex, as well as thalamus and pons. The brainstem activation was localized to the NCF (possibly involving PBN) and the PAG, brain regions that receive input from corticolimbic networks (including the rostral ACC), send projections to the rostroventral medulla and are part of a cortico-limbic-pontine pain modulation circuit [680,681] (see also Figure 36). There is preliminary evidence to suggest that patients with IBS may also show abnormal activation of brain circuits involved in pain modulation [660-682,683]. Two studies were performed by Wilder-Smith and coworkers [660-683] to study the central correlates of heterotopic pain inhibition. In the first study, they performed an fMRI study in 10 female patients with IBS (5 constipated-, 5 diarrhea-predominant bowel habit) and 10 female healthy control subjects to test the hypothesis that IBS patients show abnormal activation of diffuse noxious inhibitory control (DNIC) systems in response to a noxious stimulus [660]. DNIC activation can be quantified by the perceptual modulation of a painful stimulus (in this case noxious rectal balloon distension) by a secondary heterotypically applied nociceptive stimulus (in this case ice water immersion of the foot). They found that subjective pain ratings of rectal volume distension by the heterotypic cold pain stimulus was reduced in healthy controls but not in the IBS patient group, suggesting an inadequate activation of DNICs in the IBS patients. Following the heterotypic cold stimulus, a complex set of differences in response to rectal pain were found among the controls and the two IBS bowel habit-based sub-groups. These included decreased activation in insula, thalamus and PAG in...
the control group (perhaps reflecting the DNIC process) that was absent in the IBS patients. In the second study, similar perceptual results were found and differences were also found between IBS and controls during expectation of rectal pain, without actual distension [683].

More recent brain imaging studies in patient populations provide more direct support for alterations in cortico-limbic-pontine pain modulation networks in IBS patients leading to visceral hypersensitivity. Mayer et al. [682] examined three groups of male subjects, ulcerative colitis patients with quiescent disease (n = 9), patients with IBS (n = 9), and healthy male controls (n = 9), during actual and expected but undelivered rectal distensions using H215O-PET. This study found similar responses in all three groups in the homeostatic afferent network (anterior insula and dACC). However, IBS patients compared to both the ulcerative colitis and control groups showed consistently greater activation of limbic/paralimbic brain regions (amygdala, hypothalamus, ventral/rostral ACC, dorsomedial PFC), suggestive of increased activation of pain facilitatory pathways. In addition, the results showed activation in the ulcerative colitis and control subjects, but not IBS patients, in the lateral frontal regions and a brain region including the PAG. A connectivity analysis using structural equation modeling supported these regions acting as part of a pain inhibition network that involves lateral and medial frontal influences on the PAG.

In summary, a small group of hypothesis-driven studies aimed at evaluating specific mechanisms of visceral pain modulation (e.g. descending modulation) are beginning to demonstrate the activation of cortico-limbic-pontine networks, which may be the biological substrate of such endogenous modulation. The concept emerging from these studies is the ability of brain regions and networks involved in emotional generation (limbic circuits) as well as in emotion regulation (orbitofrontal, ventrolateral PFC) to modulate activity within the homeostatic brain matrix [655, 656]. Observations obtained with rectal and with bladder stimuli show many similarities in these activations [482]. Differences in the activation of these networks by cognitive or somatic stimuli between IBS patients and control populations suggest a possible role of such differences in the pathophysiology of enhanced visceral perception in IBS.

The concept of homeostatic emotions with a sensory feeling dimension (processed in the anterior insula) and a motivational dimension (processed in the dACC) provides a general framework to understand the interactions between peripheral afferent signals arising from the pelvic viscera, and centrally-mediated influences (including psychological factors, cognitions and emotions) on the conscious perception and associated autonomic responses to such stimuli. The deconstruction of symptoms into distinct contributions of specific brain networks mediating a variety of cognitive, emotional and motivational influences on the basic homeostatic afferent processing network may help to understand the pathophysiology of a variety of chronic disorders, including IBS and PBS/IC. A whole range of chronic disorders characterized by physical or emotional discomfort and pain (including functional visceral and somatic disorders, as well as disorders of mood and affect) can be conceptualized as disorders of homeostatic emotions. The ability to study a neurobiological substrate (e.g. brain activity) rather than relying on highly variable subjective symptoms, may make it possible to obtain insights about the role of genetic factors, receptor physiology, and drug interventions from much smaller samples of subjects, compared to epidemiological or traditional pharmacological studies.

VLPP  Valsalva Leak Point Pressure
USI  Urodynamic Stress Incontinence
For this fourth International Consultation on Incontinence, the Committee on Pathophysiology is organized to consider causes of pelvic prolapse and faecal, as well as urinary incontinence. For any woman, childbirth and pregnancy contribute to the development of urinary as well as faecal incontinence; therefore these two conditions have been naturally integrated into a single chapter. Special problems of the elderly have also been included for this ICI. We have also been asked to consider pathophysiological mechanisms underlying pelvic organ prolapse. These three areas urinary incontinence, pelvic organ prolapse and faecal incontinence, are closely interconnected by virtue of similar location within the body. In the case of women, childbirth and pregnancy may contribute to one or all of these conditions. Yet there are also neurological factors, and gender specific factors which must be considered in the evaluation of any given patient. Thus, we have tried to provide a balanced overview of the subject, keeping in mind both the common and the distinct qualities of the various conditions, while organizing them in a logical, narrative manner that make any one section of the chapter easy to read.

In the area of women's stress incontinence, intrinsic urethral function continues to receive increased attention. As newer pharmacological agents to provide neural stimulation of the striated sphincter appear, and the limits of vaginal suspensory operations for correction of urethral dysfunction are reported, considerations of pathophysiology have shifted from the 50 year old paradigm regarding urethral mobility associated with vaginal prolapse in the genesis of incontinence. However, these newer directions should be considered against the background of half a century of observation and practical clinical experience. We therefore continue to recommend a balanced approach.

In the area of men's incontinence, the greatest concern remains the problem of sphincter injury following radical pelvic surgery and brachytherapy. While many thousands of procedures are performed annually, our knowledge about sphincter anatomy and function has progressed little. Instead, empirical methods of treatment and hopefully prevention have been advanced to treat affected individuals, and insofar as prosthetic implants remain an effective method of treatment, enthusiasm for further basic research into male sphincter function remains limited. In contrast to this kind of sphincter injury, the causes of incontinence associated with bladder outlet obstruction and prostatic enlargement have been well characterized, and little new knowledge has appeared in recent years. Finally, with respect to faecal incontinence and pelvic organ prolapse, two areas for this Committee's concern, the sections addressing them may appear to provide some overlap and possible redundancy.
A. THE OVERACTIVE BLADDER

I. INTRODUCTION

The most common problem with urine storage arises when the bladder fails to remain relaxed until an appropriate time for micturition. The symptom syndrome is called “overactive bladder” (OAB), which refers to the symptoms of urgency, with or without urge incontinence, usually with frequency and nocturia [1]. According to the ICS terminology of 2002 [1], OAB symptoms are suggestive, but not diagnostic, of urodynamically demonstrable detrusor overactivity (involuntary detrusor contraction) during the filling phase which may be spontaneous or provoked. This may be further characterized as neurogenic when there is a relevant neurological condition. Common neurogenic causes include stroke, Parkinson’s disease, multiple sclerosis and spinal injury. Non-neurogenic etiologies may be related to outflow obstruction, aging estrogen deficiency, female anatomical incontinence, but most cases are idiopathic. This section focuses on pathophysiology of the overactive bladder and reviews studies that have provided insight into the mechanisms underlying bladder overactivity and OAB symptoms.

II. NEUROGENIC DETRUSOR OVERACTIVITY

1. SUPRAPONTINE LESIONS (Figure 1)

It is generally accepted that suprapontine lesions such as cerebrovascular disease and Parkinson’s disease produce detrusor overactivity. The patient with a suprapontine lesion loses voluntary inhibition of micturition, which corresponds to uninhibited overactive bladder according to a classification by Fall et al [2, 3].

Brain transaction studies in animals with an intact neuroaxis showed that suprapontine areas generally exert a tonic inhibitory influence on the pontine micturition center (PMC) [4, 5]. In humans, the cerebral cortex (medial frontal lobes) and the basal ganglia are thought to suppress the micturition reflex. Thus, damage to the brain induces bladder overactivity by reducing suprapontine inhibition.

The mechanism of overactive bladder induced by cerebral infarction or Parkinson’s disease has been further studied using animal models [6-8]. In the central nervous system, a glutamatergic pathway is known to play a role in both excitatory and inhibitory regulation of micturition [6, 9, 10]. Central dopaminergic pathways also have dual excitatory and inhibitory influences on reflex bladder activity [11]. It has been demonstrated that in the rat cerebral infarction model, bladder overactivity is mediated by NMDA glutamatergic and D2 dopaminergic excitatory mechanisms [8], suggesting that cerebral infarction may alter a balance between the facilitatory and inhibitory mechanism that results in up regulation of an excitatory pathway and down regulation of a tonic inhibitory pathway. Similarly, neuropharmacological studies in a monkey model for Parkinson’s disease have shown that detrusor overactivity may result from a loss of dopaminergic inhibition mediated by D1 receptors [4, 7].

2. SPINAL CORD LESIONS (Figure 2)

A spinal cord lesion above the lumbosacral level eliminates voluntary and supraspinal control of micturition, leading to bladder overactivity mediated by spinal reflex pathways [4, 12]. Disruption below the level of the pons leads to unsustained and uncoordinated detrusor contractions often associated with uncoordinated sphincter overactivity (detrusor-sphincter dyssynergia, DSD). Impairment or loss of bladder sensation is a typical feature.

Electrophysiologic studies of the effect of capsaicin on voiding reflexes have shown that the afferent limb of the micturition reflex in chronic spinal cats, consists of unmyelinated C-fibre afferents, whereas in normal cats it consists of myelinated A-delta afferents [4, 9, 14]. Since C-fibre bladder afferents in the cat do not usually respond to bladder distension [15], a considerable reorganization of reflex connections takes place in the spinal cord following the interruption of descending pathways from the brain. In humans with spinal cord lesions, neurogenic detrusor overactivity
is likely to be mediated by capsaicin-sensitive C-fibre afferents. Clinical experience with capsaicin supports the role of these C-fibre afferents in the pathophysiology of neurogenic bladder overactivity. Capsaicin has been used for the treatment of neurogenic bladder overactivity in patients with spinal cord injury or multiple sclerosis. When administered intravesically, capsaicin increases bladder capacity, reduces micturition contraction pressure, decreases autonomic dysreflexia and reduces the frequency of incontinence [16-18]. More recently, resiniferatoxin, an ultra-potent analogue of capsaicin, has been also used [19, 20].

In addition to changes in reflex pathways (i.e., C-fibre afferent-mediated micturition reflex), it has been demonstrated that a functional outlet obstruction resulting from DSD may alter the properties of bladder afferent neurons. For example, in chronic spinal animals, afferent neurons innervating the bladder increase in size, a change prevented by urinary diversion [21]. These observations suggest that some factors released in the obstructed bladder may be responsible for the neural change. Subsequently, the factors have been identified as nerve growth factor (NGF) [22].

Another type of plasticity in C-fibre bladder afferent neurons is evident as a change in excitability. Whole cell-patch clamp recordings have shown that hypertrophied bladder afferent neurons exhibit increased excitability due to a shift in expression of sodium channels from high-threshold Tetrodotoxin (TTX) resistant to low-threshold TTX-sensitive channels [23, 24]. In normal animals, TTX-resistant sodium channels are mainly expressed in C-fibre afferent neurons [25, 26].

III. NON-NEUROGENIC DETRUSOR OVERACTIVITY

1. OUTFLOW OBSTRUCTION (Figure 3)

Detrusor overactivity associated with outflow obstruction has long been recognized [27]. A recent study shows that approximately 50% of patients with symptomatic benign prostatic enlargement exhibit bladder outlet obstruction [28]. However, detrusor overactivity and OAB symptoms often occur independently of bladder outlet obstruction. Thus, detrusor overactivity and OAB symptoms in the male patients may result from outflow obstruction or a primary bladder abnormality [29]. The following review focuses on studies supporting outflow obstruction as the causative factor for detrusor overactivity.

a) Partial denervation

The hypothesis that denervation underlies obstructed non-neurogenic detrusor overactivity comes from the morphological studies of Gosling et al [30]. They demonstrated a reduction in acetylcholine esterase (AChE) staining nerves in obstructed human bladder muscle. Pharmacological studies performed on detrusor biopsies from patients with bladder outlet obstruction [31] have shown that muscle strips from patients with detrusor overactivity exhibit denervation supersensitivity to acetylcholine (the main excitatory neurotransmitter to the human bladder) and a reduction in nerve-mediated responses, as compared with strips from normal, stable bladder. Similar pharmacological and morphological evidences of denervation have been shown in studies using animal models of detrusor overactivity caused by urethral obstruction [32-34], demonstrating that there were significant increases in sensitivity to acetylcholine and other agonists such as high potassium, and the response to intramural nerve stimulation was significantly reduced (despite increased responsiveness of the muscle to exogenous acetylcholine), with both cholinergic and non-cho-
linergic (purinergic) neurotransmission being affected. These changes suggest a post-functional supersensitivity secondary to partial denervation of the obstructed detrusor muscle, and may be the basis of unstable bladder behaviour.

However, it is not clear how denervation develops in outflow obstruction. One possibility is that there is a reduction of blood flow due to the effect of raised intravesical pressure during voiding or the increased tissue pressure of hypertrophied bladder wall during filling. Such haemodynamic change has been demonstrated in a canine model of outlet obstruction [35]. Greenland and Brading also showed that bladder-outflow obstruction is associated with repeated episodes of prolonged detrusor ischemia in pigs [36]. Thus, the role of ischemia in changes in bladder function and structure following outlet obstruction has been well characterized. A more recent study using iNOS knockout mice [37] suggests that generation of NO soon after obstruction is necessary to prevent detrusor dysfunction, since NO produces vasodilatation and decreases platelet aggregation.

b) Changes in detrusor muscle contractility

Obstruction can alter the properties of the detrusor muscle. In the obstructed guinea pig bladder, the detrusor muscle shows a decrease in force development, suggesting a deterioration in detrusor contractility [38]. The cable properties of detrusor cells are also changed [39]. The length constant is reduced, suggesting a decrease in cell to cell propagation of electrical activity. The time constant of the cell membrane is prolonged, leading to greater instability of membrane potential. This may facilitate depolarization of the cell and activate L-type calcium channels. Such a mechanism could be further amplified by depolarizing currents supplied by a purinergic system, which has been shown to emerge in human obstructed bladder [40]. These findings suggest that, in general, individual cells are more irritable while synchronous activation is damaged, findings that are consistent with the abnormal bladder behaviour of obstructed bladder, i.e., the decreased contractility coexisting with bladder overactivity. In this respect, the changes in intercellular communication through gap junction have been evaluated. Gap junction protein, connexin 43(C?43) was shown to decrease in rat detrusor muscle with chronic partial bladder outlet obstruction [41]. However, other studies indicate that connexin mRNA and C?43 protein are increased in a rat model of bladder overactivity induced by outflow obstruction [42, 43].

Recently, a role of Rho-kinase in obstruction-induced changes in detrusor muscle contractility has received attention. One main pathway for inhibition of myosin light chain phosphatase and indication of Ca2+ sensitization involves a specific kinase(Rho-kinase), which is activated by RhoA via G-protein coupled receptors [44-46]. Ca2+ sensitization, mediated by the RhoA/Rho-kinase pathway, enables the detrusor muscle to contract at low intracellular Ca2+ concentration. It has been demonstrated that partial bladder outlet obstruction increased the expression of RhoA and Rho-kinase in rabbits [47, 48]. This upregulation of Rho-kinase may contribute to increased detrusor muscle tone or sustained contraction induced by the different contractile transmitter/mediators in the obstructed bladder [47, 49, 50].

c) C-fibre-mediated micturition reflex

A different interpretation for the mechanism underlying the development of detrusor overactivity is a possible reorganization of spinal micturition reflexes following outlet obstruction. Partial urethral ligation in a rat model results in hypertrophy of bladder afferent as well as efferent neurons [22, 51]. This hypertrophy of bladder neurons is accompanied by increased expression of NGF in the bladder as well as in sacral autonomic centres [52], leading to facilitation of the spinal micturition reflex [22, 52]. Similarly, in patients with outflow obstruction, a spinal reflex may be responsible for the development of detrusor overactivity. This reflex is thought to be mediated by C-fibres and clinically detected as a positive response to the ice water test. C-fibre neurons are also known to contain tachykinin and other peptides as neurotransmitters. It has been suggested that in rats with bladder outlet obstruction, tachykinins can influence via NK receptors both the spinal and supraspinal control of the bladder [53, 54].

With regard to the possible mechanisms for activation of afferent C-fibre nerves, Araki et al suggest a role for the epithelial sodium channel(ENaC) expressed in human urinary bladder urothelium [55]. They found that the expression levels of alpha-ENaC, beta-ENaC and gamma-ENaC were significantly greater in the obstructed bladders than those in controls. In addition, the quantified ENaC expression was shown to correlate significantly with the storage symptom score. Thus, the ENaC expressed in the bladder urothelium might be implicated in the mechanosensory transduction in the bladder afferent pathway, thereby inducing detrusor overactivity by outflow obstruction [55].

2. AGING

Major epidemiologic studies [56-58] indicate that the prevalence of OAB in both men and women increases with age. A study of men and women without underlying disease causing micturition disorder shows that storage symptom scores also increase with age, suggesting that bladder function in both sexes is subject to common age related alterations [59]. However, in the elderly, the boundaries between neurogenic and non-neurogenic are uncertain, since age associated neurogenic diseases such as subclinical cerebrovascular disorders, autonomic neuropathy and chronic brain failure commonly occur.
Computerized tomography, magnetic resonance imaging or functional brain imaging sometimes can detect the presence of cerebral lesions in elderly patients with detrusor overactivity [60, 61]. This may distinguish neurogenic from idiopathic detrusor overactivity in a considerable number of older patients.

With regard to aging-related detrusor overactivity, Elbadawi et al. have proposed a possible explanation based on detailed ultrastructural study [62-64]. Electron microscopic findings of detrusor biopsies have revealed a characteristic structural pattern in specimens from the elderly with detrusor overactivity. The main ultrastructural features of this dysfunctional pattern were abundant distinctive protrusion junctions and abutments which it was proposed mediated electrical coupling between the muscle cells and were involved in generation of myogenic contraction in the overactive bladder. In addition, if the patients had impaired detrusor contractility, there was superimposed widespread degeneration of muscle cells and nerve axons, which matched the special group of elderly patients with DO (Detrusor Overactivity) [65].

Age-dependent alterations in detrusor function have also been evaluated. Cystometry in conscious rats shows that bladder compliance decreases with aging [66]. In the rat detrusor muscle, the relaxant response to noradrenaline or isoproterenol has been shown to decrease with age, a change which may be related to decreased density of beta-adrenoceptors and decreased cyclic adenosine Monophosphate (cAMP) production [67]. In addition, age-related changes in cholinergic and purinergic neurotransmission have been studied recently in human detrusor muscle, showing that during electrical nerve stimulation, acetylcholine (Ach) release is decreased while ATP release is increased with aging [68, 69]. These changes in neurotransmission may contribute to the changes in bladder function in the elderly.

3. ESTROGEN DEFICIENCY

Lower urinary tract symptoms (LUTS) are common in elderly women. Menopause and subsequent estrogen deficiency have been implicated in the etiology of LUTS such as OAB symptoms. There have been few controlled trials to confirm the impact of -estradiol estrogen therapy on OAB. However, in a placebo-controlled trial of 17 vaginal tablets, the LUTS of frequency, urgency and urge incontinence significantly improved in the estradiol-treated group [70]. A meta-analysis of the effects of estrogen therapy on symptoms suggestive of OAB in postmenopausal women also showed that estrogen therapy was associated with significant improvements in all symptoms of OAB [71]. These studies suggest that the menopause at least has a significant role in the development of bladder overactivity and OAB symptoms.

Estrogen receptors (ERs) have been identified in the bladder and urethra [72, 73]. The mechanisms producing the effects of estrogen on bladder function have yet to be elucidated, but estrogen can influence bladder contractility in animals [74]. Particularly, bladder compliance has been to decrease with estrogen deprivation [75-77]. The effects of oophorectomy and estrogen replacement on the function of Rho-kinase in rat bladder smooth muscle have been investigated, demonstrating that estrogen might inhibit the function of Rho-kinase in bladder smooth muscle [78]. Since Rho-kinase plays an important role in the regulation of detrusor muscle tone [49, 50], this finding suggests that if estrogen deficiency results in increased Rho-kinase activity, detrusor muscle tone increases, thereby decreasing bladder compliance: features suggestive of bladder overactivity. In addition, a recent study [79] of the female rat bladder showed that as a result of estrogen deficiency, stretch-induced acetylcholine(Ach) release possibly from the urothelium increased, which may be a contributing factor to the development of detrusor overactivity (described later). It was also demonstrated that Ach release from cholinergic nerves was decreased by ovariectomy [79], suggesting that reduced Ach release from cholinergic nerves may cause the decrease in detrusor contractility. This may explain an abnormal bladder behaviour in elderly women that shows a coexistence of detrusor overactivity and impaired contractility [65].

4. PELVIC FLOOR DISORDERS

Detrusor overactivity is known to be associated with female stress urinary incontinence as a result of pelvic floor relaxation. This condition is called “mixed incontinence” which is defined as the combination of stress and urgency incontinence. Mixed incontinence accounts for approximately 33% of all cases of incontinence in women [80]. Successful surgical repair of stress incontinence (Burch colposuspension, TVT, etc) is associated with the cure of the urgency incontinence in 50% to 85% of patients [80-84].

This clinical experience suggests a connection between urethral afferents and the micturition reflex. Barrington reported that running water through the urethra or distension of the proximal urethra caused contraction of the detrusor in the cat [85]. Jung et al. also showed that in the rats urethral perfusion facilitated detrusor activity, and that intraurethral lidocaine(1%) caused a significant decrease in bladder contraction frequency [86]. These studies suggest that mechanosensitive afferent nerves activated by fluid entering the urethra can increase the excitability of the micturition reflex. In patients with stress incontinence, urine easily enters the posterior urethra, which may induce involuntary detrusor contraction and urgency to void. This mechanism is assumed to involve the pathophysiology of mixed incontinence.
5. IDIOPATHIC DETRUSOR OVERACTIVITY (Figure 4)

The diagnosis of idiopathic detrusor overactivity requires the exclusion of all known causes, but this should include all situations where etiology is unknown. Thus, the term is used to apply to a wide range of different conditions that may have a common final pathophysiologic pathway [87]. The following mechanisms are considered to be involved in the pathophysiology of idiopathic detrusor overactivity.

a) Myogenic basis

Brading and Turner [88, 89] have emphasized that myogenic changes (regardless of etiology) may contribute to the pathophysiology of idiopathic detrusor overactivity. On the basis of observation that denervation is consistently found in detrusor biopsy specimen from patients with various forms of non-neurogenic detrusor overactivity [90], they have proposed that partial denervation of the detrusor may alter the properties of smooth muscle, leading to increased excitability and increased coupling between cells. Thus, local contraction (activity) that occurs somewhere in the detrusor will spread throughout the bladder wall, resulting in coordinated myogenic contraction of the whole bladder. However, electrophysiological studies [91] have shown that gap junction coupling is reduced rather than increased in detrusor muscle from patients with detrusor overactivity, suggesting the opposite effect on intercellular communication. Thus, it remains to be elucidated whether local activity spreads throughout the bladder wall.

In addition, this local contraction in the bladder wall has been shown to generate afferent discharge [92]. Recently, localized bladder activity was assessed by the micromotion detection method, demonstrating that women with increased bladder sensation on filling cystometry had a significantly higher prevalence of localized activity than the control group [93]. This observation suggests that localized distortion of the bladder wall simulates afferent activity, which would precipitate a feeling of urgency and detrusor overactivity [93-95].

Thus, as Brading has stated [88], the changes in smooth muscle properties seem to be a necessary prerequisite for the production of detrusor overactivity.

b) Urothelial afferent function

Recently, the roles of the urothelium and suburothelial myofibroblasts in afferent activation have become the focus of intense interest. The C-fibre afferents generally have endings in the suburothelial layer of the bladder wall, but in some cases, they also penetrate the urothelium [96, 97]. Ferguson et al [98] demonstrated that ATP was released from the urothelium by bladder distension. In addition, ATP receptors(P2X3) are expressed on sensory afferent nerves [99, 100]. Thus, bladder filling causes a release of ATP from the urothelium, and ATP, in turn, can activate P2X3 receptors on afferent nerve terminals to evoke a neural discharge. Supporting this view, P2X3-deficient mice exhibit marked bladder hyporeflexia, associated with decreased voiding frequency and increased bladder capacity [101, 102].

In addition to ATP, prostanoids and nitric oxide(NO) are synthesized locally in both mucosa and muscle, and they are also released by bladder distension [103-106]. It is most likely that a cascade of stimulatory (eg.ATP, prostanoids, tachykinins) and inhibitory (eg.NO) mediators are involved in the transduction mechanisms underlying the activation of sensory afferent fibres during bladder filling [107].
This urothelial afferent transduction process suggests that up-regulation of the afferent activation mechanisms (e.g., an increased generation/release of ATP, increased sensitivity of afferent nerves to mediators, increased number of afferent nerves) can induce detrusor overactivity, causing the symptoms of OAB. Smet et al [108] have shown that the density of nerve fibres immunoreactive for substance P and CGRP was significantly higher in women with idiopathic detrusor overactivity than in normal age-matched women.

Furthermore, intravesical vanilloids (capsaicin and resiniferatoxin) have been shown to improve OAB symptoms in patients with idiopathic detrusor overactivity as well as with hypersensitivity disorders [109-111]. These studies suggest that C-fibres play an important role in idiopathic detrusor overactivity.

This sensory process is more complex than originally thought. A suburothelial layer of myofibroblasts (interstitial cells) that from a functional syncitium through C?43 gap junction can be identified in the bladder wall [112, 113]. These myofibroblasts make close appositions to unmyelinated nerves (afferent C-fibre nerves) [112]. The studies investigating human myofibroblasts show that the cells can respond to ATP by generating an intracellular Ca\(^{2+}\) transient, which is mediated by a P2Y receptor, most likely including a P2Y6 [114, 115]. On the basis of these observations, it has been hypothesized that the close relation between nerves and myofibroblasts allows for an amplification of the afferent system in its response to stimulatory mediators such as ATP.

c) Muscarinic mechanisms

Recent evidence supports a role for muscarinic mechanisms in urothelial sensory function. As mentioned previously, the bladder urothelium releases signalling molecules (ATP, prostaglandin, etc) that are considered to act on underling afferent nerve fibres. Acetylcholine (Ach) is one of these urothelial signalling molecules [116, 117]. Recently, several studies [116-118] have shown the presence of Ach-synthesizing enzymes (ChAT, CarAT) in the bladder urothelium. Yoshida et al. [116] found by microdialysis technique that there is a basal Ach release in human bladder, and that the released Ach was of non-neuronal origin, at least partly, generated by the urothelium. This non-neuronal release of Ach was shown to increase when bladder strips with intact urothelium were stretched [116], implying that the shear stress of the urothelium during distension of the bladder may be one of the releasing mechanisms.

Muscarinic receptors (mRNA and protein levels) are found in the urothelium [119-122]. The receptor subtypes identified by radioligand binding have been demonstrated to be predominant M2 receptors with a minor population of M3 and M1 receptors [120]. Furthermore, one study [122] showed M2 and M3 receptor immunoreactivity on suburothelial myofibroblast-like cells in the human bladder.

Thus, Ach released from the urothelium can activate muscarinic receptors in the urothelium in an autocrine fashion. Activation of muscarinic receptors in the urothelium releases substances (e.g., ATP) that modulate afferent nerves [123].

Ach and ATP released from the urothelium can activate muscarinic receptors and P2Y receptors, respectively on myofibroblasts that may be involved in the transfer of information between the urothelium and suburothelial afferent nerves [115]. In addition, Ach could be expected to enhance the myogenic localized activity which may increase firing of afferent nerves [92].

Based on this evidence, it can be assumed that an increase in Ach release from the urothelium and/or upregulation of muscarinic receptors in the urothelium as well as in suburothelial myofibroblasts may increase afferent nerve activity and contribute to the development of detrusor overactivity.

Supporting this view, Yoshida et al [116] showed that in isolated human detrusor, the non-neuronal Ach release was age-dependent and significantly higher in bladders from old (>65 years) than from young (<65 years) patients. These age-related changes in Ach release may contribute to the increased prevalence of OAB in the elderly. Mukerji et al. [122] also showed a significantly increased M2 and M3 muscarinic receptor immunoreactivity in myofibroblasts-like cells in bladder specimens from patients with idiopathic detrusor overactivity as compared with that in controls. Furthermore, the increase in M2 and M3 immunostaining in myofibroblasts significantly correlated with the urgency score.

6. PATHOPHYSIOLOGY OF NOCTURIA

Nocturia is now recognised as a clinical entity in its own right [124], and is highly prevalent and bothersome condition [125]. Whilst it may often co-exist with other LUTS, its pathophysiology is complex and multifactorial. Patients may experience nocturia for a wide variety of reasons [124], and it is crucial that the physician accurately identify the pathophysiology of the condition in each individual. This may include such diverse causes as endocrine disorders, sleep problems, OAB, BPO and so on, However, there is an increasing body of literature indicating that the most prevalent cause of nocturia is nocturnal polyuria (overproduction of urine at night). Half of all adults experience nocturia [125], and studies show that as many as 84% of these have nocturnal polyuria, either alone or in combination with other conditions [126-129]. Amongst women with a diagnosis of OAB, around 62% have nocturnal polyuria [129] amongst men with a diagnosis of BPO, up to 95% have nocturnal polyuria [130]. However, if patients have a diagnosis of BPO...
or OAB, the additional – or in some cases, only – true causal factor, nocturnal polyuria, can be overlooked.

This lack of awareness amongst physicians of the need to check for, and treat, nocturnal polyuria, can mean that for many patients, prescribed therapies (eg α1-blockers and anticholinergics) do not meaningfully improve their nocturia. Brubaker & Fitzgerald (2007) [129] report that, in the 62% of their OAB patients who had a nocturnal polyuria, solifenacin monotherapy led to no significant improvement in nocturia compared with placebo. Furthermore, discontinuation and non-adherence rates on OAB therapy are notably high, with only 32% on oxybutinin IR therapy adhering past 30 days [131]. Whilst poor adherence is a challenge that exists throughout the medical field, 68% discontinuation within a month is an unacceptably high rate, and may reflect the fact that patients do not perceive their medication as useful. The case is similar in BPO, with failure of traditional therapies often being attributable to the presence of underlying nocturnal polyuria: Yoong et al (2005) [132] report that 85% of BPO patients with nocturia unresponsive to α1-blocker treatment have nocturnal polyuria. Surgery (TURP) and traditional pharmacological therapies for BPO therefore frequently fail to provide a significant reduction in night-time voiding [133, 134].

Since nocturia is reported to be one of the most bothersome of LUTS [135, 136], it is crucial that patients are adequately treated. However, confusion or lack of awareness amongst physicians regarding the likely pathophysiology of nocturia means that many patients are not prescribed therapy that can improve their condition, and that they continue to experience night-time voiding to the detriment of their daytime quality of life. Patients may then assume that their nocturia cannot be treated, rather than continuing to seek help by requesting that their doctor reassess their condition. Steps to raise physicians’ awareness of the pathophysiology of nocturia should therefore be taken in order to improve the standard of care provided to patients.

B. PREGNANCY, CHILDBIRTH AND THE PELVIC FLOOR

Reduction in both perinatal and maternal mortality rates in recent decades has focused increasing attention on maternal morbidity and the long-term sequelae of childbirth. Antenatal education encourages expectant mothers to anticipate normal vaginal delivery, leading to an early restoration of normal pelvic floor function after the performance of routine pelvic floor exercises. Not least because of improved investigative techniques available during the past decade, the incidence and mechanisms of obstetric injury to the pelvic floor have come under scrutiny. A survey of female British obstetricians [137] revealed that one third indicated a personal preference for elective caesarean delivery of their own hypothetical uncomplicated singleton pregnancy; a general fear of pelvic floor trauma was cited as the most common reason for this choice. Despite being based on incomplete prognostic data, this sentiment may be echoed increasingly among obstetric patients and may lead to an unselective, and even misguided, increase in caesarean delivery rates.

Epidemiological studies have reported prevalence of stress incontinence ranging from 23 to 67 percent during pregnancy and 6 to 29 percent after childbirth, but little is known about how the condition affects women at this time. However, the prevalence of urinary incontinence may be nearly the same 8 weeks postpartum as during pregnancy.

About half of all women develop transient urinary incontinence during pregnancy. Three months postpartum, the prevalence and incidence rates of urinary incontinence are 9% to 31% and 7% to 15%, respectively. Antenatal incontinence increases the risk of postpartum incontinence, which in turn increases the risk of long-term persistent incontinence. After the first delivery, women delivered vaginally have two-fold more incontinence than those delivered by caesarean. The protective effect of caesarean on urinary incontinence may dissipate after further deliveries, decreases with age, and is not present in older women. Data are mixed about whether caesarean done before labour confers greater protection than caesarean done after labour. To understand the true impact of caesarean delivery on urinary incontinence, future studies must compare incontinence by planned (not actual) delivery modes, consider a woman’s entire reproductive career, focus on leakage severe enough to be problematic, consider other bladder symptoms as well as incontinence, and take into account other risk factors, particularly ante partum urinary incontinence. [138]

Caesarean section rates are progressively rising in many parts of the world. One suggested reason is increasing requests by women for caesarean section in the absence of clear medical indications, such as placenta praevia, HIV infection, contracted pelvis and, arguably, breech presentation or previous caesarean section. The reported benefits of planned caesarean section include greater safety for the baby, less pelvic floor trauma for the mother, avoidance of labour pain and convenience. The potential disadvantages, from observational studies, include increased risk of major morbidity or mortality for the mother, adverse psychological sequelae, and problems in subsequent pregnancies, including uterine scar rupture and greater risk of stillbirth and neonatal morbidity. An unbiased assessment of advantages and disadvantages would assist discussion of what has become a contentious issue in modern obstetrics.
Lavender et al. assessed, from randomised trials, the effects on perinatal and maternal morbidity and mortality, and on maternal psychological morbidity, of planned caesarean delivery versus planned vaginal birth in women with no clear clinical indication for caesarean section. A search of the Cochrane Pregnancy and Childbirth Group’s Trials Register (December 2005), MEDLINE (1974 to April 2005), EMBASE (1974 to April 2005), CINAHL (1982 to April 2005) and PsycNFO (1887 to April 2005) was carried out. Studies were selected for comparisons of intention to perform caesarean section and intention for women to give birth vaginally; random allocation to treatment and control groups; adequate allocation concealment; women at term with single fetuses with cephalic presentations and no clear medical indication for caesarean section. No studies were identified that met the inclusion criteria. Thus, there is no evidence from randomised controlled trials, upon which to base any practice recommendations regarding planned caesarean section for non-medical reasons at term. In the absence of trial data, there is an urgent need for a systematic review of observational studies and a synthesis of qualitative data to better assess the short- and long-term effects of caesarean section and vaginal birth. [139]

Lal et al. compared the incidence and severity of anal incontinence in primiparas after caesarean delivery versus spontaneous vaginal delivery. The trial comprised 184 primiparas who delivered by caesarean (104 emergency, 80 elective) and 100 who delivered vaginally were interviewed 10 +/- 2 months postpartum. Anal incontinence assessed by a comprehensive bowel function questionnaire was first present in nine (5%) mothers after caesarean delivery and eight (8%) after vaginal delivery (relative risk 0.611, 95% confidence interval 0.25, 1.53). Severe symptoms necessitating pad use affected two (3%) mothers after elective caesarean and one (1%) after vaginal delivery. Two (3%) mothers after elective caesarean, one (1%) after emergency caesarean, and two (2%) after vaginal delivery had at least two symptoms. Anal incontinence followed prelabor emergency caesarean in two mothers. Of the 22 mothers who sustained a second-degree tear, five (23%) had new anal incontinence compared with only one (3%) of 40 mothers with an intact perineum (Fisher exact test value = 9.697, P = .014).

Because severe anal incontinence followed elective and prelabor emergency caesarean, it seems that pregnancy itself can lead to pelvic floor disorders. A high incidence of anal incontinence is associated with a second-degree tear. Measures to detect and reduce postpartum anal incontinence should target all pregnant women and mothers, even after prelabor caesarean delivery. [140]

It is important that contributory obstetric factors are identified and their occurrence minimized. Vaginal birth has been recognized as being potentially traumatic to the pelvic floor. Women who have sustained significant anal sphincter injury are at greater risk of further damage of faecal incontinence with subsequent deliveries.

I. EFFECTS OF PREGNANCY ON PELVIC FLOOR FUNCTION

In spite of the great advances that have been made in many areas of obstetric care, ignorance still persists regarding the fundamental physiological facts about the impact of pregnancy and delivery on lower urinary tract function. There is a striking dearth of prospective studies regarding the relationship of pregnancy and delivery to the problem of urinary incontinence among women. Further research may reveal that stress incontinence in women is related, at least in part, to the pregnant state itself, rather than to trauma sustained at delivery. If true, this has significant implications for subsequent research efforts investigating the etiology of female urinary incontinence. Cutner and Cardozo have summarized the few papers that do exist as follows [141]:

"Lower urinary tract symptoms are so common in early pregnancy that they are considered normal. Their progression throughout the ante partum period and their resolution postpartum has been documented by several authors. However, the data are confusing and the underlying causes remain uncertain. The effects of normal pregnancy on the physiology of the lower urinary tract remain largely uninvestigated, in spite of the common pronouncements on this subject in the obstetrical literature [142-145]".

"It is commonly assumed that stress incontinence develops (at least in part) as the result of delivery trauma to the pelvic floor. However, several researchers have documented that many young nulliparous women suffer from occasional stress incontinence which is a significant clinical problem in as many as 5 % [146-148]".

In a study of the relationship of pregnancy to stress incontinence, Francis [142] found that 40 % of primigravid women had a history of occasional stress incontinence before becoming pregnant, and that if such a history was present their stress incontinence invariably became worse during pregnancy. If incontinence developed during pregnancy, it tended to disappear after the puerperium, but recurred with subsequent pregnancies and became progressively worse, eventually becoming a clinical problem when these women were no longer pregnant. Francis concluded that in women who develop stress incontinence in middle life, pregnancy itself, rather than parturition, revealed the defect and made it worse. Similar conclusions have been reached by other researchers [149-151].
The prevalence of persistent stress urinary incontinence is reported to be significantly higher in grand multiparae compared with nulliparae [152].

Moreover, Buchsbaum et al. investigated the role of vaginal delivery and familial factors in the development of urinary incontinence by comparing the prevalence of this condition in nulliparous women and their parous sisters. Among this sample of biological sisters, urinary incontinence was reported by 47.6% of nulliparous women and by 49.7% of parous women (P = .782). Considering the high concordance in continence status between sister pairs, and considering that the majority of parous women are continent, an underlying familial predisposition toward the development of urinary incontinence may be present [153].

II. PATHOPHYSIOLOGIC MECHANISMS OF BIRTH INJURY TO THE PELVIC FLOOR

Vaginal delivery, notably the first, is strongly associated with later surgery for stress incontinence, but the association is modified by maternal conditions and interventions during delivery. Vaginal delivery may initiate damage to the continence mechanism by direct injury to the pelvic floor muscles, damage to their motor innervations, or both. Additional denervation may occur with aging, resulting in a functional disability many years after the initial trauma. Physical and emotional health problems are common after childbirth, and are in frequently reported to health professionals despite the fact that many women would like more advice and assistance in dealing with them. There would seem to exist four major mechanisms by which childbirth (vaginal delivery) might contribute to the increased risk of urinary incontinence among women:

1. Injury to connective tissue supports by the mechanical process of vaginal delivery, especially instrumental vaginal delivery (forceps > ventouse delivery)
2. Vascular damage to the pelvic structures as the result of compression by the presenting part of the fetus during labour
3. Damage to the pelvic nerves and/or muscles as the result of trauma during parturition
4. Direct injury to the urinary tract during labour and delivery. The physiologic changes produced by pregnancy may make pregnant women more susceptible to injury from these pathophysiological processes

In a three-dimensional computer model Lien et al. predicted levator ani muscle stretch during vaginal birth. Serial magnetic resonance images from a healthy nulliparous 34-year-old woman, published anatomic data, and engineering graphics software were used to construct a structural model of the levator ani muscles along with related passive tissues. The model was used to quantify pelvic floor muscle stretch induced during the second stage of labour as a model the fetal head progressively engaged and then stretched the iliococcygeus, pubococcygeus, and puborectalis muscles. The medial pubococcygeus muscles undergo the largest stretch of any levator ani muscles during vaginal birth. They are therefore at the greatest risk for stretch-related injury [154].

Furthermore, in a prospective observational study Dietz et al. investigated 61 nulliparous women at 36-40 weeks of gestation and 2-6 months post partum. The assessment included an interview and 3-dimensional translabial ultrasound and was repeated 2-6 months postpartum. Fifty women (82%) were seen postpartum. Of the 39 women delivered vaginally, levator avulsion was diagnosed in 14 (36%, 95% confidence interval 21-51%). Among those delivered vaginally, there were associations with higher maternal age (P = .10), vaginal operative delivery (P = .07), and worsened stress incontinence postpartum (P = .02). Avulsion of the inferomedial aspects of the levator ani from the pelvic sidewall occurred in approximately one third of all women delivered vaginally and was associated with stress incontinence 3 months after childbirth [155].

Boreham et al described levator ani (LA) anatomy in postterm nulliparas using 3-dimensional (3-D) magnetic resonance (MR). LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in 92% of the 84 women. The LA shape was characterized as “U” in 53% and “V” in 47%. Mean LA volume was 13.5 (3.7) cm³. There was a positive association between LA volume and higher fetal station (P = .02) and increasing BMI (P < .001). However, no relationship between LA volume and station was found after adjusting for BMI. BMI was correlated with LA volume in postterm nulliparas. LA insertion into the symphysis and the iliococcygeus arch were well-preserved overall and morphometry was variable [156].

Vaginal delivery causes partial denervation of the pelvic floor (with consequent re-innervations) in most women having their first baby. Pelvic floor muscle strength is impaired shortly after vaginal birth, but for most women returns within two months. In a few this condition is severe and is associated with urinary and faecal incontinence. For some it is likely to be the first step along a path leading to prolapse and/or stress incontinence [157].

There is a growing body of evidence that multiparity, forceps delivery, increased duration of the second stage of labour, partially due to epidural anaesthesia, third degree perineal tear and high birth weight (> 4000 g) are important factors leading to pudendal nerve damage [158-161].
To identify obstetric factors associated with clinical significance [164].

Marker for pelvic floor denervation makes it of uncertain value during the first pregnancy, the risk of stress incontinence occurring 15 years later is doubled. Squeeze pressure improved during the same period and to establish whether pelvic floor denervation after vaginal delivery in 80% of women who have a long active second stage of labour and heavier babies show the most EMG evidence of nerve damage. An elevation in perineal body position as well as a decrease in the area of the urogenital hiatus and of the levator hiatus at two weeks postpartum suggests a return of normal levator ani geometry after vaginal delivery in most patients [163].

In a longitudinal study of a cohort of 96 primigravidae followed up 7 and 15 years pelvic floor neurophysiology was performed and questionnaires were administered to determine the natural history of stress incontinence and to establish whether pelvic floor denervation after the first delivery is associated with symptoms of stress urinary incontinence in the future. Urinary incontinence symptoms were recorded and pelvic floor neurophysiology was performed antenatally and postnatally. Repeat neurophysiological tests and questionnaires were completed by those relocated 7 and 15 years later. Prevalence of stress incontinence was highest during pregnancy and had increased seven years after the first postnatal period (P = 0.0129). Two-thirds of women with antenatal stress incontinence had stress incontinence 15 years later. One-third of women with stress incontinence at any time appear to undergo resolution of symptoms. Motor unit potential duration increased at seven years (P = 0.036). Vaginal squeeze pressure improved during the same period (P = 0.0007). When stress urinary incontinence arises during the first pregnancy, the risk of stress incontinence occurring 15 years later is doubled. Although pelvic floor reinnervation progressed after the postnatal period, the absence of an adequate marker for pelvic floor denervation makes it of uncertain clinical significance [164].

To identify obstetric factors associated with development of levator ani injury after vaginal birth magnetic resonance images were taken of the pelvic floor of 160 women 9 to 12 months after first term vaginal delivery. Half the women had de novo stress incontinence and half were continent controls. Abnormalities of the pubovisceral portion were identified on magnetic resonance as present or absent. Defect severity was further scored in each muscle from 0 (no defect) to 3 (complete muscle loss). A summed score for the 2 sides (0 to 6) was assigned and grouped as minor (0-3) or major (4-6). Obstetric details were collected. The following increased odds ratios for levator defect were found: forceps use 14.7 (95% confidence interval [CI] 4.9-44.3), anal sphincter rupture 8.1 (95% CI 3.3-19.5) and episiotomy 3.1 (95% CI 1.4-7.2) but not vacuum delivery 0.9 (95% CI 0.19-4.3), epidural use 0.9 (95% CI 0.4-2.0), or oxytocin use 0.8 (95% CI 0.3-1.8). Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labour. Injuries to the levator ani muscles in women after their first vaginal delivery are associated with several obstetric factors indicating difficult vaginal birth and with older age. LEVEL OF EVIDENCE: II-3. [165]

Baytur investigated the respective roles of the mode of delivery and strength of pelvic floor muscles in the sexual function of women. Pelvic floor muscle strength was significantly lower in the group vaginally delivered compared with the group delivered by caesarean section and the nulliparous group (P<0.05). There was no difference between the groups regarding sexual function (P>0.05), and there was also no correlation between sexual function and pelvic muscle strength [166].

To compare pelvic floor symptoms at three years following instrumental delivery and caesarean section in the second stage of labour and to assess the impact of a subsequent delivery Bahl et al. conducted a prospective cohort study of 393 women with term, singleton, cephalic pregnancies who required instrumental vaginal delivery in theatre or caesarean section at full dilatation between. 283 women (72%) returned postal questionnaires at three years. Urinary incontinence at three years post delivery was greater in the instrumental delivery group as compared to the caesarean section group (10.5% vs 2.0%), OR 5.37 (95% CI, 1.7, 27.9). There were no significant differences in ano-rectal or sexual symptoms between the two groups. Pelvic floor symptoms were similar for women delivered by caesarean section after a failed trial of instrumental delivery compared to immediate caesarean section. A subsequent delivery did not increase the risk of pelvic floor symptoms at three years in either group. An increased risk of urinary incontinence persists up to three years following instrumental vaginal delivery compared to caesarean section in the second stage of labour. However, pelvic floor symptoms are not exacerbated by a subsequent delivery [167].

Female pelvic floor dysfunction is integral to the woman’s role in the reproductive process, largely because of the unique anatomic features that facilitate vaginal birth and also because of the trauma that can occur during that event. Interventions such as primary elective caesarean delivery have been discussed for the primary prevention of pelvic floor dysfunction; however, existing data about potentially causal factors limit our ability to evaluate such strategies critically.
The risk of pelvic floor disorders is independently associated with vaginal delivery but not with parity alone. Caesarean delivery has a protective effect, similar to nulliparity, on the development of pelvic floor disorders when compared with vaginal delivery. LEVEL OF EVIDENCE: II-2. [168, 169]

Younger white primiparous women had a better recovery at 6 months than older white women [170].

The pudendal nerve terminal motor latency (PNTML) measured 48–72 h after delivery is increased in women delivered vaginally compared to nulliparous control subjects.

Multiparity, forceps delivery, increased duration of the second stage of labour, third degree perineal tear and high birth weight are important factors leading to pudendal nerve damage [158].

Compared with spontaneous vaginal births, women having forceps or ventouse extraction have increased odds for perineal pain, sexual problems, and urinary incontinence [159].

Vaginal delivery, notably the first, is strongly associated with later surgery for stress incontinence, but the association is modified by maternal conditions and inter-ventions during delivery [171].

Women with three or more deliveries were more likely to have incontinence and excessive pelvic floor descent [171].

There is no evidence to suggest that at five years after delivery use of the ventouse or forceps has specific maternal benefits or side effects [172].

Meyer et al. found that, after spontaneous and instrumental deliveries, 21% and 34% of women complained of stress urinary incontinence and 5.5% and 4% reported faecal incontinence, respectively. Substantial bladder neck hypermobility was present together with diminished functional urethral length and intravaginal and intra-anal pressures. Only 22% of patients with stress urinary incontinence during pregnancy had such incontinence after delivery [173].

Women with postpartum urinary stress incontinence have significantly greater antenatal bladder neck mobility than those women who were continent post partum [174].

To investigate and compare the effects of different modes of delivery on urethral sphincter volume, bladder neck mobility, and changes to levator hiatus distensibility using ultrasound imaging, 156 women underwent antenatal ultrasound pelvic floor assessment. One hundred and ten (71%) completed the 6-month follow-up. There were no differences in the urethral sphincter volume between the different modes of delivery. Overall, the urethral sphincter was smaller after delivery compared to the third trimester.

Vaginal delivery was associated with a significantly larger levator hiatus area on valsalva antenatally and at rest, squeeze, and valsalva postnatally compared to caesarean section. Antenatal and postpartum bladder neck mobility was also significantly greater in the women who delivered vaginally. Urethral sphincter changes postpartum are independent of mode of delivery. Vaginal delivery is strongly associated with a larger, more distensible levator hiatus and a greater degree of bladder neck mobility both antenatally and postpartum [175].

Displacement and recovery of the vesical neck position during pregnancy and after childbirth and to discriminate between compliance of the vesical neck supporting structures with and without pelvic floor contraction. Compliance of the supporting structures remains relatively constant during pregnancy and returns to normal values 6 months after childbirth. Hysteresis, however, showed an increase after childbirth, persisting at least until 6 months post partum [176].

### III. EPIDURAL ANALGESIA DURING LABOUR

Regional anaesthesia for the relief of labour pain has become more popular during the past 20 years. Despite interest in its possible obstetric consequences, little attention has been paid to its potential effects on the pelvic floor and perineal injury. The available published data describe conflicting results. Some studies suggest that epidural analgesia, by enabling relaxation of the pelvic floor, leads to greater control of delivery of the fetal head and consequently fewer perineal lacerations [177] but prolongation of the second stage may also increase the incidence of pudendal nerve damage [161, 178].

Robinson et al. [179] recently examined the relationship between epidural analgesia and perineal damage, and found that the rate of significant perineal injury was higher with epidural analgesia (16.1 % compared with increased use of operative intervention). Episiotomy and instrumental delivery were responsible for this difference. Such an association may partly explain why institutions are reporting increased rates of significant perineal injury, paralleling local increases in epidural usage [171].

In a study of 82 women Meyer et al assessed the effects of epidural analgesia on pelvic floor function. Eighty-two primiparous women (group 1, consisting of 41 given an epidural, and group 2 of 41 not given an epidural) were investigated during pregnancy and at 2 and 10 months after delivery by a questionnaire, clinical examination, and assessment of bladder neck behaviour, urethral sphincter function and intravaginal/intra-anal pressures. Ten months after spontaneous
delivery, there were no significant differences in the prevalence of stress urinary incontinence and decreased sexual vaginal response, or in bladder neck behaviour, urethral sphincter function and pelvic floor muscle strength between women who had or had not had epidural analgesia [180].

Comprising 70 matched pairs of primiparous mothers Sartore et al. found no significant difference in the incidence of stress urinary incontinence, anal incontinence and vaginal prolapse in the two study groups. No significant differences were found between the study groups with regard to the digital test, vaginal manometry and urine stream interruption test. The use of epidural analgesia is not associated with symptoms related to perineal trauma and pelvic floor muscle weakness [181].

1. ROLE OF EPISIOTOMY (Figure 5)

Episiotomy is a widely performed intervention in childbirth, despite equivocal scientific evidence regarding its benefit. Practice patterns vary widely, as do professional opinions about maternal risks and benefits associated with routine use. It is one of the few surgical procedures performed without the patient’s consent and is the most commonly performed surgical procedure in the United States. There is a widespread assumption that it may do more harm than good [171, 179].

Restrictive episiotomy policies appear to have a number of benefits compared to routine episiotomy policies. Proponents of routine episiotomy claim that it avoids spontaneous uncontrolled tears and long-term relaxation of the pelvic floor, but these advantages are difficult to substantiate. There is no evidence that either first or second-degree perineal tears cause long-term consequences [143].

So any argument that episiotomy prevents such spontaneous tears is inconsequential. A growing body of evidence suggests that episiotomy offers no protection against third and fourth-degree tears, which are associated with adverse sequelae. A recent overview by Myers-Helfgott and Helfgott emphasized the absence of scientific evidence to support a role for liberal elective episiotomy in the reduction of third-degree lacerations during childbirth [144].

Indeed, several reports have implicated routine episiotomy in the genesis of major perineal and anal sphincter tears, even after controlling for confounding variables [145-147, 182].

In particular, midline episiotomy is associated with significantly higher rates of third and fourth-degree perineal tears than are mediolateral episiotomies [149-151].

Midline episiotomy is not effective in protecting the perineum and sphincters during childbirth and may impair anal continence [183].

Coats et al., in a randomized controlled trial of 407 women, found that with midline episiotomy, 11, 6% of patients experienced lacerations of the anal canal versus 2% who experienced these complications in association with mediolateral episiotomies. This association is compounded when instrumental delivery is employed, with anal sphincter injury rates of 50% reported with the use of midline episiotomy and forceps [184].

In spite of these data, midline episiotomy is still bewilderingly widespread, presumably because it is perceived to heal better and cause less postnatal discomfort.

Restrictive episiotomy policies appear to have a number of benefits compared to routine episiotomy policies. There is less posterior perineal trauma, less suturing and fewer complications, no difference for most pain measures and severe vaginal or perineal trauma, although there was an increased risk of anterior perineal trauma with restrictive episiotomy [185, 186].
Women who have episiotomies have a higher risk of faecal incontinence at three and six months postpartum compared with women with an intact perineum. Compared with women with a spontaneous laceration, episiotomy triples the risk of faecal incontinence at three months and six months postpartum, and doubles the risk of flatus incontinence post partum compared with women who have a second degree spontaneous tear. The effect of episiotomy is independent of maternal age, infant birth weight, and duration of second stage of labour, use of obstetric instrumentation during delivery, and complications of labour. Therefore, midline episiotomy is not effective in protecting the perineum and sphincters during childbirth and may impair anal continence and should be restricted to specified fetal-maternal indications [183, 187-190].

Routine midline episiotomy increases the risk of third- and fourth-degree perineal lacerations, which may lead to faecal incontinence. Routine use of mediolateral episiotomy does not prevent urinary incontinence (UI) or severe perineal tears. It is possible to reduce the rate of mediolateral episiotomy to as low as 20% in primiparas without increasing the risk of anal sphincter damage.

Control of obesity before delivery, as well as pelvic floor exercises and regular physical exercise both before and after delivery, seem to reduce the risk of postpartum UI [191, 192].

In a systematic review Hartmann et al. looked for the best evidence available about maternal outcomes of routine vs restrictive use of episiotomy. Immediate maternal outcomes of routine episiotomy, including severity of perineal laceration, pain, and analgesia use, are not better than those with restrictive use. Evidence is insufficient to provide guidance on choice of midline vs mediolateral episiotomy.

Evidence regarding long-term sequelae is fair to poor. Incontinence and pelvic floor outcomes have not been followed up into the age range in which women are most likely to have sequelae. With this caveat, relevant studies are consistent in demonstrating no benefit from episiotomy for prevention of faecal and urinary incontinence or pelvic floor relaxation. Likewise, no evidence suggests that episiotomy reduces impaired sexual function—pain with intercourse was more common among women with episiotomy. Evidence does not support maternal benefits traditionally ascribed to routine episiotomy. In fact, outcomes with episiotomy can be considered worse since some proportion of women who would have had lesser injury instead had a surgical incision.

Another systematic review using the Medline Database set was performed with the key words: episiotomy, dyspareunia, faecal incontinence, urinary incontinence, maternal morbidity, pelvic floor defects and sexual function. When performed liberally, episiotomy appears to increase the risk of post partum bleeding. More restrictive use does not appear to increase the risk of serious perineal injury.

In the event of instrumental extraction, use of episiotomy appears to be associated with more severe damage. Medial episiotomy does not appear to be associated with third or fourth degree tears. Episiotomy appears to be the cause of more perineal pain and dyspareunia during the early post partum weeks [193].

2. PERINEAL TRAUMA (Figure 6)

Awareness of perineal damage after vaginal delivery has increased in recent years, due in part to better understanding of its consequences, improved methods of accurate neurophysiological evaluation and accumulation of data on prognosis. Faecal incontinence represents a distressing social handicap, and vaginal delivery is now recognized as its principal cause [194].

Obstetricians should have an awareness of the causes, symptoms, appropriate investigation and treatment options available for this complication of childbirth. Limiting episiotomy can be strongly recommended. In the absence of strong data to the contrary, women should be encouraged to engage in perineal massage if they wish and to adopt the birth positions of their choice. Factors shown to increase perineal integrity include avoiding episiotomy, spontaneous or vacuum-assisted rather than forceps birth, and in nulliparas, perineal massage during the weeks before childbirth. Second stage position has little effect [195].

Further information on techniques to protect the perineum during spontaneous delivery is badly needed. Wherever possible, women with post partum faecal incontinence should be assessed in a specialized clinic, which has developed a close liaison with physiotherapy, dietetic and colorectal surgical advisers.

Episiotomy, forceps use, and birth weight are important predictors of third and fourth-degree tears. However, determinants of sulcus tears appear to be present before pregnancy. Third and fourth-degree tears are related to physician management. Exercise mitigates the potential for severe trauma induced by episiotomy [196].

Eason et al. have systematically reviewed techniques proposed to prevent perineal trauma during childbirth and performed a meta-analysis of the evidence gathered from randomized controlled trials regarding their efficacy. The conclusion was that avoiding episiotomy decreased perineal trauma (absolute risk difference 0.23, 95% confidence interval (CI) -0.35, 0.11). In nulliparas, perineal massage during the weeks before giving birth also protected against
perineal trauma (risk difference -0.08, CI -0.12, -0.04). Vacuum extraction (risk difference -0.06, CI -0.10, 0.02) and spontaneous birth (-0.11, 95% CI -0.18, 0.04) caused less anal sphincter trauma than forceps delivery. The mothers’ position during the second stage had little influence on perineal trauma (supported upright versus recumbent: risk difference 0.02, 95% CI -0.05, 0.09).

Factors shown to increase perineal integrity include avoiding episiotomy, spontaneous or vacuum-assisted rather than forceps birth, and in nulliparas, perineal massage during the weeks before childbirth. Second-stage position has little effect. Further information on techniques to protect the perineum during spontaneous delivery is needed [197].

Reduction in both perinatal and maternal mortality rates in recent decades has focused increasing attention on maternal morbidity and the long-term sequelae of childbirth. Antenatal education encourages expectant mothers to anticipate normal vaginal delivery, leading to an early restoration of normal pelvic function after the performance of routine pelvic floor exercises. Not least because of improved investigative techniques available during the past decade, the incidence and mechanisms of obstetric injury to the pelvic floor have come under scrutiny. A survey of female British obstetricians [137] revealed that one third indicated a personal preference for elective caesarean delivery of their own hypothetical uncomplicated singleton pregnancy; a general fear of pelvic floor trauma was cited as the most common reason for this choice.

Despite being based on incomplete prognostic data, this sentiment may be echoed increasingly among obstetric patients and may lead to an unselective, and even misguided, increase in caesarean delivery rates. Epidemiological studies have reported prevalence of stress incontinence ranging from 23 to 67 percent during pregnancy and 6 to 29 percent after childbirth, but little is known about how the condition affects women at this time. However, the prevalence of urinary incontinence may be nearly the same 8 weeks postpartum as during pregnancy. It is important that contributory obstetric factors are identified and their occurrence minimized. Vaginal birth has been recognized as being potentially traumatic to the pelvic floor. Women who have sustained significant anal sphincter injury are at greater risk of further damage of faecal incontinence with subsequent deliveries.

The factors necessary for the urethra to remain closed at rest and during increased abdominal pressure have been well characterized, but their functional inter-relationships are still not fully understood. These factors include: 1) healthy, functioning striated sphincter controlled by pudendal innervation, 2) well vascularised urethral mucosa and sub-mucosa, 3) properly aligned and functioning intrinsic urethral smooth muscle, and 4) intact vaginal wall support.

Detailed descriptions of the urogenital diaphragm have been made by Max Brodel working with Howard Kelly [198], Oelrich [199] and further expanded by DeLancey [200]. These reports have provided clear descriptions of the urethral rhabdosphincter. The proximal one-third of the urethra is surrounded by a sleeve of striated muscle continuous with a longer ascending cone which extends to the vaginal introitus. Manometric and electrophysiological recordings from this proximal one-third of the urethra have shown that it generates the highest level of resting pressure and electromyographic activity.

This portion of the urethra is an intra-pelvic structure located immediately posterior to the pubic bone. In the past, much has been made of the loss of this intra-pelvic position in stress incontinence. It had been suggested that when the urethra descended away from its intra-abdominal position, intra-abdominal forces no longer constricted it during straining. This concept has survived and been modified into the “hammock hypothesis” [201] which suggests that the posterior position of the vagina provides a backboard against which increasing intra-abdominal forces compress the urethra. Data supporting this hypothesis are drawn from urethral pressure transmission studies showing that continent patients experience an increase in intra-urethral pressures during coughing. This pressure increase is lost in stress incontinence and may be restored following successful operations designed to stabilize or elevate the sub-urethral vaginal wall [202-211].

The urethra is supported posteriorly and inferiorly by the anterior vaginal wall. The superior vaginal sulcus, most clearly found in nullipara, exists at this junction
of the lower and middle third of the vaginal wall. This point represents the two lateral insertion points of the vaginal "hammock". Portions of the pubococcygeus muscle attach to these sulci within the pelvis and can produce elevation during voluntary contraction.

Immediately anterior to the proximal urethra are found the reflections of the endopelvic fascia. The most prominent of these, the pubo-urethral ligaments, are sufficiently condensed to form distinct and recognizable ligaments on either side of the pubis. Although these structures form one continuous complex, they are distinguished by their names, as posterior and anterior pubo-urethral ligaments. The posterior pubo-urethral ligaments, which can be seen at the time of retropubic surgery, are the more familiar of these. These are strong fascial condensations which most likely maintain their characteristics throughout life. Previous investigators, however, have suggested that elongation of these structures may be responsible for the loss of urethral support seen in stress incontinence.

While the lower one-third of the vagina is oriented more vertically in the nullipara, the upper two-thirds of the vagina deviate horizontally. This orientation is due:

1) to the posterior attachments of the cervix by the cardinal and utero-sacral ligaments and 2) to the anterior position of the levator hiatus. Barium vaginograms have demonstrated this horizontal angulation of the upper two-thirds of the vagina, and show that during coughing and stressful manoeuvres, the levator hiatus is shortened in an anterior direction by the contraction of the pubococcygeus muscles.

Thus, the pelvic organs receive support from the shape and active contraction of the levator muscles. Modifications of the genital hiatus determining an increase in the genitohiatal distance can be associated with urodynamic stress incontinence. In a retrospective study of 396 women with urodynamic stress incontinence [212], pelvic floor ultrasound revealed a negative association of the genitohiatal distance to urodynamic functional urethral parameters such as the functional profile length, the maximum urethral closure pressure and a low Valsalva leak-point pressure ($r = -0.148$, $P = 0.018$ and $r = -0.227$, $P = 0.009$, $r = -0.199$, $P = 0.02$ respectively).

### II. EFFECT OF CHILDBIRTH, VAGINAL PROLAPSE AND URETHRAL POSITION ON URINARY CONTINENCE

Labour and delivery alter vaginal and pelvic anatomy and innervation in several ways as has been discussed in other sections of this chapter. Each of these may contribute to the eventual development of urinary incontinence (Figure 7):

1. Direct crushing or traction on the pudendal nerve has been discussed above and has previously been suggested as a primary cause of sphincter incompetence in stress incontinence.

2. Cardinal and utero-sacral ligaments may be stretched or torn, resulting in anterior displacement of the uterus during straining or under the influence of gravity.

*Figure 7: Anatomical and functional interaction of the urethra, bladder and the anterior vaginal wall (PCM = Pubococcygeus muscle, PUL = Pubourethral ligaments)*
The vagina itself may be torn away from its intrapelvic attachments with subsequent loss of the superior vaginal sulcus. There may be direct attenuation of the vaginal wall itself, manifested by loss of vaginal rugae and a thin appearance. Cullen Richardson has suggested four distinct kinds of vaginal injuries: paravaginal, central, distal, and cervical, the first two being the most commonly seen in women with stress incontinence. These defects have been identified by sonographic examination [213].

Finally, stretching, tearing and avulsion of the levator muscles result in a longer and wider levator hiatus. Consequently, the perineum is displaced anteriorly and posteriorly under stress and temporarily fails to support the pelvic organs. These changes in the levator hiatus with or without associated relaxation of cervical support result in chronic anterior displacement of pelvic organs with a loss of both active and passive organ support during rest and especially during straining.

In the patient with stress urinary incontinence these changes typically give rise to a rotational descent of the proximal urethra away from its retropubic position. Radiographic images of stress urinary incontinence in women have noted this and generated our earliest concepts of this condition. Jeffcoate and Roberts [214], using lateral cystourethrograms, concluded:

“…the most common characteristic anatomical change, present in four out of five cases of incontinence, is loss of the posterior urethro-vesical angle so that the urethra and trigone tend to come into line."

In 2002, fifty years later, perineal sonographic studies of urethrovaginal angle differences in incontinent and normal patients have found excellent correlation identified between angle and degree of incontinence, supporting these original observations [215].

Hodgkinson, using a suspension of barium paste placed in the bladder and a small bead chain in the urethra, produced images of the urethra at rest and during maximum straining in women with stress urinary incontinence [216, 217]. He concluded:

“...it is clear that the distinguishing topographic pathological feature is depression of the urethrovaginal junction to the lowest level of the bladder during the peak of the straining effort. It is also clear that the spatial relationships of the bladder and urethra to the symphysis make no difference in either the incidence or severity of stress incontinence."

These kinds of radiographic studies, however, cannot distinguish between lateral or central defects in vaginal wall support. Therefore, while urethral movement can be identified as an important finding in stress incontinence, one cannot determine the exact location of the vaginal defect. Because the proximal urethra rotates out of the focal plane of ultrasonographic probes or MRI, coronal images of vaginal relaxation have not yet shown anatomical detail at the moment of incontinence. They cannot distinguish central from paravaginal defects. For this, an examination of the patient is required.

Although we have considerable knowledge about anatomical defects in the majority of patients with urodynamic stress incontinence (USI), less is understood about the exact effect of these defects, and indeed, vaginal position itself, on urethral closure. Early experience with operations for stress incontinence showed that not all women with stress urinary incontinence had vaginal prolapse, that correction of vaginal relaxation did not always correct stress incontinence, and that women who redeveloped stress incontinence symptoms after apparently successful surgery did not necessarily show a recurrence of their prolapse [218].

The greater involvement of the urethral mechanism in the occurrence of post-partum stress incontinence was confirmed in a case control study evaluating urethral closure pressure and bladder neck movement assessed with ultrasound [220]. Eighty primiparous women complaining of de-novo stress incontinence 9-12 months after delivery were compared with 80 primiparous continent and 80 nulliparous continent women. Lower maximal urethral closure pressure was most associated with de novo stress incontinence after first vaginal birth followed by vesical neck mobility.

III. EMERGING CONCEPTS OF URETHRAL WEAKNESS AND ISD

The idea that primary urethral weakness could cause urinary incontinence independent of vaginal weakness appeared in a proposed classification by Blaivas et al [221]. In their classification, they named this Type III incontinence to distinguish it from Types I and II, each of which showed movement, while Type III did not. This term still remains in the contemporary literature, although it has now been largely replaced by the term intrinsic sphincter deficiency (ISD), focusing attention on urethral elements which appear to be independent of vaginal position and mobility. These elements include pudendal innervation, striated sphincter mass and function, and urethral smooth muscle, mucosa and submucosal cushions.
When ISD was first introduced as a concept to explain surgical failures and the presence of stress incontinence in the absence of vaginal mobility, the diagnostic tendency was to consider the cause of stress incontinence as a dichotomy, due either to hypermobility (displacement, or prolapse of the vaginal wall) or ISD. The typical patient with ISD was described as having low urethral closure pressures, a “stovepipe” appearance on cystoscopy, and opening or funnelling of the urethra under resting or minimal increases in intra-abdominal pressures on radiographic images. The common causes were thought to be surgical injury, ischemia following previous pelvic or vaginal surgery or radiation damage.

It appears now, that these examples of ISD may have represented the most advanced or extreme forms.

IV. HYPERMOBILITY VS. ISD: FROM DICHOTOMY TO CONTINUUM

Currently, there appears to be a shift away from this simple categorization of stress incontinence as being due either to hypermobility or ISD. This has arisen in part because of the development of the concept of Valsalva Leak Point Pressure (VLPP) [222, 223] and more recent analyses of long term results of stress incontinence surgery [224].

VLPP emerged as an alternative method to study urethral closure during stress for studies of urethral bulking with collagen. Investigators recognized that improvements in continence following urethral bulking did not correlate with urethral closure pressures, but did correlate with the amount of pressure required to produce leakage in the absence of intrinsic detrusor contraction. Although VLPP still lacks specific anatomic or theoretical grounding and many uncertainties related to standardization of recording methods and associated prolapse remain, low VLPP (without specified or established values) has been widely embraced as an indicator of ISD.

Just as the concept of VLPP blurred the previous distinction between simple ISD and simple hypermobility, long term outcome studies of correction of hypermobility have suggested that there may be more urethral weakness among patients with hypermobility than had been previously considered. Long term outcome studies of stress incontinence surgery have shown that there is a much greater failure rate of many of the commonly performed stress incontinence operations than had been generally appreciated, and that slings providing direct sub-urethral support seemed to give the greatest long term protection against recurrence of incontinence [224]. Since slings had traditionally been the procedure of choice for recurrent incontinence or “Type III” (now ISD) incontinence, the possibility that ISD was more common than previously thought was more widely considered. Recently, Horbach and Ostergaard have found that age is a significant, independent predictor of ISD in the setting of urodynamic stress incontinence [225], suggesting that age-related reduction in muscle mass, slowed reflexes or repeated episodes of prolapse may all contribute to the condition.

In two interesting studies Perucchini et al [226, 227] showed that aging can cause a decrease in the number and density of urethral striated muscle fibres at the bladder neck and along the ventral wall of the urethra. (Figure 8 and 9 [226])

These two developments have led to a growing clinical impression that some degree of ISD may exist in many patients who, until recently, were thought to have only hypermobility as a cause of their incontinence. A typical expression of this approach can be found in the conclusion of Kayigil et al. [228]
following examination of 50 patients; “The high rate of intrinsic sphincter deficiency in patients with urethral hypermobility indicates that the incidence with stress incontinence may be greater than previously believed, and may influence the apparently higher failure rates after bladder neck suspension.” In contemporary clinical practice, this impression has given rise to a growing tendency to recommend suburethral sling surgery as a form of primary surgical treatment for all women with stress incontinence, whereas as formerly this approach was reserved almost exclusively for patients with recurrent stress incontinence or significant ISD [229, 230].

1. DIRECT STUDIES OF URETHRAL FUNCTION

As recognition of the importance of urethral function has increased, so too have the number of investigations of urethral position, urethral closure and transmission pressure profiles, Valsalva leak point pressure measurements and electromyographic examinations of the pudendal nerve and the striated sphincter.

a) Studies of urethral position

Stress incontinence is frequently associated with loss of urethral position. This has been the primary pathophysiological paradigm since the observations of Hodgkinson and Jeffcoate and Roberts. Similar observations are still reported today [231, 232]. Even when some displacement is seen in continent nulliparous females, continent women show a greater degree of mobility [233].

Successful suspensory operations, whether by sling or paraurethral suspension stabilize urethral position [218] and, when studied, increase pressure transmission during stress. It is not clear if the active contraction of urethral support seen in the female is restored after surgery, nor is it known if it is necessary for continence. It has been suggested that passive support alone is what restores continence after suspension.

b) Studies of urethral pressure and resistance

Stress incontinence is generally thought to be characterized by a decrease in urethral transmission profiles and resting closure pressure. The correlation between low resting pressures and low leak point pressures is still controversial. With a bladder filled up to 200ml Almeida et al [234] reported a significant correlation between MUCP and LPP. Patients with a LPP of 60 cm H2O or less also had shorter urethral functional length and lower sphincter activity. Moreover Sinha et al [235] showed that women with urodynamic stress incontinence were more likely to leak at cough leak point pressure than the Valsalva manoeuvre, with the opposite happening for women with detrusor overactivity. On the contrary Martan et al [236] could not find any significant correlation between MUCP and VLPP.

Different urodynamics parameters have also been considered to assess urethral function and to correlate with women with stress incontinence. Digesù et al [237] showed that urethral resistance pressure (URP) and pressure flow parameters were reduced in women with stress incontinence. Salvatore et al [238] found that the opening vesical pressure is significantly correlated to ISD.

Sonographic studies have recently shown a relationship between low urethral resistance and decreased urethral smooth and skeletal muscle layers [239].

Improvement in transmission pressures is associated with successful outcomes after suspensory operations for STRESS URINARY INCONTINENCE[202, 206, 209, 210, 240, 241]. The exact mechanism for this increase in transmission is not clear. Increased exposure to intra-abdominal forces has been suggested [211, 242, 243]. Compression against the pubis by the pelvic viscera has also been suggested [244]. The final position of the urethra, however, may not be the key variable [202].

c) Electrophysiological studies of urethral function

Snooks and Swash [245, 246] first brought attention to the importance of urethral denervation after childbirth and its possible contribution to urinary and faecal incontinence. Stress incontinence is frequently associated with a decline in the electrophysiological function of the pudendal nerve [247], the striated urethral sphincter [248], and the pelvic floor muscles [249, 250]. Most recent studies continue to support the finding of prolonged pudendal nerve terminal motor latency in STRESS URINARY INCONTINENCE [251].

Electromyographic studies of normal sphincter function show that in continent women, pressures begin to rise in the urethra before rising in the bladder, suggesting an active muscular component [252]. Women with stress incontinence have an altered pattern of pelvic floor muscle response during successive coughing efforts [253] with a sharp decrease in MUCP after repeated coughs [254]. EMG studies have also shown that women with persistent stress incontinence after previous surgery have poorer urethral neuromuscular function than naïve stress incontinent women [255]. Experimental studies of urethral function and the role of Onuf’s nucleus in the sacral spinal cord have led to recent practical innovations in the development of serotonin uptake inhibitor agents in the treatment of stress incontinence [256]. Most electrophysiological studies have concentrated on motor rather than sensory innervation, however, and the role of urethral sensation in urodynamic stress incontinence is unknown.

d) Genetic factors

Recent research is now focusing on the identification
of factors related to stress incontinence which might be genetically determined. Chen et al [257] reported that genes involved in elastin metabolism were differentially expressed in vaginal tissue from women with stress incontinence, suggesting that elastin remodelling may be important in the molecular etiology of stress incontinence. Wen et al [258] recently reported a decreased expression of alpha2-M mRNA and protein and protease inhibitory activity in the vaginal wall tissues of women with stress incontinence. There is a need for a hypothesis which would integrate these various observations regarding hypermobility, ISD and pudendal nerve function, place them within the context of an abnormal pelvic floor and provide a model to guide research and studies of the natural history of the condition.

2. ROLE OF ADVANCED IMAGING IN UNDERSTANDING PATHOPHYSIOLOGY

Radiographic imaging has provided considerable insight into pathophysiology of stress incontinence, ever since the advent of bead chain cystograms and simple static and straining lateral cystograms.

Magnetic resonance imaging (MRI) and real time ultrasonography, in addition to showing the events of stress incontinence on both a global pelvic and local urethral scale, have suggested a relationship of the proximal urethra to vaginal wall movement.

a) Magnetic resonance imaging

Dynamic fastscan MRI can visualize all compartments of the female pelvis during increased intraabdominal straining [259]. MRI is comparable to standard cystography in demonstrating cystocele defects [260]. Using the pubococcygeal line as a reference marker, the normal displacement of bladder base, cervix or cervical cuff, and the rectum can be identified and compared to women with prolapse. The urethra is shown in the context of global pelvic relaxation [261]. Although most MRI studies have been descriptive rather than quantitative, they still show far more soft tissue detail than earlier radiographic studies and continue to offer promising research opportunities. Recent studies have utilized an endovaginal coil to obtain higher resolution images of the urethra [262].

Dynamic MRI with cine-loop reconstruction produces vivid, intuitively appealing images which can show movement of all compartments of the relaxed pelvis during straining [261]. Static MRI shows details of urethral and peri-urethral anatomy and the striated sphincter can be clearly seen [263]. Pending further improvements in resolution, MRI remains a most promising tool for studying details of urethral movement [264].

Ultrasonography, however, is simpler and less expensive, and, for now, provides better visualization of moving structures.

Functional MRI has recently been evaluated to assess the efficacy of pelvic floor muscle training with EMG-biofeedback in women with stress incontinence. After a 12-week training period a more focused activation in the primary motor and somatosensory cortical representation sites of the lower urogenital tract was found [265]. (Figure 10)

b) Real time ultrasonography

Several sonographic approaches have been used for the study of stress incontinence: suprapubic, translabial and transperineal. As resolution of sonographic probes has improved, the detail previously best seen with the transrectal approach may now be seen by a transperineal approach (Figure 11).

Earlier studies with a transrectal approach have shown that funnelling of the proximal urethra was the sonographic sign most-frequently associated with loss of urine [266]. In about half the patients with stress incontinence in this study, funnelling was seen
only with straining. In the other half, some degree of funnelling was already present at rest, increasing with straining and present with actual leakage. Enhanced views of the urethra are possible with sonographic contrast material [267]. Most recently, 3-D reconstruction from translabial views of the urethra has been used to compare findings in normal volunteers and those with ISD [268].

The most recent sonographic study of women with stress urinary incontinence found funnelling at rest in 109 of 330 patients, and found that the degree of vaginal relaxation as well as the parameters of intrinsic urethral function, including VLPP and urethral closure pressures, were worse in patients with funnelling than without. The authors of this study concluded that: “In primary genuine stress incontinence, bladder neck funnelling on ultrasound cystourethrography implies the potential coexistence of poor anatomic support and an intrinsic sphincter defect. [269].” Ghoniem et al [270] also found that urethral funnelling was more likely to be associated with low closure pressures, low VLPPs, and a higher incidence of ISD in patients with stress urinary incontinence. However, recently, Tunn et al [271] could not find an association between the ultrasound findings of urethral funnelling with stress incontinence using an introital approach, demonstrating it only in 59% of the patients with stress urinary incontinence.

Ultrasound has been used to identify paravaginal defects prior to Burch colposuspension to guide surgical modification, and then repeated after surgery to show correction of the defects [272].

Urethral movement and funnelling seen by ultrasound resemble the rotational descent previously described by Nichols and Randall [273]. It is also consistent with the previously cited descriptions of Jeffcoate and Roberts, and that of Hodgkinson. Improved soft tissue detail seen with ultrasound has permitted an extension of these original observations. The anterior and posterior walls of the proximal urethra appear to move differently during increases in intra-abdominal pressure. At first, they appear to move together: the urethra begins its descent as a single unit. At some point, however, the anterior urethra becomes arrested in its rotational movement and appears to move more slowly. The posterior portion of the urethra continues to descend along with the vaginal wall [266, 274]. This difference in movement suggests a shearing apart of the two walls, leading to the appearance of funnelling, which can be seen as urine leaks out of the urethra.

Anatomic correlation suggests that the pubourethral ligaments may restrict the movement of the anterior urethral wall, facilitating downward traction by the prolapsing vagina during stress, contributing to the shear. At the level of the pubis, the posterior portion of the pubourethral ligament travels beneath the pubis to form an anterior portion, which supports the clitoris in women, and the corpora cavernosa in men. Both Nichols and Milley [275] and Zacharin [276-278] have previously suggested that the posterior pubourethral ligaments might support the urethra, and their laxity might contribute to the descent of the urethra in stress incontinence. These studies, however, suggest a different interpretation. Longitudinal and cross-sectional views of the proximal urethra show that the ligaments travel along only the anterior portion of the urethra as they pass beneath the pubis to emerge as the anterior pubourethral ligaments. The vagina and its bilateral attachments forming the lateral sulcus support the posterior part of the urethra. It is more likely that the vaginal wall and its attachments become weaker than the strong condensations of endopelvic fascia forming these ligaments. Therefore, the pubourethral complex, even if attenuated, probably remains stronger than the underlying vaginal wall. Sonographic examination of the prolapsing urethra thus suggests arrest of anterior urethral wall movement by the pubourethral complex, while the vaginal wall continues to rotate, pulling the posterior wall of the urethra along with it.

These anatomical considerations, combined with current knowledge about pudendal nerve activity in normal, prolapse or stress incontinence, suggest an inter-relationship regarding urethral closure and vaginal movement. As intra-abdominal pressure increases, the proximal urethra experiences two kinds of forces, which may lead to opening. The first of these is a shearing force produced by the unequal separation of the anterior and posterior urethral walls from the pubis during straining. This is the effect of vaginal mobility on urethral closure. The second is an expulsive force, produced by the transmission of intra-abdominal forces to the bladder, which must be resisted by the urethra if opening is to be prevented. The urethra
resists this primarily by intrinsic closure of the pudendally innervated striated sphincter, aided by vaginal support.

3D ultrasound has been recently introduced new insights in the image of urethral sphincters. Athanasiou et al [279], using a transvaginal approach, reported a close correlation between the urethral sphincter volume and the degree of incontinence assessed on videocystourethrography (r = -.65; P < .001).

Urethral vasculature has also been postulated to play a role in the continence mechanism and different Doppler parameters have been studied to evaluate correlation with STRESS URINARY INCONTINENCE. However, also for this aspect, results are controversial since some authors [280] reported less periurethral vessels and flow in women suffering from stress urinary incontinence whereas others [281] could not find any difference in the appearance of the urethral vasculature in subjects with or without stress urinary incontinence.

It is likely that these shearing and expulsive forces are generated simultaneously as intra-abdominal pressure rises. One can easily imagine that the urethra can be brought to a continence threshold beyond which urethral closure cannot be maintained.

One can further imagine that repeated episodes of prolapse may eventually stretch, tear or attenuate sphincter mass and contribute to a chronically weakened urethra manifested by low VLPP or low urethral closure pressures, characteristic of ISD.

After severe or prolonged untreated prolapse and stress incontinence, vaginal support alone may not be sufficient to correct the deficiencies of an exhausted sphincter. Although theoretical rather than evidence-based, such considerations may direct future research efforts towards a more integrated hypothesis regarding stress incontinence in women.

The relative contributions of abnormal vaginal mobility and intrinsic urethral function should be considered as part of a continuum rather than a dichotomy. Current research and interest has concentrated mostly on ISD as the primary cause of stress urinary incontinence in women, but the relationship of the many factors affecting urethral support and function should remain a perspective in interpreting emerging findings.

V. CONCLUSIONS

We are approaching a new classification of stress incontinence which will integrate hypermobility and urethral dysfunction as inter-related elements on a spectrum of change. Certain concepts have stood the test of time, and they are included below, along with conclusions:

1. Many patients with urodynamic stress incontinence show urethral mobility (Level 2), though it is not yet known what it is about that mobility which permits urethral opening during stress.

2. Some patients who present with minimal mobility or who have recurred after successful surgery have primary or residual sphincter insufficiency.

3. Sphincter insufficiency is related to a decline in striated sphincter muscle mass and function as measured by electrophysiological studies of pudendal nerve and sphincter function, and MRI and sonographic estimates of muscle mass (Level 1). If repeated episodes of vaginal traction can be shown to enhance sphincter damage, then the effect of early treatment of stress incontinence and prolapse on future development of ISD should be investigated, since advanced ISD remains difficult to treat.

4. Successful operations can restore urethral position but probably do not restore urethral function. A good surgical outcome probably requires a certain reserve of urethral function. It is in the area of functional understanding of urethral anatomy that the greatest progress is likely to be made.

D. PELVIC ORGAN PROLAPSE

I. PATHOPHYSIOLOGY OF PELVIC ORGAN PROLAPSE

Normal pelvic organ support depends on the integrity of the endopelvic fascia, i.e. connective tissue, the pelvic floor muscles and adequate nerve supply. Theoretically, if one of these factors fails, the others might be able to compensate to a certain degree. Our knowledge as to which structure fails and why remains limited. Table 1 lists structural elements of pelvic organ support, their possible damage and subsequent site of pelvic organ prolapse. In Table 2 anatomical and functional determinants of normal pelvic organ support are listed. The possible nature of failure and its potential causes, established and theoretical risk factors are also summarised.

For many years vaginal delivery has been considered the most important causal factor in the development of pelvic organ prolapse [282-287]. However, some large community-based epidemiological studies have described pelvic floor symptoms in women who gave birth by caesarean section only [283, 288]. It seems that pregnancy itself plays an important role in the development of pelvic floor dysfunction. Still not sufficiently investigated, the hormonal and enzymatic preparation of the connective tissue to soften and

stretch adequately during vaginal birth might be an imperative factor. Although muscular, neural and connective tissue damage has been demonstrated in women after vaginal deliveries, these changes do not automatically result in pelvic floor dysfunction. Epidemiological studies have also emphasised the contributing effects of ageing, genetic predisposition, obesity, constipation and hormone therapy.

1. GENETIC AND ETHNIC PREDISPOSITION

Comparative studies have drawn attention to the higher incidence of pelvic floor dysfunction amongst relatives, most notably amongst identical twins [289-292]. Familial incidence of POP was reported as high as 30% [292].

Genetic variants have been documented that run in families with an increased incidence of pelvic organ prolapse [293]. One study examined gene expression of structural proteins that are related to actin and myosin in five women with and five women without pelvic organ prolapse in the pubococcygeal muscle. There were several genetic differences between subjects and controls with under and overexpression of genes [294]. Altered gene expression of elastin has also been described in women with pelvic organ prolapse [295]. In mice, HOXA11 has been identified as the gene that is responsible for the development of the uterosacral ligaments [296]. In HOXA11-null mice the uterosacral ligaments were absent. HOXA11 and collagen expression were significantly decreased in the uterosacral ligaments of women with pelvic organ prolapse [296].

Also, it has long been suspected and recently been studied that connective tissue diseases like Ehlers-Danlos and Marfan’s syndrome predispose to pelvic organ prolapse [297]. Young women with pelvic organ prolapse are more likely to have neurological or connective tissue diseases and congenital abnormalities [298]. Intrinsic joint hypermobility is another well recognised connective tissue disease that is associated with pelvic organ prolapse [299-302].

Differences between ethnic groups have been described in some studies with regard to pelvic floor function. White women seem to have a higher risk of pelvic organ prolapse compared with Afro-American women [303]. However, prolapse is highly prevalent in rural Gambia, West Africa e.g. with 14% of 1067 having moderate to severe prolapse [287]. In one study Hispanic women had an increased risk for prolapse compared to white women [304]. The thickness of the puborectalis muscle measured on perineal ultrasound varies between Caucasian and Chinese women [305].

Signs of a rectocele on ultrasound examination were found in 12% of young nulliparous women in a small observational study raising the question of a congenital fascial defect [306]. Pelvic organ prolapse in young women has also been linked with abdominal hernias [292]. As a deep pouch of Douglas is frequently present in young nulliparous women, without pelvic organ prolapse this implies a congenital variation and may be predisposition [307].

2. ALTERATIONS OF COLLAGEN, ELASTIN AND SMOOTH MUSCLE OF THE VAGINAL AND SUPPORTIVE TISSUES

Many studies have found alterations in supportive tissues in women with pelvic organ prolapse [308]. One study revealed that the general amount of collagen in the parametria is reduced in pre and postmenopausal women with pelvic organ prolapse compared with women without prolapse. In biopsies from the vaginal apex there were no differences [309].

Type III collagen is the primary collagen subtype in the vagina and its supportive structures. The ratio of collagen I to III is an indicator of tensile strength. The higher the amount of collagen type III the lower the mechanical strength. A lower collagen I/III ratio due to increased type III collagen has been demonstrated in women with pelvic organ prolapse in the vaginal subepithelium and uterosacral and cardinal ligaments, independent of age and parity [310-312]. Menopause seems to decrease the collagen I/III ratio [311, 313]. Type I collagen content was similar in women with and without uterine prolapse, but the quality of the fibres was different. In this study, hormonal status did not affect collagen content [314]. Unfortunately there are only cross-sectional studies and the direction of the association between pelvic organ prolapse and increased collagen III is not clear. Is the decreased collagen I/III ratio a response to the prolapse or does it cause it? However, due to the reduced tensile strength of the connective tissue progression of pelvic organ prolapse is likely.

Other studies have focussed on examining active components and factors suggestive of connective tissue remodelling. Active remodelling of vaginal connective tissue in women with prolapse has been suggested as a result of “biomechanical stress” [310]. A higher expression of tenascin -a glycoprotein that is involved in tissue repair – was found in cardinal and uterosacral ligaments of prolapsed uteri [311, 315]. This implies traumatic factors caused by the prolapse. The activity of matrix metalloproteinases (MMP) has been examined in women with and without pelvic organ prolapse with different results emphasising the heterogeneity of pelvic floor dysfunction as well as difficulties with standardisation of specimens, sites and tests [316-318]. Results do however show an active remodelling of the connective tissue in women with prolapse.

Elastin also plays an important role in connective tissue and pelvic floor integrity. As it is thought to be
very stable with little turnover during a woman's lifetime apart from childbirth, demonstrated elastin differences between women with and without pelvic organ prolapse are suggestive of a structural defect rather than a secondary result of prolapse [319].

In mice it has been shown that impaired homeostasis of elastin after parturition due to insufficient LOXL1 expression (lysyl oxidase) leads to prolapse [320]. LOXL1-deficient mice seem to develop prolapse due to a global defect in connective tissues that correlates with inferior biomechanical properties with a decrease of ultimate load at failure [321]. Altered elastin metabolism and elastin gene expression were found in women with pelvic organ prolapse [295, 315, 322] (Figure 12).

The significance of highly prevalent smooth muscle in pelvic floor supportive tissues is not clearly understood. In women with normal pelvic organ support smooth muscles fibres in the anterior vaginal wall are organised in "tightly-packed" bundles orientated in circular and longitudinal directions [323]. In comparison, in women with pelvic organ prolapse the bundles were smaller, fewer and disorganised [323]. These features were also demonstrated in biopsies from the upper posterior vaginal wall after hysterectomy in women with prolapse [324]. Loss of smooth muscle content was related to the degree of prolapse [324]. Smooth muscle content was also reduced in the round ligament of women with prolapse [325]. Caldesmon, a protein in smooth muscle that inhibits actin-activated myosin adenosine triphosphatase, plays a role in regulating smooth muscle contractility. As it has been found to be increased in vaginal tissues in women with prolapse, it may have led to impaired smooth muscle contractility and force maintenance [326].

Biomechanical factors have been assessed with different techniques. The tensile strength of the connective tissue is significantly reduced in women with pelvic organ prolapse [327] whereas extensibility was shown to be greater. Interestingly these differences of extensibility were not demonstrated in the skin of the forearms implying that prolapse in these women was related to local rather than systemic connective tissue alterations [328]. Elongation of vaginal apical tissues of women during pelvic reconstructive surgery seems very variable between 15 to 42 mm [329]. The authors concluded that this might be a reason for otherwise unexplained failure of prolapse surgery [329].

3. NEUROLOGICAL FACTORS

Intact innervation of the levator ani muscle, anal, and urethral sphincters is critical to normal pelvic function. It has been suggested that neurological damage induced by transvaginal reconstructive surgery results in suboptimal outcome [330]. Perineal terminal motor latency served as a surrogate parameter. However, the authors have reported rather low success rates after bilateral sacrospinous ligament fixation which emphasises the importance of surgical technique [331].

Vaginal birth is an established factor for nerve damage. Prospective EMG studies performed before and after childbirth substantiated the evidence of childbirth induced pelvic floor denervation detecting increased fibre density after vaginal delivery. Ageing leads to further deterioration of pelvic floor denervation [164, 332].

Histologically, there were smaller and fewer nerve bundles in women with posterior vaginal wall prolapse compared with women without prolapse [324]. The density of peptide-containing nerves in the periurethral tissue and in the levator ani muscle in women with prolapse was reduced [333, 334] (Figure 12: Tissue sample of a 54 old woman with POP. Black areas show fragmented elastic connective tissue fibres as a sign of pelvic floor tissue defect. [291])
4. PREGNANCY- EPIDEMIOLOGY AND CONNECTIVE TISSUE AND PELVIC FLOOR MUSCLE REMODELLING

Recently some studies have drawn attention to the occurrence of clinically significant pelvic organ prolapse during pregnancy in nulliparous women [335-338]. These studies employed the validated quantitation of pelvic organ prolapse of the International Continence Society. Pelvic organ prolapse stage 2 was found in 26-48% whereas none of the 21 age and race matched non-pregnant controls demonstrated stage 2 prolapse [336, 337]. Prolapse stage increased during pregnancy and persisted postpartum in women who were delivered vaginally [335-338]. The most frequent site of prolapse was the anterior vaginal wall in all of these studies.

The causes of the development of pelvic organ prolapse during pregnancy might be multifactorial but certainly hormones and enzymes are involved. Progesterone is known to reduce the tone in ureters, bladder and urethra because of its smooth muscle relaxing and estrogen antagonising effects [339]. Relaxin, a peptide hormone similar to insulin, increases markedly during pregnancy. It modifies the connective tissue and has a collagenolytic effect to allow for appropriate stretching during vaginal birth in guinea pigs [340]. As a likely result of connective tissue remodelling in preparation for birth, Landon and colleagues [341] found that the connective tissue of the rectus sheath fascia and the obturator fascia could be stretched to greater length during pregnancy, but it is also much weaker. In some women these changes may be irreversible or further stretching beyond physiological limits may result in permanent dysfunction.

5. CHILDBIRTH

Vaginal birth has long been considered the most important risk factor for pelvic organ prolapse. Most epidemiological studies demonstrate an association with parity in general [283, 286, 287, 342-344] and specifically with vaginal birth [168, 283, 303, 345]. Mechanical damage to the pelvic floor musculature, connective tissue and nerve supply occurs particularly during the second stage of labour when the fetal head distends and stretches the pelvic floor. Apart from direct muscle rupture and muscle and connective tissue stretching there might also be biochemical damage to the soft tissue, especially during long second stages. The recent development of three and four dimensional ultrasound has enabled us to directly study pubovisceral muscle detachment after vaginal delivery. Dietz et al., in a small study, revealed levator avulsion in 36% of 39 women after vaginal birth. This injury was associated with stress incontinence [155].

Employing the ICS pelvic organ prolapse standardisation, Sze et al. [337] prospectively studied nulliparous women and found that postpartum, 52% had stage 2 prolapse, 37% of women developed a new prolapse and 15% revealed a more severe prolapse compared to antenatal examinations.

Childbirth in mice has been investigated in an intriguing study analysing the elastin and LOXL1 expression [346]. There is degradation before and a high turnover of elastic fibres after childbirth that allows the tissues to recover. During parturition monocytes are present in the vagina which may induce elastolysis by chemotaxis. Mice injected with elastases into the posterior vaginal wall post partum demonstrated protrusion 2-4 hours later. Fibulin, an elastin-binding protein that is crucial for elastogenesis and effective cross linking is thought to be important for regeneration and to counteract elastin degradation. In 33 of 36 mice with null mutations in fibulin-5 pelvic organ prolapse was found to progress with age. Drewes et al. concluded that there might be different factors initiating prolapse like ageing, smoking and childbirth but the final pathway seems to be a reduction in number of functional elastic fibres [346].

6. CAESAREAN SECTION- ONLY PARTIALLY PROTECTIVE

In most post partum as well as long-term studies caesarean section might reduce but not totally prevent urinary and anal incontinence. Pelvic organ prolapse however seemed considerably lower after caesarean section [283, 343] but was still described in a rare prospective study before and 6 weeks after childbirth in 35% of 26 women after caesarean section during active labour compared to 32% of 41 women who had spontaneous vaginal deliveries [337]. The influence of labour versus no-labour pure caesarean delivery on pelvic organ prolapse has been negated in one epidemiological study using validated questionnaires [168].

7. OBSTETRICAL AND MATERNAL FACTORS

Age at first delivery may theoretically have an impact on the development of pelvic organ prolapse. However, studies are controversial considering younger age (25 versus 28 years of age) [347] as well as older age (more than 30 years) [348] at first delivery a risk factor. Another large study did not reveal an association at all [303].

A higher birth weight especially more than 4000g has been shown to increase the risk for pelvic organ prolapse in univariate and multivariate analyses [303, 304, 343, 349]. An extensive vaginal rupture has also been associated with prolapse [349]. Instrumental delivery is an established risk factor for anal incontinence but has only been shown in one study to be associated with prolapse [347] A mediolateral episiotomy did not prevent or result in a higher incidence of pelvic organ prolapse three months post partum [303, 350].
8. HORMONES

Hormone therapy has been shown to increase urogenital symptoms in some studies [351-353]. Whereas the negative effect of systemic hormone therapy on incontinence status seems established this has not been clearly demonstrated for pelvic organ prolapse. Most epidemiological studies did not reveal a significant association [286, 304, 343]. In a univariate analysis of self-reported prolapse symptoms in a population-based study, current estrogen use increased the risk. However, multivariable regression did not confirm this [303].

In prolapse patients, the cardinal ligaments and levator ani fascia express more estrogen receptors than in women without prolapse [354, 355]. Long term estrogen treatment however led to a decline in estrogen receptor expression [282, 284, 287, 344]. Menopause seems to decrease the collagen I/III ratio [313].

9. AGE

Most epidemiological studies have determined age as a main risk factor for pelvic organ prolapse [286, 342, 343, 356]. However, the interaction of age, menopause and hormonal status seems inseparable.

10. OBESITY: BODY MASS INDEX AND WAIST CIRCUMFERENCE

Many studies have examined the influence of obesity on pelvic organ prolapse prevalence, some studies also of progression and regression. Body mass index and waist circumference are the most commonly measured variables. An increased BMI increases the risk for prolapse [285, 304, 306, 347, 357] and specifically for progressive rectoceles [342]. Increased waist circumference was associated with more pelvic organ prolapse in some studies [342, 343]. Handa et al. demonstrated this for cystoceles [342]. Whereas some studies do and some do not reveal obesity as a risk factor, no study found overweight protective.

11. CONSTIPATION

Similar to obesity, constipation has frequently been described to increase the risk for pelvic organ prolapse [303, 306, 357, 358] and has never been found to be protective.

12. CHRONIC PELVIC FLOOR STRESS

Occupational heavy lifting has long been associated with pelvic organ prolapse [359]. Prolapse was more prevalent in labourers or factory workers compared with housewives or service workers [360, 361] Chronic lung disease seems likely to increase prolapse but has rarely been shown to be an independent risk factor [284].

13. PREVIOUS OPERATIONS

Whether previous hysterectomy increases the risk for subsequent pelvic organ prolapse is not clear. In some epidemiological studies previous hysterectomy seems to predispose to prolapse and further reconstructive surgery [285, 362] One case-control study (114/6214 women who had undergone hysterectomy, 236/6100 controls randomly selected) looked at the risk factors for reconstructive pelvic surgery. The incidence was 4.3 per 1000 women years if pelvic organ prolapse was grade 2 before the initial hysterectomy but only 0.6 if it was grade 0 or 1. Vaginal hysterectomy itself did not increase the risk [356]. The empirical fact that younger women and women operated on for severe prolapse are more likely to have recurrent prolapse has been confirmed in one follow up study of 389 women [363]. Previous surgery for pelvic organ prolapse appears to be a consistent risk factor.[364, 365]

Isolated enteroceles may occur after pelvic surgery. The classical example is the development of enteroceles after Burch colposuspension in up to 32% [366-369] Symptoms suggestive of a rectocele like digitation to defecate were more frequently observed after hysterectomy [370]. The anterior compartment is the main site of recurrence after sacrospinous fixation. In two comprehensive reviews the apical success rates after a follow up of 12 or more months were 79 – 97% (mean 92%) but the failure rate for cystoceles was 10-30% (mean 21%) [371].

14. THE BONY PELVIS

There is evidence from several case control studies that variations in axial and pelvic skeletal structure can be associated with increased risks of POP. These include increasing degrees of thoracic kyphosis, a decrease in lumbar lordosis and in vertical orientation of the pelvic inlet, and an increase in the transverse diameter of the pelvic inlet [372-374]. In a case control study Handa [375] compared 59 women with pelvic floor disorders with controls using standardized pelvimetry techniques during MRI.

After controlling for age, race and parity, using a multiple logistic regression analysis, pelvic floor disorders were significantly associated with a wider transverse inlet (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.23). The association between early age, advanced stage POP and the severe disruption of pubic bone and pelvic muscle structure in women with bladder extrophy is well recognized [376].
15. CONCLUSION AND RECOMMENDATIONS

There are genetic alterations that predispose to pelvic organ prolapse (LEVEL OF EVIDENCE 2). Differences in collagen type and ratios as well as smooth muscle organisation and neurogenic structures between women with and without prolapse are well-known but the cause and effect remain unclear (LEVEL OF EVIDENCE 2). Altered metabolism and gene expression of elastin is thought to be the cause of pelvic organ prolapse (LEVEL OF EVIDENCE 2) whereas active remodelling of the connective tissue (increase in tenascin e.g.) is likely to be a result of biomechanical stress due to the prolapse (LEVEL OF EVIDENCE 2).

POP increases with age (LEVEL OF EVIDENCE 2). Modifiable risk factors for POP are obesity (increased BMI and waist circumference), occupational heavy lifting and constipation (LEVEL OF EVIDENCE 3). Previous pelvic floor surgery increases the risk of prolapse (LEVEL OF EVIDENCE 2).

Pregnancy itself can lead to prolapse (LEVEL OF EVIDENCE 2). Vaginal delivery increases the risk for prolapse further (LEVEL OF EVIDENCE 1) but caesarean section is only partially protective (LEVEL OF EVIDENCE 2). Obstetrical aspects that are associated with loss of pelvic organ support are birth weight of more than 4000g and instrumental delivery (LEVEL OF EVIDENCE 3). The effect of maternal age at delivery remains unclear. There is no association between episiotomy and POP.

Further research should focus on modifiable risk factors and their impact on the development and prevention of pelvic organ prolapse and its recurrence. The course of pregnancy with hormonal changes cannot be altered and caesarean section is not a universal alternative to vaginal delivery. Although we should aim to make vaginal birth safer for mother and child, the mainstay of prevention of prolapse are modifiable risk factors.

II. ASSOCIATED PELVIC FLOOR CONDITIONS

Pelvic organ prolapse (POP) has a strong inter-relationship with the urinary tract and urinary incontinence commonly co-exists with POP. Thus, it is important for incontinence specialists to have a well-grounded understanding of POP in order to provide optimal patient care for the many women worldwide whose quality of life is impacted by pelvic floor disorders.

1. BLADDER FUNCTION

In a large community-based questionnaire survey, 44% (104/239) of women who had prolapse symptoms (239/3799) also complained of stress urinary incontinence and 37% of overactive bladder [377]. Animal experiments performed by Barrington in the first half of the twentieth century have suggested a mechanism by which urethral relaxation may evoke reflex detrusor contraction: when urine enters a relaxed proximal urethra, the desire to void may be evoked, an extension of his experimental observations in anesthetized rabbits, that water running through the urethra, or mechanical distension of the urethra produced a bladder contraction [378-380]. This mechanism might explain the high co-occurrence-rate of POP and bladder symptoms.

Schick et al [381] looked at 255 women with urodynamic stress incontinence and found a statistically significant correlation between urethral hypermobility and the degree of urethral incompetence assessed with the abdominal leak point pressure. However, with greater degrees of anterior vaginal wall prolapse (Stage III and IV) fewer women have symptoms of stress incontinence [382]. Increased prolapse stages (especially point Ba on the POPQ) are associated with obstructive symptoms, as severe prolapse can descend and obstruct the urethra, making assessment and management of the continence mechanism in such patients problematic [282, 382-384] [385].

Multiple studies have described an occult stress incontinence rate after various methods of reducing the prolapse during preoperative testing of [258-261]. However, Bump et al described an only 4% de novo incontinence rate in women with Stage III or IV prolapse who had been randomized to a bladder neck plication procedure as their only prophylaxis, also concluding that preoperative barrier testing was not useful in identifying women who required a urethropexy [386]. Klutke et al determined that preoperative barrier testing was most useful in identifying those women who do not leak with reduction of the prolapse, since such patients did not undergo urethropexy and had better outcomes with regard to both USI and DO rates [387]. Because of this uncertainty, the least invasive method of bladder neck stabilization seems preferred for such patients [388].

Pelvic organ prolapse can negatively affect voiding function [385, 389], although one study noted that the majority of women with severe prolapse still void effectively [390]. Looking at 228 women with urinary tract disorders and/or prolapse, Dietz et al [391] found that enterocele had the worst effect on voiding function (P<0.001), whereas the relationship between anterior vaginal wall prolapse and voiding was complex: using ultrasound the finding of an intact retrovesical angle was related to difficulties in voiding (P<0.001);
funnelling and opening of the retrovesical angle was associated with improved voiding (P<0.001). Fitzgerald found that preoperative voiding studies with the prolapse reduced by a pessary was the best predictor of normalization of residuals post operatively [392]. The impact of pelvic organ prolapse on the upper urinary tract is not well described in the surveyed literature, consisting primarily of case reports of acute or chronic renal failure attributed to urethral obstruction by Stage IV uterine or vaginal vault prolapse. Hydroureter and hydronephrosis was demonstrated in such cases, resolving post repair [393-397].

2. BOWEL FUNCTION

Bowel symptom like incontinence of flatus and obstructed defecation are common in women with POP. In several surveys, the incidence of anal incontinence ranges from 15-50% ([398-402], [377, 398, 403-405]. Faecal incontinence was reported in 5-22% of women with prolapse [398, 404, 405] which was significantly more than bowel symptoms in a control group [404]. There were no associations found between prolapse stages and symptoms after adjusting for age and BMI [403, 405].

There are also disparities between the degree of pelvic organ prolapse, pelvic floor symptoms and defecography results [406, 407]. Two series of defecographies in consecutive patients with prolapse and/or evacuation disorders describe defecographic findings that changed the patients diagnosis (though not always the management) in 46 of 62 of cases and noted enteroceles that were not found on physical exam in approximately 50% of cases [408-410]. Sigmoidoceles are present in 4-11% of reported series, and are nearly always missed on physical examination [410, 411]. Their clinical impact and management remain however unclear. Defecography is not a routine investigation in women with POP and interpretation may be difficult in some cases since normal asymptomatic women may have focal defecographic abnormalities demonstrated [407].

The prevalence of abnormal colonic transit time is approximately 20% in patients presenting with evacuation disorders [412]. An abnormal preoperative colonic transit study is the most consistently cited risk factor for failure of rectocele repair to relieve evacuatory symptoms, regardless of the surgical technique [413-415]. Recently Goh et al [416] reviewed the management of rectocele and clearly describe the complexity of clinical conditions resulting from the possible combination of various gynaecological and colorectal symptoms with anatomical abnormalities and the different surgical approaches.

3. SEXUAL FUNCTION

Dyspareunia, coital incontinence and vaginal dryness are common complaints in women with pelvic floor disorders [417, 418]. Although sexual dysfunction appears to be more frequently observed in these women, pelvic organ prolapse did not negatively impact on sexual satisfaction when controlled for confounders like age [418-420].

E. FAECAL INCONTINENCE: GASTROENTEROLOGICAL PERSPECTIVE

Faecal incontinence is maintained by the structural and functional integrity of the anorectal unit. Consequently, disruption of the normal anatomy or physiology of the anorectal unit leads to faecal incontinence. Faecal incontinence is often due to multiple pathogenic mechanisms and rarely due to a single factor [421].

I. STRUCTURE AND FUNCTION OF THE ANORECTUM

The rectum is a hollow muscular tube, 12 cm to 15 cm long, composed of a continuous layer of longitudinal muscle that interlaces with the underlying circular muscle [422]. The anus is a muscular tube 2 cm to 4 cm long. At rest, it forms an angle with the axis of the rectum of approximately 90°; during voluntary squeeze the angle becomes more acute, approximately 70°; during defecation, the angle becomes more obtuse, about 110° to 130°.

1. THE ANAL SPHINCTER

The anal sphincter consists of two muscular components: the internal anal sphincter (IAS), a 0.3 cm to 0.5 cm thick expansion of the circular smooth muscle layer of the rectum, and the external anal sphincter (EAS), a 0.6 cm to 1.0 cm thick expansion of the striated levator ani muscles. Morphologically, both sphincters are separate and heterogenous [423]. The EAS is a predominantly slow-twitch, fatigue resistant muscle [424, 425]. The IAS generates mechanical activity, with a frequency of 15 to 35 cycles per minute, and ultra-slow waves at 1.5 to 3 cycles per minute [426, 427]. The ultra-slow waves generate pressures fluctuating between 20 mm Hg and 50 mm Hg in 10% of control subjects [428-430]. The IAS contributes approximately 70% to 85% of the resting sphincter pressure, but only 40% after sudden distension of the rectum and 65% during constant rectal distension [431]. Thus, the IAS is chiefly responsible for maintaining anal continence at rest [431].

The anus is normally closed by the tonic activity of the IAS. This barrier is reinforced during voluntary squeeze by the EAS. The anal mucosal folds, together with the expansive anal vascular cushions, provide a tight
These barriers are further augmented by the pubourethral muscle, which forms a flap-like valve that creates a forward pull and reinforces the anorectal angle [434].

2. NERVE STRUCTURE AND SENSATION

The anorectum is richly innervated by the sensory, motor, and autonomic nerves and by the enteric nervous system. The principal nerve is the pudendal nerve, which arises from the second, third, and fourth sacral nerves (S2, S3, S4) and innervates the EAS. The pudendal nerve is a mixed nerve that subserves both sensory and motor function [435]. Pudendal nerve block creates a loss of sensation in the perianal and genital skin and weakness of the anal sphincter muscle, but it does not affect rectal sensation [431]. It also abolishes the rectoanal contractile reflexes, suggesting that pudendal neuropathy may affect the rectoanal contractile reflex response. It is not completely understood how humans perceive stool contents in the anorectum. Earlier studies failed to demonstrate rectal sensory awareness [436, 437]. But more recent studies have confirmed that balloon distension is perceived in the rectum and that such perception plays a role in maintaining continence [438, 439]. Furthermore, sensory conditioning can improve both hypo-sensitivity [440, 441] and hypersensitivity [442] of the rectum. Mechanical stimulation of the rectum can produce cerebral evoked responses [443] confirming that the rectum is a sensory organ. Although there are no organized nerve endings, both myelinated and unmyelinated nerve fibres are present in the rectal mucosa, and the myenteric plexus [437, 444]. These nerves most likely mediate the distension or stretch-induced sensory responses as well as the viscerovisceral, [445] the recto-anal inhibitory, and the recto-anal contractile reflexes [444]. The sensation of rectal distension is most likely transmitted along the S2, S3, and S4 parasympathetic nerves [444]. Rectal sensation and the ability to defecate can be abolished completely by resection of the nervi erigentes [446]. If parasympathetic innervation is absent, rectal filling is only perceived as a vague sensation of discomfort. Even paraplegics or persons with sacral neuronal lesions may retain some degree of sensory function, but virtually no sensation is felt if lesions reach the higher spine [439, 447]. Thus, the sacral nerves are intimately involved with the maintenance of continence. It has been suggested that bowel contents are periodically sensed by anorectal “sampling,”[448, 449] the process by which transient relaxation of the IAS allows the stool contents from the rectum to come into contact with specialized sensory organs, such as the Krause end-bulbs, Golgi-Mazzoni bodies and genital corpuscles, and the sparse Meissner’s corpuscles and Pacinian corpuscles in the upper anal canal [436, 444, 450]. Specialized afferent nerves may exist that subserve sensations of touch, temperature, tension, and friction, but are incompletely understood [444]. Incontinent patients appear to sample rectal contents infrequently [449]. The role of anorectal temperature sensation is also subject to debate [451-453]. The likely role of anal sensation is to facilitate discrimination between flatus and faeces and the fine-tuning of the continence barrier, but its precise role needs to be characterized.

3. RECTAL DISTENSION

Rectal distension is associated with a fall in anal resting pressure known as the rectoanal inhibitory reflex. The amplitude and duration of this relaxation increases with the volume of rectal distension [454]. The arrival of flatus mimics sudden rectal distension and this is associated with a fall in anal pressure [455]. Although this process may facilitate discharge of flatus, rectal distension is also associated with an anal contractile response, a subconscious reflex effort to prevent release of rectal contents, such as flatus [456-458].

The amplitude and duration of the rectoanal contractile reflex also increases with rectal distension up to a maximum volume of 30 ml [454]. Abrupt increases in intra-abdominal pressure, such as those caused by coughing or laughing, are associated with increases in anal sphincter pressure [459]. This may be achieved through multiple mechanisms, including reflex contraction of the pubourethra [460].

4. ANAL ENDOVASCULAR CUSHIONS

The blood-filled vascular tissue of the anal mucosa also plays an important role in producing a more perfect closure of the anus. An in vitro study showed that even during maximal involuntary contraction, the internal sphincter ring was unable to close the anal orifice completely and a gap of approximately 7 mm was left open. This gap was filled by the anal cushions [461]. Anal cushions may exert pressures of up to 9 mmHg and thereby may contribute 10% to 20% of resting anal pressure [462].

II. PATHOGENIC MECHANISMS AND ETIOLOGY

Faecal incontinence occurs when one or more mechanisms that maintain continence is disrupted to an extent that other mechanisms are unable to compensate. Hence, faecal incontinence is often multifactorial [421, 463]. In a prospective study, 80% of patients with faecal incontinence had more than one pathogenic abnormality [421]. Although the pathophysiological mechanisms often overlap, they may be categorized under the four subheadings shown in Table 3. For each category, the probable cause(s) and the mechanism through which it leads to faecal incontinence is also summarized in Table 3.

1. STRUCTURAL ABNORMALITIES

a) Anal sphincter muscles

Disruption or weakness of the EAS muscle causes urge-related or diarrhoea-associated faecal incontinence. In contrast, damage to the IAS muscle or the anal endovascular cushions may lead to a poor seal and an impaired sampling reflex. These changes may cause passive incontinence or faecal seepage, often under resting conditions. In most patients, both sphincters may be defective. The extent of muscle loss can influence the severity of incontinence.

The most common cause of anal sphincter disruption is obstetric trauma [464, 465]. However, it is unclear why most women who have sustained an obstetric injury in their 20’s or 30’s typically present with faecal incontinence in their 50’s. The injury may involve the EAS, the IAS, the pudendal nerves, or a combination of these structures. In a prospective study, 35% of primiparous (normal anti-partum) women showed evidence of anal sphincter disruption following vaginal delivery [465, 466]. Other important risk factors include forceps-assisted delivery, prolonged second stage of labour, large birth weight, and occipito posterior presentations [465, 467, 468]. Furthermore, perineal tears, even when carefully repaired, can be associated with incontinence and patients may either present several years following delivery [468]. Episiotomy is believed to be a risk factor for anal sphincter disruption. In one study, medial episiotomy was associated with a nine-fold higher risk for anal sphincter dysfunction [469]. However, in a large 30 year retrospective cohort study, the prevalence of frequent faecal incontinence was 6.9% for women whose index delivery was complicated by anal sphincter disruption, 18% for the control group, and 0% for women who had caesarean section; bothersome incontinence was experienced by 27.6%, 25.8%, and 15.2% of the respective groups. This study suggests that regardless of the type of delivery, faecal or flatus incontinence occurs in a surprisingly large number of middle-aged women. This raises the issue of whether age-related changes that affect the pelvic floor are a predisposing comorbid problem in the pathogenesis of faecal incontinence [470]. Whether anal sphincter pressures change with aging is debatable [471]. In both men and women 70 years of age there was a 30% to 40% decrease in sphincter pressures compared to patients 30 years [472]. In another study, elderly subjects were found to have lower sphincter pressures, [473] but many were taking medications that may have affected muscle function. In contrast, other studies that have examined anal pressures have reported only insignificant decreases with age [474]. However, in all age groups squeeze pressure has been shown to be significantly lower in women than in men [471, 474, 475]. Furthermore, in women, there appears to be a rapid fall in squeeze pressure after menopause [475, 476]. Recently, estrogen receptors have been identified in the human striated anal sphincter [477]. In an experimental study of adult rats, ovariectomy led to atrophy of the striated anal sphincter muscle, [477, 478] which suggests that the strength and vigour of the pelvic floor muscles is influenced by hormones. Also, in older women, pudendal nerve terminal motor latency [PNTML] is prolonged [472, 479] and there is excessive pelvic floor descent on straining [472, 473]. These mechanisms may lead to progressive damage to the striated anal sphincter muscle due to repeated stretch injury during straining [479-481]. An anal endosonography study also showed that aging was associated with an increase in the thickness and echogenicity of the internal sphincter muscle [482].

Other causes of anatomic disruption include iatrogenic factors such as anorectal surgery for haemorrhoids, fistula, or fissures. Anal dilation or lateral sphincterotomy may result in permanent incontinence due to fragmentation of the anal sphincter apparatus [483, 484]. Contrary to the belief of many surgeons, haemorrhoidectomy can cause incontinence by inadvertently damaging the IAS [485] or through the loss of endovascular cushions. Accidental perineal trauma or a pelvic fracture may also cause direct sphincter trauma leading to faecal incontinence. Interestingly, a study of homosexual men showed that although the anal resting pressure of the subjects was lower and the anal sphincters were thinner than those of controls, there was no evidence of sphincter injury from anoreceptive intercourse [486]. These results suggest that anal intercourse may not cause sphincter trauma, at least in men. Finally, in the absence of traumatic structural defects, internal sphincter dysfunction may also occur because of myopathy, [464] internal sphincter degeneration, [487] or as a complication of radiotherapy [488].

b) Puborectalis muscle

Sir Allan Parks believed that the pressure exerted by the anterior rectal wall together with the puborectalis muscle was fundamental to maintaining continence as it formed a flap valve mechanism [489]. This concept was disputed in another study that imaged the rectum radiologically while simultaneously measuring rectal and anal canal pressures, as well as anal electromyogram (EMG) activity, during defecation manoeuvres [490]. The authors concluded that continence was maintained primarily by increased activity of the EAS muscle and the puborectalis muscle and that rectal pressures were consistently lower than those generated within the anal canal [490]. Similar observations were made by another group [491].

Also, after successful sphincter repair, continence was associated with higher sphincter pressures and not with an altered ano-rectal angle [492]. These findings suggest that an obtuse ano-rectal angle may represent an epiphenomenon in patients with
incontinence. The nerve supply for the upper portion of the puborectalis muscle arises from direct branches of the anterior S3 and S4. Thus, the puborectalis muscle and the external anal sphincter have separate neurological innervation. Consequently, pudendal blockage does not abolish voluntary contraction of the pelvic floor [493] but completely abolishes EAS function.11, [431, 493] It has been suggested that continence can be preserved following division of the EAS and IAS provided the puborectalis muscle is intact [494]. Moreover, division of the puborectalis muscle posteriorly does not produce incontinence as long as anal sphincter pressures are normal [495]. Thus, although the puborectalis plays an integral role in maintaining continence, its precise role is poorly understood.

c) Neuropathy

An intact innervation of the pelvic floor is essential for maintaining continence. Sphincter degeneration secondary to pudendal neuropathy and obstetric trauma may cause faecal incontinence in women [481]. The neuropathic injury is often sustained during childbirth, probably due to stretching of the nerves during elongation of the birth canal or through direct trauma during the passage of the fetal head. The nerve damage is more likely to occur when the fetal head is large, when the second stage of labour is prolonged, and when forceps are applied, especially high forceps delivery or if there is prolonged labour [465, 468, 481, 491, 496, 497]. Damage to the innervation of the pelvic floor musculature is usually asymmetrical [498]. Subsequent vaginal deliveries may further damage the pudendal nerves [466]. In another study of women who sustained obstetric sphincter injury, the only risk factor associated with the development of faecal incontinence was prolonged PNTML [499].

III. AUTONOMIC NEUROPATHY

The role of extrinsic autonomic innervation is somewhat controversial. Animal studies have shown that the pelvic nerves convey relaxatory fibres to the rectum [500]. Consequently, these nerves may play a role in accommodating and storing faeces and gas [501]. Damage to the pelvic nerves may lead to impaired accommodation and rapid transit through the rectosigmoid region, overwhelming the continence barrier mechanisms. Sympathetic efferent activity, as studied by stimulating the pre-sacral sympathetic nerves, tends to relax the IAS, [501, 502] whereas parasympathetic stimulation may cause contraction of the anal sphincter. The upper motor neurons for voluntary sphincter muscle lie close to those innervating the lower limb muscles in the parasagittal motor cortex adjacent to the sensory representation of the genitalia and perineum in the sensory cortex [497]. Consequently, damage to the motor cortex from central nervous system (CNS) lesions may lead to loss of bowel control and to incontinence. In some patients with neurogenic incontinence there is damage to both the sensory and motor nerve fibres, resulting in sensory impairment [438, 503, 504]. This can impair conscious awareness of anal filling [505] as well as the associated reflex responses in the striated pelvic floor sphincter muscles. Approximately 10% of patients with faecal incontinence may have lesions more proximal than the intrapelvic or perianal nerves. The primary abnormality in these patients is cauda equina nerve injury [497] which may be occult and not evident through clinical evaluation. These patients have a prolongation of nerve conduction along the cauda equina nerve roots without an abnormality in PNTML muscles [497, 506, 507]. In a minority of patients, however, there is a combination of peripheral and central lesions [506]. Other disorders such as multiple sclerosis, diabetes, and demyelination injury (or toxic neuropathy from alcohol or traumatic neuropathy) may also lead to incontinence [508-514].

a) Rectal accommodation and reservoir function

The rectum is a compliant reservoir that stores stool until social conditions are conducive for its evacuation [514, 515]. If rectal wall compliance is impaired, a small volume of stool material can generate high intrarectal pressure that can overwhelm anal resistance and cause incontinence [516]. Etiologies include radiation proctitis, ulcerative colitis, [516, 517] or Crohn's disease, an infiltration of the rectum by tumour or following radical hysterectomy [518]. Likewise, rectal surgery, in particular pouch surgery, [519] and spinal cord injury, [520, 521] may also be associated with loss of rectal compliance.

IV. FUNCTIONAL MECHANISMS

1. ANORECTAL SENSATION

An intact sensation not only provides a warning of imminent defecation, but also helps to discriminate between formed stool, liquid faeces, or flatus. Elderly persons, [522] physically and mentally challenged individuals, and children with faecal incontinence [523] often show blunted rectal sensation. This impaired sensation may lead to excessive accumulation of stool, causing faecal impaction, mega-rectum (extreme dilation of the rectum), and overflow [522, 523]. Impaired rectal sensation may also occur as a result of neurological damage such as multiple sclerosis, diabetes mellitus, or spinal cord injury [511, 520]. Less well known is the fact that analgesics (particularly opiates) and antidepressants may also impair rectal sensation and produce faecal incontinence. That the rectum is important in preserving continence has been shown elegantly through surgical studies in which preservation of the distal 6 cm to 8 cm of the rectum,
along with its parasympathetic nerve supply, helped subjects avoid incontinence [450]. In contrast, both rectal sensation and the ability to defecate can be abolished completely by resection of the nervi erigentes [446]. An intact “sampling reflex” allows the individual to choose whether to discharge or retain rectal contents. Conversely, an impaired “sampling reflex” may predispose a subject to incontinence [449]. However, the role of the sampling reflex in maintaining continence remains unclear. In children who have had colonic pull through surgery, some degree of sensory discrimination is preserved [524].

Because the anal mucosal sensory zone is absent, it has been suggested that sensory receptors (possibly located in the puborectalis muscle) may play a role in facilitating sensory discrimination [524]. Also, traction of this muscle is a more potent stimulus for triggering both defecation and rectal distension [524].

I. NEUROGENIC TRAUMA

The mechanism that maintains continence is complex and affected by various factors such as mental function, lack of a compliant rectal reservoir, enhanced colonic transit and changes in stool consistency and volume. However the most important factors appear to be an anatomically intact anal sphincter complex and neurological function. In about 80% of women with presumed “idiopathic” anorectal incontinence there is histological evidence of denervation of the striated pelvic floor muscles, particularly the puborectalis and external anal sphincter (EAS) [530]. This feature has also been demonstrated electrophysiologically by means of an increased fibre density in patients with idiopathic faecal incontinence indicating re-innervation following denervation [531]. Another finding in these patients is a conduction delay in pudendal nerves as measured by pudendal nerve terminal motor latency (PNTML) [532].

Although Hertz in 1909 suggested that pelvic floor damage may result from a normal vaginal delivery, objective scientific evidence for this was only produced in 1984 [245] and a follow-up of 14 patients 5 years later [332]. These authors studied 122 women, 71 after delivery with manometry, perineometry, PNTML and EMG, and 51 before and after delivery with EMG. This study demonstrated an increase in anal sphincter striated muscle fibre density in the vaginal delivery group at 2 months post-partum indicating evidence of re-innervation following denervation. The fibre density was not altered following elective caesarean section. Thirty three percent of primiparae and 50% of multiparae had prolonged PNTML within 48 hours of delivery. However by 2 months, the PNTML had returned to normal in 60% of these women, indicating that damage to pudendal nerve conduction is reversible. Multiparity, forceps delivery, increased duration of the second stage of labour, third degree perineal tears and high birth weight were important factors leading to pudendal nerve damage. In the 5 year follow-up study of 14 women, only multiparae who did not have a forceps delivery were selected; the denervating process was found to be progressive in the majority of women and 5 women suffered from stress incontinence of urine, 3 of whom were also incontinent to flatus.

In another prospective neurophysiological study, Allen et al [157] reported on 96 nulliparous women with EMG, PNTML and vaginal pressure measurements during pelvic floor contraction. They found evidence of re-innervation in the pelvic floor muscles of 80% of primiparae 2 months after vaginal delivery. The only obstetric factors associated with re-innervation were a high birth weight and a longer active stage of labour. Forty five of the original 96 women were studied again 6 years later and they concluded that changes in

F. CHILDBIRTH AND FAECAL INCONTINENCE

Pregnancy and childbirth have a significant impact on the emotional and physical wellbeing of a woman. It is reported that as many as 91% of women report at least one new symptom eight weeks post-partum [525]. A fall in maternal mortality accompanied by an increase in female life expectancy (80 years in the UK) has now shifted the focus of attention towards identification of factors that may minimise morbidity. Although pre-existing bowel symptoms may be aggravated during pregnancy and childbirth, the development of symptoms de novo is a more frequent occurrence. Obstetric trauma is the most common cause of faecal incontinence.

However the onset of symptoms may occur many years after delivery with a peak incidence in the perimenopausal years. This may reflect the effect of contributory factors such as the process of aging, the effect of the menopause or progression of neuropathy. This section focuses on the association between obstetric trauma and faecal incontinence. However to avoid confusion, the term anal incontinence is used to include incontinence to flatus, liquid and solids.

Anal incontinence has been reported to occur between 5 [465, 526] to 26 [527] percent of women during the first year following vaginal delivery. In a Canadian study [528] involving 949 consecutive women who delivered vaginally, 26% reported anal incontinence while 3% reported faecal incontinence. They identified forceps delivery and third/fourth degree tears as independent risk factors. In a population based study of 8774 women in Oregon, USA, more than 25% reported faecal incontinence within 6 months of childbirth [529].
pelvic floor neurophysiology occur with time and do not appear to be related to further childbearing [533].

A third prospective study [534] measured anal pressures, anal sensation and the perineal plane in 72 antenatal women and repeated 72 hours postpartum and in 41 women 2 months postpartum. Anal sensation was unchanged. Cornes et al [535] measured anal sensation in 96 primiparous within 10 days after delivery and measurements were repeated in 74 women 6 months after delivery. They found that at 6 months anal sensation had returned to normal. Anal sensation remained unchanged after caesarean section. In women who had a torn EAS, only impairment of sensation in the upper anal canal persisted at 6 months. More than half the women who admitted to persistent anal incontinence had normal anal sensation. Chaliha et al [536] measured anal electrosensitivity before and after childbirth and found it unchanged. Anal sensation in isolation therefore probably plays a minor role in the development of obstetric related faecal incontinence.

II. MECHANICAL TRAUMA

Until the recent advent of anal ultrasound, mechanical trauma to the anal sphincters was only suspected when there was history of a difficult vaginal deliveries and particularly recognised third or fourth degree tears collectively known as obstetric anal sphincter injuries (OASIS). Consequently, when anal endosonography was performed in patients believed to be suffering from "neurogenic" faecal incontinence unsuspected internal anal sphincter (IAS) and EAS defects were identified [537]. The sonographic appearance of EAS defects has been verified histologically to represent fibrosis [538] while the appearance of IAS defects have been validated prospectively in patients undergoing lateral internal anal sphincterotomy [539]. Trauma as identified by ultrasound may be unrecognised (previously referred to as occult) or recognised OASIS.

1. UNRECOGNISED (OCCULT) ANAL SPHINCTER TRAUMA

Sultan et al [465] performed the first prospective study (before and after childbirth) to demonstrate both “occult” anal sphincter trauma (Figure 10) and pudendal nerve damage during childbirth in both primiparous and multiparous women (n=150). In 35% of primiparous and 44% of multiparous women anal sphincter defects were identified at 6 weeks postpartum by anal endosonography that were not present before vaginal delivery. Thirteen percent and 23% respectively developed defecatory symptoms (faecal urgency and/or anal incontinence) after delivery. Only 2 of the 150 women (both primiparous) had recognised tears of the anal sphincter at the time of delivery. A strong association was demonstrated between the presence of any defect and the development of symptoms. Only 4% of multiparous women sustained new sphincter damage following a subsequent delivery. The single independent factor associated with anal sphincter damage was forceps delivery. The 23 women delivered by caesarean section remained asymptomatic and none developed sphincter defects. No relationship was demonstrated between PNTML measurements and defecatory or urinary symptoms.

Donnelly et al [540] interviewed 219 nulliparae regarding bowel habit in the third trimester and performed anal vector manometry. At 6 weeks postpartum 184 women returned and the same bowel symptom questionnaire was completed and anal vector manometry plus PNTML measurements were performed. Anal endosonography was performed in 81 women with altered faecal continence or abnormal physiology. Instrumental vaginal delivery and a passive second stage of labour prolonged by epidural analgesia were significantly associated with the greatest risk of anal sphincter trauma and impaired faecal continence. As instrumental delivery is a known risk factor (8 fold increased risk of sphincter trauma), early use of oxytocin was recommended to shorten the second stage. A continuation of the same study [541] reported that PNTML was prolonged and the squeeze pressure increment was reduced in women who had a caesarean section in the late first stage (>8cm cervical dilatation) or second stage.

Chaliha et al [536] measured anal sensation and manometry in 286 nulliparous during the third trimester and repeated it in 161 women postpartum when anal endosonography was also performed. Anal endosonography revealed sphincter defects in 38% of women and this was associated with the presence of a lowering of anal squeeze and resting pressures. Threshold anal electrosensitivity remained unchanged and bore no relationship to symptoms. Postpartum sphincter defects were associated with perineal lacerations and vaginal delivery.

Abramowitz et al [542] performed a prospective study of 233 women who had anal endosonography performed before and 6 to 8 weeks after childbirth Of the 233 women (118 primiparae) 202 had a vaginal delivery. Postpartum anal incontinence in the 233 women was reported by 13% of primiparae and 8.5% of multiparae and anal sphincter defects in 21% and 12% respectively. However the prevalence of anal sphincter defects amongst those who had a vaginal delivery (n=202) was 26% and 13% respectively. Previous studies [543, 544] including others mentioned in Table 4 and 5 have shown that the first delivery is at greatest risk for anal sphincter trauma but this study is at variance as it claimed that secundiparous females have the same risk as primiparous women. However this finding remains unsubstantiated and is further disputed by a subsequent prospective study [544].

*Ultrasound performed < 1 week after delivery
** Anal ultrasound performed immediately after delivery before perineal repair
Fynes et al [545] undertook a prospective study of 59 previously nulliparous women through 2 successive pregnancies and found that 34% had anal sphincter injury after their first delivery but only 2 new injuries occurred after the second delivery confirming the findings in Sultan's study [465]. An important finding in this study was that 42% of women (5 of 12) who had occult sphincter injury during their first delivery (squeeze pressure increment < 20mmHg or anal sphincter defect > one quadrant) developed anal incontinence after the second delivery.

Willis et al [546] performed anal vector manometry, endosonography, PNTML and rectal sensitivity at the 32 weeks and 6 weeks postpartum. Using the Kelly-Holschneider score they reported anal incontinence in 5% and identified occult injuries in 19%. PNTML and rectal sensitivity was unaffected by vaginal delivery.

Nazir [547] et al performed vector manometry and endoanal ultrasound in 73 nulliparous woman at 25 weeks and 5 months postpartum (Table 4). There was no correlation between vector manometry and anal endosonography or clinical variables.

Belmonte-Montes [548] performed anal endosonography in 98 nulliparous women 6 weeks before and 6 weeks after delivery and after excluding 20 third degree tears found occult sphincter injuries in 13%. Seventy five percent of women with defects were symptomatic and there was a good correlation between defects and symptoms. However it is not clear how many with occult defects were symptomatic (Table 4).

In 3 further studies [549-551] anal ultrasound was performed only after delivery and defects were identified in 11.5 to 34% (Table 5). Varma et al [549] studied 159 postnatal women (105 primiparous and 54 secondiparous) and found occult anal sphincter defects in 11.5% of primiparous and 19% of secondiparous vaginal deliveries but 80% of forceps deliveries. None of their patients suffered faecal incontinence but only 72% of questionnaires were returned. However their cohort had a high caesarean section rate (25%) and a low forceps rate (4%).

Some 15 years after having first coined the term “occult” OASIS Sultan [465] questioned whether the 28% sonographic anal sphincter defects (Table 6) were genuine occult defects in that they were not visible following delivery. They therefore conducted a prospective study [585] in which 241 women having their first vaginal delivery had their perineum re-examined by an experienced research fellow and endoanal ultrasound was performed immediately after delivery and repeated 7 weeks postpartum. When OASIS was identified by the research fellow, the injuries were confirmed and repaired by the duty registrar or consultant. The prevalence of clinically diagnosed OASIS increased from 11% to 25% (n=59).

Every clinically diagnosed injury was identified by postpartum endoanal ultrasound. However there were 3 women with sonographic defects in whom the injury was not identified clinically. Two of these had only small IAS defects that were not considered clinically significant. The other was a combined defect of both the IAS and EAS and while this could be classified as an occult tear it is most probably an undiagnosed tear. At 7 weeks no de novo defects were identified by ultrasound. This study concluded that most sphincter defects that have previously been designated as “occult” injuries (Table 6) were in fact OASIS that could have been identified by a trained clinician [586] and that less than one percent are genuine occult OASIS (if they exist). Interestingly, 87% of midwives and 27% of junior doctors failed to recognise OASIS clinically. Although it is likely that some of these injuries would have been detected at the time of suturing the tear, it is concerning that clinical recognition of OASIS is suboptimal [586]. However this finding is not unique as Groom and Patterson [587] also found that the rate of third degree tears rose to 15% when all “2nd degree tears” were re-examined by a second experienced person.

These studies [585, 587] confirm inadequate training that was previously highlighted by Sultan et al [588] who reported that 91% of doctors who had done at least 6 months of training in obstetrics and 60% of midwives indicated inadequate training in perineal anatomy and 84% and 61% respectively reported inadequate training in identifying 3rd degree tears. Another possible reason for under-diagnosis is that tears of the anal sphincter have been wrongly classified and therefore anal sphincter tears have been under-reported. Any involvement of the anal sphincter should be classified as third degree. However 41% of doctors and 16% of midwives classified a torn anal sphincter as a 2nd degree tear [588]. Sultan and Thakar [589] reviewed every relevant text book (n=65) in the library of the Royal College of Obstetricians and Gynaecologists (RCOG) and found that there was a lack of consistency in classification and in about 40% the classification was omitted or wrong. Furthermore previous classifications were incomplete because they did not incorporate depth of EAS rupture or involvement of the IAS. This therefore has epidemiological, clinical and medicolegal implications. If a third degree tear is incorrectly classified as second degree, then inappropriate repair could result in sub-optimal outcome (see below). Sultan [590] has therefore proposed the following classification [591] that has been incorporated into the 29th RCOG green top guidelines [585] and the first edition of this book:

**First degree:** laceration of the vaginal epithelium or perineal skin only.

**Second degree:** involvement of the perineal muscles but not the anal sphincter.
Table 6. Prevalence of anal incontinence following primary repair of obstetric anal sphincter rupture (faecal incontinence ie. excluding flatus incontinence only is shown in parentheses)

*Includes 2 with secondary sphincter repair
Third degree: disruption of the anal sphincter muscles (Figures 13 & 14) and this should be further subdivided into:

3a: <50% thickness of external sphincter torn.
3b: >50% thickness of external sphincter torn.
3c: internal sphincter torn also.

Fourth degree: Third degrees tear with disruption of the anal epithelium.

An isolated rectal tear without involvement of the anal sphincter is rare and should not be included in the above classification.

2. RECOGNISED OBSTETRIC ANAL SPHINCTER INJURIES

Primary repair of OASIS (third and fourth degree tears) are usually performed by obstetricians using the end-to-end repair technique [468]. However as shown in Table 6, anal incontinence occurs in 39% (range 15 to 61%) and in addition, urgency can affect a further 6 [468] to 28% [579]. Frank faecal incontinence affected 14% [468] (range 2 [527] to 29% [581]). In five studies [468, 569, 574, 579, 583] anal endosonography was performed to demonstrate persistent anal sphincter defects following repair in 40 to 91% of women. The extent of the sphincter injury may be related to outcome of repair. However in some studies (Table 6) the data was not interpretable [560], incomplete [583] or inclusive of symptoms other than anal incontinence [575]. Forceps delivery, first vaginal delivery, large baby, shoulder dystocia and a persistent occipito-posterior position have been identified as the main risk factors for the development of OASIS [468, 542, 543, 569].

The most popular method of EAS repair is the end-to-end technique but colorectal surgeons prefer the overlap technique for secondary repair because of better outcome [592]. It is now known that like other incontinence procedures, outcome can deteriorate with time and one study has reported 50% continence at 5-year follow-up [593]. However, at least one third of women in this study had more than one attempt at sphincter repair and therefore these findings cannot be extrapolated to that following primary repair of acute injury [593]. Sultan et al [592] were the first to describe the overlap technique for acute EAS rupture and in addition advocated the separate identification and repair of the IAS. Until then very little importance was given to torn IAS during primary repair. However subsequently in a study involving 500 consecutive women with OASIS it has been shown that sonographic evidence of IAS injury was predictive of faecal incontinence [594]. When a patient presents with faecal incontinence, it is almost impossible to perform a successful IAS repair highlighting the importance of identification and repair immediately after delivery [591]. Compared to matched historical controls [468] who had an end-to-end repair, Sultan et al [592] found that anal incontinence could be reduced from 41% to 8% when the overlap technique was used for EAS repair with separate repair of the torn IAS [592] and therefore they recommended a randomised trial.

The first published randomised trial by Fitzpatrick et al [579] reported no significant difference between end-to-end and overlap repair although there appeared to be trend towards more symptoms in the end-to-end group. However there were methodological differences in that the torn IAS was not identified and repaired separately and they used a constipating agent for 3 days after the repair. Unfortunately they included partial EAS tears in their randomised study. A true overlap [591, 592] is not possible if the sphincter ends are not completely divided and it would be expected that if an overlap is attempted, the residual intact sphincter muscle would have to curl up and hence there would be undue tension on the remaining torn ends of muscle that would be overlapped. This technique would therefore go against the general principles of surgery of deliberately placing tissue under avoidable tension [591].

Garcia et al [573] also performed a randomised trial of the two techniques and took great care to include only complete ruptures of the EAS (full thickness 3b,3c and 4th degree tears). There were 23 women in the end-to-end group and 18 in the overlap group. Unfortunately only 15 and 11 women respectively returned for follow-up which was only at 3 months. No significant difference was found between the groups in terms of symptoms of faecal incontinence or transperineal ultrasound findings. However the authors acknowledged that the major limitations of their study were that randomization was inaccurate and that their study was underpowered.

Recently, Williams et al [595] performed a factorial randomized controlled trial (n=112) in which women were randomized into 4 groups: overlap with polyglactin (Vicryl; Ethicon, Edinburgh, UK); end-to-end repair with Vicryl; overlap repair with polydioxanone (PDS; Ethicon, Edinburgh, UK); end-to-end repair with PDS. This trial was specifically designed to test the hypothesis regarding suture related morbidity (need for suture removal due to pain, suture migration or dyspareunia) using the two techniques. At six weeks there were no differences in suture related morbidity. The authors claim that there were no differences in outcome based on repair technique. Unfortunately the majority of patients included in this trial were partial tears of the EAS (3a tears and as mentioned above, a true overlap [591, 592] cannot be performed if the EAS is only partially torn. Furthermore their follow up rate at 12 months was only 54%. This data therefore needs to be interpreted by caution.

Fernando et al [596] performed a randomized
Figure 13: Anal ultrasound image of the mid anal canal. EAS = external anal sphincter. IAS = internal anal sphincter. The area between the arrows at 10 and 10 o’clock represents an external anal sphincter defect.

Figure 14: Schematic representation of 3rd and 4th degree tears (with permission from Springer) [620]
controlled trial of end-to-end vs overlap technique. The study had adequate power (n=64) and the primary outcome was faecal incontinence at one year. All repairs were performed by two trained operators and superficial partial tears of the EAS (3a) were excluded. At 12 months (81% follow-up rate), 24% in the end-to-end and none in the overlap group reported faecal incontinence (p=0.009). Faecal urgency at 12 months was reported by 32% in the end-to-end and 3.7% in the overlap group (p=0.02). There were no significant differences in dyspareunia and quality of life between the groups. At 12 months 20% reported perineal pain in the end-to-end and none in the overlap group (p=0.04). During twelve months 16% in end-to-end and none in the overlap group reported deterioration of defeatory symptoms (p=0.01). Further calculation revealed that four women need to be treated with the overlap technique to prevent one woman with OASIS developing faecal incontinence. On the basis of this randomized trial one can conclude that the overlap technique of external sphincter repair accompanied by separate repair of the torn internal sphincter is performed by trained clinicians it is superior to the end-to-end repair. However as the other randomized trials included 3a tears and did not evaluate operator expertise [595] it remains to be established whether the same results would be obtained when the repair is performed by trainees.

3. MANAGEMENT OF SUBSEQUENT PREGNANCY AFTER OASIS

All women who sustained a third/fourth degree tear should be assessed in hospital by a senior obstetrician 6 to 8 weeks after delivery. Some centres have established dedicated multidisciplinary perineal clinics. It is important that a careful history is taken regarding bowel, bladder and sexual function. As these symptoms are embarrassing, a structured questionnaire may be useful. A careful vaginal and rectal examination should be performed to check for complete healing, scar tenderness and sphincter tone [585, 597, 598]. Mild incontinence (faecal urgency or flatus incontinence) may be controlled with dietary advice, constipating agents (loperamide or codeine phosphate), physiotherapy or biofeedback. However women who have severe incontinence should, in addition, be offered secondary sphincter repair by a colorectal surgeon. Asymptomatic women must be advised to return if symptoms develop [591].

There are no randomised studies to determine the most appropriate mode of delivery. Women who have had a successful secondary sphincter repair for faecal incontinence should be delivered by caesarean section [599]. Some women with faecal incontinence may choose to complete their family prior to embarking on anal sphincter surgery. It remains to be established whether these women should be allowed a vaginal delivery as it could be argued that damage has already occurred and risk of further damage is minimal and possibly insignificant in terms of outcome of surgery.

Until recently [591] the management in a subsequent pregnancy after OASIS has not been discussed in any detail [589]. It has been suggested that a caesarean section should be performed even after transient anal incontinence [499] but this has been questioned [599].

In order to counsel women with previous 3rd/4th degree tears appropriately, we find it useful to have a symptom questionnaire, anal ultrasound and manometry results. If vaginal delivery is contemplated then these tests should be performed during the current pregnancy unless performed previously and found to be abnormal. In a prospective study over a 5 year period, Scheer et al [600] found that when women who had no evidence of significant anal sphincter compromise based on anal endosonography and manometry were allowed a vaginal delivery (the others offered caesarean section) there was no deterioration in symptoms, anorectal function or quality of life. Although 11% of textbooks recommend a prophylactic episiotomy [589] there is limited evidence that an elective episiotomy prevents subsequent anal sphincter disruption [566] while other studies have indicated that episiotomy may increase the prevalence of anal sphincter disruption.

III. INSTRUMENTAL VAGINAL DELIVERY

Although only 4% of women delivered by forceps sustain a 3rd/4th degree tear, up to 50% of those that do tear have an instrumental delivery [468]. Vacuum extraction is associated with fewer 3rd/4th tears than forceps and this view is supported by 2 large randomised studies [601, 602]. A UK study [601] where mediolateral episiotomy is practised reported severe vaginal lacerations in 17% of forceps compared to 11% of vacuum deliveries and a Canadian study [602] where midline episiotomy is practised reported 3 3rd/4th tears in 29% of forceps compared to 12% of vacuum deliveries. In a Cochrane review (ten trials) [603] use of the vacuum extractor instead of forceps was associated with significantly less maternal trauma (odds ratio 0.41, 95% confidence interval 0.33 to 0.50) and with less need for general and regional anaesthesia. There were more deliveries with vacuum extraction (odds ratio 1.69, 95% confidence interval 1.31 to 2.19) and fewer caesarean sections were carried out in the vacuum extractor group. However the vacuum extractor was associated with an increase in neonatal cephalhaematomas and retinal haemorrhages. Serious neonatal injury was uncommon with either instrument.

The reduction in cephalhaematomas and retinal haemorrhages seen with forceps may be a com-
IV. EPISIOTOMY

There is now considerable observational data to indicate that a reduction in episiotomy rate is not associated with an increase in OASIS [608]. The Cochrane database [185] shows that restricting the use of episiotomy is associated with less posterior trauma. Although anterior perineal trauma was increased it had no effect on the development of urinary incontinence. Henriksson et al [609, 610] performed an observational study in which they noted when midwives who previously had a high episiotomy rate reduced their rate, the prevalence of OASIS also reduced. However this beneficial effect was abolished when midwives with a low rate of episiotomy attempted to reduce it even further. Based on this evidence, it was suggested that the ideal episiotomy rate should lie between 20 to 30% and no more. Midline episiotomies are more popular in North America as it is believed that they are more comfortable and recovery is less complicated. However Coats et al [611] performed a quasi-randomised study of 407 primiparae and found 12% of midline episiotomies extended into the anal sphincter compared to 2% of mediolateral episiotomies. Although the perineum was significantly less bruised in the midline group and sexual intercourse commenced earlier, pain and wound breakdown was similar in both groups. However care needs to be taken to ensure that mediolateral episiotomies are performed correctly as Andrews et al [612] have shown that only 22% of doctors and no midwife made the incision commencing from the posterior fourchette with a 40 to 60 degree angle from the midline. Another study demonstrated for every six degrees away from the midline there was a 50% reduction in OASIS [613].

V. DELIVERY TECHNIQUES

Pirhonen et al [614] compared the frequency of anal sphincter rupture in low risk deliveries between two Scandinavian countries (26 541 vaginal deliveries) and found the risk to be 13 times higher in Sweden (Malmo) vs Finland (Turku). They speculated that the only explanation for this was a difference in manual support given to the baby's head during crowning and pushing the perineum under the chin. The following interventions with randomized controlled trials evidence regarding effectiveness demonstrated no effect on OASIS: antenatal perineal massage, pelvic floor exercises in pregnancy, water births, positions during labour and birth, epidural analgesia, early vs delayed pushing with epidural and second stage pushing advice [607].

VI. TRAINING

McLennan et al [615] who surveyed 1177 fourth year residents and found that the majority of residents had received no formal training in pelvic floor anatomy, episiotomy or perineal repair and supervision during perineal repair was limited. Stepp et al [616] found that textbooks used in American practice offered little in terms of prevention and repair of perineal trauma. There is evidence from one study [588] that perineal anatomy is poorly understood by midwives and trainee doctors, who perform the bulk of deliveries in the UK. In this study 41% of trainees and 16% of midwives incorrectly classified a partial or complete tear of the EAS as 'second degree'. Inconsistency in classification of tears would allow many injuries to pass, unre-
cognised. It has been shown that hands-on workshops on perineal repair (www.perineum.net) can change practice [617, 618] and therefore intensive and focused training in perineal anatomy and repair should therefore become an essential module in the programme for trainees.

**VII. IRRITABLE BOWEL SYNDROME (IBS)**

IBS affects 3-17% in selected populations and the cause remains unknown. Donnelly et al [619] recruited 312 primiparous women and reported that 11% of young primiparous women (n= 34 of 208) suffered from pre-existing IBS prior to their first pregnancy. Twenty four percent reported symptoms of impaired faecal continence in the puerperium but symptoms were found significantly more frequently in those with IBS compared to those with normal bowel habit (71% vs 18%). However women suffering from IBS are no more likely to incur mechanical or neurologic injury to the anal sphincter. Women with IBS delivered by caesarean section did not have altered continence postpartum. However 6 months postpartum there were no symptomatic differences between those with IBS and those without but only 90 of the 107 women who had either impaired faecal continence or abnormal anal manometry were studied. Treatment is directed towards the predominant symptom and although antispasmodics such as hyoscine, mebeverine and dicyclomine are used widely to relax intestinal smooth muscle, they should be avoided during pregnancy.

**VIII. CONCLUSIONS AND RECOMMENDATIONS**

a) Compared to forceps the vacuum extractor is associated with less perineal and anal sphincter trauma and should therefore be the instrument of choice. (*Level 1*)

b) Compared to midline episiotomy, mediolateral episiotomy is associated with a lower risk of anal sphincter rupture (12% vs 2%). (*Level 1*)

c) Liberal use of episiotomy is not beneficial (*Level 1*) and restricting the rate of episiotomy to about 30% may reduce the risk of trauma to the anal sphincter. (*Level 4*)

d) A prolonged active second stage of labour is associated with denervation of the pelvic floor and one study has suggested that this also occurs with a prolonged passive second stage of labour with epidural analgesia. In these circumstances, early use of oxytocics in the second stage of labour may be useful. (*Level 4*)

e) Selective use of caesarean section particularly in those who have evidence of compromised anal sphincter function and those who have had previous successful continence or prolapse surgery. (*Level 5*)

f) Modification in techniques of delivery of the baby may reduce anal sphincter injury and further research is needed (*Level 5*)

g) A more focused training program for doctors and midwives needs to implement. There is a poor understanding of perineal and anal sphincter anatomy and hence identification of anal sphincter trauma, incorrect classification and poor outcome of repair (*Level 5*)

h) In experienced hands the overlap technique of external anal sphincter repair is superior to the end-to-end technique and further studies await completion to establish whether these findings can be generalized (*Level 1*)

**G. PATHOPHYSIOLOGY OF INCONTINENCE IN MEN**

Urinary incontinence in men as in women may be caused by either an abnormality of the bladder, an abnormality of the bladder outlet (sphincter), or a combination of both [621-623]. Changes in bladder ultrastructure and function that can occur as a result of neurological disease or aging (that can cause detrusor overactivity or underactivity) are similar in men and women. However there are causes of bladder and sphincter dysfunction that are unique to men. Many of these center around benign and malignant diseases of the prostate and their treatment. For example, the prevalence of detrusor overactivity and impaired compliance causing incontinence is associated with obstruction (usually caused by benign prostatic obstruction) far more often in men than in women. Also sphincter incontinence does not generally occur as the result of aging or other associated normal conditions such as pregnancy and childbirth, but rather is usually attributed to surgery or radiation of the prostate (for benign or malignant conditions) or neurological injury. Extra-urethral incontinence, which is very rare in men, is caused only by urinary fistula. Because of embryological considerations, ectopic ureter in the male does not cause incontinence as its insertion into the lower urinary tract is always proximal to the distal urethral sphincter.

In this section, we will focus on the Pathophysiology of incontinence as it relates to prostatic obstruction and its treatment and the treatment of prostate cancer.
The proximal urethral sphincter (PUS) extends from the bladder neck through the prostatic urethra above the verumontanum. The distal urethral sphincter (DUS) extends from the prostatic urethra below the verumontanum through the membranous urethra. DUS includes the rhabdosphincter (intrinsic skeletal and smooth muscle) and extrinsic paraurethral skeletal muscle. (Modified from Hadley HR, Zimmern PE, Raz S: The treatment of male urinary incontinence. In Walsh PC, Gittes RF, Perlmutter AD (Eds) Campbell’s Urology, Eds 5. B.: London, WB Saunders, 1986, p 2658) (Figure 15).

For simplicity, the normal male urinary sphincter mechanism may be divided into two functionally separate units, the proximal urethral sphincter (PUS) and the distal urethral sphincter (DUS) [624]. The PUS consists of the bladder neck, prostate and prostatic urethra to the level of the verumontanum. It is innervated by autonomic parasympathetic fibres from the pelvic nerve. This portion of the continence mechanism is removed during prostatectomy, leaving only the DUS to prevent urinary leakage. The DUS extends from the verumontanum to the proximal bulb and is comprised of a number of structures that help to maintain continence. The male DUS urethral sphincter complex is composed of the prostatomembranous urethra, cylindrical rhabdosphincter (external sphincter muscle) surrounding the prostatomembranous urethra, and extrinsic paraurethral musculature and connective tissue structures of the pelvis. The rhabdosphincter is a concentric muscular structure consisting of longitudinal smooth muscle and slow-twitch (type I) skeletal muscle fibres which can maintain resting tone and preserve continence [625, 626]. The striated muscle of the rhabdosphincter is considerably thicker ventrally and thins dorsally. Skeletal muscle fibres of the rhabdosphincter have been shown to intermingle with smooth muscle fibres of the proximal urethra, suggesting a dynamic and coordinated interaction [627]. The rhabdosphincter is invested in a fascial framework, and supported below by a musculofascial plate that fuses with the midline raphe, which is also a point of origin for the rectourethralis muscle [627]. Superiorly, the fascial investments of the rhabdosphincter fuse with the puboprostatic ligaments [628]. This dorsal and ventral support probably contributes to the competence of the sphincter. The striated fibres of the extrinsic paraurethral muscle (levator ani complex), on the other hand, are of the fast-twitch (type II) variety [625]. During sudden increases in abdominal pressure, these fibres can contract rapidly and forcefully to provide continence. Continence has been showed to be maintained after inducing paralysis of the striated sphincter [629] indicating that this structure is not solely responsible for continence. Unlike in the female where urethral support can be compromised as a result of childbirth and aging, in the male compromise to the rhabdosphincter usually occurs after trauma or surgery (e.g. prostatectomy). The striated muscle fibres of the rhabdosphincter intermingle with smooth muscle fibres of the proximal urethra and in fact have been shown to be inseparable from each other in the

I. CONTINENCE MECHANISM IN THE MALE

Figure 15: Functional anatomy of the male continence mechanism.
human male fetus [630]. However the smooth muscle fibres, which are continuous with the bladder, are divided during radical prostatectomy and the muscular vesico-prostatico-urethral continuance is interrupted. Thus continence is maintained primarily by the striated muscle of the rhabdosphincter (Figure 16).

The innervation of the DUS has been extensively studied; however, the exact details remain a point of controversy amongst anatomists. It is generally agreed that the DUS is innervated by both the autonomic (via the pelvic nerve) and somatic (by the pudendal nerve) nervous systems. Nerve fibres are seen proximally in a dorsolateral position (5 to 7 o’clock), while more distally, they are located primarily laterally, and at varying distances from the urethra [627, 631]. The intrinsic smooth muscle of the proximal urethra receives parasympathetic innervation from pelvic nerve branches of the inferior hypogastric plexus [631, 632]. The rhabdosphincter may also receive somatic innervation. Hollabaugh and colleagues described the so-called “putative continence nerves” as branches of the pelvic nerve travelling under the endopelvic fascia which pick up intrapelvic branches of the pudendal nerve, given off before it enters the pudendal canal [631]. It has also been proposed that somatic innervation from the pudendal nerve after it exits the pudendal canal is primarily sensory in origin, facilitating reflex contraction of the sphincter complex to maintain continence. [633].

A recent elegant histological and immunohistochemical study with three dimensional reconstruction in the male fetus has confirmed mixed autonomic and somatic innervation [630]. Unmyelinated (autonomic) nerve fibres destined for smooth muscle fibres run alongside of the myelinated (somatic) fibres. The majority of the unmyelinated fibres approach the smooth muscle layers at 5 and 7 o’clock while the majority of myelinated fibres penetrate the striated sphincter at 3 and 9 o’clock.

Structure and innervation are important components of sphincter function. In addition, Tuygun and associates [634] have found a much higher incidence of periurethral (or peri-sphincter) fibrosis in incontinent vs. continent men after prostatectomy. Using MRI at least 6 months after prostatectomy they discovered that all 22 incontinent men had periurethral fibrosis while only 4/14 (29%) continent men did.

In summary, sphincter continence is dependent on the integrity of the PUS and/or DUS, its support structures and neural innervation. Following removal of the PUS with prostatectomy, continence is maintained by the DUS mechanism, consisting of soft tissue supportive structures, smooth muscle, and striated muscle. The smooth muscle and slow twitch skeletal muscle of the rhabdosphincter is probably most responsible for sphincter continence; however, skeletal muscle contractions of the periurethral and paraurethral muscle are likely assist. After radical prostatectomy, the integrity or continuity of the smooth muscle fibres is lost, which may have a significant effect on their contribution to continence. Damage to the innervation (parasympathetic and somatic) of the

Figure 16: The rhabdosphincter is invested in a fascial framework, and supported below by a musculofascial plate that fuses with the midline raphe, which is also a point of origin for the rectourethralis muscle. Superiorly, the fascial investments of the rhabdosphincter fuse with the puboprostatic ligaments. This dorsal and ventral support likely contributes to the competence of the sphincter. (From Burnett AL, Mostwin JL. In situ anatomical study of the male urethral sphincter complex: relevance to continence preservation following major pelvic surgery. J Urol 1998; 160:1301-1306). [627]
smooth and skeletal muscle may indirectly contribute to post-prostatectomy incontinence. In addition compromise of the sphincter support mechanism or post operative changes such as fibrosis can compromise sphincter function.

II. INCONTINENCE ASSOCIATED WITH BPH AND ITS TREATMENT

Benign prostatic hyperplasia (BPH) and benign prostatic obstruction (BPO) and their treatments have long been associated with incontinence in men. Detrusor overactivity (DO), impaired compliance and urge incontinence are prevalent in men with BPO. In men undergoing urodynamic testing detrusor overactivity is present in 40-80% of patients with obstruction [635-637]. In addition, impaired compliance, another potential cause of incontinence has been shown to have a high correlation with outlet obstruction in men [638]. Thus even before treatment of BPH and BPO there is a notable incidence of bladder dysfunction and incontinence.

Incontinence after the treatment of BPH may be related to persistent bladder dysfunction, new onset bladder dysfunction or sphincter dysfunction (injury). Turner-Warwick et al. [639] first directed attention to the relationship of bladder outlet obstruction, the symptoms of frequency, urgency and urge incontinence (now commonly known as LUTS: Lower Urinary Tract Symptoms) and the correlation of these symptoms with detrusor overactivity seen on cystometry. They noted that in 75% of men, symptoms were relieved by prostatectomy. Leng and McGuire [640] showed improvement in compliance after relief of obstruction in 7/9 men with severely impaired compliance (< 5 ml/cmH2O), but only one man was restored to "normal" compliance. Several contemporary explanations for the cause of persistent overactivity after obstruction endure. These include denervation supersensitivity of the bladder muscle [33, 89, 641], alterations in collagen composition of the obstructed bladder [642], emergence of altered and increased sensory reflexes mediating the micturition reflex [22, 51], and physical changes in detrusor myocytes affecting electrical transmission [39]. In addition, the bladder itself and particularly the trigone may be inadvertently resected during surgery, causing bladder dysfunction. Causes of sphincter damage after transurethral resection or open prostatectomy for BPH include direct damage to endolumenal tissue distal to the verumontanum because of surgical error or loss of landmarks, unexpected infiltration of the sphincter by carcinoma with loss of urethral compliance, and electrocautery or thermal injury to the sphincter [643].

Recently, Han et al [644] conducted a retrospective data analysis using a managed care data set (Integrated Healthcare Information Services National Benchmark Database) from 1997 through 2003. They identified a cohort of men this BPH using International Classification of Diseases, Ninth Revision (ICD-9) codes. From a total of over 12 million men, 411,658 men with BPH (3.3%) were identified. The group then determined the nature of incontinence in these men with BPH focusing on its incidence, prevalence, and management. Furthermore they stratified patients by therapeutic subgroups of watchful waiting, alpha blockers, 5-alpha reductase inhibitors and surgery. Of the total cohort, 2.7% had a diagnosis of incontinence. Most of these men (87.5%) did not have prior BPH surgery, but of those who did have surgery 12.5% were diagnosed with incontinence. The rates were almost identical whether the procedure was transurethral resection or incision, laser, transurethral needle ablation, transurethral microwave therapy or open prostatectomy. The rate of incontinence was 1.4% for both stress and mixed incontinence, 4.5% for urge incontinence and 6.5% for unspecified incontinence. Incontinence rates for men on watchful waiting, alpha-blockers, 5-alpha reductase inhibitors and combination therapy were 6.4%, 5.7%, 5.1%, and 6, 5% respectively. This study provides some interesting data but must be interpreted with caution. The diagnosis of incontinence was limited by what the patient and provider considered incontinence and was often not confirmed by objective testing. Furthermore one cannot assume cause and effect related to treatments as many of these men may have sought treatment because they were incontinent. Nevertheless, the relationship of BPH and incontinence can clearly be inferred.

Until the last decade, transurethral resection of the prostate and open prostatectomy accounted for the majority of surgical procedures to treat BPO. In 1989, the American Urological Association published two major series on TURP and its complications. The AUA cooperative study included 3,885 patients from 13 teaching centres and private practices [645], while the second consisted of a survey of all practicing urologists in the United States of whom 2,716 urologists responded [646]. Rates of post-TURP incontinence requiring a pad or collection device were 0.4% in the first and 3.3% in the second study. The AUA Cooperative study also reported mild stress incontinence in 1.2% [647]. In 1994, the Agency for Health Care Policy and Research published clinical guidelines for the diagnosis and treatment of benign prostatic hyperplasia. The guidelines panel reviewed 27 articles about transurethral prostatectomy and 30 articles reporting open prostatectomy to analyze treatment outcomes. The panel reported that the risk of total incontinence, defined as complete loss of voluntary control over micturition was of great concern to patients facing a treatment decision for BPH. In an overall ranking of 15 different outcomes, the panel’s proxy judges ranked total incontinence of urine as the fourth most important outcome influencing a
treatment decision. After TURP, 2.1% of patients experienced stress incontinence, 1.9% had urge incontinence, and 1.0% had total incontinence. The panel attempted to abstract data on urge incontinence, but found very few studies reporting this particular outcome, therefore a statistical analysis was not performed. For open prostatectomy stress incontinence occurred in 1.9%, urge incontinence in 0.5% and total incontinence in 0.5% of patients.

Most studies evaluating post TURP and open prostatectomy incontinence have found a significant incidence of sphincter and bladder dysfunction. The incidence of sphincter dysfunction ranges from 20-92% and bladder dysfunction from 56-97% [648-653]. The relatively high incidence of sphincter dysfunction may seem somewhat surprising as the incidence of DO before treatment is so high and it persists in 18-59% after surgery to relieve obstruction [636, 639]. Therefore one might expect that a large number of patients would have persistent detrusor overactivity and urge incontinence. However, in large series, sphincter dysfunction appears to be the main cause of incontinence. The high incidence of sphincter dysfunction is likely to represent a selection bias, e.g. large numbers of patients referred to tertiary centres for treatment of stress incontinence. Nitti et al [654] evaluated patients with voiding dysfunction after TURP and found that of those who had incontinence 75% had bladder dysfunction, while only 20% had sphincter dysfunction (the cause of incontinence could not be identified in 5%). Twenty-seven percent of incontinent patients with bladder dysfunction also had obstruction.

In the past decade, alternatives to TURP for the treatment of BPH have emerged. Most notably are thermal therapies and laser resection/enucleation of the prostate. Thermal therapies are considered “less invasive” and outcomes in most series are not comparable to traditional TURP with respect to efficacy. However some laser treatments provide similar efficacy in well selected patients, at least in the short term. Studies that have evaluated holmium laser enucleation (HoLEP), holmium laser resection (HoLRP) or potassium titanyl phosphate (KTP) laser vaporization of the prostate have shown a similar incidence of incontinence. Two randomized controlled trials of holmium laser versus TURP have shown rates of stress incontinence to be very similar. Westenberg, et al [655] showed the incidence of stress incontinence with or without urge incontinence to be 7% for HoLRP versus 6.7% for TURP at a minimum of 4 years follow-up. Kuntz and colleagues [656] found just 1% stress incontinence in each group at 12 months. They also showed a similar rate of resolution of preoperative urge incontinence for both groups (81% versus 85%). Two other prospective non-randomized trials of HoLEP found 0.6% -2.5% incidence of stress [657]. Two randomized controlled trials of KTP (green light) laser versus TURP reported 0% and 1% stress incontinence in each group respectively [658, 659] while a third randomized trial did not mention incontinence [660]. Retrospective studies on Green light showed a 2-3.3% incidence of stress incontinence [661, 662]. Te et al [663] reported 1 year results of green light in the first US multicenter prospective trial. At 12 months 2 of 139 men had persistent new onset urge incontinence. They reported no stress incontinence.

III. INCONTINENCE ASSOCIATED WITH RADICAL PROSTATECTOMY

1. INCIDENCE

The incidence of incontinence after radical prostatectomy has been a source of controversy over the past several decades as reported rates have varied greatly depending on the definition and methodology of data collection. The incidence has probably declined over the past two decades, owing to advances in surgical technique and to earlier recognition of lower stage disease in younger patients, however the prevalence of post-prostatectomy incontinence has risen; paralleling the increase in surgical procedures performed annually [664].

In 1991, Foote et al tabulated data from series published between 1977 and 1990, and reported a range of incontinence rates from 2.5 to 87 percent after radical prostatectomy [665]. In general, older single-institution studies utilizing physician assessments to determine incontinence rates report relatively low rates (5-8%) [666-671]. A variety of definitions of incontinence were used, making comparison of data difficult. Since then, validated patient questionnaires have been developed, which help to standardize definitions of incontinence, allow easier comparison between institutions, and assess of the impact of incontinence on quality of life. This eliminates physician bias perhaps improving accuracy [672-674], although it introduces the cave at that questionnaire-based data may reflect subjective urine leakage but does not correlate with bother or actual urine, especially for mild degrees of incontinence [675, 676]. As expected these studies show the incidence of incontinence to be significantly higher, 13-65%, depending upon the definition.

In the past several years robotic radical prostatectomy has gained popularity. Similar to what is seen with open radical prostatectomy the continence rates tend to increase with longer follow-up and may continue to improve even beyond 12 months [677]. The continence rates from several large recently published series ranged from 68 to 97% at 12 months post surgery [677-681]. 20 - 27% achieving immediate continence following catheter removal [678, 680, 681]. Recently anterior vesicourethral reconstruction [682], posterior vesicourethral reconstruction [683] and total reconstruction [684] have been described to increase the continence rate and hasten time to recovery of
continence. As in earlier open prostatectomy series, robotic series tend to be single institution studies with physician reported outcomes and continence status based on no or 0-1 pads.

In 1993, The American College of Surgeons Commission on Cancer reviewed the reported results of 2,122 patients treated by radical prostatectomy performed at 484 institutions in 1990 [685]. Only 58% reported complete continence, 23% reported occasional incontinence not requiring pads, 11.2% wore 2 or fewer pads per day, 4% wore more than 2 pads per day, and 3.6% were completely incontinent. Fowler et al [686] published the results of an outcomes study on a series of Medicare patients with less encouraging results. In this series patients age >65 surveyed by mail, telephone, and personal interview, over 30 percent reported currently wearing pads or clamps to deal with wetness; over 40 percent said they dripped urine during cough or when the bladder was full; 23 percent reported daily wetting of more than a few drops. Six percent had surgery after the radical prostatectomy to treat incontinence.

There appear to be differences in physician vs. patient reported outcomes and centers of excellence versus community surgeons’ outcomes. When trying to interpret all of the data, it is clear that the varying definitions of incontinence make comparisons impossible. Even using the definition of pad free as totally continent has its limitations. Rodriguez et al [687] found that 70% of men who attained “pad-free continence” after radical prostatectomy have occasional incontinence. Conversely, Lepor et al [688] asked the single question “Do you consider yourself continent?” at 3-24 months after surgery. 97.1% of men answered yes. They found that the best correlation of objective measures with a positive were 0 or 1 pad, total control or occasional dribbling, and no or slight problem from incontinence on the UCLA/RAND questionnaire [688]. There is a dearth of good quality prospective studies evaluating incontinence after prostatectomy in an objective manner. One such study compared continence in patients undergoing open versus laparoscopic radical prostatectomy at one year, using a 24 hour pad test, symptom scores and quality of life measures [689]. Incontinence was defined as a pad weight of > 8 grams/24 hours. There were no difference in objective and subjective measures between the two groups. Urinary incontinence was present in 13% of open and 17% of laparoscopic cases. In practical terms incidence of incontinence that produces bother, no matter what its degree, is the true parameter of interest. However, because of the individual variability of bother and the way data has been collected, we must realize the limitations of the historical data in the literature. Tables 7 and 8 highlight the reported rates of post-prostatectomy incontinence.

in large contemporary series using physician-gathered and self-reported data respectively. Most large series are on radical retropubic prostatectomy as opposed to radical perineal prostatectomy.

2. RECOVERY OF CONTINENCE AFTER RADICAL PROSTATECTOMY

While the majority of patients experience incontinence immediately following RRP, in most this is transient with a gradual improvement over time. Most studies report progressive return of continence up to one year after surgery and in general intervention for incontinence is usually delayed until one year after surgery unless absolutely no progressive improvement is seen. Thus, most prostatectomy series report continence rates at 1 year. Lepor and Kaci [688] showed that continence may continue to improve up to 24 months based on objective and subjective measures. They showed modest improvements in bother (UCLA RAND questionnaire) pad usage and total control rates between 12 and 24 months. Pad weights were not determined so it is possible that some “improvements” could have been related to patient tolerance and expectations over time. Smither et al [697] objectively assessed the natural history of post radical prostatectomy incontinence using a standardized 1 hour pad test. They showed a rapid improvement in urinary control during the first 18 weeks post-RRP with a flattening of the recovery curve beyond that point. Minimal incontinence defined as ≤ 1 gm on a 1 hour pad test was as demonstrated in 3, 37, 66, 85, 87 and 91% of patients at 2, 6, 18, 30, 42, and 54 weeks. They concluded that the 18 week marker appears to be the time point after which the majority of patients have achieved urinary control, although a small percentage will have continued objective improvement.

3. RISK FACTORS

An increased risk towards post-prostatectomy incontinence in older men is supported in theory by anatomical observations. With advancing age, there is evidence of atrophy of the rhabdosphincter [627] and neural degeneration [698]. Several studies have shown advancing age to be a risk factor for postoperative incontinence [666, 667, 669, 671, 690, 699]. Steiner, et al [670] found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older. Catalona et al [666] reported that “Recovery of urinary continence occurred in 92% (1,223 of 1,325 men) and was associated with younger age (p<0.0001).

Most large series have found no correlation between the stage of disease and incontinence rates [666, 667, 672, 676]. However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing) and rates may be higher, but this appears to be a reflection on surgical technique and not disease stage [667]. Authors of several single-institution studies have argued that surgeon experience and surgical technique are important determinants of post-operative incontinence rates [631, 650, 667, 700, 701] and many have found that changes in their own technique have led to reduced rates of incontinence or a reduced time to continence recovery [631, 667, 684, 702-704]. This includes procedural modifications such as, nerve-sparing (probably secondary to a more careful dissection) bladder neck preservation, preservation of anterior urethral ligamentous attachments and urethrovesical junction reconstruction.

Patients who have undergone prior radiation for prostate cancer are at high risk of developing incontinence after radical prostatectomy. Rates of significant incontinence after salvage prostatectomy range from 57-64% [705, 706]. Sanderson and colleagues [707] reported that 45% of men underwent artificial urinary sphincter placement after salvage prostatectomy and another 31% without an artificial sphincter had incontinence greater than occasional dribbling. This has prompted some to recommend urinary diversion at the time of salvage radical prostatectomy [708].

4. ETIOLOGY AND PATHOPHYSIOLOGY OF POST RADICAL PROSTATECTOMY INCONTINENCE: SPHINCTER VS. BLADDER DYSFUNCTION

There is fairly extensive literature on urodynamic investigation of post prostatectomy incontinence. While it is well established that both bladder and sphincter dysfunction may be present after radical prostatectomy, most studies agree that sphincter dysfunction (stress incontinence) is the main cause. [648, 698, 709-712]. In these series the incidence of sphincter dysfunction ranges from 88–98.5%, with associated bladder dysfunction (detrusor overactivity and less commonly impaired compliance) in 26-46%. Bladder dysfunction, on the other hand, was present in 34–45% of patients but was the sole cause of incontinence in only 1.5–4%. Bladder dysfunction when present in association with sphincter dysfunction may not always be clinically significant. Ficazzola and Nitti [710] found that although 46% of patients had bladder dysfunction, incontinence on urodynamic study was demonstrated in only 27%. Even in those patients, sphincter dysfunction was the main cause of incontinence in the overwhelming majority. Groutz and colleagues [709] found a 33% incidence of bladder dysfunction, but found that it was the main cause of incontinence in only 7.25%. Two earlier series reported a higher incidence of bladder dysfunction [649, 650]. Some authors feel that in some patients with severe intrinsic sphincter deficiency bladder dysfunction may occur as a result of filling the bladder to volumes that it is not accustomed to holding [710]. Filling to capacity may produce detrusor overactivity or decreased accommodation. Thus, bladder dysfunction is in a
sense an artefact. This may explain why the outcomes for artificial urinary sphincters for the treatment of stress incontinence are not adversely affected by the presence of detrusor overactivity [713, 714]. In addition bladder dysfunction may be chronic and stem from obstructive uropathy present before prostatectomy. Table 9 summarizes the urodynamic findings in eight series. It must be emphasized that patient selection, urodynamic technique and timing of urodynamic evaluation maybe responsible for the differences seen among the different studies. It is also important to note that most of these studies are performed in men seeking treatment for there incontinence. However, it appears that sphincter dysfunction is the main cause of post-radical prostatectomy incontinence, but bladder dysfunction may be present in a significant number of men (though rarely alone) and must not be completely discounted when planning treatment.

The majority of evidence in the literature supports the conclusion that sphincter damage is the primary cause of incontinence after total prostatectomy. Direct exposure and manipulation of the sphincter during radical prostatectomy would suggest that sphincter damage is the most likely cause of incontinence. Successful treatment with the artificial urinary sphincter and male sling procedures also indirectly suggests that primary sphincter injury is the major cause of incontinence, since outcome is usually not complicated by bladder dysfunction. Bladder dysfunction after prostatectomy may have been present preoperatively, for example due to pre-existing outflow obstruction, may be caused by the operation itself, or may be due to age related changes in bladder function. Many patients who have prostate surgery have pre-existing bladder dysfunction, which may or may not be symptomatic. While it is obvious how overzealous TURP with resection into the trigone can cause detrusor overactivity; it is less apparent how radical prostatectomy affects detrusor function. Some have suggested that denervation of the urethra or the bladder may occur during radical prostatectomy. John et al [715] studied trigonal innervation by biochemical markers and found that "urinary incontinence was associated with decreased trigonal innervation, a high sensory threshold and low maximal urethral closure pressure".

**IV. INCONTINENCE RELATED TO RADIATION THERAPY FOR PROSTATE CANCER**

Radiation therapy, whether external beam or brachytherapy, can be a cause of voiding dysfunction and incontinence. Sometimes this is a direct effect of the radiation or it can be related to the treatment of other sequelae such as urinary retention. The initial response to is primarily oedema and then gradually degeneration, fibrosis and disorganization overcomes the bladder musculature. While radiation is primarily delivered to the prostate, portions of the bladder may also be affected. Perivascular fibrosis of blood vessels may then cause vascular occlusion followed by ischemia of the bladder wall which can then progress to fibrosis within 6 to 12 months [716]. Choo et al. [717], found that urodynamic bladder capacity decreased by an average of 54 ml, 18 months after radiation therapy. Blaivas et al [718] evaluated 47 men with symptomatic LUTS after brachytherapy and found that 71% were incontinent and 85% had detrusor overactivity. Similarly, radiation can cause damage to the distal urinary sphincter which can result in incontinence. However, this usually does not manifest until the patient undergoes treatment such as transurethral resection or incision of the prostate which compromises the proximal urethral sphincter.

Urinary retention and increased obstructive LUTS are other common problems that radiation therapy and

</table>
particularly brachytherapy is urinary retention. The incidence of retention has been reported to range from to be 2% to 30% after brachytherapy [719-722]. Most patients with retention will have resolution of their obstruction within weeks others go on with surgical procedures. A retrospective review of over 2,100 Medicare patients who underwent brachytherapy for prostate cancer found that 8.3% required a surgical procedure to relieve bladder outlet obstruction post-brachytherapy [723]. Flam, et al [724] reported that 19 of 600 (3.1%) patients receiving brachytherapy required TURP. Kollmeier and colleagues [725] reported a similar rate of 2% in 2050 men. Most authors have found significant rates of post TURP incontinence after radiation. Incontinence following TURP after brachytherapy has been reported in 0-70% and is often severe. [724-726]. External beam radiation is also a risk factor as Green et al [727] reported a 33% incidence of incontinence following TURP in patients post-irradiation for prostate cancer. Some authors have emphasized that incontinence can be minimized by performing a limited resection [728] or by performing TURP within 2 years of brachytherapy [725]. In the latter study, two of 24 patients (8%) that underwent TURP within 2 years of treatment were incontinent and 5 of 14 patients (36%) that underwent TURP 2 years or more after brachytherapy were incontinent (p=0.04). However, others suggest that delaying TURP until 5 years after radiation can actually reduce the risk of incontinence [729, 730].

V. CONCLUSIONS

Incontinence in the male as in the female can be broadly divided into that which is caused by bladder dysfunction and that which is caused by sphincter dysfunction. The pathophysiology of incontinence as it relates specifically to the male is fairly well described; however advances in science and anatomy will undoubtedly provide a more intricate understanding in the future. For example, the causes of sphincter insufficiency are known (i.e. damage to muscle, nerve and/or supporting structures) but clinicians are not able to accurately assess the exact cause of sphincter insufficiency in any given patient. Therefore much of our understanding of post treatment incontinence “pathophysiology” is derived from reports of incontinence (incidence/prevalence) after surgery or radiation. In addition investigators have not done a good job in defining the incidence of incontinence related to interventions for prostatic disease, whether benign or malignant. Problems have been two-fold: first in defining incontinence and what is bothersome/significant and second in accurately reporting data. New technologies for the treatment of BPH have provided us with Level 1 evidence regarding the incidence of incontinence in trials comparing new technology to TURP and Level 2 evidence through meta-analysis and prospective series. Data regarding the incidence of post radical prostatectomy and post radiation incontinence has been less robust and of a lower quality – level 2-4. Even the level 2 evidence lacks a consistent definition.

VI. RECOMMENDATIONS

Level of evidence 1 regarding the incidence of post prostatectomy and post radiation incontinence is needed. It is hoped that the advent of new technologies will prompt controlled trials of different therapies for prostate cancer with incontinence as a primary endpoint. These studies must start with a standardized definition of incontinence and how it affects quality of life, thus objective and subjective measures will be necessary. Such an understanding will allow clinicians to better select, prepare and treat patients and ultimately prevent or at least limit incontinence.

H. CAUSES OF TRANSIENT INCONTINENCE IN OLDER ADULTS

Transient causes probably accounts for one-third of incontinent cases among community-dwelling older people (>65 years old), up to one-half of cases among acutely-hospitalized older people, and a significant proportion of cases among nursing home residents [732-734]. Most causes of transient incontinence in the older population lie outside the lower urinary tract but two points are worth emphasizing. First, the risk of transient incontinence is increased if, in addition to physiologic changes of the lower urinary tract, the older person also suffers from pathologic changes. Overflow incontinence is more likely to result from an anticholinergic agent in a person with a weak or obstructed bladder, just as urge incontinence is more likely to result from a loop diuretic in someone with detrusor overactivity and/or impaired mobility [735, 736].

This fact may explain why some controversy persists regarding some causes of transient incontinence. It also emphasizes that continence depends on the integrity of multiple domains-mental state, mobility, manual dexterity, medical factors, and motivation, as well as lower urinary tract function. Although in younger individuals incontinence usually results from lower urinary tract dysfunction alone, incontinence in older patients often results from deficits in multiple domains that together result in incontinence [737]. Attention to any one or more of these risk factors can restore
continence or at least improve it. Second, although termed “transient,” these causes of incontinence may persist if left untreated, and so they cannot be dismissed merely because the incontinence is of long duration.

II. QUALITY OF DATA

In older people, continence status is often not absolute, especially in those who are frail. Infrequent leakage of small amounts may appear and disappear, and reporting accuracy varies as well [738]. Furthermore, ethical constraints and methodological issues preclude robust investigations of the conditions commonly impugned as causes of transient incontinence. Thus, it is not surprising that evidence supporting the association between these conditions and transient incontinence consists predominantly of case reports and case series.

III. RESULTS OF LITERATURE REVIEW

Transient causes of incontinence in older people are shown in Table 10 and can be recalled using the mnemonic DIAPPERS [739]

Table 10. Causes of Transient Incontinence in Older People

| D | Delirium |
| I | Infection (UTI, symptomatic) |
| A | Atrophic urethritis/vaginitis |
| P | Psychological (e.g. severe depression, neurosis) |
| P | Pharmacologic |
| E | Excess urine output |
| R | Restricted mobility |
| S | Stool impaction |

1. DELIRIUM

“D” is for delirium, a confusional state characterized by fluctuating inattentiveness and disorientation. Its onset occurs over hours to days, as contrasted with dementia, which develops over years. Delirium can result from almost any medication and from virtually any acute illness, including congestive heart failure, deep vein thrombosis, or infection. Many of these conditions may present atypically in older patients, and if the patient becomes confused because of them, incontinence may be the first abnormality detected [740]. Delirium leads the list because, if unrecognized, it is associated with significant mortality. Thus, in this case, meticulous medical evaluation - not cystometry-is crucial.

2. URINARY INFECTION

Symptomatic urinary infection is another cause of incontinence, although it is an uncommon one [732]. However, asymptomatic urinary infection, is much more common in older people [741, 742].

3. ATROPHIC VAGINITIS

Atrophic vaginitis in older women is frequently associated with lower urinary tract symptoms, which occasionally include incontinence. As many as 80% of such women attending an incontinence clinic are reported to have physical evidence of atrophic vaginitis, characterized by vaginal mucosal atrophy, friability, erosions, and punctuate haemorrhages. Atrophic vaginitis has been associated with urgency and occasionally a sense of “scalding” dysuria, but both symptoms may be relatively unimpressive. More recent epidemiologic and clinical studies have called these beliefs into question since they have demonstrated an association with estrogen treatment and the onset of incontinence. Unfortunately, limitations in their design allow for the possibility of both bias and confounding factors. Further research is warranted.

4. MEDICATIONS

Pharmaceuticals are one of the most common causes of incontinence in older people, with several categories of drugs commonly implicated [743] (Tables 11 and 12). Of note, many of these agents also are used in the treatment of incontinence, underscoring the fact that most medications used by older people are “double-edged swords.” The first category of relevant drugs is the long-acting sedative/hypnotics, such as diazepam and flurazepam, which can cloud an older patient’s sensorium. “Loop” diuretics, such as furosemide or bumetanide, by inducing a brisk diuresis,

can also provoke leakage. Drugs with anticholinergic side effects are a particular problem and include major tranquilizers, antidepressants, antiparkinsonian agents (e.g., benztriptine mesylate or trihexyphenidyl), first generation (sedating) antihistamines, anti-arrhythmics (disopyramide), antispasmodics, and opiates. By decreasing detrusor contractility, they can cause urinary retention and overflow incontinence. They also can cause confusion. Anticholinergic agents are particularly important to ask about for two reasons. First, older patients often take more than one of them at a time. Second, they are contained in many non-prescription preparations that older people frequently take without consulting a physician.

Adrenergically-active agents have also been associated with incontinence. Many alpha-adrenergic antagonists (used mainly for treatment of hypertension) block receptors at the bladder neck and may induce stress incontinence in women (744). Older women are particularly at risk because their urethral length and closure pressure normally decline with age. Thus, prior to considering other interventions for stress incontinence in a woman taking such a drug, substitution of an alternative agent should be tried and the incontinence re-evaluated. Calcium channel blockers can cause incontinence. As smooth muscle relaxants, they can increase residual volume, especially in older adults with impaired detrusor contractility. The increased residual urine may occasionally lead to stress incontinence in women with a weak urethral sphincter, or to overflow incontinence in men with concurrent urethral obstruction. Finally, angiotensin converting enzyme inhibitors, by inducing cough (the risk of which is age-related), may precipitate stress incontinence in older women whose urethra has shortened and sphincter weakened with age.

5. DIURESIS

Excess urinary output can also cause incontinence, especially in individuals with impaired mobility, mental state, or motivation, particularly if they also have detrusor overactivity. Causes of excess output include excess intake, diuretics (including theophylline-containing fluids and alcohol), and metabolic abnormalities (e.g., hyperglycemia and hypocalcaemia). Nocturnal incontinence can be caused or exacerbated by disorders associated with excess nocturnal excretion, such as congestive heart failure, peripheral venous insufficiency, hypoalbuminemia (especially in malnourished older people), and drug induced peripheral oedema associated with NSAIDs, thiazolidinediones, and some calcium channel blockers (e.g., dihydropyridines such as nifedipine, isradipine, and nicardipine). The role of caffeine and timing of drinking fluids (e.g. in the evening or before bedtime) is still not clear, but should nonetheless be considered a possible contributing cause for nocturia and nocturnal incontinence.

6. RESTRICTED MOBILITY

Restricted mobility is an easily understood but frequently overlooked cause of incontinence. In addition to obvious causes, restricted mobility may be associated with orthostatic or postprandial hypotension, poorly-fitting shoes, poor physical state, or fear of falling, all of which are common geriatric conditions.

7. FAECAL IMPACTION

Finally, faecal impaction has been implicated as the cause of incontinence in up to 10% of older patients seen in acute hospitals or geriatric incontinence clinics. One possible mechanism involves stimulation of opioid receptors [746]. A clue to the presence of faecal impaction is the onset of both urinary and faecal incontinence, usually associated with oozing of loose stool around the impaction.

IV. SUMMARY

Apart from re-challenge data for alpha adrenergic agents (Level of Evidence = 2), the level of evidence for most of these causes is Level 3-4. Nonetheless, because they are easily addressed and contribute to morbidity beyond the lower urinary tract, they are worth identifying even if the evidence is not strong.

V. RECOMMENDATIONS

Despite the current lack of compelling data, these seven “transient” causes of urinary incontinence should be searched for in older incontinent patients before embarking on more complex assessment and management. Their prevalence is high, their treatment straightforward, and they contribute to morbidity beyond the urinary tract. Moreover, addressing them may improve the incontinence even if it does not eliminate it, and it may make the incontinence more amenable to subsequent therapy. (Grade of recommendation C)

VI. RESEARCH PRIORITIES

Further research should be performed on the mechanisms, prevalence, incidence, and remission rates of each of the known causes of transient incontinence, and possible additional causes should be identified as well. Since older people are heterogeneous, studies should be conducted among several subgroups, including independent and homebound community-dwelling older people, bedbound and mobile institutionalized older people, and acutely hospitalized older people.

INTRODUCTION

Organization of this committee report

Urinary (UI) and faecal incontinence (FI) are a concern for individuals of all ages and both sexes. This report reviews the “initial assessment” of urinary and faecal incontinence – and in addition, reviews the available outcome measures for symptom assessment and quality of life for these disorders. Therefore, the report is divided into 2 major sections: 5A-A initial assessment of urinary incontinence (UI) in adult male and female patients, 5A-B initial assessment faecal incontinence (FI) and 5B outcome measures. The initial assessments for the conditions of incontinence in paediatric, neurogenic, and geriatric patients and for patients with pelvic pain are presented in the specific Committee reports pertaining to these sub-groups and conditions.

5A- A. INITIAL ASSESSMENT OF URINARY INCONTINENCE IN ADULT MALE AND FEMALE PATIENTS

For the purpose of this report, the ‘initial assessment’ represents the components of the history, physical examination, laboratory tests, and basic office testing to:

1. Establish a presumptive or condition specific diagnosis, and exclude underlying organ-specific related or unrelated conditions that would require intervention.
2. Assess the level of bother and desire for intervention from information obtained from the patient or caregiver.
3. Institute empiric or disease specific primary therapy based on the risk and benefit of the untreated condition, the nature of the intervention and the alternative therapies.
4. Prompt the recommendation of additional more complex testing or specialist referral.

Within the initial assessment of UI, various sub-populations / subgroups are recognized because of the differences within patient groups or the interrelationship between the conditions. The subsections in this report should be utilized in conjunction with other population or condition specific Committee Reports of the Consultation and the final recommendations of the Consultation which are presented in simplified form along with treatment algorithms in the Management Recommendations. These sub-groups include patients with lower urinary tract symptoms (LUTS) without incontinence and with pelvic pain. The requirements of specific sub-populations negate the ability to recommend a ‘universal’ initial evaluation. Pelvic organ prolapse in the female and prostatic obstruction in the male require uniquely different approaches to lower urinary tract dysfunction. Congenital and maturational issues in the paediatric subgroup and the effects of ageing on the lower urinary tract and medical co-morbidities in the geriatric group present unique challenges. Specific risks for combined storage and emptying abnormalities and upper urinary tract deterioration in the neurogenic bladder population demand a more involved initial evaluation.

This committee report is evidence based and utilizes the ICUD - EBM grades. A search of the available literature in English obtained from Medline® and Pubmed® up to June 2008 by the individual committee members utilized multiple search terms related to assessment (eg., ‘urinary incontinence’, ‘faecal incontinence’, ‘lower urinary tract symptoms’, ‘vaginal prolapse’, and terminology related to ‘outcome assessments’ and ‘quality of life measures’).
Purpose of the initial assessment

The initial assessment must consider the degree of bother, and the costs of further evaluation, balanced against the consequences of a failure to diagnose an underlying condition, the risk and benefits of conservative management or pharmacological therapy and the need for an accurate diagnosis before more complex intervention or empiric therapy. The burden of these conditions and the availability of resources to different patients, physicians, and health care systems require that primary intervention strategies be formulated, when available from evidence based findings and decisions emanating from the initial evaluation. As will be noted, especially in this committee report, the amount and sophistication of the literature that contributes to the levels of evidence that are available for determining the grades of recommendation in the area of “initial assessment” may often rely on expert opinion of the panel.

Of note, LUTS cannot be used to make a definitive diagnosis of a specific lower urinary tract condition or lower urinary tract disease (LUTD), as these symptoms may suggest and indicate pathologies such as urinary infection or more serious underlying conditions. Basic laboratory tests, such as testing for urinary or faecal infection or blood, and appropriate screening for malignancy should be considered before the decision is made to choose therapy for incontinence.

Concomitant pathology may affect urinary or faecal production as co-morbid contributory issues, by affecting fluid balance or renal function (dietary or alimentary function) and may need to be addressed. The physician should elicit neurological symptoms and signs that may indicate alterations in the control of the lower urinary tract / bowel function or the cognitive, motivational, physical, and environmental factors that determine the ability to perform toileting functions effectively.

1. STORAGE SYMPTOMS

Overactive Bladder (OAB) - Urgency with or without urge incontinence usually with frequency and nocturia in the absence of an underlying metabolic or pathological condition.

Urinary incontinence (UI) is the complaint of any involuntary leakage of urine. In each specific circumstance, urinary incontinence should be further described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage (wearing of protection, number and type of pads and change of underwear or outer clothes) and whether or not the individual seeks or desires help because of urinary incontinence. Urinary leakage may need to be distinguished from perspiration or vaginal discharge.

Stress urinary incontinence (SUI) is the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing (NIH – the patient’s or caregiver’s statement of involuntary loss of urine during physical exertion).

Urgency urinary incontinence (UUI) is the complaint of involuntary leakage accompanied by or immediately preceded by urgency. Urge incontinence can present in different symptomatic forms; for example, as frequent small losses between micturition or as a catastrophic leak with complete bladder emptying. Information should be sought on triggering events such as cold, running water and ‘latch key’ incontinence.

Mixed urinary incontinence (MUI) is the complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing or coughing.

Continuous urinary incontinence is the complaint of continuous leakage.

Other types of urinary incontinence may be situational, for example the report of incontinence during sexual intercourse. Coital incontinence may occur during arousal, on penetration, throughout intercourse, or specifically at orgasm; although urodynamic stress incontinence is the most common urodynamic finding in each of these situations, detrusor overactivity is found more often when leakage is restricted to orgasm [3].

Urgency is the complaint of a sudden compelling desire to pass urine which is difficult to defer (NIH – the statement that the patient feels a strong need to pass urine for fear of leakage).

Increased daytime frequency is the complaint of voiding too often by day (NIH - the statement that the patient voids eight or more times in 24 hours).

Increased daytime frequency may arise in the presence of a normal bladder capacity when there is
excessive fluid intake, or when bladder capacity is restricted secondary to detrusor overactivity, impaired bladder compliance, or increased bladder sensation.

**Nocturia** is the complaint that the individual has to wake at night one or more times to void (NIH - *the statement that the patient wakes from sleep to pass urine*). The term ‘night time frequency’ differs from that for nocturias, as it includes voids that occur after the individual has gone to bed, but before he/she has gone to sleep, and voids which occur in the early morning which prevent the individual from getting back to sleep as he/she wishes. These voids before and after sleep may need to be considered in research studies. If this definition were used then an adapted definition of daytime frequency is required. Nocturia may arise for similar reasons to daytime frequency, but may also occur due to an increase in fluid output due to other physiological abnormalities resulting in ‘nocturnal polyuria’. (see Bladder diaries below).

**Nocturnal enuresis** is the complaint of loss of urine occurring during sleep. Enquiry should include previous childhood nocturnal enuresis as delayed bladder control in childhood is associated with detrusor overactivity in adulthood.

**Bladder sensation** may be categorised as:

- **Normal**: the individual is aware of bladder filling and increasing sensation towards capacity.
- **Increased**: the individual feels an early and persistent desire to void.
- **Reduced**: the individual is aware of bladder filling but does not feel a definite desire to void.
- **Absent**: the individual reports no sensation of bladder filling or desire to void.
- **Non-specific**: the individual reports no specific bladder sensation but may perceive bladder filling as abdominal fullness, vegetative symptoms, or spasticity. These symptoms are most frequently seen in neurological patients, particularly those with spinal cord trauma or malformation.

**2. Voiding Symptoms**

Voiding symptoms may occur in situations of overactive outlet, or under active detrusor[1]. The former may be secondary to outlet obstruction from urogenital prolapse, urethral stricture or following previous bladder neck surgery. Detrusor atonia or hypotonia is however much more common in the female, and may arise idiothetically, or secondarily to over distension after parturition or surgery, in peripheral neuropathy due to diabetes mellitus, and in other neurological conditions. Women with prolapse may require to digitate vaginally to initiate or complete voiding.

**Slow stream** is the individual’s perception of reduced urine flow, usually compared to previous performance or in comparison to others.

**Intermittent stream (intermittency)** is when the individual describes urine flow which stops and starts, on one or more occasions, during micturition.

**Hesitancy** is when an individual describes difficulty in initiating micturition resulting in a delay in the onset of voiding after the individual is ready to pass urine.

**Straining to void** describes the muscular effort used to initiate, maintain or improve the urinary stream.

**Terminal dribble** is the term used when an individual describes a prolonged final part of micturition, when the flow has slowed to a trickle.

**Post-micturition symptoms**

Post micturition symptoms are experienced immediately after micturition.

**Feeling of incomplete emptying** is a self-explanatory term for a feeling experienced by the individual after passing urine.

**Post micturition dribble** is the term used when an individual describes the involuntary loss of urine immediately after he or she has finished passing urine, usually after leaving the toilet in men, or after rising from the toilet in women.

**3. Measuring the Frequency and Severity of Lower Urinary Tract Symptoms**

The frequency-volume chart or micturition diary records a patient’s voiding pattern during normal daily activities. In some women it may be therapeutic as it provides them with insight into their bladder behaviour [4]. The ICS has described three different forms of diary, namely the micturition time chart which records the timing of voids in twenty four hours; the frequency volume chart (FVC) which also includes the volumes voided , and the bladder diary which in addition includes incontinence episodes, pad usage, fluid intake, degree of urgency and degree of incontinence. However, increasing either the complexity of the diary or duration of recording is associated with poorer compliance [5]. The optimum duration of recording depends on the clinical context and the purpose of the measurement. A properly performed 1-day FVC, which includes the first morning void the following day, is a reasonable tool to gain insight into voiding habits during normal daily routine.

However, a 3-day FVC or diary is recommended for accurate assessment of lower urinary tract symptoms and for confirming a consistent clinical pattern in day-to-day practice. Although never completely diagnostic, several different diary patterns have been described which may characterise normal and abnormal states[6]. For atypical clinical scenarios, a 7-day FVC or diary should be used. Equally, a 7-day diary has been recommended for clinical research, [7] however, of note, most pharmacological studies now employ a
three day diary as a standard for improved patient compliance (see Committee Report Pharmacology for further recommendations.

The following measurements can be abstracted from frequency volume charts and bladder diaries:

**DAYTIME FREQUENCY** is the number of voids recorded during waking hours and includes the last void before sleep and the first void after waking and rising in the morning.

**NOCTURIA** is the number of voids recorded during a night’s sleep; each void is preceded and followed by sleep.

**NIGHT-TIME FREQUENCY** is the number of voids recorded from the time the individual goes to bed with the intention of going to sleep, to the time the individual wakes with the intention of rising.

**24-HOUR FREQUENCY** is the total number of daytime voids and episodes of nocturia during a specified 24 hours period.

**24-HOUR PRODUCTION** is measured by collecting all urine for 24 hours; this is usually commenced after the first void produced after rising in the morning and is completed by including the first void on rising the following morning.

**POLYURIA** is defined as the measured production of more than 2.8 litres of urine in 24 hours in adults. It may be useful to look at output over shorter time frames.

**NOCTURNAL URINE VOLUME** is defined as the total volume of urine passed between the time the individual goes to bed with the intention of sleeping and the time of waking with the intention of rising. Therefore, it excludes the last void before going to bed but includes the first void after rising in the morning.

**NOCTURNAL POLYURIA** is present when an increased proportion of the 24-hour output occurs at night (normally during the 8 hours whilst the patient is in bed). The night time urine output excludes the last void before sleep but includes the first void of the morning. The normal range of nocturnal urine production differs with age and the normal ranges remain to be defined. Therefore, nocturnal polyuria is present when greater than 20% (young adults) to 33% (over 65 years) is produced at night. Hence the precise definition is dependent on age.

**AVERAGE VOLUME VOIDED** is the mean volume of urine passed in each void. This is calculated by dividing total voided volume by number of voids.

**NORMALISED MICTURITION FREQUENCY** is a more meaningful way of expressing voided volume. This is defined as the number of micturitions required to pass 1 litre of urine, and is calculated by dividing 1000 ml by average volume voided. This is a more specific measure of bladder function than micturition frequency, since it takes into account behavioural, dietary and pharmacological factors that affect urine volume.

**MAXIMUM VOIDED VOLUME** is the largest volume of urine voided during a single micturition and is determined either from the frequency/volume chart or bladder diary.

**INCONTINENCE EPISODE FREQUENCY** is the number of episodes of accidental urine leakage that occur over a specified period (e.g. 24 hours).

**URGENCY** is the complaint of a sudden compelling desire to pass urine, which is difficult to defer, and which leads to a fear of incontinence. The impact of this symptom may be derived from a bladder diary by recording episodes of urgency, episodes of urgency leading to incontinence and severity of urgency (e.g. using a daily visual analogue scale).

**PAD USAGE** is the number of pads used over a specified period (e.g. 24 hours).

**Recommendations**

1. **Lower Urinary Tract Symptoms (LUTS) cannot be used to make a definitive diagnosis; they may also indicate pathologies other than Lower Urinary Tract Disease (LUTD).** Specific to this report, LUTS may include Overactive Bladder (OAB) a syndrome which may be associated with urgency incontinence (OAB-wet) or without incontinence (OAB-dry). Likewise, bowel symptoms should prompt consideration and as appropriate, an evaluation for other similar symptom based pathology. (Level 5 - Grade D)

2. **Urinary and faecal incontinence should be described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage and whether or not the individual seeks or desires help.** (Level 5 - Grade D)

3. **Urinary incontinence should be categorized by symptoms into urgency incontinence, stress incontinence or mixed incontinence and conservative (non-invasive) therapies may then be started based on this classification to treat the most troublesome component, or either component of the incontinence.** (Level 5 - Grade D) More sophisticated testing (eg. urodynamic studies) is not required prior to the institution of conservative therapy (see indications for urodynamics in the Committee Report on Urodynamic Studies). (Level 3 - Grade C)
4. A bladder diary is recommended in order to document and communicate the frequency of voids and incontinence episodes experienced by the patient - as well as additional metrics. Additional information as appropriate may include volume of intake, voided volume, and/or symptoms such as urgency or discomfort. Additional metrics may be added for research purposes such as degree of urgency or time from urgency to toileting. A bladder diary is recommended for a minimum of 3 days for accuracy (Level 3 - Grade C) as the ideal duration is not clear (Level 4). The committee acknowledges the difficulty with patient compliance and acknowledges some value of shorter periods for patient compliance. (Level 5 - Grade D).

5. Referral to a specialist is recommended for hematuria (visible or microscopic), urinary tract infection (persistent or recurrent), prolapse (symptomatic or below the introitus), obstruction or retention (symptoms or findings of palpable bladder, hydronephrosis or obstructive renal insufficiency), suspected neurological disease, mass (urethral, bladder or pelvic - benign or malignant), fistula (urinary or bowel), faecal incontinence, a history of prior pelvic surgery or radiation (incontinence, oncologic) (Level 5 - Grade D).

**Future research**

1. Standardisation of the ‘definition of symptoms’ and the ‘measurements of symptom frequency, severity and bother’ are essential for patient care and research. Continued research into the appropriate scales and metrics should be accompanied by a significant attempt to establish best practice guidelines for their use and a consensus on the adoption of universal standards.

2. Recognition and resolution of the differences in common language usage and scientific utilisation of terms should continue (e.g. common use of ‘urge to void’ and the ‘desire to void’ versus the ICS terminology of “urgency”). In addition, continued research into the development of accurate measures to objectify subjective symptoms such as “urgency”. This would include resolution of the differences in the ICS and NIH definitions (in addition to other regulatory agencies) is essential for communicating data with respect to patient care, research, and treatment outcomes.

3. Further development and standardisation of symptom assessment tools (questionnaires) to improve the diagnostic accuracy of lower urinary tract symptoms. (Refer to section 2 of this committee’s report)

4. Further validation of the accuracy of specific components of the history and physical findings to establish an accurate diagnosis and initiate non-invasive conservative or pharmacological therapy. In addition, to further identify components that would indicate the need for more invasive testing, complex therapeutic interventions, and indications for referral.

**II. URINALYSIS IN THE EVALUATION OF THE PATIENT WITH LUTS AND UI**

“The urinalysis is a fundamental test that should be performed in all urological patients. Although in many instances a simple dipstick urinalysis provides the necessary information, a complete urinalysis includes both chemical and microscopic analysis” [8].

In relation to urinary incontinence, dipstick urinalysis is not a diagnostic test, but a screening test, important in order to detect haematuria, glucosuria, pyuria and bacteriuria. Haematuria can indicate important pathology such as urothelial carcinoma in situ, leading to lower urinary tract storage symptoms including incontinence [9]. Glucosuria is relevant, as a potential indicator of diabetes mellitus. This can cause symptoms via several mechanisms including polyuria secondary to osmotic diuresis, peripheral autonomic neuropathy affecting bladder innervation leading to impaired bladder emptying and chronic urinary retention and finally due to increased risk of urinary tract infection (UTI), directly related to the glucosuria and as a sequel to impaired bladder emptying.

Pyuria and bacteriuria, detected from urinary dipstick leukocyte esterase and nitrite tests respectively, are important signs of urinary tract infection. The specificity and sensitivity of these latter tests for UTI is increased when used together compared to either individual test [10,11]. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved, although the use of urinalysis should always be associated with prognostic significance [12]. A positive dipstick urinalysis will prompt formal urine microscopy and culture to detect UTI prior to antibiotic treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence and lower urinary tract symptoms, the value of urinalysis can be illustrated by the finding that 60% of women with stable bladder will develop detrusor overactivity at the time of UTI.

The importance of urinalysis in the basic assessment of patients with urinary incontinence and lower urinary tract symptoms is not dependent on gender, age or aetiology. Indeed, it has been recommended in the evaluation of geriatric patients including nursing home residents who are incontinent, [13,14] in peri- and postmenopausal women, [15] and in older women...
reporting urinary incontinence [16]. In the latter context, it has been suggested that significant urine samples can even be obtained from disposable diapers in elderly incontinent women [17].

A Norwegian survey of general practitioners’ management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) [18]. Another survey proposed that urinalysis is one of the three-part assessment of urinary incontinence together with patient history and physical examination [19].

The clinical relevance of asymptomatic bacteriuria (without pyuria) and pyuria (without bacteriuria) in the elderly is controversial, as eradication of bacteriuria appeared to have no effect on resolution of incontinence, and many suggest that it does not deserve any treatment. [20,21].

**Recommendation**

1. It is considered standard to perform a urinalysis either by using a dipstick test or examining the spun sediment. (Level 5 - Grade D)

2. If a dipstick test is used, it is recommended that a “multiproperty” strip that includes fields for haematuria, glucose, leukocyte esterase and nitrite tests be chosen. (Level 5 - Grade D)

3. Additional tests available on urine dipstick strips, such a protein, bilirubin, ketones and pH, may be helpful in the broader medical management of patients. However, they are not essential in the context of evaluation of the patient with urinary incontinence or lower urinary tract symptoms. (Level 5 - Grade D)

**Future research**

1. Determine the role of urinalysis as a screening test in various incontinent populations, specifically the elderly patient with acute or established incontinence in combination with asymptomatic bacteriuria. Specifically, to determine the relevance of asymptomatic bacteriuria without pyuria, and pyuria without bacteriuria, in elderly patients. (see Geriatric Committee Report).

2. Determine the prognostic significance of urinalysis results and the impact of therapy the outcome of treatment of urinary incontinence.

---

**III. THE UTILITY OF POST-VOIDING RESIDUAL [PVR] URINE VOLUME DETERMINATION IN THE INITIAL ASSESSMENT OF INCONSCIENT PATIENTS**

The PVR is the volume of urine remaining in the bladder following a representative void. PVR measurement can be accomplished within a few minutes of voiding either by catheterisation or by calculation of bladder volume using a portable ultrasound scanner. Several studies have compared volumes measured with portable ultrasound scanners versus catheterisation and found portable scanners to be 85-94% accurate [22,23]. A study has imaged the bladder volume after catheterisation and found that the volume of urine remaining in the bladder after catheterisation accounted for most of the difference between the two measurements [22]. Bimanual palpation cannot reliably estimate the post-void residual urine volume [24].

Since PVR may vary, one measurement of PVR may not be sufficient [25]. PVR should probably be measured several times to increase its reliability. Griffiths et al found a significant variability in PVR measurement depending on the time of the day, with the greatest volume occurring in the morning [26]. A non-representative PVR is particularly common if the patient’s bladder is not full enough to yield an urge to void.

An increased PVR alone is not necessarily problem, but if combined with high pressures it can lead to upper tract problems. If related to UTI’s, PVR may need to be treated since UTI’s may not be eradicated in the presence of an infected residual. A significant PVR also decreases the functional bladder capacity and contributes to urgency/frequency, urge incontinence and nocturia. However, a Scandinavian study in nursing home residents found that an elevated PVR was not associated with bacteruria and incontinence [27].

Review of the literature does not show an evidence-based specific maximum PVR that is considered normal, nor is there a minimal PVR that is considered abnormal. The amount of residual urine that precludes treatment by various therapies has also not been determined. The AHCPR guidelines state that, in general, a PVR less than 50 ml is considered adequate bladder emptying and over 200 ml is considered inadequate emptying (expert opinion of the panel members) [28].
“Normal values” of PVR have been determined in several groups of non-incontinent and incontinent women. Gehrich et al studied 96 women (mean age 60 ± 11 yrs) that were seen in a well-women clinic. These women had no history of incontinence, retention, symptomatic prolapse or neurologic disorders. Most (97%) had a minor (asymptomatic) degree of prolapse, 80% was post-menopausal and 30% had had a hysterectomy. The median PVR was 19 ml (range 0-145 ml; mean 24 ± 29 ml); only 5% had PVR > 100 ml. Only, age > 65 yrs was associated with higher PVR [29]. Tseng et al studied 107 women with urodynamic stress incontinence. They found a mean PVR of 62.5 ml by bladder scan and 38.5 ml by catheterization. Only 15.9% had a PVR greater than 100 ml. The PVR determined by bladder scan offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 ml [30]. Haylen et al studying women with lower urinary tract dysfunction found that 81% had a PVR of less than 30 ml Postvoid residual volumes higher than this level are significantly associated with increasing age, higher grades of prolapse, and an increased prevalence of recurrent UTIs. [31]. Fitzgerald et al studied women with urgency, frequency and urge incontinence: 10% had an elevated PVR of > 100ml. In these women with OAB, the following independent risk factors of increased PVR were found: vaginal prolapse, symptoms of voiding difficulty and absence of stress-incontinence [32]. Lukacz et al found that only 11% of women with pelvic floor disorders had an elevated PVR [33]. Wu and Baguley studied 319 consecutive patients (196 women, 123 men) in a subacute general, but predominantly geriatric, rehabilitation unit. 22 had been admitted with catheter and were excluded. Of the 297 “asymptomatic” patients, 21.5% had PVR volumes of 150 mL or more. Patients with elevated PVR (> 150 ml) were significantly more likely to have a urinary tract infection at admission and have urinary incontinence on discharge [34]. Milleman et al retrospectively reviewed 201 women (mean age 55; range 20-90) who presented with complaints of urinary frequency, urgency and/or urge incontinence. 19% had an elevated PVR of more than 100 ml (mean 211 ml; range 100-997 ml). On multivariate analysis the following independent predictors of raised PVR were identified: age > 55 yrs [OR 3.71], prior incontinence surgery [OR 4.32], a history of multiple sclerosis [OR 15.32] and pelvic organ prolapse grade 2 or greater [OR 3.61] [35].

In summary, an elevated PVR > 100 ml was found in 5% of women visiting a well-women clinic, in 10-15% of women with OAB, in 11% of women with pelvic floor disorders and in 15.9% of women with urodynamic SUI.

Does a significant PVR have an impact on the outcome of treatment in patients with incontinence? Nager et al studied the predictive value of urodynamic measures on stress urinary incontinence outcomes after surgery for stress urinary incontinence. They found that urodynamic measures do not predict outcomes. However, since women with PVR > 150 ml were excluded in this study, one can only conclude that PVR volumes < 150 ml did not have an adverse impact on stress incontinence outcome [36].

**POST VOIDING RESIDUAL URINE IN THE MALE PATIENT**

PVR measurement is especially recommended in men with suggestive of bladder outlet obstruction (BOO). PVR can be measured within a few minutes of voiding by catheterization to confirm that the bladder is empty [37] or by ultrasonography [38]. The AHCPR guidelines state that, in general, a PVR less than 50ml is considered adequate bladder emptying and over 200ml is considered inadequate emptying. More recently, a dedicated ultrasound system has been developed for automatic measurement of PVR, thereby improving the accuracy over catheterization [39] which has been largely abandoned in clinical practice. International Consultation on BPH defined a range of 50 to 100 ml as the lower threshold to define abnormal PVR [40]. Both the AUA and the EAU guidelines suggest a threshold of 300 ml to identify patients at risk of unfavorable outcome following LUTS / BPO treatment [41,42].

There is no consensus about the relation between PVR and UTI in the male patient. Although the negative role of large residuals has been reported, the evidence is controversial. Large residual urine volume has been considered a bad prognostic factor for disease progression. However, in the standard patients, renal failure, acute retention and UTIs are uncommon in men with large, chronic residuals [43]. No factors are available to identify patients, with significant residual urine, who are at risk for progression [44].

Therefore, on the basis of these trials, untreated LUTS may place the male patient at risk for potential clinical deterioration. Thus, periodical measurements of PVR are recommended in such patients.

**Recommendations**

1. Female patients who present with storage specific symptoms, with normal sensation and no complaints of decreased bladder emptying, and no anatomical, neurological, organ-specific, or co-morbid risk factors for retention may be assessed for bladder emptying by history and physical examination alone, depending on the potential morbidity of the failure to diagnose and the nature of the intended therapy. (Grade B).

2. A palpable bladder on physical exam is an indication for referral to a specialist (Grade D).
3. Residual urine determination by bladder scan is preferable to catheterisation due to the increased morbidity associated with instrumentation. (Grade D).

4. Due to the increased possibility of bladder outlet obstruction due to prostatic obstruction is increased in the male patient, the threshold for investigating residual urine in the male is significantly lower (Grade D).

5. A PVR should be performed in patients where decreased bladder emptying is suspected, especially if treatments that decrease bladder contractility or increase outlet resistance are being considered. (Grade D)

Summary of recommendations

Varying degrees of decreased bladder emptying or urinary retention may be a cause of LUTS that are associated with symptoms of decreased urinary storage.

The decision to perform a PVR in disease specific sub-groups of patients (eg., male patients with bladder outlet obstruction, in neurogenic patients who demonstrate combined disorders of storage and emptying, and preoperatively in female patients being considered for incontinence surgery) should be based on an association of the condition with poor bladder emptying (Grade D), whereas in individual patients this decision may be based on symptoms or physical findings. (Grade C)

Future Research

1. Development of more specific indications for PVR testing for diagnosis and prior to instituting therapy based on history, physical examination, and disease specific findings.

2. Further development of low cost, minimally invasive, and accurate means of measurement of PVR that do not require catheterisation.

3. Continued research in subsets of patients is required to determine the need for PVR assessment and the correlation between elevated PVR and treatment outcome, generally, to determine the effect of varying levels of PVR on the outcomes of observational, conservative, pharmacological and surgical interventions, and more specifically, the female patient prior to surgeries that increase outlet resistance, the male patient with bladder outlet obstruction where medications that can potentially decrease bladder contractility are considered, and the patient with elevated residual urine where intermittent catheterization is not practical and where recurrent urinary tract infections and decreased functional bladder capacity are potential complicating factors.

IV. THE FEMALE PATIENT

1. GENERAL MEDICAL HISTORY

The general history should include questions relevant to precipitating and aggravating factors of urinary loss, time of onset and duration of symptoms, and degree of bother. Acute symptoms may be further defined by documenting patterns of fluid intake and output, acute infection, recent surgery or trauma. Chronic symptoms may be further defined by eliciting a history of congenital abnormalities, neurological disease, relevant surgery or general health. Information must be obtained on medications with known or possible effects on the lower urinary tract. The general history should also include assessment of menstrual, obstetric, sexual and bowel function. The reader is referred to the report of the Committee on Epidemiology for risk specific risk factors to be considered during the medical history and to the second section of this report for recommendations for disease specific questionnaires.

2. URINARY SYMPTOMS

Women with urinary incontinence may have had the condition for many years before presenting; they are often embarrassed in disclosing their condition and are likely to have undertaken significant adaptations to their lifestyle to ameliorate their symptoms [45]. In establishing the history the opportunity should be taken not only to describe symptoms, but also their progression, impact on lifestyle and possible risk factors. Multiple symptoms are commonly reported, [46] and during the history it is important to define the most troublesome symptoms and the patient’s expectations from treatment.

Section 2 of this Committee Report presents a complete review and evaluation of questionnaires that are applicable for clinical and research use in evaluating patient symptoms. Structured condition specific questionnaires may be used, [47]and may be either clinician or self-administered. Questionnaires may facilitate disclosure of embarrassing symptoms, ensure that symptoms are not omitted, and standardise information thereby aiding audit and research.

3. CORRELATION OF SYMPTOMS AND SIGNS WITH SOPHISTICATED TESTING

Harvey & Versi evaluated the symptom and sign of stress incontinence in predicting the presence of urodynamic stress incontinence, using the results of a MEDLINE search for ‘urinary incontinence’, ‘urodynamic’ or ‘urodynamics’ [48]. Of 42 articles evaluated, 12 yielded analysable data. The isolated symptom of stress incontinence had a positive predictive value (PPV) of 56% for the diagnosis of pure urodynamic stress incontinence (USI) and 79% for USI with other abnormalities. The PPV for stress
incontinence with other symptoms was 77% for USI with or without other abnormalities. A positive cough test had a PPV of 55% for the diagnosis of pure USI and 91% for USI with other abnormalities. They concluded that in isolation, either symptom or sign were poor predictors of USI, although in combination prediction may be more promising [48].

Horbach reviewed the literature regarding the reliability of stress symptoms in predicting USI; PPV values ranged from 64% to 90% [49]. Summitt et al reported that 53% to 71% of women with detrusor overactivity (DO) gave similar histories to those with pure USI [50]. The PPV of a history of pure urge incontinence may be as low as 37%, [51] and overactive bladder symptoms (OAB) only 54%, [52] in the diagnosis of DO. It is however of interest to note that in a secondary analysis of data from a drug study in patients with predominant stress incontinence, the main determinant of concurrent urge symptoms was not the pathophysiological condition present (i.e. the presence of concurrent detrusor overactivity) but the severity of incontinence [53].

Martin et al, have reported a systematic review of methods of assessing urinary incontinence (54). From an electronic search of MEDLINE, EMBASE and CINAHL between 1966 and 2002 they identified 6009 individual papers; only 197 were relevant, and of these 121 reached the standards required of their report. Only a limited number could be combined and synthesised, although they were able to conclude that a large proportion of women with urodynamic stress incontinence can be correctly diagnosed in primary care from clinical history alone (sensitivity 0.92; specificity 0.56). The value of validated scales and pad tests could not be determined from the available data. The urinary diary appears to be the most cost effective of tests that might be used alongside clinical history within the primary care setting (sensitivity 0.88; specificity 0.82) [54].

Holroyd-Leduc performed a systematic review concerning the most accurate way to determine the type of urinary incontinence during an office assessment was performed incorporating a review of the literature form 1966-July 2007. The authors found that “In women, simple questions modestly helped diagnose stress urinary incontinence but are more helpful in diagnosing urge urinary incontinence. They concluded that a positive bladder stress test may help diagnose stress urinary incontinence, however, a negative test is not as useful. Also, a systematic assessment combining the history, physical examination, and results of bedside tests to establish a clinical diagnosis appears to be of modest value in diagnosing stress urinary incontinence. In addition, a systematic assessment is less helpful in diagnosing urge urinary incontinence They concluded that “the most helpful component for diagnosing urge urinary incontinence is a history of urine loss associated with urgency. A bladder stress test may be helpful for diagnosing stress urinary incontinence [55].

The reader is referred to the report of the Committee on Sophisticated Testing - Urodyamics for specific indications for complex testing

4. OTHER SYMPTOMS OF PELVIC FLOOR DYSFUNCTION IN THE FEMALE PATIENT

a) Prolapse symptoms

The feeling of a lump (“something coming down”), low backache, heaviness, dragging sensation, or the need to digitally replace the prolapse in order to defaecate or micturate, are amongst the symptoms women may describe who have a prolapse. Prolapse symptoms may be associated with urinary storage or emptying symptoms. Outlet symptoms as diverse as genuine or occult stress incontinence or obstruction, and bladder overactivity or underactivity may have a common aetiology, exist as a cause or effect, or co-exist with lower urinary tract dysfunction.

b) Bowel symptoms

In addition to urinary complaints, women may have symptoms relating to bowel function, sexual function, and pelvic organ prolapse (POP). Jackson et al. evaluated 247 women with either UI or POP. Thirty one percent of women with UI and 7% with POP had concurrent anal incontinence (AI) [56]. In a report from Sweden, 62% of 21 consecutive women undergoing a Burch colposuspension for urodynamic stress urinary incontinence had concurrent faecal incontinence [57]. In a Norwegian study of women presenting with a complaint of urinary incontinence (UI), 38% of the women were found to have significant prolapse and 19% reported faecal incontinence [58]. All these aspects of the pelvic floor and pelvic floor function must be included to plan a comprehensive treatment strategy.

c) Symptoms associated with sexual dysfunction

Dyspareunia, vaginal dryness and coital incontinence are amongst the symptoms women may describe during or after intercourse. These various symptoms are reported by one third to two thirds of women with stress incontinence, and 68% report their sex life to be spoilt by their urinary symptoms [59]. Symptoms of sexual dysfunction should be described as fully as possible; it is helpful to define urine leakage as occurring during arousal, on penetration, during intercourse, or at orgasm (vide supra) [3].

5. PHYSICAL EXAMINATION

a) General examination

There are few data linking bladder, bowel, or sexual function to variations in examination findings of women seeking routine gynaecological care. Similarly data on
women with complaints of urinary incontinence do not include detailed, specific information about their pelvic examinations.

Physical examination is essential in the assessment of all women with lower urinary tract dysfunction. Height and weight should be recorded so that body mass index can be calculated (Kg/M²); this has recently been shown to be a significant risk factor for incontinence [59].

Neurological examination should be performed, with attention to the sacral neuronal pathways. Assessment of gait, abduction and dorsiflexion of the toes (S3) and sensory innervation to the labia minora (L1-L2), sole and lateral aspect of the foot (S1), posterior aspects of the thigh (S2), and perineum (S3) and cutaneous sacral reflexes (bulbo-cavernosus and anal reflexes) may be assessed. A rectal examination will provide a subjective assessment of resting and voluntary anal tone (S2-S4). For patients with possible neurogenic lower urinary tract dysfunction, a more extensive neurological examination is needed (vide infra).

The agitated patient with urgency and frequency might have a behavioural cause and those who are clinically depressed have a less successful response to surgical treatment for stress urinary incontinence. A mental state assessment will assess cognitive function, and is particularly helpful in the elderly (vide infra). Restriction in mobility may lead to functional incontinence and a lack of hand dexterity may preclude self-catheterisation and the use of prosthetic continence devices.

b) Abdominal examination

Scars from previous surgery should be noted. Increased abdominal striae may be found in association with other markers of abnormal collagen metabolism, and are more likely in patients with prolapse and stress incontinence [60].

An attempt should be made to palpate the kidneys, particularly where a voiding dysfunction or neurogenic bladder dysfunction are suspected. A distended bladder may be identified by abdominal palpation or by suprapubic percussion. In one study designed to look at the clinical utility of basic assessment in elderly women, palpable enlargement indicated a post-void residual volume of at least 300ml [61].

c) Perineal/genital inspection

Inspection of the vulva and perineum allows a description of the skin and, for example, the presence of any abnormal anatomical features, of atrophy or excoriation, and erythema due to incontinence and the wearing of pads.

The patient should be asked to cough and strain to demonstrate stress urinary incontinence and to observe urethral length, position, and mobility, and reflex contraction of the external anal sphincter. Howard and associates tested vesical neck descent during cough and Valsalva manoeuvre [62]. They found incontinent women have similar vesical neck mobility with both manoeuvres, whereas continent women have less vesical neck descent with a cough than with Valsalva.

The clinical sign of urinary incontinence is defined as urine leakage seen during examination; this may be urethral or extra-urethral.

Stress urinary incontinence is the observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing. If stress urinary incontinence is suspected, provocative stress testing (direct visualization) can be performed by having the individual relax and then cough vigorously while the examiner observes for urine loss from the urethra. Optimally these tests should be done when the patient's bladder is full, but they should not be performed when the patient has a precipitant urge to void. The test is usually performed initially in the lithotomy position, although if no leakage is observed, it should be repeated in the standing position, since the yield is increased when the test is repeated in the upright position. Coughing may induce a detrusor contraction, hence the sign of stress incontinence may only be a reliable indication of urodynamic stress incontinence when leakage occurs synchronously with the first cough and stops at the end of that cough. It has however been shown that following an increase in intra-abdominal pressure, and the immediate fall in urethral closure pressure, there follows a 'refractory period' of several seconds during which the urethra maintains a lower pressure than at rest [63].

The extent of pressure loss, and the time to recovery are both less in stress continent then stress incontinent women [64]. If further increases in intra-abdominal pressure occur during this time, stress leakage is more likely to be demonstrated after a series of coughs than following a single cough.

Bonney's original stress test was performed to demonstrate urinary leakage during coughing [65]. Subsequent modifications of the test require support of the urethra-vesical junction during coughing in women who leak during a stress test. These modifications are not reliable in selecting a surgical procedure or in predicting cure.

Extra-urethral incontinence is defined as the observation of urine leakage through channels other than the urethra. This may result from congenital abnormality such as ectopic ureteric opening, or from urogenital fistula.

d) Urethro-vesical junction (bladder neck) mobility

Urethro-vesical junction (bladder neck) mobility should
 postmenopausal women. 

be assessed in all women with urinary incontinence. It is generally felt that women with urodynamic incontinence fall into several categories based on assessment of urethral support and urethral function. The choice of therapy may be affected by the assessment of bladder neck mobility [66]. One method of assessing bladder neck mobility is by visual inspection. When the patient is in lithotomy position, the urethral meatus is horizontal to the floor in a woman with good bladder neck support. When she decreases intra-abdominal pressure you can observe for posterior rotation of the anterior vagina and deflection of the meatus toward the ceiling, both signs of some loss of support. You may ask her to contract the pelvic muscles to determine if urethral support improves with muscle contraction, a sign pelvic floor training may be therapeutic.

The cotton swab or Q-tip test is a simple out-patient procedure to quantify bladder neck mobility [66]. A sterile, lubricated cotton or Dacron swab (Q-tip) is inserted into the urethra until it lies just within the urethra-vesical junction. Using a goniometer, the angle circumscribed by the distal end of the swab is measured relative to the horizontal while the woman is performing a maximum Valsalva effort. Urethra-vesical junction hypermobility is defined by a maximum strain axis exceeding +30 degrees from the horizontal.

There are no published reports about the reproducibility of the cotton swab test for measuring bladder neck hypermobility, despite its widespread clinical application in the evaluation and management of women with urinary incontinence. The validity of this test for diagnosing stress urinary incontinence was not systematically evaluated until 15 years after its introduction. At that time, investigators found that a sizable minority of women with the urodynamic diagnosis of stress incontinence did not have a positive cotton swab test result [66] (considered a straining angle >30°) and that many women with a positive cotton swab test result did not have stress urinary incontinence on urodynamic testing. The test was not able to distinguish women with stress incontinence from continent control subjects [67,68], or women with stress incontinence from those with other urologic disorders [69]. The cotton swab test is now used primarily to assess results of incontinence surgery or to determine whether the degree of urethral hypermobility may influence treatment outcomes. Although the test is simple to perform, the insertion of the small cotton swab may be uncomfortable for some women. Investigators have explored other methods to assess hypermobility, including the POP-Q anatomic evaluation system and ultrasonography. In one study, the correlation coefficient between the cotton swab straining angle and point Aa (the urethro-vesical junction) on the POP-Q system was 0.47 [70]. However, the cotton swab test was positive in 95% of patients with stage II prolapse at point Aa and in 100% of patients with stages III and IV prolapse at point Aa, which suggests that the test may be unnecessary in patients with stage II or greater prolapse at point Aa.

A study evaluating the use of a urinary catheter to assess urethral hypermobility used the Q-tip test for comparison in women with urinary incontinence and pelvic organ prolapse. Results of the study showed reduced angles of excursion from resting to Valsalva manoeuvre using a catheter [71].

Ultrasoundography can be used to measure the angle between the urethra and an axis corresponding to the pubic symphysis, the urethra, the bladder base, and the position of the internal urethral meatus. Other tests to document bladder neck mobility are used, including bead-chain cystourethrography, and videocystourethrography. The report of the Committee on Imaging of the urinary tract addresses the place of these techniques.

A comparison study was conducted to assess the interobserver reliability of the Q-tip test, the Sensor-Q trade mark test and ultrasonographic measurement of urethral mobility in women. 90 women took part in the study; and underwent one method of the assessment by two different clinicians. The correlation coefficient of the Q-tip test, the Sensor-Q trade mark test and the ultrasonographic measurement was 0.83, 0.92 and 0.43, respectively. The Sensor-Q trade mark and Q-tip test showed a higher inter-observer reliability for the evaluation of urethral mobility compared to ultrason sound assessment [71,72].

The Q-tip test has been used in a number of studies evaluating changes in urethra-vesical junction hypermobility and efficacy of surgical treatment of stress incontinence including mid-urethral tapes, vaginal wall sling procedures and Burch colposuspension [73-80]. A study investigating factors associated with severity of stress incontinence in women found that reduced urethral mobility using the Q-tip test was associated with greater severity of urinary incontinence [81].

Correlation of Q-tip test and urethroscopic imaging of the f bladder neck was assessed in stress incontinent women. After the Q-tip test, patients underwent an urethroscopy; at bladder capacity the patient was asked to strain and opening or closing of the bladder neck was noted. An abnormal Q-tip test during Valsalva (> 30°) was observed in 80% of patients. The authors suggest that a Q-tip test could diagnose bladder neck opening with a sensitivity of 91% and a specificity of 35% [82]. The correlation between the straining Q-tip angle and anterior vaginal wall prolapse assessed using the POP-Q system has been investigated in a number of studies. Noblett et al assessed the correlation between urethral mobility and anterior wall prolapse, in order to determine whether the Q-tip test was necessary in patients with stage 0/1 prolapse graded using the POP-Q system.
Results of this study suggested that the POP-Q system was highly predictive of urethral hypermobility; the positive and negative predictive values were 82% and 94% respectively [83].

A retrospective analysis conducted by Larrieux et al also concluded that descent at point Aa is a strong predictor of urethropelvic junction mobility, however urethral length did not affect the correlation between Q-tip angle and point Aa [84]. Zyczynski et al investigated the correlation between POP-Q graded anterior vaginal wall prolapse and Q-tip test findings in urinary incontinent women. The study showed that on clinical examination, one third of the study participants with urethral hypermobility by Q-tip test had a well supported urethropelvic junction. The results of this study suggested that clinicians who determine urethral mobility by watching descent of the distal anterior vagina during Valsalva manoeuvre may underestimate the true incidence of urethral hypermobility [85]. Mattison et al and Rosencrantz et al conducted retrospective reviews of a clinical database in order to determine the correlation between POP-Q evaluation of anterior vaginal wall prolapse and the straining Q-tip angle [86]. Mattison et al found the correlation between Q-tip straining angle and point Aa was 0.54 (P<0.001). Rosencrantz found correlation values between 0.26 and 0.78. Both studies concluded that urethral hypermobility could not be predicted from POP-Q measurement alone [87]. The Q-tip has not been shown to be predictive of Valsalva leak point pressures in women with urethral hypermobility and stress urinary incontinence [88].

e) Vaginal examination

Presently there are few scientific data documenting the parameters of a normal pelvic examination in women of various ages and with various obstetrical histories. The components of the examination have not been universally agreed upon. It seems intuitive the examination should include an assessment of the bony architecture, pelvic floor muscle tone and muscle mass, connective tissue support, the epithelial lining of the vagina, the size, location, and mobility of the uterus, the adnexal structures, and innervation of the pelvic floor structures.

It is important to establish the oestrogen status as oestrogen receptors are present within the lower urinary tract [89], and are shown to influence cell proliferation [90]. Women with oestrogen deficiency may complain of urgency and frequency and recurrent urinary tract infections may develop because of loss of urethral mucosal coaptation. In women of reproductive age symptoms may vary with the menstrual cycle [91].

The well oestrogenised vagina has a thickened epithelium, with transverse rugae in its lower two-thirds. The poorly-oestrogenised vagina has a thinned epithelium with loss of transverse rugae [92]. A number of authors have shown that vaginal pH levels are generally 5 or less in women with no infection and other definitive signs of good oestrogen effect. The use of a pH indicator paper may help you evaluate the oestrogen status in women with no vaginal infection [93]. The appearance of vaginal secretions may suggest a vaginal infection; urine within the vagina suggests genitourinary fistula, hypospadias or ectopic ureter.

Bimanual examination is performed to determine the size of the uterus and of the ovaries. Some women have co-existent pelvic disease which may require attention in addition to the urinary incontinence. When hysterectomy or oophorectomy is indicated, there is no adverse effect on surgical success with a colposuspension procedure. Pelvic masses are rarely the cause of urinary incontinence, and rarely does hysterectomy by itself relieve incontinence.

Urethral diverticula are occasionally congenital but most are acquired. They may have either a simple or complex sacculation. Many patients with urethral diverticula are asymptomatic and need no treatment. Symptomatic patients report recurrent cystitis, frequency, dysuria, dyspareunia, urinary incontinence and voiding difficulties. On clinical examination a sub-urethral mass may be palpable; the urethra is usually tender; and, if the sacculation communicates with the urethra, it may be possible to express a purulent exudate from the urethra. Occasionally, a stone may develop within the diverticulum [94].

6. PELVIC ORGAN PROLAPSE

The anterior, superior, and posterior segments of the vagina should be examined for pelvic organ prolapse. The examiner may use a mirror to demonstrate the findings to the patient; she can then confirm that the examiner has identified the extent of prolapse that she experiences. If the patient indicates that she normally has a greater amount of prolapse that you presently see, provocative manoeuvres which normally are associated with her symptoms may be undertaken, and the examination repeated while the patient is standing.

Several systems for the description and classification of prolapse have been described. This may be quantified descriptively as slight, moderate, marked [95], or first, second and third degree, or objectively using the Baden and Walker halfway method [96], or the International Continence Society Pelvic Organ Prolapse Quantification (ICS POP-Q) [97], or modified POP-Q [98]. In the latter, utilizing the introitus as the threshold, six specific vaginal sites and the vaginal length are assessed using centimetres of measurement from the introitus. In addition, the lengths of the genital hiatus and perineal body are measured in centimetres. Figure 1 demonstrates the summary diagram of this quantitative system.
A simplified technique for use of the POP-Q system was evaluated for inter-examiner agreement and inter-system association with the standard POP-Q exam in 48 subjects. The four areas examined are the anterior and posterior vaginal walls, the apex/cuff, and the cervix. In a patient who is post-hysterectomy, only three measurements are taken: the anterior and posterior vaginal walls and the cuff scar/apex. Kappa statistics (0.86) revealed good agreement between examiners using the simplified POP-Q system. Inter-system agreement was evaluated using Kendall’s tau-b statistic (0.90) also indicating good agreement between the two classification systems [99].

The pelvic organ prolapse quantification index (POP-Q-I) has been proposed for use in the research setting, as it provides a continuous variable rather than categorical variables. The POP-Q was modified such that points Aa, Ab, C, Bp, and Ap are measured. Point D is used only for the identification of patients with cervical hyperplasia. Genital hiatus, perineal body, and total vaginal length are not assessed. The POP-Q-I has not undergone rigorous validation [100,101].

The original POP-Q system has been used extensively in research settings for the assessment of short-and long-term outcomes of pelvic floor surgeries [102-105] including the use of mesh [106-120], laparoscopic surgery [121-123], robotic assisted vault suspension [124], sexual dysfunction associated with pelvic organ prolapse, [125-128], and also in community-based prevalence studies and selected patient populations with pelvic organ prolapse [129-138].

The POP-Q has been used in the validation of the Brazilian version of the vaginal symptoms module of the ICIQ, [139] and for an interviewer-administered pelvic floor symptoms questionnaire [140].

A novel speculum has been designed to facilitate use of the POP-Q system. The top and bottom blades of the speculum are adjustable and are marked in centimeters from the tip to the base of the blade. [141] Figure 2.

**POP-Q definitions ICS report - simplified**

Pelvic organ prolapse is defined as the descent of one or more of anterior vaginal wall, posterior vaginal wall, and apex of the vagina (cervix/uterus) or vault (cuff) after hysterectomy.

**Anterior vaginal wall prolapse** is defined as descent of the anterior vaginal wall so that the urethra-vesical junction (a point 3cm proximal to the external urinary meatus) or any anterior point proximal to this is less than 3cm above the plane of the hymen.

The well-supported anterior vaginal wall should not cross the longitudinal axis of the vaginal canal. Hypermobility of the urethra-vesical junction is demonstrated by having the patient perform a maximum Valsalva effort. In women with hypermobility the increase in intra-abdominal pressure causes descent of the urethra-vesical junction (bladder neck). On vaginal examination there may be loss of the transverse crease between the lower and middle thirds of the anterior vaginal wall and descent of the anterior vaginal wall. Anterolateral protrusion into the vaginal canal may represent unilateral or bilateral detachment of the pubocervical fascia along the anterolateral vagina sulcus from its attachment to the arcus tendineus fascia pelvis (white line). Central protrusions of the anterior vaginal wall may represent defects in the pubocervical fascia below the trigone and base of the bladder. Advanced prolapse of the upper anterior vaginal wall may obstruct a well-supported bladder neck.

**Prolapse of the apical segment of the vagina** is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix, below a point which is 2cm less than the total vaginal length above the plane of the hymen. Descent of the cervix or of the vaginal apex following hysterectomy, below the level of the ischial spines is evidence of a defective vaginal suspension mechanism. In some women, the intravaginal portion of the cervix may become elongated and cause the cervix to extend into the lower vaginal canal, simulating prolapse; however the fundus may have good support. In other women the uterus may prolapse fully outside the hymen as uterine procidentia. Following hysterectomy the vaginal cuff may be well supported or may prolapse fully outside the hymen along with other vaginal segments.

**Posterior vaginal wall prolapse** is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3cm above the level of the hymen or any posterior point proximal to this, less than 3cm above the plane of the hymen. The well-supported posterior vaginal wall should not cross the longitudinal axis of the vaginal canal. Posterior protrusions into the vaginal canal are most commonly caused by defects in the recto-vaginal fascia allowing protrusions of the small bowel (enterocoele) and/or rectum (rectocele). Normally, the anterior vaginal wall lies upon the posterior vaginal wall. Therefore, protrusions of the posterior vaginal wall can affect the function of the urethra and bladder which lie upon the anterior vaginal wall. For example, distal loss of support in the posterior segment may result in a bulge which compresses the urethra and affects voiding.

As with most new systems, clinicians and researchers have mixed opinions regarding this system. Excellent inter- and intra-observer reliability has been established, although patient position may affect reproducibility in that the degree of pelvic organ prolapse was higher when women were examined in a birthing chair at a 45° angle rather than in dorsal lithotomy. This system has been widely adopted for
Figure 1: ICS POP-Q. Six sites (points Aa, Ba, C, D, Bp, and Ap), genital hiatus (gh), perineal body (pb), and total vaginal length (tvl) used for pelvic organ support quantitation.

Figure 2: Speculum with adjustable blades and scale markings designed to allow easier assessment of pelvic organ prolapse using the POP-Q system. (Diokno AC, Borodulin G. A new vaginal speculum for pelvic organ prolapse quantification (POPQ). Int Urogynecol J Pelvic Floor Dysfunct. 2005 Sep-
pelvic organ prolapse researchers. In addition to collecting specific centimetre measures, an ordinal stage (0-IV) can be assigned.

Absence of prolapse is categorised as stage 0 support; prolapse can be staged from stage I to stage IV. The clinical utility of such a classification might be questioned, since clearly some degree of descent is the norm especially in a parous population. In a study of 477 women attending for annual gynaecological examination, Swift et al found that the average number of positive responses to a 7-question prolapse questionnaire was 0.27 in patients with stage 0 prolapse, 0.55 for stage I, 0.77 for stage II, and 2.1 for stage III. They concluded that women with prolapse with the leading edge beyond the hymenal ring had a significantly increased likelihood of having symptoms.

In a general population of Swedish women ages 20-59, the prevalence of prolapse was found to be 31%, whereas only 2% of all women had a prolapse that reached the introitus. It might seem more reasonable therefore to define prolapse not on the basis of any finding greater than stage 0, but on the basis of findings with a significant likelihood of being associated with symptoms.

Urinary incontinence and pelvic organ prolapse are separate clinical entities which often coexist. Significant protrusions of the vagina can obstruct voiding and defecation. Surgical repair of one pelvic support defect without repair of concurrent asymptomatic pelvic support defects appears to predispose to accentuation of un repaired defects and new symptoms. Women with pelvic organ prolapse may have to reduce their prolapse in order to void. Women with pelvic organ prolapse and a large PVR should be evaluated for voiding phase dysfunction (e.g., outlet obstruction, detrusor hypotonia).

Although anatomy can be measured and assessed accurately, reproducibly and reliably, the relationship of these anatomic findings with functional abnormalities is not well understood. For example, support abnormalities in the anterior vaginal wall are common in vaginally parous women; however, stress urinary incontinence is not always associated with this anatomic alteration. Likewise, distal posterior vaginal wall support abnormalities may exist with or without defecation abnormalities. The important relationships between anatomy and function are one of the most pressing research needs in the field of physical examination for women with pelvic organ prolapse.

Other important research needs include the development of clinically relevant ordinal staging that more accurately separates meaningful prolapse from anatomic changes following vaginal delivery. Such revised staging would allow a meaningful dialog about the appropriate surgical indications for pelvic organ prolapse and development of clinically relevant anatomic outcome measures.

7. RECTAL EXAMINATION

Digital rectal examination allows the description of observed and palpable anatomical abnormalities and is the easiest method of assessing pelvic floor muscle function in children and men. In addition, rectal examination is essential in children with urinary incontinence to rule out faecal impaction. In all women a digital rectal examination is also performed to assess sphincter tone (both resting and active) and to detect faecal impaction or a rectal mass.

8. ADDITIONAL BASIC EVALUATION

a) Pad tests

The objective of pad testing is to quantify the volume of urine lost by weighing a perineal pad before and after some type of leakage provocation. This test has also been used in an attempt to distinguish continent from incontinent women. Pad tests can be divided into short-term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a full bladder or with a fixed known volume of saline instilled bladder before beginning the series of exercises. A pad weight gain >1 g is considered positive for a 1-hour test, and a pad weight gain >4 g is positive for a 24-hour test. There is wide variation in the pad weight gain in incontinent women participating in clinical trials. Although some studies have found high test-retest correlations in pad tests [142,143], other studies have reported low inter-subject and intra-subject reliability [144,148]. Traditional pad testing may be negative in women with mild leakage; an alternative “paper towel test” was shown to be a simple and reliable measure of cough-related urine loss typical of mild stress incontinence. (149) Long-term tests are more reproducible. The correlation coefficient between total leakage during two 24-hour pad tests is good, at 0.66 [150] and 0.82 [151] and increased to 0.90 in one study in which two 48-hour periods were compared. There was no correlation between the leakage volume found in the 48-hour test and a standard 1-hour test.

b) Dye testing

When it has proved impossible to confirm a patient’s complaint of urinary leakage, it may be appropriate to seek to confirm firstly that the reported discharge is in fact urinary, secondly that the leakage is extra-urethral rather than urethral, and thirdly to establish the site of leakage. Although other imaging techniques undoubtedly have a role in this regard, carefully conducted dye studies should be considered. Excessive vaginal discharge or the drainage of serum from a pelvic haematoma postoperatively may simulate a urinary fistula. If the fluid is in sufficient quantity to be collected, biochemical analysis of its urea content in comparison to that of urine and serum will confirm its origin. Phenazopyridine may be used orally (200mg
txs), or indigo carmine intravenously, to stain the urine and hence confirm the presence of a fistula. The identification of the site of a fistula is best carried out by the instillation of coloured dye (methylene blue or indigo carmine) into the bladder via catheter with the patient in the lithotomy position. The traditional ‘three swab test’ has its limitations and is not recommended; the examination is best carried out with direct inspection; multiple fistulae may be located in this way. It is important to be alert for leakage around the catheter, which may spill back into the vagina creating the impression of a fistula. It is also important to ensure that adequate distension of the bladder occurs as some fistulae do not leak at small volumes; conversely, some fistulae with an oblique track through the bladder wall may leak at small volumes, but not at capacity. If leakage of clear fluid continues after dye instillation a ureteric fistula is likely, and this is most easily confirmed by a ‘two dye test’, using Phenazopyridine to stain the renal urine, and methylene blue to stain bladder contents[152].

c) Pelvic floor muscle strength

Pelvic floor muscle function: can be qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, weak or absent or by a validated grading system (e.g. Oxford 1-5). A pelvic muscle contraction may be assessed by visual inspection, by palpation, electromyography or perineometry. Factors to be assessed include strength, duration, displacement and repeatability.

The continence mechanisms imply that integrity of the levator ani and external urethral sphincter is necessary to maintain continence [153]. It is therefore important to test the contractility of these muscles. Once the patient understands how to contract the pelvic floor muscles correctly, the evaluation is carried out during a maximum contraction [154].

**Strength** is defined as the maximum force or tension generated by a muscle or muscle group [155]. It reflects the power, endurance and functional status of the muscle.

**Weakness** is defined as failure to generate the expected force.

**Fatigue** is defined as failure to maintain the expected force with continued or repeated contraction [156].

When considering methods/devices used to measure pelvic muscle strength, cost and availability should be recognized as important factors. Four methods of assessment are considered here: observation, digital palpation, perineometry and cotton swab (Q-tip) testing.

**Observation** - This qualitative measure can detect an in-drawing of the anus, lifting of the posterior vaginal wall and narrowing of the vaginal introitus (females); an in-drawing of the anus and slight lifting of the penis (males).

**Digital palpation** - Palpation of the right and left levator ani, per vaginam. Palpation of the perineal body.

**Perineometer** - Manometric measure of change in a vaginal/anal pressure probe. Sensitivity depends on the device.

**Cotton swab (Q-tip) test** - Downward, posterior movement of stem (measured on a goniometer) is dependent on the strength of the contraction of the pubo-coccygeus muscles, and mobility of the urethra [160].

- **Advantages**: Suitable for both sexes and all age groups, where an internal evaluation may be inappropriate. Inexpensive. Able to detect reflex contraction with cough, and bulbocavernous reflex. Observe accessory muscle activity.
- **Disadvantages**: Subjective. Cannot distinguish right and left sides independently. Generally observing activity of the superficial perineal muscles, and assuming levatores are responding in a like manner. Difficult to observe when the patient is standing.

**Advanced palpatory methods**

- **Advantages**: Suitable for both sexes. Inexpensive. Able to differentiate right from left. Qualitative - using modified Oxford scale or other systems [157,158]. Able to measure strength and endurance. Can detect reflex contraction with cough and patient’s ability to hold contraction during a cough. Can be used when the patient is standing.
- **Disadvantages**: Subjective. Not sensitive.

**Invasive methods**

- **Advantages**: Suitable for both sexes. Inexpensive. Able to measure strength and endurance. Quantitative. Can be used when the patient is standing.
- **Disadvantages**: Unable to distinguish right from left. Pressure changes may be caused by increase in intra-abdominal pressure, due to co-contraction of the abdominal muscles. No ‘Gold Standard’ device; different results with different probe sizes and materials [159].

The information learned from assessment of pelvic floor muscle strength has the following practical applications:

1. The patient has good pelvic floor muscles that need skill training to help maintain continence. DeLancey and associates have described ‘knack’ teaching [161,162].
2. The patient has weak muscles that are capable of contracting but need strength and skill training.
An effective exercise program should increase resting tone (Type I fibres) as well as improve the ability of fast twitch (Type II) fibres to respond to increases in intra-abdominal pressure [163].

3. The patient has no perceptible contractions and needs further evaluation (EMG, MRI, neurophysiologic testing) or passive contraction therapy i.e., functional electro stimulation.

Recommendations

1. Although the value of individual urinary symptoms and symptom complexes in predicting the underlying abnormality of lower urinary tract function is not high, a significant proportion of women with stress incontinence can be correctly diagnosed from basic evaluation only. Grade C

2. The frequency/volume chart or urinary diary is the most effective additional test for use alongside basic evaluation in primary or secondary care. Grade C

3. In assessing patients with urinary or faecal incontinence, the clinician should consider all aspects of pelvic floor dysfunction, i.e. urinary, bowel, prolapse, and sexual function. Grade D

4. Prolapse visible at the introitus or below may be associated with symptoms (Level 3) In describing patients with pelvic organ prolapse, one of the several systems available for classification and quantification of urethral hypermobility and pelvic prolapse should be employed. The ICS recommends the POP-Q. (Grade D). In addition, an assessment of pelvic floor identification and strength should be considered. Grade D

Future research

1. Correlation of symptoms and physical findings with urodynamic and colorectal investigations, and both basic and complex evaluations with treatment outcomes.

2. The development of a clinically relevant ordinal staging that meaningfully separates significant from insignificant pelvic organ prolapse.

3. Impact of surgical interventions for incontinence on pelvic organ support, and for pelvic organ prolapse on continence mechanisms.

V. THE MALE PATIENT

1. CHARACTERISTICS OF MALE INCONTINENCE?

In the male patients, lower urinary tract dysfunction, and obstruction from benign prostatic enlargement presents a multi-factorial paradigm for symptom aetiology. Lower urinary tract symptoms (LUTS) in men have a significant effect on quality of life (QOL), as compared with the unaffected general population. [163]. Several epidemiological reports demonstrated that overactive bladder (OAB) syndrome also increase with age in men [164,165]. Older age and higher grade of obstruction has been reported in men with bladder outlet obstruction and idiopathic detrusor overactivity [166].

In the NOBLE study, a different sex-specific pattern emerged for OAB with or without urge incontinence [165]. The prevalence of OAB with urge incontinence displays a steeper age-related increase among women than among men and the gender difference is statistically significant. In women, OAB with urge incontinence increased more than nine-fold from 2.0% in those 18-24 years of age to 19.1% among those 65-74 years of age. In contrast, a substantial increase in prevalence of OAB with urge incontinence among men did not occur until 65 years of age, reaching 8.2% for ages 65-74 years and 10.2% for those 75 years and older. In men, OAB without urge incontinence increased approximately three-fold, from 8.5% below 45 years of age to 21.8% after 55 years of age, whereas OAB without urge incontinence gradually increased in women less than 44 years of age and reached a plateau in women over the age of 44 years.

‘Prevalence ratios for OAB with urge incontinence and for OAB without incontinence were significantly elevated for men who self-reported with a history of prostate problems. Thus, the evaluation of men with symptoms of OAB syndrome depends on the identification and assessment of lower urinary tract obstruction that may be a cause (in part or in entirety) of the presenting symptoms.

The aetiology of obstructive symptoms may vary, from benign prostatic hyperplasia (BPH), urethral stricture, primary bladder neck dysfunction, or abnormal voiding dynamics of detrusor. Chronic prostatic pain syndromes (e.g. non-bacterial chronic prostatitis) and other pelvic floor dysfunctions can also present with
a component of symptoms compatible with OAB. In younger men, primary bladder neck dysfunction is a common cause of LUTS, with or without pelvic pain [167]. Functional abnormalities of striated sphincter relaxation may also occur in young men [168]. The complexity of the presenting symptoms and the various differential diagnoses mandate a thorough basic assessment of the lower urinary tract in men to plan optimal therapeutic intervention.

Another important issue in male patients is incontinence after surgery or intervention for BPO and prostate cancer. A survey in England of 5276 patients who had undergone TURP found that one-third of men (n=1759 men) who were continent before surgery reported some incontinence 3 months post-TURP [169]. Recently many minimally invasive and surgical techniques in management of BPO have been reported. A systematic review of the literature showed Urinary incontinence is more often seen following TURP (1.4%). The rate of urinary incontinence after other techniques are as follows: HIFU: 0.0%, ILCP: 0.1%, TUMT: 0.1%, TUNA: 0.0%, TUVP: 0.9%, VLAP: 0.2%, HoLEP: 1.2% [170].

It has been reported that after permanent prostate brachytherapy, urinary incontinence was observed 0-19% [171]. After radical prostatectomy, Donnellan et al reported that 6 % of men were mildly incontinent, 6 % were moderately incontinent and 4 % were severely incontinent at 1 year after surgery [172]. Carson et al. reported that incontinence occurs in 0.5 to 1.0% of all patients undergoing prostatectomy for benign disease; high rates (5 to 30%) are associated with radical prostatectomy [173].

Although prostatectomy has a clinically significant beneficial effect on LUTS with significant improvements of AUA symptom index and flow rate, [174,175] urinary leakage can have a major impact on QOL. Greater degrees of urine loss are correlated with greater bother and more significant life-style changes [172]. A Medicare survey by Fowler showed that in 1072 patients, more than half of the patients with urinary leakage considered it to be a medium or large problem [176]. In spite of these findings, many investigators have been encouraged by overall patient satisfaction with surgery and patients willingness to undergo surgery again, if faced with the same situation [176].

In the immediate postoperative period, stress and urge incontinence are common. This has been attributed to varying degree of oedema and inflammation present in the healing prostatic urethra. The majority of men achieve continence without invasive intervention following total prostatectomy. Final continence status should be measured using self-administrated disease specific instruments at 24 months after operation [176]. And no factors (age, severity of LUTS, Gleason score, bilateral nerve sparing surgery and estimated blood loss) were identified that predicted early return of continence [172].

Post-prostatectomy incontinence may be caused by sphincter malfunction and/or bladder dysfunction. [177,178]. Urinary control in the adult male depends on integrity of both the internal and external sphincters. During TURP, the internal sphincter mechanism is virtually destroyed, and in some cases, the external sphincter is also damaged. Thus post-prostatectomy stress incontinence may result.

In a recent study of patients undergoing radical prostatectomy that specifically evaluated detrusor dysfunction [179] de novo detrusor underactivity and impaired or poor compliance, presumed to be a consequence of bladder denervation, occurred in a limited proportion of patients (28.6% and 18.4% respectively), and this bladder dysfunction resolved in the majority within 8 months. Detrusor underactivity and decreased bladder compliance are also pre-existing conditions in about 30% and 20% of patients.

The conditions relate to the presence of BOO, and they do not appear to be influenced by prostatectomy. Persistent detrusor overactivity after obstruction relief is probably related to concomitant sphincter deficiency and stress urinary incontinence, which increase afferent nerve activity of the proximal urethra and induce involuntary detrusor contractions [180].

Obstruction after prostatectomy, resulting from an anastomotic stricture or residual prostatic tissue (post TUR-P), may also play an important role in the development of post-prostatectomy incontinence. Obstructing stricture often causes increase in post-void residual urine, resulting in the urinary leakage and/or a weak urinary stream. It has been reported that the anastomotic stricture treatment rates after radical prostatectomy are 16% to 33% [181,182].

2. GENERAL MEDICAL HISTORY

The medical history should focus on the urinary tract, previous surgical and radiation therapy history, medical condition and symptoms that may cause to bladder dysfunction or polyuria, familial history of prostate diseases (BPH and cancer), and a review of sexual and bowel habits. Urinary incontinence is rare in men without a history of previous trauma or prostatic or pelvic surgery; therefore, neurogenic bladder dysfunction must be considered in men with no history of surgery or trauma. A critical assessment of current medications is recommended to exclude the effects of any pharmacological agents on lower urinary tract function.

In the evaluation of the patients with post-prostatectomy incontinence, an important aspect of the history should be a description of the type and severity of incontinence and precipitating events. Severity may be determined by the number of episodes per day, the
need for protection (e.g., pads, penile clamp, external catheter), and the impact of incontinence on activities of daily living. Bladder diaries and pad tests can quantify severity. The presence of other LUTS such as OAB and decreased force of urinary stream should be determined.

3. SYMPTOM ASSESSMENT

Diagnostic assessment of men with LUTS depends on an initial estimation of subjective bother and objective data on bladder emptying. Because the occurrence of LUTS does not necessarily indicate concomitant prostate enlargement and/or obstruction, specific modalities should be used to ascertain the potential for the aetiologic role of these entities. A bladder diary may be useful in almost all male patients, especially in those with OAB. Bladder diary completion by the patient provides useful evidence about the normal urinary habits of the patient, including giving some estimate of bladder capacity and diurnal and nocturnal frequency, urgency and incontinence. The data obtained from frequency-volume chart provide a strong correlation to cystometric capacities and are reasonably immune to the effect of detrusor overactivity in men with LUTS [183].

A variety of symptom scores have been described to assess male patients with LUTS. In men, the American Urological Association symptom score for BPH (AUA-7) is most commonly used in North America for assessment of subjective symptoms. However, equally reproducible data can be obtained from the International Prostate Symptom Score (IPSS), the ICSmale questionnaire (now renamed the ICIQMLUTS, long and short forms, as part of the ICIQ modular questionnaire: www iciq net).

The IPSS has been the most widely used (in many countries and languages), but neglects the symptom of urgency incontinence, a symptom that produces significant bother. The ICIQMLUTS (ICSmale-SF) is slightly longer, but takes into account the symptom of urgency incontinence, and in fact may be divided into voiding and incontinence subscores. To date, it has not been as widely used as the IPSS, but may see more widespread use as part of the ICIQ Modular Questionnaire.

Among LUTS, urgency, nocturia, and hesitancy are most bothersome, whereas weak stream, urgency, and frequency are the most prevalent in pooled populations being evaluated for BPH [184]. Post-micturition dribbling is often provoked by an obstructing disease such as BPH or urethral stricture but can also be a symptom of a urethral diverticulum. Post-void residual urine volume and careful palpation of the genitalia are recommended in these patients.

To determine the cause of post-prostatectomy incontinence, many studies have stressed the lack of reliability of symptoms and emphasised the important role of urodynamic testing [185,186]. Nevertheless, valuable information can be gained from a careful history with regard to incontinence, especially when related to sphincter dysfunction. The symptom of stress incontinence is highly predictive of the presence of sphincter dysfunction. Chao and Mayo found that 67 of 71 men with post-prostatectomy incontinence secondary to sphincteric dysfunction complained of the symptom of stress incontinence [187]. Similarly, Ficazzola and Nitti found 95% positive predictive value and a 100% negative predictive value for symptom of stress incontinence [177]. Urge incontinence as a predictor of bladder dysfunction dose not seem to be as valuable, and the presence of bladder dysfunction cannot be determined accurately without urodynamic testing [177,187].

4. PHYSICAL EXAMINATION

A general physical examination with specific attention to the presence or absence of a distended bladder, excoriation of the genitals secondary to urinary incontinence, evidence of urethral discharge and a focused neurological examination is also highly recommended.

The assessment and treatment algorithm focuses on the abdominal examination, digital rectal examination (DRE) and neurological testing of the perineum and lower extremities. In a patient suspected of neurogenic bladder, evaluation of perineal sensation and lower extremity neuromuscular function, and anal sphincter tone, which is often decreased in neurogenic patients [188] is important. A focused neurogenic examination should also assess the patient’s general mental status and ambulatory status. The examination should also include external genitalia, location of the urethral meatus, retractability of the foreskin and evidence of congenital malformation. Abdominal palpation should be performed to evaluate bladder distension, especially in elderly incontinent men, who may have overflow leakage due to obstruction. In patients suspected of urinary retention, post-void residual volume (PVR) should be measured. The patients with incontinence should be asked to cough and to perform a Valsalva manoeuvre so that the presence of stress incontinence can be ascertained.

DRE should include palpation of the prostate to assess size, symmetry and consistency of the gland and its relation to the pelvic sidewall and the rectum. The locally advanced prostatic cancer can also produce OAB-like symptoms. DRE may exclude prostatic cancer, although its specificity and sensitivity is low [189]. DRE tends to underestimate the true prostate size: if the prostate feels large by DRE, it usually also is found to be enlarged by ultrasound or other measurement technique [190, 191]. Prostate volume has been recently associated with the risk of BPH.
Epidemiological studies in community dwelling men have shown the absence of any association between BPO / BPE / BPO and chronic kidney disease [197] suggesting that screening for renal function is not justified in male patients. Recently, data from the MTOPS study showed that the risk of developing de novo renal failure in men with LUTS is low (less than 1 %) suggesting that is not necessary to monitor renal function in patients with LUTS / BPO [197].

7. MEASUREMENT OF THE SERUM PROSTATE-SPECIFIC ANTIGEN (PSA)

In most patients, a normal DRE may be sufficient to exclude locally advanced cancer as a cause of LUTS or OAB. There is no consensus as to the measurement of prostate specific antigen (PSA) in patients with LUTS. The rationale for measuring PSA is twofold: to screen for prostate cancer [198] and to measure a parameter with prognostic value for the progression of BPH and the response to treatment [192,193]. Because prostatic cancer is one of the potential causes of LUTS or OAB in men, PSA (together with DRE) is a relatively sensitive way to exclude prostatic cancer as a diagnosis [199,200]. However, it is important to understand that about 25% of men with BPH have a serum PSA greater than 4 ng/ml. Because of the overlap between serum PSA values in men with BPH and those with clinically localised prostate cancer, other parameters (PSA velocity, free/total PSA ratio, complexed PSA and PSA density) will assist diagnostic specificity [201, 202]. It has been suggested that a relationship between initial PSA level and subsequent prostate cancer detection with a stepwise increase in cancer detection rate (from <1% to 58%) in patients with <1.0 ng/ml, 1.1-2.5, 2.6-4.0, 4-1-10.0 and >10 ng/ml PSA value in over 26,000 patients enrolled in a screening programme [203]. In addition, Thompson reported data on prostate cancer prevalence from the prostate cancer prevention trial [204] confirming a stepwise increase in the risk of having a prostate cancer in patients with serum PSA from 0.5 to 4.0 ng/ml but showing the limitation of the current threshold of 4.0 ng/ml. Change of PSA threshold from 4.0 to 2.0 ng/ml has been proposed but currently no consensus exists [205]. PSA measurement is recommended in men with LUTS and a life expectancy of over 10 years in whom the diagnosis of prostate cancer would change the management of patient’s symptoms.

It has been reported that the role of IPSS score in the assessment of BOO is questionable, and that the grade of obstruction is more related to prostate volume, PVR, and Qmax [44]. It has been demonstrated that moderate-to-severe LUTS in men can result in urinary retention. The incidence of retention in men with untreated LUTS in community-based trials is 6.8 per 1000 during longitudinal follow-up of 4 years [206]. If only patients with moderate-to-severe symptoms are considered, the rate of retention increases to 25 per 1000 [207]. Moreover, in considering men with weak
urine flow, symptoms, and increased age, without urodynamic evaluation, other parameters become independently predictive of the development of acute urinary retention. In a meta-analysis of predictors of retention in pooled groups of placebo patients from clinical trials of men with LUTS undergoing active interventions (4300 patients), Roehrborn et al. found prostate-specific antigen and prostate volume to be strong independent predictors of urinary retention and the need for surgery in men with LUTS followed up longitudinally in clinical trials [191,208].

Recently, Laniado et al (2004) [209] have also tested the hypothesis that PSA level could be used to predict the presence or absence of BOO, evaluated by pressure flow studies. In patients with LUTS, those with a PSA more than 4 ng/ml are significantly more likely to have some degree of BOO. Conversely patients with PSA less than 2 ng/ml have a 33% risk of BOO.

Therefore, on the basis of these trials, untreated LUTS may place the male patient at risk for potential clinical deterioration. Thus, periodical measurements of PVR are recommended in such patients.

**Recommendations**

1. Male patients differ from female patients in the presentation of LUTS. The incidence of OAB wet is lower until the 7th decade. (Level 2)
2. Urinary stress incontinence is primarily associated with surgery of the prostate in male patients. (Level 2)
3. Disorders of bladder emptying from benign prostatic enlargement should be considered before treating male patients for OAB symptoms. (Level 2) ((Grade B).

**Future research**

1. Improve the understanding of the underlying pathophysiology and contributory clinical factors involved in the development and treatment of detrusor overactivity in the male patient, especially in differentiating the condition from female patients.
2. Development of simple, non-invasive, cost-effective methods to determine the contribution of bladder storage and bladder emptying abnormalities in male patients.

---

**5A- B. INITIAL ASSESSMENT OF FAECAL INCONTINENCE**

**I. FAECAL INCONTINENCE ASSESSMENT**

Basic assessment of faecal incontinence focuses on determining:

1. Type of incontinence
2. Functional limitations resulting from incontinence
3. Cause(s) of incontinence

**1. HISTORY**

History gathering requires particular tact in dealing with this taboo symptom, but also a willingness to ask direct questions about the complaint. In taking a history, the necessary first step is to determine the nature of the incontinence being experienced by the patient. True faecal incontinence must be differentiated from conditions that cause seepage such as external haemorrhoids, fistulas, low rectal or anal tumours, and poor perineal hygiene.

Diagnostic administration of an enema may be useful in this respect; retention of the enema suggests that the patient does not have clinically significant faecal incontinence. This serves to both clarify the patient’s history, but also begins to suggest the anatomical deficit causing the incontinence (see below). The key importance of the history and examination is to identify any conditions that are amenable to condition specific management – these are cited in logical sequence in the text below, and listed in the recommendation box.

**a) Type of incontinence**

- **Flatus incontinence** – incontinence of flatus due to inability to differentiate gas from solid or liquid
- **Passive leakage** – involuntary soiling of liquid or solid stool without patient awareness
- **Urge incontinence** – inability to defer defaecation once the urge is perceived, for long enough to find a toilet

The first two forms are primarily related to internal anal sphincter dysfunction, the latter form due to external anal sphincter dysfunction. (Grade B) [210]. Soiling after defaecation is typically related to either a defect in the internal sphincter or poor “snapping shut” of the external sphincter after voiding. (Grade C) [211]. It is also important to determine if the incontinence is for solid or only liquid stool; if for liquid stool, the possibility of a colonic cause of diarrhoea needs to be considered. (Grade B) [212].

---

353
**b) Functional status**

After confirming the nature of faecal incontinence, it is necessary to determine the impact of the condition on a patient's lifestyle and quality of life. This assessment offers the opportunity to both empathise with the patient and to understand the pertinent emotional and social factors in the manifestation of symptoms. The history should include:

- Need to wear tissues or pads in underwear – indication of severity. (Grade B) [213-215]
- Degree of soiling of tissues, pads or underwear. (Grade C) [213,215]
- Duration, frequency and timing of incontinence episodes – indication of severity. (Grade C) [213,216]

Ability to wear clothing of choice, eat food of choice, participate in work and social activity. (Grade C) [213,216]

Severity of faecal incontinence can be classified as:

- minor - if faecal seepage occurs less than once a month,
- moderate - if there is incontinence to solids more than once a month or liquids more than once a week, and
- severe - if there is loss of control of solids several times a week or liquids on a daily basis.

An alternative classification grades continence as follows:

- Grade 1: Complete
- Grade 2: Incontinence of flatus
- Grade 3: Incontinence of flatus and liquid stools
- Grade 4: Incontinence of flatus, liquid stools, and solid stools.

**c) Aetiology**

A careful, thorough history and full physical examination are essential and will identify the majority of causes of faecal incontinence. The history should include:

- Dietary history – in particular excess ingestion of sorbitol and caffeine. (Grade C) [217]
- Medical history – particularly anti-anginals, anti-hypertensives which may reduce sphincter tone, and ferrous sulphate or antacids which may provoke diarrhoea. (Grade C) [214]
- Presence of benign anal disease – haemorrhoids, fistula, anal warts. (Grade B) [218]
- History of chronic straining – suggestive of rectal mucosal prolapse, an important cause of internal anal sphincter dysfunction. (Grade B) [219]
- Obstetric history – particularly with regard to: (Grade B) [220,221]
  - number of vaginal deliveries
  - need for forceps or Ventouse
  - birth weights
  - duration of second stage(s)
  - episiotomy
- Perianal surgery history – particularly: (Grade B) [222]
- Anal fissure surgery (sphincterotomy or anal stretch)
- Fistula surgery
- Low colonic resection surgery
- History of pelvic radiation – risk of radiation proctitis (causing heightened rectal contractions) and internal anal sphincter radiation damage (Grade B) [223]
- Symptoms of other pelvic floor problems (urinary incontinence and pelvic organ prolapse), which have similar risk factors should be elicited (Grade C) [224])
- Cognitive assessment in appropriate patients (Grade C) [225]

**2. EXAMINATION**

Examination is focussed towards the detection of evidence of incontinence and identifying the cause of incontinence.

**a) Evidence of incontinence**

Physical examination should include inspection of underclothing for soiling and staining by stool, pus, or mucus.

Perianal skin should be examined for irritation and excoriation due to over-zealous hygiene. Perianal inspection should include attempts to identify the following: (Grade B) [215,226,227]

- Perianal excoriation or erythema – suggestive of chronic passive soiling
- A patulous anus or one which gapes on gentle traction of the anal verge
- A “keyhole” deformity of the anal canal – suggesting a persisting sphincter defect

**b) Cause of incontinence**

Inspection may reveal scars from previous episiotomies or obstetric tears. Abnormalities at the anal verge from previous surgery or a gaping anus suggestive of marked loss of function may be present. Perianal inspection should identify: (Grade C) [215, 226,227]
• Scars from previous surgery
• Perianal disease – prolapsing haemorrhoids, fistula, anal warts
• Absence of perineal body – suggestive of obstetric trauma; at its worst this may manifest as a cloacal deformity
• Inspection for sphincter asymmetry whilst patient contracts sphincter – suggestive of regional sphincter defect
• Function of the puborectalis muscle (palpable at the anorectal junction) is assessed by asking the patient to squeeze the sphincter at which time the puborectalis should push the examiner’s finger anteriorly.

Digital examination should identify: (Grade C) [210,226,227].
• Rectal content – if faecal impaction is present this could explain incontinence
• Resting tone – indicative of internal anal sphincter function
• Voluntary and involuntary squeeze pressure – indicative of external anal sphincter function and potential function, respectively. The latter is elicited most commonly by asking the patient to cough while assessing sphincter tone – a cough causes a near-maximal external sphincter contraction (analogous to the guarding reflex in the bladder)
• Regional sphincter defects – detected as asymmetry
• A thickened sphincter – suggestive of chronic straining and occult rectal mucosal prolapse

If suggested by earlier findings (history of straining, thickened sphincter), the patient should be asked to sit on a commode and attempt voiding – the perineum should then be inspected for evidence of a rectal mucosal or full thickness prolapse (Grade C) [219]

Proctoscopy or rectosigmoidoscopy with a rigid instrument is a bedside test of value in excluding potentially treatable causes of faecal incontinence:
• Anal tumours or polyps
• Low rectal cancers or adenoma (Grade B) [228].
• Solitary rectal ulcer syndrome – a functional disorder of evacuation, in which repeated straining at stool and rectal self-digitation results in an ulcerated area of the anterior rectal wall (Grade) [229].

Vaginal examination using a Simms speculum may show a rectocele, cystocele and/or uterine prolapse, all of which may contribute to developing faecal incontinence (Grade C) [230].

Physiological and complimentary radiological tests are used to confirm clinical suspicions and provide objective data on the function of the anorectum. Pelvic floor dysfunction is a complex problem and multiple tests may be needed based on the initial findings and complexity of the planned intervention.

KEY RECOMMENDATIONS FAECAL INCONTINENCE

• It is essential to perform a baseline assessment comprising:
  - focussed medical history
  - a general examination
  - an anorectal examination
  - a cognitive assessment (when appropriate)

• The following conditions should be specifically assessed for as they may be amenable to definitive treatment:
  - rectal prolapse or third-degree haemorrhoids
  - faecal loading
  - potentially treatable causes of diarrhoea (eg inflammatory bowel disease and irritable bowel syndrome, infection, adenomas)
  - acute anal sphincter injury including obstetric and other trauma
  - acute disc prolapse/cauda equina syndrome

Future research

• Development and validation of a digital (finger) instrument to assess anal sphincter function (analogous to the instrument in existence for urological assessment of pelvic floor musculature).
• Development of a psychometrically valid and reproducible instrument to assess quality of life in faecal incontinence.

In the first three International Consultations on Incontinence reports, the impact of incontinence on quality of life (QoL) and methods of measuring these factors were described with questionnaire recommendations for use in research and clinical practice [1, 2]. This triennial update is a departure from previous reports in that the scope of this chapter encompasses not only quality of life, but all patient-reported outcomes (PRO); and will also include a review of screening tools, not just outcome measures. Additionally, this chapter will extend and update the prior literature reviews of PROs, broaden the review to include lower urinary tract (LUTS) and bowel incontinence outcomes measures, and provide recommendations for questionnaire selection for use in clinical practice and research. In addition, this summary will review the purpose and content of the ICI questionnaire (ICIQ) modules. Given the burgeoning literature in this area, a complete review of all studies with PROs will not be provided, but rather PRO highlights will be included.

The expansion in scope of this review to include all types of patient reported outcomes (PRO) is an important step in recognising the inherent conceptual differences of various PROs each with different assessment goals. A PRO is an objective assessment of the patient's subjective experience and can include aspects of the patient's health. PROs measure different aspects of disease and therapeutic impact such as: symptom frequency or symptom bother, health-related quality of life (HRQL), treatment satisfaction, or work productivity measures (Figure 1). An essential component of selecting a PRO for use is to ensure that the selected PRO is consistent with the objective of the study or clinical purpose. For example, if the goal is to assess treatment satisfaction, then a treatment satisfaction measure should be incorporated into the study design or as a clinical outcome. The matching of appropriate PRO selection with one's desired outcomes is critical to success when assessing PRO's and will be reviewed further in this chapter.

Ultimately, the last decade has been one of tremendous growth in the area of PROs with influences from scientific and regulatory communities. As such, the ICI will endeavour to continually update the recommendations it offers on the basis of emerging data and published evidence based on the sound and rigid recommendations of the previous three reviews.

A number of different electronic databases were searched, limited to adults over the age of 18 years and human studies from January 2004 to June 2008, including Pub-Med, Medline, PsychInfo, the LOCATORplus database for books, serial titles and audiovisuals, the Cochrane Library for randomised controlled trials, and the NLM Gateway database. The following keywords were used separately and/or
In combination: "urinary incontinence", "urinary symptoms", "urgency", "overactive bladder", "stress incontinence", "incontinence", "questionnaire", "epidemiology", "prostate", "prolapse", "fecal", "faecal", "bowel", "anal" and "quality of life", "sexual" and "health utilities". Questionnaires identified in previous ICI reports were also searched in PubMed and Medline.

Incontinence and other lower urinary tract symptoms (LUTS) as well as bowel problems and their impact on patients and their lives can be assessed in a number of ways. Traditionally, the clinical history has been used to gain a summary view of the symptoms experienced by patients and in some cases the impact on their lives. Increasingly however, patient-completed methods of measuring incontinence and LUTS are being used, including voiding diaries and questionnaires.

Patient self-completed questionnaires or patient reported outcomes (PROs) represent the most important clinical review of symptom impact and treatment benefit from a patient perspective. PROs provide a method for the standardised collection of data, or an objective assessment of a subjective phenomenon, from patients relating to incontinence, other LUTS, and bowel problems. Clinicians' assessments of patients' outcomes have often been shown to underestimate the degree of bother perceived by patients, and to focus on issues of lesser importance to patients [3-6].

PRO questionnaires can be used to record the presence and severity of urinary symptoms including incontinence, as well as the impact of symptoms on everyday activities and health-related quality of life (HRQL). To ensure that the results obtained with PROs are clinically useful, data must be gathered using valid and reliable instruments. Questionnaire design and development is not a simple process. Developing such instruments requires a multistep, structured process that incorporates cognitive psychology, psychometric theory, and patient and clinician input. The process begins by determining the intent and purpose of the PRO and culminates in studies that demonstrate the measure's validity, reliability, and responsiveness. The specific steps required for developing a PRO questionnaire are outlined in the following section and are shown diagrammatically in Figure 2.

The development of a PRO is a rigorous, scientific process to provide confidence that the PRO is measuring what it is intended to measure, that it does this reliably, and is appropriate for use in the patient

**Figure 2**: The development of a patient reported outcome is a multistep process. Food & Drug Administration (3). Guidance for industry - patient-reported outcome measures: Use in medical product development to support labeling claims. Silver Spring, MD: FDA; February 2006.
or population group under investigation. The final instrument must have demonstrated validity and reliability in the intended target population. PROs need to be developed with patient and clinician input and have the psychometric, or measurement, properties of the PRO evaluated to determine that it is a valid outcome measure. To be a useful measurement tool, a PRO instrument must also be easy to administer, reliable, and valid. Only PROs that have undergone this process and have published validation data are discussed in this chapter.

1. DETERMINING QUESTIONNAIRE INTENT AND PURPOSE

The first task in developing a PRO measure is to determine why the instrument is needed. Given the current number of disease-specific questionnaires available in the field of incontinence and related pelvic disorders, a new PRO measure must fill a need that has not already been met by an existing instrument. Once the need for the measure is recognised, its purpose and clinical usefulness need to be considered because the purpose dictates the validation design process. For example, a symptom- and a treatment-satisfaction measure would be developed and validated differently because the outcome is different.

The development stage would focus on the outcome of interest (eg, symptoms patients experience and the significance of each symptom, or what issues patients consider when determining how satisfied they are with treatment) with the items derived directly relating to the outcome of interest. Validation efforts would include designing a study focused on the outcome of interest with the appropriate patient inclusion/exclusion criteria to enhance generalisability while maintaining internal consistency and providing opportunities to test—at a minimum—reliability and construct validity.

2. DEVELOPING THE ITEMS

Designing a clinically useful PRO measure involves more than just developing a series of questions. In addition to clinician input and literature review, questionnaire items should be generated from patient input. This is obtained through focus groups or one-on-one interviews to provide qualitative data on issues pertinent to patients and to identify the words patients use to describe their symptoms or disease impact. Focus groups and one-to-one interviews should be carefully planned to address the goals of the questionnaire being developed. For example, if a measure is intended to assess symptom bother, interview questions should pertain to the patient’s symptom experience. Importantly, rather than using clinical terminology which patients may not comprehend, the words used during the focus groups or interviews should be common to patients. After items are generated, the newly drafted questionnaire should be reviewed by other patients and experts to ensure its readability and content validity.

An alternative approach to questionnaire development is to adapt an existing measure to meet the needs of the desired questionnaire. Although no patient input is required at the outset when adapting an existing instrument, patients need to be involved after the questionnaire is adapted to ensure that the revised measure is pertinent to the population of interest. Also, the adapted questionnaire must be validated on its own in the target population; the validity of the original questionnaire does not apply to an adapted measure.

For newly developed and adapted questionnaires, think-out-loud interviews or cognitive debriefing interviews should be used to ascertain the correctness and validity of the revised questionnaire. In a think-out-loud interview, patients are asked to review a question and describe what they are thinking as they cognitively process the question; the patients think out loud about what the question means to them. For a cognitive debriefing approach, patients review and respond to the questionnaire items, then are interviewed about what each item meant to them as they completed the questionnaire. Both approaches provide information about what patients consider when responding to each question.

3. DETERMINING THE MODE OF ADMINISTRATION OF A QUESTIONNAIRE

Once items have been generated, the mode of administration must be considered. Will the measure be completed by the patient (ie, self-administered) or administered by an interviewer (ie, interviewer-administered)? How the questionnaire will be completed needs to be determined before the validation stage because mode of administration can affect patient responses. For highly personal or intimate questions, a self-administered questionnaire is recommended to avoid response bias. Questionnaires that are self-administered are preferable to interviewer-administered questionnaires because the data collection burden is reduced and patients are more likely to provide unbiased information on self-administered questionnaires. Importantly, if a questionnaire has been validated for a particular mode of administration, this does not make the questionnaire valid for all modes of administration. Each mode of administration should be validated separately.

4. QUESTIONNAIRES’ PSYCHOMETRIC PROPERTIES

All PRO measures must demonstrate reliability, validity, and responsiveness, which are described in detail below. This can be accomplished in several ways:

1. Perform a stand-alone cross-sectional study to validate the questionnaire in the patient population for which it was designed;
2. Administer the untested questionnaire in a clinical trial and use the baseline data to perform psychometric validation (the end-of-study data can also be used to evaluate responsiveness); or

3. Perform a stand-alone longitudinal study with an intervention to determine the instrument’s psychometric performance and responsiveness in a non-clinical trial setting.

The following psychometric properties must be tested for and demonstrated in a validated questionnaire.

**Reliability** refers to the ability of a measure to produce similar results when assessments are repeated (ie, is the measure reproducible?) [4, 5]. Reliability is critical to ensure that change detected by the measure is due to the treatment or intervention and not due to measurement error [6]. One measure of reliability is the questionnaire’s internal consistency, which indicates how well individual items within the same domain (or subscale) correlate [7]. Cronbach’s alpha coefficient is used to assess internal consistency reliability, with higher alphas indicating greater correlation [6]. Typically, Cronbach’s alpha should be greater than 0.70 to indicate good internal consistency reliability [6, 7]. If the item-to-total alpha is less than 0.20, the question should be removed or rewritten [4].

**Test-retest reliability**, or reproducibility, indicates how well results can be reproduced with repeated testing. To assess test-retest reliability, the same patient completes the questionnaire more than once, at baseline and again after a period of time during which the impact of symptoms is unlikely to change (e.g., a few days or weeks) [4, 6, 7]. The Pearson correlation coefficient and intraclass correlation coefficient are used to demonstrate reproducibility. For group data, a Pearson correlation coefficient or an intraclass correlation coefficient of at least 0.70 demonstrate good test-retest reliability [6, 7].

**Interrater reliability** indicates how well scores correlate when a measure is administered by different interviewers or when multiple observers rate the same phenomenon [7]. Demonstration of interrater reliability is not necessary for self-administered questionnaires but is necessary for instruments based on observer ratings or using multiple interviewers. A correlation of 0.80 or higher between raters indicates good interrater reliability [7].

**Validity** refers to the ability of an instrument to measure what it was intended to measure [4, 6, 7]. A measure should be validated for each specific condition or outcome for which it will be used. For example a measure designed to assess stress incontinence would not be valid for OAB unless it were specifically validated in patients with OAB symptoms.

**Content validity, convergent validity, discriminant validity** and criterion validity typically are required to validate a questionnaire [7]. Content, or face, validity is a qualitative assessment of whether the questionnaire captures the range of the concept it is intended to measure [6, 7]. For example, does a measure of symptom severity capture all the symptoms that patients with a particular condition have, and if so, is the measure capturing the items in a manner meaningful to patients? To obtain content validity, patients and clinical experts review the measure and judge whether the questions are clear, unambiguous, and comprehensive [4].

**Convergent validity** is a quantitative assessment of whether the questionnaire measures the theoretical construct it was intended to measure [4, 6]. Convergent validity indicates whether a questionnaire has stronger relationships with similar concepts or variables. Stronger relationships should be seen with the most closely related constructs and weaker relationships seen with less-related constructs [6]. **Discriminant validity** indicates whether the questionnaire can differentiate between known patient groups (eg, those with mild, moderate, or severe disease) [6] - generally, measures that are highly discriminative are also highly responsive.

**Criterion validity** reflects the correlation between the new questionnaire and an accepted reference, or gold standard [6, 7]. One difficulty in establishing criterion validity is that a gold-standard measure might not be available [6, 7]. When criterion validity can be established with an existing measure, the correlation should be 0.40 to 0.70; correlations approaching 1.0 indicate that the new questionnaire may be too similar to the gold-standard measure and therefore redundant [7].

**Responsiveness** indicates whether the measure can detect change in a patient’s condition [5]. An important aspect of responsiveness is determining not only whether the measure detects change but whether the change is meaningful to the patient. This can be done by determining the **minimal important difference (MID)** of the measure. The MID is the smallest change in a PRO questionnaire score that would be considered meaningful or important to a patient [6, 8-10]. A treatment that is statistically significantly better than another may not necessarily have made a meaningful difference to the patient; the MID indicates whether the treatment made such a difference from a patient perspective [8-10].

Unfortunately, there is no scientific test for MID as it is an iterative process that involves two methodologies to determine the MID of a questionnaire: an anchor-based approach and a distribution-based approach [11, 12]. With the anchor-based approach, the MID is determined by comparing the measure to other measures (or “anchors”) that have clinical relevance [12], such as a global measure of well-being or
psychometric equivalence, should also be demonstrated after linguistic validation, demonstrating international implementation. It is also important to note that the questionnaires discussed in this chapter have multiple linguistically validated versions making them useful for use in different populations. Linguistic and cultural adaptation of a questionnaire can occur during the development phase before validation, or it can be done after the questionnaire is validated in the language in which it was initially developed, with the latter being the more common approach. Ensuring the linguistic and cultural validity of a questionnaire is especially important for measures used in multinational clinical trials [14].

The principal steps in adapting a measure for different languages and cultures are as follows:

1. Two forward translations of the original instrument into the new language;
2. Quality-control procedures that may include a backward translation (translating the instrument back into the original language) (15);
3. Adjudication of all translated versions;
4. Discussion by an expert panel to ensure clarity of the translated questionnaire; and
5. Testing the translated instrument in monolingual or bilingual patients to ensure that it measures the same concepts as the original instrument [4, 7, 14, 15].

However, if a backward translation of the measure does not produce a semantically equivalent instrument, then the instrument may need to be developed in the target language, rather than just translated [15].

After cultural and linguistic validation, PROs should also be psychometrically validated within the target language. Thus, reliability, validity, and responsiveness need to be assessed with each language translation to confirm the same measurement properties are present in the translated language(s) to ensure psychometric equivalence. If psychometric equivalence is not present (e.g., not achieving similar or better results in new language translation), the cultural and linguistic translations need to be re-evaluated and perhaps a new instrument may need to be developed.

The ICIQ questionnaires and many of the other questionnaires discussed in this chapter have multiple linguistically validated versions making them useful for international implementation. It is also important to note that the step after linguistic validation, demonstrating psychometric equivalence, should also be demonstrated to ensure that the PRO performs equivalently in different languages and cultures.

6. REGULATORY OVERSIGHT

As clinicians and scientists have begun to appreciate and accept PROs as appropriate outcome measures, regulatory authorities have issued guidance documents on current best practices in the development and implementation of PRO in clinical trial settings [3, 16]. For PROs to be acceptable outcome measures for regulatory authorities, documentation of measurement properties must be present as well as evidence of inclusion of the patient perspective and understanding of the PRO and a cohesive conceptual framework that stipulates how the PRO is related to the intervention. While PROs within this document may have a "recommended" status, they may not meet all of the required regulatory guidelines and may require additional validation work either from a qualitative or quantitative perspective. It is strongly suggested that regulatory authorities be contacted early in the process of selecting a PRO for clinical trials to ensure regulatory acceptance of the PRO.

7. QUESTIONNAIRE DEVELOPMENT - A CONCLUSION

Patient self-completed questionnaires are the most suitable method for assessing the patient's perspective of their lower urinary tract, vaginal and bowel symptoms [17]. Questionnaires may be long and detailed for use in research, but need to be short and easy to use to be relevant for clinical practice. In addition to being valid and reliable, they need to be easy to complete, and, if they are being used to measure outcome, sensitive to change. Developing a new questionnaire and testing it thoroughly takes a great deal of time and is only necessary if there is not an existing instrument available.

There are many questionnaires currently available for use and these have been reviewed and described with recommendations from the Committee for their use in the last three ICI reports.

The major purpose of the ICI has been to provide a definitive international review and consultative opinion regarding the recommended measures to assess patient reported outcomes within the area of urinary incontinence and LUTS. To this end since the First Consultation, the ICI has worked to develop a modular format for the various patient reported outcomes including health related quality of life (HRQL) allowing clinicians and researchers to select internationally recommended questionnaires for the assessment of their patients in both clinical practice and clinical trials. In this the fourth ICI review, the ICIQ modular questionnaires (supported by the International Consultation) are presented in detail and their use evaluated. Whilst some of the modular questionnaires are still currently under full evaluation their content and format are presented within this chapter.
A detailed review of recommended questionnaires was provided in the First Consultation chapter [18]. At the Second Consultation, the Committee developed standardised grades of recommendation for questionnaires which attempted to reflect the Oxford Centre for Evidence Based Medicine’s Levels of Evidence. These were applied to evaluate questionnaires concerned with urinary incontinence [19]. At the Third Consultation, these grades were revised and updated to take into account the increasing numbers of published questionnaires concerned with LUTS and incontinence, and also broadening of the field to include pelvic organ prolapse (POP) and faecal incontinence (FI) as well as LUTS and urinary incontinence (UI).

At the Second and Third Consultations, the Committee devised three grades of recommendation [19] (Table 1).

- Questionnaires were ‘highly recommended’ and given a Grade A if the Committee found “Published data indicating that the questionnaire is valid, reliable and responsive to change following standard psychometric testing. Evidence must be published on all three aspects and questionnaires must be relevant for use with persons with incontinence.”

- Questionnaires were “recommended” and given a Grade B if the Committee found “Published data indicating that the questionnaire is valid and reliable following standard psychometric testing. Evidence must be published on two of the three main aspects (usually validity and reliability).”

- Questionnaires were considered to have “potential” and given Grade C if the Committee found “Published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing.”

The Committee decided that evidence published in abstracts or posters could be used to indicate a developing questionnaire’s potential, but was not sufficiently peer-reviewed to provide the basis for a stronger recommendation.

This current Fourth Consultation represents a departure from the recommendation scheme of the last review. In this fourth review questionnaires will still be graded A, B, or C as outlined above. However the recommendation will be to preferably utilise questionnaires from the ICIQ modules described in detail below. Many, but not all, of these questionnaires are Grade A questionnaires by previously stipulated criteria. Within the description of the ICIQ modules below the grade assigned to each module is indicated.

Should none of the modular questionnaires be deemed appropriate for specific research or clinical purposes, ICI’s recommendation is to use a Grade A questionnaire as previously recommended and where no suitable instrument exists a Grade B or C questionnaire.

For UI and UI/LUTS, the Committee examined the quality of the psychometric evidence. Only where published data were scientifically sound was the label ‘with rigour’ allowed. Where the Committee had concerns about the quality of evidence, this is noted in the descriptions of the questionnaires below. The Committee considered that the number of high quality questionnaires means that there are now sufficient questionnaires for most purposes and it is not necessary to encourage the development of new questionnaires, except for particular patient groups (see below). As for the last Consultation, it is expected that by the next Consultation, Grade A new questionnaires will either be promoted to Grade A because of further high quality publications or relegated to Grade B if further development does not occur.

The Committee felt that the development of questionnaires in the areas of pelvic organ prolapse (POP) and faecal incontinence (FI) was at a much earlier level. This necessitated a slightly different set of grades of recommendation so that researchers are

The ICIQ modular questionnaire was developed to meet the need for a universally applicable standard guide for the selection of questionnaires for use in clinical practice and clinical research [18, 19]. The decision to develop standard questionnaire modules was taken by the Committee after the first ICI meeting in 1998, and resulted in the development of the ICIQ core questionnaire discussed in this section. It was recognised at that time that there were many good validated questionnaires each developed for a specific purpose and each subtly different. Although developers of the questionnaires were familiar with their content and use, the increasing number of questionnaires made appropriate selection difficult and limited the ability to compare similar clinical and research data due to different data collection methods.

An international advisory board was established to continue the development of the modular ICI questionnaire outside the limits imposed by triennial convening of the ICI Committee. Early discussions with the advisory board resulted in the decision to expand the concept to include wider urinary symptoms, bowel symptoms and vaginal symptoms. The advisory board consisted of clinicians and researchers with experience in the design and use of questionnaires representing the major societies involved in the assessment and research of lower genital tract, lower urinary tract and bowel function. The members of the advisory board of the ICI can be seen on the ICIQ website at www.iciq.net. The ICIQ modular questionnaire was then established.

### I. AIMS AND OBJECTIVES

The ICIQ’s objective is to provide international consensus on the use of patient completed questionnaires for the assessment of lower pelvic symptoms and their impact on patient’s lives. Three aims underpin the ICIQ in order to achieve clarity over questionnaire use:

- To recommend high quality self-completion questionnaires according to evidence of validation as stipulated by the three prior ICI Committees;
- To promote wider use of questionnaires to standardise assessment of lower urinary tract and pelvic dysfunction and its impact on patients’s lives, in order to;
- Facilitate communication in different patient settings and different patient groups both in clinical practice and wider clinical research.

The ICIQ recognised that many high quality published questionnaires already existed and, with permission from the authors, those instruments were adopted into the modular project. It was not possible to adopt all available questionnaires and where more than one option existed the most appropriate questionnaire for the purpose was included. Where high quality questionnaires were not available, the need to develop a new questionnaire/s was acknowledged. Collaborative efforts to develop new questionnaires are welcome and encouraged.

The ICIQ’s international nature requires that linguistically validated translations are available. More than 50 language versions of various modules have been validated to date, conducted according to established protocol.

Thirteen ICIQ modules/questionnaires are currently available for use, with further modules in development (discussed in detail below). Clinicians or researchers are able to select module(s) to meet the particular requirements of their study or clinical practice. In order to simplify this selection process, modules have been categorised as shown in Table 3. It must be stressed that although multiple questionnaires can and probably should be used they must be used in the format in which they were originally designed and the questionnaires cannot be merged together.

In this chapter questionnaires forming part of the ICIQ modular format are referred to as those preferred for usage. Although many of the modules are Grade A questionnaires, others are still under various phases of development and are graded appropriately.

Gray: In development; black: Grade A or A (New)
Questionnaires that are in early stages of development and have yet to reach Grade C are described as "in development". Where an ICIQ module is not available it is recommended that a Grade A or B or C questionnaire is used.

II. ICIQ SYMPTOM AND BOTHER MODULES

1. CORE MODULES

Questionnaires to assess the core symptoms of lower pelvic dysfunction:
- Lower urinary tract symptoms (male and female specific versions).
- Urinary incontinence (male and female applicable version).
- Vaginal symptoms (female version only).
- Bowel symptoms including incontinence (male and female applicable version).

Each module is intended for the comprehensive yet succinct measurement of symptoms and associated ‘bother’. The bother item attached to each symptom enables the individual to indicate areas that cause the greatest negative impact on HRQL as perceived by them. This can be a more sensitive indicator of treatment goals than frequency of symptoms alone.

2. SPECIFIC PATIENT GROUPS

Questionnaires to assess specific conditions or symptom complexes such as nocturia and overactive bladder are contained in this section. This category also includes specific patient groups, for example, children. These instruments contain only question items characteristic of the symptom complex or have been developed specifically for use in a diverse group making the items/questionnaire only utilisable in that population.
- Nocturia (male and female applicable version).
- Overactive bladder (male and female applicable version).
- Patients with spinal cord disease.
- Patients using long term catheters.

Bother sub-items are again included for all except the children’s questionnaire.

III. ICIQ HEALTH-RELATED QUALITY OF LIFE AND SEXUAL FUNCTION MODULES

1. CORE MODULES

These questionnaires incorporate modules for assessment of health-related quality of life (HRQL) and sexual matters and are recommended to be completed alongside symptom evaluations. The core symptom modules described above contain bother items indicating impact on quality of life directly related to symptoms. The HRQL questionnaires recommended here cover specific issues that are a consequence of symptoms, such as limitations on activities and impact on relationships.
- HRQL associated with lower urinary tract symptoms (male and female applicable version).
- HRQL associated with vaginal symptoms (female version only).
- HRQL associated with bowel symptoms (male and female applicable version).
- Sexual matters associated with lower urinary tract symptoms (male and female specific versions).
- Sexual matters associated with vaginal symptoms are included in the symptom questionnaire as the issues were considered too intrinsically linked to separate for evaluation.

Bother sub-items are again included to provide more detailed information about impact on quality of life than frequency of impact alone. The assessment of symptoms in combination with quality of life enables a more thorough and detailed evaluation of the patient's experience [20,21]. Given the nature of lower pelvic dysfunction, sexual matters can also be affected and questionnaires are available to evaluate this where appropriate.

2. SPECIFIC PATIENT GROUPS

In the same manner as the symptom modules, HRQL modules are available for specific symptom complexes:
- HRQL associated with nocturia (male and female applicable version).
- HRQL associated with overactive bladder (male and female applicable version).

IV. OPTIONAL MODULES

This category includes lengthier questionnaires for more exploratory evaluation of the core symptoms of lower pelvic dysfunction. Whilst these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of broader associated symptoms may be desired.
- Lower urinary tract symptoms (male and female specific versions).
- Urinary incontinence (male and female applicable version).
V. POST-TREATMENT MODULE

The ICIQ module for post-treatment satisfaction is in the early stages of development. Assessment of a patient’s satisfaction with treatment (behavioural, surgical or medication) provides information on treatment impact on their condition and life and includes their perception of effectiveness, tolerability and convenience. It is not yet clear if satisfaction following treatment can be characterised by a set of common question items that are applicable to all disorders of the lower urinary tract and pelvic floor. As with HRQL, there are generic and disease specific questionnaires that assess satisfaction. Ongoing studies will provide further evidence on which to make suggestions regarding post treatment evaluation but it is likely that this will encompass both generic and condition specific measures. Ultimately, the development of post treatment modules will also rely on advice from regulatory authorities (eg FDA) to ensure that measures capture a recognised multidimensionality of satisfaction.

VI. GUIDANCE FOR USE OF THE ICIQ

The ICIQ recommends the use of a ‘core’, ‘symptom-specific’, or ‘add-on’ modules that match the intended purpose of a study. Whilst this may necessitate the use of a module from each section, there is no requirement to do so. The characteristics of each module is summarised below, although more extensive information can be found on the project website, www.iciq.net.

VII. ICIQ MODULES

Tables 4, 5 a,b,c

VIII. ICIQ QUESTIONNAIRE IMPLEMENTATION

The ICIQ modular questionnaire has attracted considerable attention from both clinicians and researchers worldwide since its structure was finalised in 2004. More than 500 requests for use of the various modules have been documented and over 40 published studies were identified up to April 2008, with the majority originating from Europe, particularly the UK.

The most widely applied module is the ICIQ-UI Short Form, particularly to evaluate female urinary incontinence, though a handful of studies evaluating severity of incontinence in men resulting from prostatectomy for cancer or treatment for bladder outlet obstruction related to benign prostatic enlargement have been reported [31, 32]. Most studies relate to epidemiological research, including prevalence surveys of urinary incontinence or lower urinary tract symptoms [33, 34]; and outcomes research, including prospective and randomised clinical trials of treatments including surgery [35], drug therapies [36] and conservative treatments [37]. For example, a recent placebo-controlled randomised trial found that duloxetine significantly reduced ICIQ scores in women with mixed urinary incontinence[36].

Reports on further validation and translations of the ICIQ and related educational projects have also been published. A recent study conducted by Franco, Lee and Fynes [38], for example, compared various validated subjective measures of urinary incontinence severity to the one hour pad test in women and reported that only the ICIQ correlated significantly with this clinical variable, thereby recommending its use in routine clinical practice as an alternative to pad tests. Encouraging relationships between the ICIQ and other urodynamic parameters have also been reported [39].

The ICIQ has also been applied to hospital and general practice settings, and has been adopted in national guidelines for the management of urinary incontinence in primary care by the Scottish Intercollegiate Guidelines Network (www.sign.ac.uk/pdf/sign79.pdf) and in a primary care resource pack by the British Society of Urogynaecology.

IX. CONCLUSION

The ICIQ modular questionnaire project (www.iciq.net) provides a series of standardised questionnaires for the patient reported assessment of lower pelvic dysfunction symptoms and their impact on patients lives. The ICIQ provides clarity over the selection of questionnaires by recommending only those with evidence of high quality and robust psychometric validation including validity, reliability and sensitivity to change. This assurance provides the user with confidence in the results obtained, which is important in clinical practice and research where treatment decisions or trial outcomes depend on this evidence. Increasing awareness of the ICIQ aims to promote increased use of standardised questionnaires, thereby facilitating communication between clinicians and researchers and enable more widespread comparisons between different treatments and patient groups worldwide.

5B - D. PATIENT REPORTED OUTCOME (PRO) QUESTIONNAIRES TO ASSESS THE IMPACT OF URINARY INCONTINENCE, OAB AND LOWER URINARY TRACT SYMPTOMS

There are a variety of PRO measures available for use in clinical practice and research that assess a range of concepts (e.g. HRQL, patient satisfaction, symptom bother, etc). This section and table series provides an overview and assessment of those measures. Importantly, clinical practitioners and researchers need to clearly determine their clinical and research objectives before selecting a PRO as it is these objectives and the target patient population that will help determine which validated PRO is appropriate to use. Tables 6 to 10 provide a brief overview of all current PRO measures for urinary incontinence and LUTS, their purpose, psychometric properties, translation availability, and recommended ICI grade.

Certainly an area which has rapidly grown with PRO measures is that of urinary incontinence and HRQL assessments (Table 6). The literature supporting HRQL assessments was reviewed and a Grade A to C recommendation assigned. Please note, as instrument development and validation is an ongoing process, the tables below contain publications prior to July 2008. As additional work may have been performed on an instrument, it is always prudent to conduct a further literature search and/or contact the instrument developer prior to selecting an outcome measure for your clinical practice or study.

One trend that has become more apparent since the previous Consultations is the modification of more established urinary incontinence questionnaires for use in selected patient groups (e.g., pelvic organ prolapse; males; different cultural/language groups). When using a questionnaire in a patient group other than the group in which it was initially developed, cognitive debriefings with the new patient population should be held to review the applicability of the questionnaire to the new patient group. Several of the main questionnaires to be discussed below have now had modified versions published in the literature. The Committee’s view is that although it may be appropriate to modify established questionnaires for use with some populations, it is advisable to keep such modifications to a minimum, and to use the original versions whenever possible. Any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument, and thus all modified instruments should be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument’s construct validity, reliability, and test-retest reliability, at a minimum, and sensitivity to change, in intervention studies.

For some of the more widely used instruments listed below, several modified, shortened versions have been published. Information regarding the modified versions is provided under the original source versions of the questionnaires, but the modified versions are evaluated and graded separately, based on the available information regarding their psychometric properties and performance.

I. HEALTH-RELATED QUALITY OF LIFE MEASURES

1. BFLUTS AND BFLUTS-SF

The long form of BFLUTS [23, 26] was developed for use with women, following the pattern established for the questionnaire developed for the ICS-‘BPH’ study. The questionnaire covers the occurrence and bothersomeness of symptoms relating to incontinence and other lower urinary tract symptoms [23, 26]. It has shown good levels of validity and reliability and has been increasingly used in epidemiological and outcome studies [40-45]. Validity, reliability and responsiveness have been demonstrated, and a scored short form has been produced, which is now the recommended version [22].

2. DAN-PSS

This questionnaire was designed in Denmark to measure the degree to which men are bothered by urinary symptoms [46, 47]. A composite score is achieved by the multiplication of the ‘symptom’ by the ‘bother’ score, with a total range of 0 to 108 [46, 47]. A computer version of this questionnaire has been validated and patients seemed to appreciated more this new version than the paper version [48]. It is primarily a questionnaire for the assessment of the occurrence and bothersomeness of a wide range of LUTS in men.

3. ICSMALE AND ICSMALE SF

The ICSmale questionnaire contains 22 questions on 20 urinary symptoms, and, for most questions, the degree of problem that the symptom causes [26]. It has exhibited acceptable levels of validity, reliability and sensitivity to change following a range of treatments including surgery, minimally invasive therapies and drug treatments [26, 27, 49]. This long version has been largely replaced now by a scored short-form – ICSmaleSF [25]. A modified form of ICSmale has been used to assess LUTS and incontinence in prostate cancer [50]. It also continues

</tbody>
</table>
to be used to assess LUTS in men [51] and minimally invasive therapies and drug treatments [52-55]. It is primarily a questionnaire for the assessment of the occurrence and bothersomeness of a wide range of LUTS in men.

The scored short-form – ICSmaleSF, [25] was developed from the longer ICSmale questionnaire to assess LUTS in men. The short form has two major scored sections: ICSmaleVS (voiding subscore) containing five questions (hesitancy, straining, reduced stream, intermittency, incomplete emptying), and ICSmaleS (incontinence subscore) containing six questions (urge, stress, unpredictable and nocturnal Incontinence, urgency, postmicturition dribble). The scores are obtained by simple addition. The authors indicate that questions to assess nocturia, frequency and impact on quality of life should be added to provide full data, but these questions should not be included in the score as they are separate constructs [25]. The ICSmaleSF has been used in studies focusing on prostate cancer [56, 57] and on LUTS [51] as well as minimally invasive therapies and drug treatments [52, 53].

4. INCONTINENCE IMPACT QUESTIONNAIRE (IIQ) AND IIQ-7

This questionnaire was developed to assess the psychosocial impact of urinary incontinence in women and consists of 30 items (24 on the degree to which incontinence affects activities and 6 on the feelings engendered) [58-60]. Scores are obtained overall or for four subscales determined by factor and cluster analyses: physical activity, travel, social relationships, and emotional health. The IIQ has been found to have acceptable levels of reliability and validity across a range of studies [61-67]. The IIQ has also been produced in a short form comprising 7 items, also with evidence of validity and reliability [67, 68]. Responsiveness of the IIQ has been assessed in several intervention studies [69-74].

5. I-QOL

This questionnaire was designed to be used in clinical trials to measure the impact of incontinence on men and women [75]. Psychometric information on translated versions of the I-QOL have been reported for French, Spanish, Swedish, German, Korean and Thai language versions [76-78]. Other cultural and linguistic adaptations are available but have not been validated. In all countries, the use of three subscales, and an overall summary score was confirmed to be useful.

6. KING’S HEALTH QUESTIONNAIRE (KHQ)

The King’s Health Questionnaire (KHQ) consists of three parts. The first section contains two questions measuring general health and overall health related to urinary symptoms. The second section includes 19 questions divided into seven domains of quality of life: incontinence impact, role limitations, physical limitations, social limitations, personal relationships, emotions, sleep and energy, severity coping measures, general health perception, and symptom severity. The third section of the questionnaire comprises 11 questions measuring the bother or impact of urinary symptoms. The KHQ has demonstrated reliability and validity in men and women [24] in 37 languages [82-84]. Sensitivity to change has been shown successfully in clinical trials where it has been used to assess the HRQL improvement following treatment for patients with OAB, USI and mixed incontinence symptoms [79, 85-88]. A minimally important difference has been derived to establish clinically meaningful interpretations of the KHQ scores and a QALY measure has been derived from KHQ scoring [89].

7. LEICESTER IMPACT SCALE (LIS)

The LIS is a condition-specific HRQL measure for men and women assessing the symptoms of urgency, frequency, nocturia, and incontinence. It is an interviewer-administered tool so it is not a true PRO as interviewer administration can introduce potential bias into the patient responses. The LIS does have utility in the clinical and research settings [90].

8. OVERACTIVE BLADDER SYMPTOM AND HEALTH-RELATED QUALITY OF LIFE (OAB-Q) AND OAB-Q SF

The OAB-q is a 33-item questionnaire developed to assess the Symptom Bother (8 items) and HRQL impact of OAB (25 items; 4 domains: Coping, Concern/Worry, Sleep, and Social Interaction.). It has demonstrated reliability, validity, responsiveness in multiple clinical studies of men and women. The OAB-q is a 33-item questionnaire developed to assess the HRQL improvement following treatment for patients with OAB, USI and mixed incontinence symptoms [79, 85-88]. A minimally important difference has been derived to establish clinically meaningful interpretations of the OAB-q scores and a QALY measure has been derived from OAB-q scoring [93]. The 19-item short-form (OAB-q SF) is a six-item symptom bother scale and 13-item HRQL scale that is a single score which has also demonstrated reliability, validity, and responsiveness to change [94]. This questionnaire was developed in the US with women to assess the degree to which symptoms associated with incontinence are troubling [59]. It contains 19 lower urinary tract symptoms and has been shown to have high levels of validity, reliability and responsiveness in a community-dwelling popu-
This 3-item questionnaire is designed to assess
1. BENEFIT, SATISFACTION, AND WILLINGNESS
   (BSW) QUESTIONNAIRE

This 3-item questionnaire is designed to assess
treatment benefit, patient satisfaction with treatment, and patient willingness to continue treatment. The BSW questionnaire was validated using data from three 12-week placebo-controlled trials of tolterodine in patients with OAB [121]. In this validation study, correlations were seen between patient-reported treatment satisfaction and improvements in the OAB-q, the KHQ, and micturition variables.

2. THE OVERACTIVE BLADDER TREATMENT SATISFACTION QUESTIONNAIRE (OAB-S)

The OAB-S is a 5 domain questionnaire which evaluates control expectations, impact on daily living with OAB, OAB control, fulfillment of OAB medication tolerability and satisfaction with control. Internal reliability coefficients were good (Cronbach’s alpha 0.76-0.96), and test retest reliability has been established (reliability coefficients 0.72-0.87) [122, 123]. Cultural and linguistic differences were considered early in the development process, and the OAB-S is available in over sixteen languages [124].

from the OAB-q questionnaire; which is a 33 item questionnaire which assess symptom bother and HRQL impact of OAB [29]. The OAB-V8 is an 8-item questionnaire, which evaluates the symptoms of overactive bladder; namely urinary frequency, nocturia, urgency and urge incontinence. Responses are graded on a 6 point Likert scale. Patients with an overall score of eight or more are directed to seek medical advice. This questionnaire is validated for use by men and women [98].

3. OAB-SS

The OAB-SS is a validated A 7-item questionnaire validated to measure overall symptom severity due to the four index symptoms of OAB. It quantifies all symptoms of OAB in men and women. The OAB-SS includes a detailed evaluation of the urgency symptom. Responses are graded on a 5 point Likert scale.

4. QUESTIONNAIRE FOR URINARY INCONTINENCE DIAGNOSIS (QUID)

The QUID is a 6-item patient administered questionnaire developed to identify and differentiate stress vs urge incontinence. There are 3 items each related to stress and urge incontinence. Scoring is 0 (not at all) to 5 (all the time) for each response. The tool was developed for use with females [128].

V. ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Measures that can be used to assess how bothered patients are by urinary symptoms are included in Table 9. The Patient Perception of Bladder Condition [138] and the Urogenital Distress Inventory are the only Grade A recommend instrument. There are several Grade B and C measures which assess bother for incontinence and LUTS.

1. PATIENT PERCEPTION OF BLADDER CONDITION (PPBC)

The PPBC is a single item questionnaire designed to rapidly assess patients’ perception of their bladder condition [138].

The questionnaire asks patients to choose one of 6 statements that best describes their present bladder condition. The scale was validated during two large 12-week clinical studies evaluating the efficacy and tolerability of Tolterodine in patients with OAB. Patients taking part in the studies completed the PPBC, OAB-q, KHQ and bladder diaries. Baseline and week 12 data was used for statistical analysis. PPBC scores were well correlated with OAB-q questionnaire scores and bladder diary variables. Correlations of the KHQ and PPBC were significant for all KHQ domains with the exception of the general health perception domain. The scale was found to be responsive to change in OAB symptoms and to have discriminant validity as reflected in the OAB-q, KHQ score and bladder diary changes. The PPBC has also shown to have good test retest reliability [117]. This scale has been widely used in studies evaluating the use of drug therapy in patients with OAB [139-141].

2. UROGENITAL DISTRESS INVENTORY (UDI-6)

The UDI-6 is a six item questionnaire which assesses the presence and bother of 6 lower urinary tract symptoms [101]. The UDI-6 assesses types of incontinence, frequency, difficulty emptying bladder and pain/discomfort in the lower abdomen/genitalia. The response options are 0-3. The instrument has demonstrated validity, reliability and responsiveness [142].

VI. ASSESSING THE IMPACT OF URGENCY

Several instruments have been developed specifically to assess urinary urgency, which is defined by the International Continence Society as “the complaint of a sudden compelling desire to pass urine which is difficult to defer” [147]. Urgency is the principle symptom of OAB [148], and, as such, assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficult-to-postpone need to urinate (urgency) [149, 150]. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein [151] make a case for describing urgency as a “compelling desire to void in which patients fear leakage of urine” as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced UUI (an event) rather than the strongest feeling of urgency (a sensation) itself. In such cases, patients who have severe urgency, but not UUI, do not have an option for endorsing the highest (worst) value, because they are not incontinent. Urgency severity scales that include a UUI response option thus may be less useful than those that do not because such scales are trying to measure 2 things at once, both urgency and UUI.

Several instruments have been developed to assess urinary urgency these are summarized in Table 10. Given no urgency measures have a Grade A rating, a brief summary of each urgency measure is presented below.

Urgency Perception Scale was designed for use in clinical trials to evaluate patient-perceived urgency

This instrument consists of a single question asking patients to describe their typical experience when they feel the need to urinate. The 3 possible responses are “I am usually not able to hold urine,” “I am usually able to hold urine until I reach the toilet if I go immediately,” and “I am usually able to finish what I am doing before going to the toilet.” [152]. This scale was validated in a clinical trial evaluating the efficacy of tolterodine in treating OAB symptoms; [152] however, its limited responsiveness may preclude its usefulness in clinical practice [153].

**Indevus Urgency Severity Scale** asks patients to rate their level of urgency on a 4-point scale, from 0 (no urgency) to 4 (extreme urgency discomfort that abruptly stops all activity/tasks) [154]. The scale has been validated in a clinical trial of trospium in patients with OAB, [154] but Chapple et al [153] question whether this scale actually measures urgency or just the normal urge to void.

**Urinary Sensation Scale** is a 5-point scale ranging from 1 (no urgency; can continue activities until it is convenient to use the bathroom) to 5 (urge incontinence; extreme urgency discomfort, cannot hold urine and have a wetting accident before arriving at the bathroom) [155]. The content validity of this scale was established through a physician survey and patient interviews [155].

**Urgency Rating Scale**, recommended by the European Medicines Evaluation Agency, consists of a 5-point rating scale to be rated with every void, ranging from 1 (no urgency; I felt no need to empty my bladder but did so for other reasons) to 5 (urge incontinence; I leaked before arriving at the toilet) [16]. This scale was used in a tolterodine clinical trial, in which responses on this scale were used to calculate sum urgency, a measure that accounts for changes in both urgency and frequency [156].

Many women present with vaginal symptoms and pelvic organ prolapse (POP) is frequently implicated. A traditional clinical history is usually used in an effort to assess the symptoms experienced by the patient and a thorough clinician will try to gain insight into how these symptoms are impacting on the patient’s life. A detailed description of the clinical techniques of pelvic floor assessment are described in another chapter in this book. However, symptoms do not always correlate with objective examination findings. Indeed the clinical assessment itself can be inconsistent, depending upon the position of the patient, whether they have been standing for a

</table>
prolonged time or have just used a pessary or tampon. While there is a little research defining the association between specific symptoms and support defects [164-166], measuring subjective outcome after treatment is problematic. Unlike lower urinary tract dysfunction, where increasingly patient-completed methods such as diaries and questionnaires are being used to measure outcome, there are fewer such instruments available for POP. Clinician based history is inconsistent, disease impact may not be assessed, leading questions can be asked and patients may be unwilling to volunteer symptoms, particularly after surgical intervention, for fear of appearing ungrateful or a nuisance. Consequently, despite the highly prevalent nature of this condition we have little idea how intervention, which is frequently surgical, alters symptoms and HRQL. As for incontinence, questionnaires to assess symptoms and HRQL impact of pelvic organ prolapse would be highly desirable.

For POP, the Committee examined the quality of the psychometric evidence and only where published data were scientifically sound was the label ‘with rigour’ allowed. The Committee noted that this is a developing area with few questionnaires currently reaching the highest levels of evidence. Thus three grades of recommendation were established (Table 11).

1. **GRADE A**

   a) **Pelvic Floor Distress Inventory (PFDI) and PFIQ (Pelvic Floor Impact Questionnaire)**

   This questionnaire is an adaptation of the well-established UDI with the aim of developing a comprehensive condition specific instrument to assess impact from pelvic organ prolapse and other aspects of colorectal-anal dysfunction, as well as LUTS [167].

---

391
The PFDI retains the 19 original items of the UDI, and adds 9 items related to lower urinary tract symptoms that are common in women with pelvic floor disorders. The three original subscales of the UDI are retained (i.e., obstructive, irritative/discomfort, and stress). Psychometric testing included internal reliability (PFDI Cronbach’s alpha 0.88, PFIQ 0.98), 1 week test-retest (interclass correlation coefficient PFDI 0.87, PFIQ 0.86).

Both correlated with stage of prolapse (Spearman correlation coefficient for pelvic organ prolapse distress inventory and impact questionnaire 0.32 p<0.01, 0.33 p<0.01). Responsiveness has not yet been tested.

PFIQ is an adaptation of the IIQ to assess quality of life impact in women with pelvic floor disorders. It contains items included in the original IIQ and new items related to other pelvic floor disorders. PFIQ has 3 scales including 92 items: IIQ (30 items), Colorectal-anal impact Questionnaire (CRAIQ) (31 items) and Pelvic Organ Prolapse impact Questionnaire (POPIQ) (31 items).

Each scale includes 4 domains of travel, social, emotional and physical activity. The psychometric properties of the PFIQ were evaluated in 100 female patients with pelvic floor dys-fuction [167].

The PFIQ showed good validity; each of IIQ, CRAIQ and POPIQ revealed significant correlation with incontinence episode and number of pad use per week, faecal incontinence per week and stage of prolapse, respectively. Internal consistency was excellent (Cronbach alpha 0.98) and test-retest reproducibility was high (overall ICC 0.86 ranging from 0.69 to 0.92). A French language version has been produced [168]. Responsiveness has not yet been evaluated.

Responsiveness of the PFDI and PFIQ was tested in women with pelvic organ prolapse undergoing surgical and conservative management with vaginal pessaries. Women undergoing surgical treatment for prolapse reported significantly greater improvement in all subscales of the PDFI and PFIQ than those patients treated with pessaries.

The PFDI was found to be more responsive to change than the PFIQ [169]. French and Spanish versions of both the PFIQ and PFDI have been produced [170, 171]. Long forms of the PFDI and PFIQ have also been validated for telephone administration [172].

Short forms of the PFDI and PFIQ questionnaires have been developed. Reliability, validity and resposiveness were tested in a population of patients before and 3-6 months after pelvic floor surgery. The short form of the PFIQ and PFDI correlated well with the long form versions of the questionnaires (r=0.88-0.94) [173] (Table 12).

2. GRADE B

- **e-PAQ Electronic Pelvic Floor Symptoms Questionnaire**

The electronic Personal Assessment Questionnaire – Pelvic Floor (ePAQ-PF) is an interactive computerised system that comprehensively measures pelvic floor symptoms and their impact on HRQL in women. It comprises a maximum of 124 items in 4 dimensions (Urinary, Bowel, Vaginal & Sexual) and includes 19 scored domains:

The original 14 domain version underwent psychometric testing in primary and secondary care, where it was found to be valid, reliable and acceptable (Radley et al 2006) [177]. Since this initial validation study, a further 5 domains have been added including: Irritable Bowel, Dyspareunia, Vaginal Capacity, Urinary Voiding and General Sex Life [178]. Each domain is scored on a scale of zero (best possible health) to 100 (worst possible health) and the symptom domains also each provide a 4-point scale. Recent tests of data quality on this version of ePAQ-PF supported the 19 domain structure of the instrument and its reliability and validity (Jones et al, 2008) [179]. The responsiveness of the instrument has also been demonstrated [177].

3. GRADE C

Several other questionnaires of Grade C level or below have been developed in the area of POP. If the validation of these instruments progress they may be useful for researchers. These include:

- P-QOL/St Mary’s Questionnaire [175] [180] -Pelvic Floor Dysfunction Questionnaire [176]
- Danish prolapse questionnaire [164]
- Pelvic symptom inventory and quality of life questionnaire [181,182]
A range of questionnaires have been developed to identify the severity of faecal incontinence (FI) and its influence on HRQL. Despite the large number, only a few are in regular use in research practice, and few services routinely use them in clinical assessment. Due to the close overlap between faecal incontinence and other pelvic floor disorders (in particular urinary incontinence), some of those questionnaires used for other pelvic disorders also include items to cover faecal incontinence. For similar reasons, items relating to faecal incontinence have often been included in questionnaires addressing general gastrointestinal and colorectal function, as well as condition specific instruments in such areas as irritable bowel syndrome and inflammatory bowel disease, conditions which are commonplace in colorectal practice as well as in other specialties dealing with pelvic floor disorders [185, 186]. It is also important to remember that the normal range of bowel function is broad, that bowel function may be highly variable within individuals without significant pathology. Consequently instruments in this field are likely to lack a degree of sensitivity or specificity for the specific bowel disorders such as IBS, IBD evacuation disorder and constipation.

Anal incontinence and bowel evacuation are intrinsically related to pelvic floor function and it may be inappropriate to consider bowel function purely in terms of continence and constipation. Evacuatory dysfunction may result from a variety of underlying pathologies including outlet obstruction, slow transit or other mechanical, physiological, metabolic, endocrine and neurogenic abnormalities [187]. Anal incontinence occurs in both sexes, but is more common in women than men [188]. Symptoms are considered crucial to diagnosis as specific symptoms are thought to reflect the underlying pathophysiology [189]. Thus, urgency (the inability to defer defecation) and urgency incontinence are thought to indicate loss of voluntary control due to impaired external anal sphincter function, whereas passive incontinence is thought to indicate impairment of the smooth muscle of the internal sphincter.

For FI, the Committee examined the quality of the psychometric evidence and noted that this is a developing area with questionnaires currently reaching the highest level of evidence. A FI outcomes measure is currently in development by the ICIQ (Table 3). A commonly used score for FI (Wexner), for example, does not appear to have published data related to its psychometric properties and thus while it is used widely cannot be recommended by the committee. The grades of recommendation are as outlined in previous sections (Tables 13,14).

1. GRADE A

No questionnaires are currently available at this level.

2. GRADE B

a) Faecal Incontinence Quality of Life Scale

The 29-item Faecal Incontinence Quality of Life Scale developed and tested by Rockwood et al. measures impact of anal incontinence over four scales of HRQL: Lifestyle (10 items), Coping/behaviour (9 items), Depression/Self perception (7 items) and Embarrassment (3 items) [190]. The instrument was designed to measure the effect on quality of life for treatment for individuals with faecal incontinence. A panel of colorectal surgeons and researchers generated the items. Psychometric properties were tested in 118 patients with faecal incontinence and 72 controls.

The questionnaire showed good discriminant validity, with significant differences between patients with faecal incontinence and those with other gastrointestinal disorders. There were also significant correlations with selected subscales of the SF-36. Test-retest reliability at a mean interval of 20 days was satisfactory, with correlations for the 4 scales of 0.8 - 0.96. Internal consistency of the 4 scales was >0.7. The instrument does not measure physical symptom severity and has not been tested in asymptomatic controls, but appears to offer a valid and reliable measure of the impact of faecal incontinence on quality of life in men and women with this condition [190]. However, in order to demonstrate discriminant validity, the researchers deemed it necessary to modify the questionnaire for use in controls. Its use in an unscreened population is as yet unreported, and no responsiveness data have yet been produced.

b) Manchester Health Questionnaire

This questionnaire consists of items adapted from the King’s Health Questionnaire [191]. It uses the same basic structure and format but items have a 5-point response scale (rather than the 4-point scale in the KHQ). It includes items in the 8 domains of HRQL as well as a symptom severity scale. Face validity was assessed by interview with 15 patients with faecal incontinence. Test-retest reliability was measured (Pearson correlation > 0.8 in all 9 domains).

The questionnaire was posted to 236 women with faecal incontinence, of which 159 returned completed questionnaires. 121 performed test-retest at a mean interval of 20 days. Cronbach’s alpha was > 0.7 in all domains tested, indicated adequate internal consistency.

Convergent validity was assessed by comparison with responses in the SF-36, which showed significant correlations between domains of the 2 instruments. Data relating to women without faecal incontinence or unscreened women are not yet available. The questionnaire’s sensitivity to change is also not yet established.

c) Birmingham Bowel and Urinary Symptoms Questionnaire (BBUS-Q)

This is a 22-item questionnaire developed to evaluate symptoms of both bowel and urinary dysfunction in women which has a published scoring manual [192, 193]. Items were generated by a panel of clinicians and scientists and following review of existing instruments in the literature. The instrument was tested in the gynaecology departments of three hospitals, a urogynaecology clinic, a functional bowel clinic and a general practice. A total of 630 women completed the questionnaire; 379 women awaiting hysterectomy, 45 women following hysterectomy, 65 women referred with functional bowel and/or urinary symptoms and 141 asymptomatic controls.

The content, construct and criterion validity, internal consistency, reliability and responsiveness of the questionnaire were measured. Low levels of missing data, peer and patient reports supported face and content validity.

Factor analysis showed a clinically relevant four-factor structure: Constipation, Evacuatory function, Anal incontinence and Urinary symptoms with low content replication able to distinguish between patient groups, indicating good internal structure. Comparison with clinical, anorectal physiological, videoproctographic, transit time and urodynamic test results supported the instrument’s criterion validity. Key domain question analysis and Cronbach’s alphas showed internal consistency. Kappa values and limits of agreement demonstrated good test-retest reliability. Some responsiveness data have been produced.

The authors recommended the questionnaire for use as both a research tool and as a useful clinical measure. This questionnaire also forms a core element in an electronic pelvic floor symptoms assessment questionnaire (e-PAQ) (see above).

3. QUESTIONNAIRES WITH POTENTIAL [GRADE C]

There are several questionnaires on faecal incontinence which have not yet reached Grade C status. They may undergo further development and be of use in future research:

- Wexner score [194]
- St. Mark’s score [195]
- Faecal incontinence survey [184,185,190,196,201,202]
- Elderly Bowel Symptom Questionnaire (EBSQ) [197].
- Postpartum Flatal and Faecal Incontinence Quality of life Scale [198].
- Bowel Disease Questionnaire [199]
- Gastro-intestinal Quality of Life index (GIQLI) [200]
Sexual function may be regarded as a dimension or aspect of overall HRQL, for which a number of dimension-specific measures have been developed and validated. There is a wide choice of available instruments, the selection of which will depend on the clinical or research setting where the instrument is to be employed. Established and widely used measures that have been shown to be valid, reliable and responsive are clearly desirable, however the feasibility and appropriateness of using a particular instrument in a particular setting must also be considered. A large number of different instruments exist in this field, which aim to evaluate specific aspects of sexual function and sexual health. A number have been specifically developed or adapted to examine sexual function in patients with pelvic floor disorders such as incontinence.

Clinicians who treat sexual problems often prefer to use unstructured rather than structured interviews or questionnaires in clinical practice as an unstructured approach allows the tailoring of questions to suit the couple or the individual being assessed. Unstructured interviews enable the clinician to support patients who feel vulnerable and encourage discussion. The experienced clinician hopes to have an appreciation of the information required to make the correct diagnosis and institute appropriate treatment. In this setting, vocabulary can be modified, as can the level of assertiveness and the depth of questioning to suit the needs of the individual. This flexibility is not readily achievable with questionnaires which individuals may also find difficult to complete due their impersonal nature or because of physical or mental impairment, cultural or language differences. However, some patients find the discussion of intimate issues with clinicians very difficult and questionnaires may allow these issues to be measured in private, at ease and more effectively before subsequently exploring questionnaire responses in the clinical interview itself (Table 15).

1. RECOMMENDED QUESTIONNAIRES
   [GRADE A]

   a) Golombok-Rust Inventory of Sexual Satisfaction

   The Golombok-Rust Inventory of Sexual Satisfaction (GRISS), is a self-report inventory which has 56 items, from them 28 are for males and 28 are for females and it takes approximately 15 minutes to complete [203]. The questionnaire was developed systematically by sex therapists at the Maudsley Hospital Sexual Dysfunction Clinic. The GRISS assesses the quality

* Grade A new
of a sexual relationship in a heterosexual couple and an individual's functioning within it. This questionnaire is designed for people who are currently in a relationship. There are 12 domain scores, 5 of which are female specific, 5 male specific and 2 non-gender specific. The 5 female specific domains are: Anorgasemia, Vaginismus, Avoidance, Nonsexuality and Dissatisfaction. The 2 non-gender specific domains are: Frequency of sexual contact and Non-communication. The questionnaire was validated on a clinical sample recruited from sexual dysfunction clinics throughout the UK, consisting of 68 men and 63 women, and a control group of 29 men and 30 women randomly selected from primary care attendees. Split half reliability was 0.94 for the female scale and 0.87 for the male overall scale. Average internal consistency of subscales was 0.74.

Both the overall female and male scores were found to discriminate well between clinical and non-clinical samples and scores on subscales successfully discriminated specific diagnostic groups. There was also a significant correlation between therapists' ratings of severity and scores on the questionnaire. Responsiveness was assessed by comparing change in the questionnaire scores with rated improvements by sex therapists. Correlations were moderate but statistically significant (0.54 for males and 0.43 for females, p<.005 and p<.01 respectively). Test-retest reliability was assessed in 41 couples receiving either marital or sex therapy. A further two subscales apply to both males and females and cover infrequency and non-communication. An additional 2 items each for males and females contribute to the overall scores but are not included in the subscales. The GRISS has been used by Hunt & Moss (1996) in a small study exploring the relationship of unwanted sexual experience to detrusor instability and sexual dysfunction [222]. High levels of sexual dysfunction were found in incontinent subjects compared to other clinical groups. The GRISS is not applicable to homosexual couples or people without a partner, but does provide an otherwise comprehensive, effective and well-used questionnaire.

b) ICIQ-MLUTSsex (ICSsex)

This forms one of the modules of the ICIQ modular questionnaire (see above) [205]. It consists of 4 items: to what extent sex life has been spoiled by urinary symptoms, ability to have erections, ability to ejaculate, and pain or discomfort on ejaculation. As with the other ICS questionnaires each item has an additional part to each item concerning the amount of bother the symptom causes i.e. how much of a problem is this for you? It has been used in both clinic and community samples to assess the relationship between urinary symptoms and sexual function, [205] and to show that urinary symptoms most frequently associated with sexual dysfunction were those related to incontinence [223]. It has also been used in a randomised trial of treatments for LUTS to investigate sexual side effects [224]. Aspects of reliability, validity and responsiveness have been tested and found to be satisfactory.

c) International Index of Erectile Function (IIEF)

The international index of erectile function (IIEF) is a 15-item self-administered questionnaire. It was designed to assess erectile function and is culturally and linguistically validated in at least 10 languages for use in multinational clinical trials. It was initially validated in 351 patients with erectile dysfunction (ED) and found to have a high degree of internal consistency (Cronbach's alpha > 0.85) and sensitivity to change with treatment. The questionnaire was culturally and linguistically validated in the following languages: Danish, Dutch, English (American, Australian and British), Finnish, French, German, Italian, Norwegian, Spanish and Swedish. The final 15-item instrument addresses five different domains of sexual function: erectile function, orgasmic function, sexual desire, intercourse satisfaction and overall satisfaction. The IIEF has a high degree of internal consistency. Test-retest repeatability was high for the domains of erectile function and intercourse satisfaction and moderately high for the other domains. Discriminant validity was good for most domains (except the sexual desire domain). Construct validity was good and all five domains showed a high degree of sensitivity to change. An abridged 5-item version of the questionnaire has also been developed (IIEF-5) [225]. Of the 5 items, 4 are from the erectile function domain and one addresses sexual intercourse satisfaction. The main difference between the 5- and the 15-item version is that the former asks patients to self-assess erectile function and satisfaction over the past 6 months while the latter refers to a time frame of 4 weeks. It has been used recently in a multinational survey of male ageing [220].

d) BPH QOL9

The QOL9 is a short form of the QOL20, a questionnaire previously validated in French for men with LUTS related to BPH [118]. The short form was developed using a large-scale cohort study of 7093 men with BPH who received alfuzosin for 3 months. The items were reduced by identifying questions that contributed most to establishing the global score and that reflected the structure of the questionnaire on principal components analysis. The final, 9-item questionnaire consists of 3 items concerning general well being, 3 items assessing BPH interferences with activities, and 3 items pertaining to patients' perceptions of their sexual life. The sexual function domain covered sexual desire, erectile function and satisfaction with sex life. The QOL9 was validated in two studies, a longitudinal study of alfuzosin, having a sample size of 4259, and a smaller cross-sectional study of men having symptomatic BPH (n=48), or no
symptoms of BPH (n=42), and a group of younger men (n=23). Feasibility and acceptability of the questionnaire were assessed by completion rates that exceeded 85%. Principal components analysis confirmed the three-factor structure. Discriminant validity was measured by comparing cases and non-cases. On the sexual function domain cases scored 10.5, non-cases 15.2 and young men 26.3. The most strongly discriminating question between cases and non-cases was satisfaction with sex life. There was also a good correlation between symptom severity and the total QOL9 score. Internal consistency of the overall scale was fair with Cronbachs alpha of 0.79 for patients with BPH and 0.85 for the control groups. Test-retest reliability was good for the total score but moderate for the sexual function subscale (ICC = 0.69 - 0.88) with the reliability of the erection item having an ICC of 0.53. After treatment the effect size of the change in the sexual function domain was linked to age and initial symptoms severity but had a mean of 0.02 and 0.55 for patients treated in each of the two studies.

e) ICIQ-FLUTSsex (BFLUTSsex)

This forms one of the modules of the ICIQ modular questionnaire (see above). The questionnaire contains 4 questions related to sexual function: pain or discomfort due to dry vagina, whether sex life has been spoilt by urinary symptoms, pain on sexual intercourse, and leakage on intercourse [23]. In addition to each of these items the respondent is asked how much of a problem this is for them. It has been used to assess sexual function after hormone replacement therapy [226] and pelvic floor muscle training [40]. There are 18 linguistic translations available and there is published evidence of validity, reliability and sensitivity to change..

f) Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ)

Rogers and colleagues in the United States have reported the development and validation of a measure of sexual function in women with urinary incontinence or pelvic organ prolapse [207]. The scale consists of 31 items spread across 3 domains: behavioural/emotive, physical, and partner-related. The measure has been found to have acceptable convergent and divergent validity and to be able to discriminate between women with and without urinary incontinence or pelvic organ prolapse [207, 227]. Test-retest ranged from 0.56 to 0.93, showing some variability in the moderate to high reliability ranges [228]. The internal consistency of the total measure and the behavioural/emotive, physical and partner-related domains was .85, .86, .77 and .43, respectively [228]. Sensitivity of the PISQ-31 has now been assessed in several studies.

A short form version of the questionnaire PISQ-12 has also been developed by the same team of researchers [229]. All subsets regression analyses with \( r > 0.92 \) identified 12 items, across all three domains, that were the most highly predictive of the PISQ-31 scores. Construct validity of the PISQ-12 was examined through correlations with the long form of the questionnaire PISQ-31 \((r=0.75-0.95)\), the Sexual History Form -12, and the IIQ-7. Correlations of the PISQ-12 with these latter measures were similar to those found for the PISQ-31.

The PISQ-12 scores were lower in those patients with poorer sexual functioning and more depressive symptoms. Test-retest reliability was moderate to high. Internal consistency reliability was stated as having been done, although the values were not reported in the article. Sensitivity of the PISQ-12 was not assessed.

An initial validation of a Spanish version of the PISQ-31 was reported for 34 bilingual patients of Mexican, Central or South American, Puerto Rican and Cuban origins living in the United States [230]. Good agreement between the Spanish and English versions was achieved for 30 of the 31 items. The three-factor structure of the original measure was validated in this sample of participants [227, 231-239].

2. RECOMMENDED QUESTIONNAIRES [GRADE B]

a) The Female Sexual Function Index (FSFI)

The Female Sexual Function Index (FSFI) [209] is a 19-item self-report questionnaire for measuring female sexual function and takes approximately fifteen minutes to complete. It provides five domains of sexual function, which have been confirmed using factor analysis they include: Desire, Lubrication, Orgasm, Arousal, Pain and Satisfaction. An overall total score is also provided. The FSFI was developed using a sample of 131 female controls (between the age of 21-68) and 128 females who met Diagnostic and Statistical Manual of Mental Disorders (DSM-IV; American Psychiatric Association, 1994) criteria for Female Arousal Disorder (FSAD). The age of the participants was matched [21-69]. Norms are available for both groups (controls and FSAD) at the individual items level, the domains level, and the full-scale scores.

The FSFI discriminated reliably between women with arousal disorder (FSAD) and a control group on each of the domains of sexual function as well as on the full-scale score. FSFI data were also compared with results from the Locke-Wallace Marital Adjustment test (1959). Correlations between the two were generally modest in magnitude, with the strongest observed for the satisfaction domain of the FSFI. Internal consistency and test-retest reliability of the FSFI have been established. Test retest reliability of the scale was assessed in women with multiple
sclerosis with associated urinary and sexual symptoms [240].

Further cross validation studies were carried out to develop cut-off scores for potential classification of female sexual dysfunction [241, 242].

The FSFI was used in a study to investigate the prevalence of sexual dysfunction in women with chronic pelvic pain and with the [243] Female sexual distress score (FSDS) to investigate sexual outcomes in women with LUTS who were successfully treated with sacral neuromodulation. A 60% increase in the FSFI overall score or 50% increase in FSDS score was regarded as significant improvement [244]. The FSFI has been used in a study of pelvic floor muscle training for women with pelvic floor disorders and a study of sexual function in women with symptomatic pelvic organ prolapse who were treated with pessaries [233, 245].

The Italian version of the FSFI has been used as a screening tool for sexual dysfunction in healthy women attending annual gynaecological health checks [246]. The impact of LUTS and urinary incontinence on female sexual dysfunction was investigated over a 3 year period in women undergoing urodynamic studies using the FSFI [247]. The Malay translation has also been validated [248].

b) The Psychosocial Adjustment to Illness Scale (PAIS)

The Psychosocial Adjustment to Illness Scale (PAIS) was designed to assess the psychological and social adjustment of male and female medical patients to their illness and is in an interview or self-report format (PAIS and PAIS-SR) [206]. It contains a sexual relationships domain consisting of 6 items assessing the quality of interpersonal sexual relationships, sexual interest, frequency of sexual activity, sexual satisfaction, sexual dysfunction and interpersonal sexual conflict. Validation was carried out on groups of patients having renal dialysis, lung cancer, cardiac problems, breast cancer, and Hodgkin’s disease.

Internal consistency of the sexual relationships domain ranged from 0.8 to 0.93 in these different clinical groups. Factor analysis confirmed the subscale structure. All 6 items in the sexual relationships domain had very marked loadings on this dimension, with no appreciable loadings from other items. Convergent validity was assessed by comparing the scale to the Global Adjustment To Illness Scale (r=0.46), the SCL-90R (r=0.13), Affect Balance Scale (r=0.42), and the Patients Attitudes, Information and Expectancies Scale (r=0.40). Discriminant validity was assessed by comparing patients screened positive and negative for lung cancer. There were differences in the mean scores between the two groups which approached significance (t=1.53, p<0.10) [206].

The PAIS has been used to investigate the impact of different types of urinary incontinence on sexual function [249] in a sample of 200 patients referred for urodynamic assessment. Compared to patients with Urodynamic stress incontinence USI, patients having detrusor overactivity DO were significantly impaired on all items of the sexual relationships subscale, apart from the ‘sexual satisfaction’ item. Some aspects of validation were also carried out in a small study of 29 patients who had been treated successfully for penile cancer [250]. Internal consistency of the sexual relationships scales was good having Cronbach alpha of 0.83. Convergent and discriminant validity was shown in significant correlations with well-being scales but not with social scales. In addition, patients who had had the most radical treatments in terms of partial or total penectomy scored lower on the sexual relationships scale as did older patients (mean age 63 years) compared to younger patients (mean age 41 years), whereas having a mental disorder showed no correlation with sexual relationship scores.

c) The Brief Index of Sexual Function for Women (BISF-W)

The Brief Index of Sexual Function for Women (BISF-W) is a 22-item self-completed questionnaire that takes 15-20 minutes to complete [208]. It is designed to assess current levels of female sexual function and satisfaction. It was originally validated in a sample of 269 sexually active women age 20-73, and used a 3-factor scoring system (Interest/desire, Sexual activity, Sexual satisfaction) with acceptable test-retest reliability. A new quantitative scoring algorithm was developed to facilitate the use of the BISF-W in clinical trials, providing an overall composite score for sexual function and 7 domain scores; Thought/desire, Arousal, Frequency of sexual activity, Receptivity/initiation, Relationship satisfaction, Pleasure/orgasm, and Problems affecting sexual function. Norms for the composite score and for each of the seven dimension scores are available, derived from a sample of 225 healthy women (age 20-55) [251]. Comparing these scores with those of 104 surgically menopausal, sexually active women who reported impaired sexual function (age 20-55), the instrument showed good discriminant validity between women with and without sexual complaints in each of the 7 sexuality domains. In a placebo-controlled study, the BISF-W was sensitive to detecting differences between treatment groups in two of the 7 sexuality domains and on the overall composite BSIF-W score.

d) Brief Sexual Function Inventory

This 22-item questionnaire concerning male sexual function was designed for clinical and research purposes in urological settings [211]. Items were generated from the literature to produce a 50-item questionnaire which was then reduced down to 22 items in a series of pilot studies prior to the final validation study. The questionnaire comprises of 5
subscases: Libido, Erectile function, Ejaculation, Assessment of significance of each domain and Overall satisfaction. Validation was carried out on a sample of 74 men with sexual dysfunction and 60 general medical patients. Mean age was 55 and 45 years respectively. The study describes development of individual subscales down to a final questionnaire of 11 items based on measures of internal consistency and test-retest reliability. Internal consistency of the subscales ranged from 0.62 to 0.95 and ICC’s from 0.79 to 0.89 for test-retest reliability.

All subscales except the drive and ejaculation subscales discriminated between patients being treated for sexual dysfunction and general medical patients, but it was not expected that drive would be reduced in patients experiencing sexual dysfunction and ejaculation did not appear to be an important issue for patients.

e) Sexual quality of life-female questionnaire (SQOL-F)

This questionnaire was developed to assess the impact of sexual dysfunction on women’s quality of life. Responsiveness to change has not been established [210]. The content validity of the SQOL-F, sexual function questionnaire (SFO) and PISQ were further assessed in a postal study of women with OAB and urinary incontinence in the United States, and the SQOL-F was rated most relevant and understandable among this group of women [252].

3. QUESTIONNAIRES WITH POTENTIAL

[GRADE C]

Several questionnaires that have potential and are currently under development or in need of further development. With further validations these instrument could provide additional resources to research:

- The Derogatis Interview for Sexual Functioning (DISF) [206]
- Sexual Behaviour Inventory (SBI) [212, 223]
- The Changes in Sexual Functioning Questionnaire (CSFQ) [213]
- Index of Sexual Satisfaction (ISS) [215]
- Multidimensional Sexuality Questionnaire (MSQ) [216, 223].
- The Sexual Interaction Inventory (SII) [214]
- McCoy Female Sexuality Questionnaire (MFSQ) [217]
- Simple Sexual Function Questionnaire [219, 219, 253]
- Sexual function questionnaire [218]
- DAN-PSSsex [220]
- Sexual life quality questionnaire (SLQQ) [221]

a) Other measures of sexual function

Many of the questionnaires assessing the psychosocial impact of LUTS and/or UI contain one or two questions related to sexual function. The majority of these are discussed above, either as symptom questionnaires or general quality of life questionnaires. Questionnaires containing just one question tend to focus on a general assessment of the overall impact of urinary symptoms on sexual functioning. The Kings Health questionnaire, [24] the Incontinence Impact Questionnaire [59] and the I-QOL [75] are recommended by the Committee for use for UI/LUTS. However, when considering the sexual items it must be borne in mind that validation of the sexual items was not always carried out or made explicit. But the questions relating to sexual function in each of the questionnaires are very similar and judgements on validity can be made by comparing questions and psychometric data between questionnaires as well as considering the psychometric properties of the scales as a whole. If more in-depth information is required concerning sexual function, the questionnaires recommended for this aspect should be used (see above).

There are other general measures of sexual function, such as the Watts Sexual Function Questionnaire, [254] and Medical Outcomes Study (MOS) Sexual Functioning Scale [255]. There are also questionnaires that have been designed for sexual dysfunction specific to particular diseases, such as Radiumhemmets Scale of Sexual Function, [256] Sexual Adjustment Questionnaire (SAQ), [257] and Prostate-targeted Health Related Quality of Life [258].

A small number of questionnaires have produced initial validation but without publications during the reporting period: Effect of Urinary Incontinence on Sexuality Questionnaire (EISQ), [259] and Effects of urinary incontinence on sexual activity [260].

X. QUESTIONNAIRES FOR SPECIFIC PATIENT GROUPS

Most studies and questionnaires have been developed for use with members of the general population or urology/gynaecology patients with incontinence or POP. However, some specific patient groups may experience particular problems with incontinence (for example, children, frail elderly or those who are severely disabled), which may require independent investigation and potentially the development of more specific measures or the addition of a new subset of items on already developed instruments. The Committee advises that researchers should use existing highly recommended or recommended questionnaires if possible as this aids comparison and to reduce the increasing proliferation of questionnaires. Many of the questionnaires developed
below for particular conditions (e.g. prostate cancer) pre-dated the development of highly recommended questionnaires, and highly recommended questionnaires should be used preferentially.

a) Older people

Urinary incontinence symptoms play an influential role on the overall HRQL in older people (>65) and causes a significant decrease in HRQL, as severe as that of many chronic disease states. Since the elderly commonly have a number of associated comorbid conditions, it may be difficult to measure the impact of urinary incontinence with generic HRQL measures. The use of incontinence specific tools to measure patient-reported outcomes in the elderly, therefore, is of considerable importance.

Validated incontinence-specific PRO questionnaires, such as IIQ, I-QOL or KHQ, are used for clinical trials or research on urinary incontinence including elderly people, but their validity has not been specifically assessed in this age group. Okamura, assessed symptoms and HRQL in older people (men and women) with lower urinary tract symptoms including incontinence, using the KHQ and IPSS. They demonstrated that symptoms and HRQL in the elderly with LUTS could be assessed by IPSS and KHQ and that urinary incontinence appeared to be more associated with a decreased HRQL in elderly women [80].

On the other hand, there are a variety of factors affecting older people, including physical, social, mental, economic or environmental conditions, which are different from those of the young. In frail elderly people with dementia or physical impairment, it may be difficult to assess the impact of urinary incontinence alone. Questionnaires specifically developed for the elderly may be of great importance in this respect. However, there is little relating to the development or validation of particular questionnaires for older people with urinary incontinence. Two questionnaires dealing with older people were found and are described below. No questionnaires dealing with patient outcomes specifically for frail older incontinent people were found.

1. The Urge Impact Scale (URIS) [Grade B]

The Urge Impact Scale (URIS) was designed and tested specifically for older persons with urgency incontinence. The URIS was developed and validated by DuBeau et al. (1999) [261] and included 32 items, reduced to 24 items (URIS-24). The URIS-24 was psychometrically assessed for validity and reliability in community-dwelling older (>65y) men and women with urge incontinence. Cronbach alpha was 0.84 for the URIS-32 and 0.94 for the URIS-24. In assessment of test-retest reliability, interclass coefficient (ICC) was 0.88. The URIS-24 had modest but nearly significant correlation with the number of urgency incontinence episodes (rho=-0.39, p=0.05). Factor analysis revealed 3 component structures corresponding to physiological burden, perception of personal control and self-concept. There was no analysis for responsiveness. They showed that the URIS-24 is an internally consistent, highly reproducible tool for the assessment of the QOL impact of urgency incontinence on older persons.

2. Swedish questionnaire [Grade C]

A questionnaire survey was conducted among men and women aged over 75 years in Sweden [262]. The questionnaire was developed specifically for the study although many questions had been used in a previous epidemiological survey [263]. The questionnaire achieved an admirable 62% response rate, but no details were published describing the psychometric properties of the questionnaire or the method of its construction.

There still remains a gap in the assessment of PROs for frail older adults by other than subjective means. Many of the commonly used measures have been used for older people as part of pharmaceutical company studies but it is not known whether these are relevant to the needs of the frail elderly or that they respond in a similar fashion when used in younger populations.

b) Children

Some questionnaires have been developed specifically to address issues for children, particularly enuresis. See Chapter (Children) and section on ICIQ modular questionnaire.

c) Spinal cord injured/neurologically damaged

Individuals who have a spinal cord injury or are neurologically damaged can experience particular difficulties with incontinence and the use of various devices. It would be useful to investigate whether Grade A questionnaires, developed for people without neurological damage, can be used in this group, or whether additional modules or instruments are required. This is an area where a small number of questionnaires are being developed with the Qualiveen being a notable exception (Also see section on the ICIQ questionnaire and below).

Qualiveen: Quality of Life Related to Urinary Problems in Spinal Cord Injury [Grade A]

The Qualiveen was developed to evaluate the specific impact of urinary dysfunction on the quality of life of spinal cord injury patients in France [264]. The initial items were developed following patient interviews, and were then assessed for validity and reliability in 281 spinal cord injury patients with urinary difficulties. The Qualiveen contains 30 items and has demonstrated good reliability and validity [264]. Further validation of the Qualiveen has occurred in multiple
sclerosis patients [265] and it has been translated and validated into English [266], German [267], and Portuguese [268]. The Qualiveen has demonstrated responsiveness in multiple sclerosis patients and has a suggested MID of 0.5 [269].

d) Prostate/bladder cancer

Many PRO questionnaires are available for assessment in this area: Post-radical prostatectomy questionnaire, [270, 271] Cancer Rehabilitation Evaluation System - Short Form (CARES-SF), [272] Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q), [273] PROSQUIOL, [274] Modified Southwest Oncology Group (SWOG), [275] Functional Assessment of Cancer Therapy - (FACT-G), Bladder form (FACT-B) and Prostate form (FACT-P), [276] Functional Assessment of Cancer Therapy Vanderviet Cystectomy Index (FACT-VCI), [277] EORTC metastatic prostate cancer, [273] Changes in Urinary Function, [277] Prostate-targeted Health Related Quality of Life [258]. While it is beyond the scope of this chapter to review and recommend PROs in this area, the principles and guidelines discussed herein apply to selecting a PRO related to prostate and bladder cancer.

e) Lower urinary tract symptoms/benign prostate disease

Many questionnaires have been developed to assess LUTS and benign prostate disease, however most do not contain a full evaluation of UI. Perhaps the most widely known urology PRO is the AUA Symptom Index, [137] I-PSS (International Prostate Symptom Score) [137, 278]. The IPSS has been utilized internationally to assess symptoms of prostate disease with documented reliability, validity and responsiveness. Additional PRO measures for BPH are as follows: Patient-completed modification of the Boyarsky [279] BPH Impact Index, [144] and BPH Health-related QoL survey [280].

XI. SELECTING PRO MEASURES FOR CLINICAL TRIALS AND CLINICAL PRACTICE

The previous sections have provided an overview of PRO measures with evidence of reliability, validity, and responsiveness. But, how does a researcher choose which instruments are most appropriate for a particular research study and/or clinical assessment? The following section provides general guidelines for use in conducting PRO assessments in clinical trials or other research investigations related to urinary or faecal incontinence.

As there are many available PROs, it is of utmost importance to select the PRO measure that is relevant and applicable to one’s desired outcome. If an intervention is designed to reduce symptom bother, then a relevant PRO would be a symptom bother measure. Multiple PROs can be included in a research study, however the designation of the PRO as a primary or secondary endpoint must be . In addition, issues of staff and participant burden, time constraints, and resources should be considered in the selection of a PRO measure.

1. SELECTING PRO MEASURES FOR RESEARCH STUDIES

a) Study Design

There are several protocol concerns that must be taken into account when using PRO measures in research studies, including the length of the study, the frequency of contact with the study participants, the timing of clinical assessments, the complexity of the trial design, the number of participants enrolled, and participant and staff burden. The goal of the PRO investigation is to "fit" the PRO measures to the protocol without compromising either the study objective or design. For example, if the study design is complex with frequent participant contacts and multiple clinical measures, it may be necessary to keep the PRO measures at a minimum or to reduce the number of times the PRO is assessed (e.g. baseline and end of study rather than during all participant contacts) to minimise participant and staff burden.

At the same time, however, PROs must be viewed as an important variable in the overall trial design and cannot be devalued in the data collection process. Consequently, PRO measures cannot be altered or reduced to accommodate study design as such alterations may yield potentially less reliable measures or may seriously diminish the integrity of the overall study design and yield useless information. Having well developed research goals and questions regarding PROs will help to guide you in the selection of measures for a study. The goal is to develop a conceptually adequate, yet practical PRO battery given the study population, the specific intervention, and the study design.

The frequency with which PRO will need to be assessed in a research study will depend upon the nature of the condition or intervention being investigated and the expected effects (both positive and negative) of treatment. At a minimum, as with all measurements collected in a research study, a baseline and end of study assessment should be completed. In addition, other PRO assessments should be timed to match expected changes in functioning due to either the intervention or the condition or the disease itself. Timing follow-up assessments to coincide with typical patient follow-up visits, if appropriate, may also reduce the costs involved in follow-up PRO and symptom assessments.
Finally, it is important to have a clear understanding of the current medications the patient population is likely to be taking prior to randomisation to the study treatment, and how these medications might interact with the trial intervention, (either a pharmacological or behavioural intervention), to influence patient outcomes.

There are two types of PRO measures: generic and condition-specific. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both healthy as well as ill individuals). These instruments are generally multidimensional, and assess at least the physical, social and emotional dimensions of life. An example of this type of instrument is the Medical Outcomes Study SF-36 Health Status Profile. [281]. A second type of measure is condition-specific (e.g., instruments designed to assess the impact of specific diseases, conditions, age groups, or ethnic groups). Condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions, but condition-specific measures also include items more specific to the particular condition or population being studied. Examples of frequently used condition specific instruments include the Incontinence Impact Questionnaire, the King’s Health Questionnaire, and the OAB-q (described above).

In general, the growing trend has been to include condition-specific outcome measures in clinical trials due to their enhanced sensitivity to change and the need to minimise participant burden. Importantly, the type of instruments selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed. In practice, clinical trials that include PROs usually incorporate a combination of PRO measures most relevant to the study population and intervention, if applicable, being mindful of resource constraints and staff and participant burden.

1. QUALITY-ADJUSTED LIFE YEAR (QALY)

Increasingly HRQL outcome measures are being used in the development of quality-adjusted life year (QALY) measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs. QALYs are widely used for cost-utility analysis [282]. In the past decades, economic evaluation has been increasingly important for the decision maker to decide which treatment or intervention is more cost-effective, in order to allocate limited healthcare resources soundly. Economic evaluation aims to compare interventions in terms of their costs and benefits,
including their patient outcome impact. Health benefits can be quantified as QALYs (pronounced “qualies”), which has become a standard measure and is now recommended in most of health economics guidelines as the method of choice [283]. The economic chapter contains additional information regarding QALYs, as do the following references: [284, 285].

2. SUMMARY

In summary, some general points to consider in selecting PRO measures for lower urinary tract and pelvic floor disorder studies:

- Ensure that the PRO research questions and study endpoints are clearly defined. Determine the PROs that are most crucial to assess and which are most likely to be affected by a particular condition and/or its treatment.
- Make good use of prior literature searches in identifying past research in the area(s) of interest, as well as in identifying the types of PRO measures other researchers have used in past work. This information can provide valuable information on how particular outcome measures have performed in previous populations, as well as provide additional information to assist in defining research questions/ issues regarding the PRO components of any given study.
- Consider the characteristics of the population in selecting measures. For example, are the study subjects to be children or older adults, well educated vs. those with limited education, or persons with low literacy? Ensure that the mode of data collection is appropriate for use with the study population. Furthermore, do not assume that an instrument validated for use with Caucasian, middle-class individuals in the U.S. will be appropriate for use in other countries, and/or those of a lower socioeconomic status or of different educational backgrounds. This chapter has indicated, where possible, the extent to which specific PRO measures have been validated, and used reliably with different populations.
- Use the questionnaires recommended in this chapter whenever possible. Do not “reinvent the wheel.” Developing new PROs is a time-consuming and complicated process. If a new scale needs to be developed, ensure that the guidelines proposed by the FDA and EMEA on developing PROs are followed and that the appropriate expertise in questionnaire development and psychometrics is available to your research team in order to guide the questionnaire development process.
- Know the strengths and weaknesses of different types of PRO measures. In general, generic measures are useful in providing information on multiple patient outcome dimensions that can be compared across different populations. They may lack sensitivity, however, in addressing concerns of specific patient populations (e.g., OAB, UI, faecal incontinence). Condition-specific instruments, in contrast, do address areas of function more specific to the condition, and tend to be more responsive to changes in clinic status, due to their increased specificity in addressing the conditions of their patient populations. Weaknesses of condition-specific instruments, however, are that they are often not appropriate for use with multiple populations, and cannot be used to make direct comparisons across different patient groups.
- Know how to score your selected PRO measures and how to interpret the scores. Specifically, ensure that the scoring method of a measure provides you with the information you need to answer your research question?
- Pilot testing of PRO measures with participants/patients similar to those in the target patient population who will be assessed in a research investigation is always advisable. Adjustments can then be made in the protocol, if necessary, prior to the initiation of the study.
- Finally, train and certify your staff to administer PRO measures using either patient interview and/or self-administration techniques, depending on the method to be used in the study. The administration process needs to be standardised and completely similarly across all participants.

5B - F. RECOMMENDATIONS FOR RESEARCH

The following recommendations were unanimous:
1. The selection of a PRO questionnaire must reflect study purpose and objectives
2. Grade A recommended questionnaires should be used in all clinical trials evaluating treatments
3. The inclusion of the ICIQ modules is preferred in all studies to standardise outcome assessment
4. Continued PRO development, refinement, and use should accurately and adequately report on the methods, samples, statistical analyses and psychometric properties of questionnaires in scientific journals (i.e. validity, reliability and responsiveness), so the quality of each study can be assessed Researchers are encouraged to use existing questionnaires and refine for specific populations when needed (e.g. frail elderly, children)
5. Researchers are encouraged to collaborate with the ICIQ project on the development and refinement of modules and translations.

Dynamic Testing

G. Hosker

A. INTRODUCTION

The first two reports of the International Consultation on Incontinence (ICI) contained chapters on “Urodynamic Testing”[1, 2]. Urodynamics is the umbrella term used to describe measurements of the function of the lower urinary tract. These measurements can be used in the management of urinary incontinence. The third report of the ICI expanded this topic to include physiological measurements of the lower gastrointestinal tract. These measurements can be used in the management of faecal or anal incontinence. Consequently, the chapter was then renamed ‘Dynamic Testing’. [3]

This is the successor to that chapter and, in this fourth consultation, we have further updated the evidence for the technical performance, clinical utility and responsiveness to treatment of these measurements. We have used the chapter on ‘Dynamic Testing’ from the previous consultation as a template for this report; retaining some of the original text and tables where there has been no change since the previous consultation.

The primary aim of the chapter is to discuss the value of the various tests to diagnose the mechanisms of continence in general, to discuss what tests ought to be performed to elucidate these mechanisms in the individual; and to make recommendations for what tests should be performed for certain groups of patients. Thus we have tried to present an overview of the best scientific evidence with regard to the role of urodynamics and lower gastrointestinal tract testing.

On the basis of this we provide recommendations for the current state of assessment of the patient with incontinence, and recommendations for future scientific evaluation or analysis of dynamic testing. The overview of scientific evidence in paragraphs, with conclusion(s) and recommendation(s) and topics(s) for research are highlighted in the text and are therefore also suitable for ‘express reading’.

The third ICI report expressed the hope that faecal (anal) incontinence and urinary incontinence could be dealt with by an integrated approach by future consultations. However, although the two topics clearly have much in common with regard to both pathophysiological mechanisms and clinical application, this committee thought it was appropriate to continue to address the two topics separately in this report.

Therefore, following this introduction, the chapter firstly considers urodynamics before considering dynamic testing for anal incontinence. For each, the tests are described and then there is a review of data about normal values and reliability of the measured parameters. This is followed by reviews of the literature regarding clinical urodynamic evaluation of different patient groups with urinary incontinence (women, men, children, neurogenic dysfunction, and the frail elderly). This is followed by reviews from the literature regarding the clinical evaluation of patients with anal incontinence. Each section concludes with the committee’s recommendations regarding dynamic testing.

B. URODYNAMICS

I. WHAT IS URODYNAMICS?

The term ‘Urodynamic studies’ (UDS) was defined by the International Continence Society (ICS) in 1988 and involves the assessment of the function and dysfunction of the urinary tract by any appropriate method. [4] A more recent report in 2002 did not alter the definition of ‘urodynamic studies’ or ‘urodynamics’ but did include a new definition of ‘urodynamic observations’. [5]

The conventional view – implicitly adopted in the previous standardisations and consultations – is that urodynamics is a series of more or less agreed-upon clinical tests, such as flow studies, filling cystometry, pressure-flow studies and/or urethral function measurements. These can be combined with simultaneous electromyography (EMG) recording and/or
imaging by either X-rays or ultrasound. Also implicitly agreed upon is that urodynamics is the only objective way to determine why people have lower urinary tract symptoms (LUTS). The attempt to gain understanding of lower urinary tract (LUT) behaviour, on the basis of test observations, in relation to what is known about normal – or expected abnormal– physiology, is what constitutes urodynamics.

Urodynamic studies can answer questions such as: ‘What causes the increased voiding frequency in this patient?’ as well as: ‘Why does this patient have urinary incontinence?’ These questions not only can be posed for individual patients but also can form part of clinical or laboratory research.

Conventionally, UDS involves the patient being connected to equipment in the laboratory in order to measure physiological parameters, such as pressures, inside the patient. The data is analysed as the test is being carried out and adjustments can be made to correct for technical problems and artefacts as they arise. If conventional urodynamic studies fail to provide an answer to the question being posed then ambulatory urodynamics may be employed in an attempt to obtain the answer. [6] In ambulatory urodynamics, pressures and other physiological parameters from the patient are fed into a small, body-worn solid-state recorder and the patient is free to move about and carry out normal activities. The test can last for many hours and the physiological data is analysed once the test has been completed.

II. WHAT SHOULD BE THE ROLE OF URODYNAMIC STUDIES IN CLINICAL PRACTICE?

There is an agreement among experts that the immediate aim of urodynamic testing is to reproduce the symptom(s) of the patient under controlled and measurable conditions, so that the cause of the symptoms can be determined and useful, objective information can be provided to the clinician. The role of urodynamic studies in broad clinical perspective can be:

a) to identify or to rule out factors contributing to the LUT dysfunction (e.g. urinary incontinence) and assess their relative importance
b) to obtain information about other aspects of LUT dysfunction
c) to predict the consequences of LUT dysfunction for the upper urinary tract
d) to predict the outcome, including undesirable side effects, of a contemplated treatment
e) to confirm the effects of intervention or understand the mode of action of a particular type of treatment; especially a new one

f) to understand the reasons for failure of previous treatments for urinary incontinence, or for LUT dysfunction in general.

The International Continence Society has provided standards for urodynamic terminology and techniques to optimise interpretation and facilitate comparison between different studies [5]. Some of the urodynamic terminology is given in Table 1.

III. THE TESTS OF CONVENTIONAL URODYNAMICS

1. UROFLOWMETRY

This is the non-invasive measurement of urine flow rate. The patient micturates into a flow meter in private when they have a normal desire to empty their bladder. [7] Urine flow rate is continuously measured and displayed graphically. Various parameters from the trace are automatically calculated and printed out together with the trace. The volume voided, shape of the curve and the maximum flow rate are usually the principal determinants of whether or not the patient is emptying their bladder normally. If an abnormal recording is obtained, it is usual to repeat the assessment to check that the result is reproducible.
Several factors, such as patient apprehension, can give an abnormal recording in patients who have no voiding difficulty. Repeating the assessment can eradicate the effect of such confounding factors and will confirm or refute the validity of the first assessment.

2. FILLING CYSTOMETRY

This is the measurement of the pressure inside the bladder to assess its storage capabilities. It is an invasive test which involves a pressure sensor being placed into the bladder, usually transurethrally, and another pressure sensor being placed rectally or vaginally (or sometimes through an abdominal stoma) to measure abdominal pressure. Subtracting the abdominal pressure from the pressure measured inside the bladder (intravesical pressure) gives a representation of pressure changes due to the action of the detrusor smooth muscle.

During this assessment, the bladder is usually filled with normal saline solution (or x-ray contrast solution in the case of videourodynamics) either through a separate catheter placed transurethrally or through the filling channel of a dual lumen catheter if such is used to measure intravesical pressure. Usually the filling rate is much faster than physiological bladder filling.

The intravesical, abdominal and detrusor pressure are monitored as the bladder is filled and before the patient has been given ‘permission to void’. The storage ability of the bladder is assessed in terms of the volumes required to elicit various sensations from the patient, its capacity, its compliance and its stability. The filling (storage) phase of cystometry is also the only method of demonstrating urodynamic stress incontinence (USI).

3. PRESSURE-FLOW STUDIES (VOIDING CYSTOMETRY)

This is a measurement of the mechanics of micturition. When the filling (storage) phase of cystometry is complete, the patient is given ‘permission to void’ and will empty their bladder on a flow meter whilst intravesical, abdominal and detrusor pressures are being monitored. The simultaneous measurement of flow rate and pressure enables voiding to be assessed and, when bladder emptying is poor, it can help determine whether poor flow is due to an outflow obstruction or poor detrusor contractility.

4. URETHRAL PRESSURE PROFILOMETRY

This is a test carried out in some centres and measures the urethra’s ability to act as a valve to contain urine within the bladder. A pressure sensor is placed transurethrally into the bladder and then withdrawn along the urethra (usually by a mechanical puller at a constant rate). The pressure along the length of the urethra is measured, usually relative to the pressure inside the bladder. The maximum pressure measured in the urethra gives an indication of the closure function of the urethra and may be of help in determining the management of the patient with USI.

5. ABDOMINAL LEAK POINT PRESSURE

This is a test carried out in some centres and is another measure of the urethra’s ability to act as a valve to contain urine within the bladder. Intravesical or abdominal pressure is measured whilst the patient is asked to increase their abdominal pressure by valsalva or by coughing. The abdominal pressure required to produce leakage from the bladder gives an indication of the closure function of the urethra. The greater the pressure required to produce leakage, the better the closure function of the urethra. This test may be of help in determining the management of the patient with USI.

IV. TECHNOLOGICAL INNOVATIONS IN URODYNAMICS

1. AIR-CHARGED CATHETERS FOR PRESSURE MEASUREMENT

Air-charged catheters have been used for pressure measurement in urodynamics for many years. However, until recently, they have been the sole preserve of enthusiasts who have manufactured and used them ‘in-house’.

Recently, commercial, single-use, air-charged catheters have been developed and used for intravesical, intraurethral and abdominal pressure measurement in urodynamics (T-Doc, Wenonah, NJ). Initial reports from a female cadaveric study showed that these catheters gave more reproducible measurements of maximum urethral closure pressure compared to microtip catheters, water filled catheters and fiberoptic catheters. [8] In a more recent study in 2004 on 45 women, their performance has been shown to be comparable to microtransducers in the measurement of maximum urethral closures pressure and Valsalva leak point pressure (VLPP). [9] However, the same study showed a difference in functional urethral length (FUL) which was attributed to the different diameters of the two catheters.

A criticism of this study was that the catheters were not used in a random order. Therefore in 2008, Zehnder et al carried out a randomised comparison of these catheters with microtip catheters in 64 women. The measured MUCP and FUL and found that the air-charged catheter was as least as reliable as the microtip for measuring these parameters. However, because the air-charged catheter gives a higher reading of both parameters compared to the microtip device, they concluded that they cannot be used interchangeably for clinical purposes. [10] These devices are being actively marketed for the
measurement of intravesical and intra-abdominal pressure during filling and voiding cystometry. However, there have been no published studies in the peer-reviewed literature concerning their performance in this way; there are only the studies mentioned above which predominantly relate to the measurement of urethral pressure. There is no reason to suspect that these devices are inappropriate for the measurement of such pressures and, indeed, the measurement of VLPP by Pollak et al [9] is encouraging that they can be used to measure intravesical pressure. Nevertheless, a comparison of the air-charged catheters with the traditional fluid-filled lines for intravesical and intra-abdominal pressure measurement would be useful; particularly comparing their measurements during relatively fast events such as coughing.

Air-charged catheters have several practical advantages over fluid-filled pressure lines because there is no fluid connection between the patient and the urodynamic equipment; just air. This means there is no hydrostatic pressure effect to account for so that there is no need to position anything at the level of the symphysis pubis. There is no need to flush the system through to exclude air; a process that is essential in a fluid-filled pressure-sensing environment. There are no artefactual fluctuations in pressure produced when the patients move. Essentially, these devices are ‘plug and play’ which means they are much easier to set up and use compared to the fluid-filled system. Therefore, they have the potential to overcome one of the problem areas of urodynamics; that of setting up. However, although they may make urodynamics easier to set up, the conduct and interpretation of a urodynamic study still requires an experienced, appropriately trained practitioner.

Conclusions (level 3)

• Air-charged catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra.

• There have been no studies to show whether air-charged catheters provide an acceptable alternative to fluid-filled lines for measuring intravesical and intra-abdominal pressure in urodynamics.

Recommendation (grade C)

• Investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure in urodynamics would be advised to check for themselves that they have an equivalent performance to their current system for measuring pressure

Topic for research

• That a study is set up to compare the performance of air-charged catheters with fluid-filled pressure lines in the measurement of intravesical and intra-abdominal pressure during filling and voiding cystometry; particularly during ‘fast’ events such as coughing.

2. OBJECTIVE ASSESSMENT OF BLADDER SENSATION

Bladder sensation during urodynamics is usually recorded by the simple expedient of asking the patient to inform the investigator when they experience different sensations. This is a somewhat subjective measurement which can be confounded by the investigators inadvertently distracting the patient whilst bladder filling is being carried out. Investigators can also bias the measurement by inadvertent prompting of the patient.

In 2005, Craggs described a patient-activated, keypad ‘urge score’ device to measure sensations during bladder filling. [11] This enables patient perceptions of bladder filling and the successive stages of increasing bladder sensation to be recorded without prompting or intervention by the investigator. The accuracy of the ‘urge keypad’ during filling cystometrography was validated in patients with urgency incontinence, and compared with data abstracted from patient voiding diaries. Craggs concluded that the device provides reliable and repeatable measures of different bladder sensations, with excellent, statistically significant consistency between bladder volumes and corresponding levels of sensation.

The development of an objective method of recording bladder sensation during filling cystometry appears to be desirable. Whether it improves the reproducibility and sensitivity of urodynamics has yet to be determined.

3. NON-INVASIVE PRESSURE-FLOW MEASUREMENTS

Over recent years, groups in Newcastle upon Tyne (UK) and Rotterdam (The Netherlands) having been developing non-invasive techniques to measure pressure-flow in males.

The UK group has developed a penile cuff device. [12] The cuff is placed around the penis and is inflated and deflated whilst the patient voids into a urine flow meter. The pressure required to interrupt the flow is assumed to be equivalent to the bladder pressure generating the flow at that time. The group has determined that cuff widths of 40 to 50 mm are optimal for ensuring good pressure transmission from the cuff to the urethra. [13]

Further development of the technique resulted in the publication of a nomogram to classify whether individuals are obstructed or not obstructed when measured by this technique. [14]
There is apparently good agreement between experienced operators regarding the measurement of the pressure at which flow is interrupted. [15] In 2008, non-invasive measurements of pressure and flow were carried out at six different sites in the UK. [16] The measurements on individuals were repeated a median of 20 days later. Only 69% of tests produced analysable data on the two occasions. Whilst the mean differences in flow rate (0.2 ml/s) and cuff interruption pressure (4 cm H₂O) were small, 33% of men changed diagnostic category with the repeat measurement (from obstructed to non-obstructed or vice versa).

There is evidence that the method is sensitive to change. In 2007, 163 men underwent non-invasive pressure flow study using the penile cuff technique before and 4 months after transurethral prostate resection. [17] There was a significant change in flow rate and cuff-interruption pressure following removal of the obstruction in addition to 80% becoming non-obstructed on the basis of their measurements.

The same group produced retrospective evidence that categorisation of bladder outlet obstruction by the penile cuff technique improves prediction of outcome from endoscopic prostatectomy. [18] In 179 men undergoing TURP following standard assessment in the institution concerned, 37% were categorised as having bladder outlet obstruction (BOO) by the penile cuff test and 87% of these had a good outcome from TURP. Whereas of the 19% the of deemed not obstructed, 56% experienced a good outcome (p<0.01). In the remaining men not categorised in these two groups, 77% had a good outcome. However, the retrospective nature of this study weakens the argument for the prognostic ability of the penile cuff test.

The penile cuff test is now commercially available as the CT3000 (Mediplus Ltd, High Wycombe, UK).

The group in Rotterdam had a similar approach to developing a non-invasive method of measuring pressure and flow in men. However, instead of using a penile cuff to interrupt flow, they used a condom catheter through which the patient voided into a urine flow meter. During flow, the stream would episodically be diverted to a pressure transducer which would record the bladder pressure at that time. [19] They were able to correctly classify most men as being obstructed or not obstructed when compared to the ICS nomogram provided that the men did not strain during voiding.

Further work on the technique in 2003 revealed that a minimum flow rate of 5.4 ml/s was necessary to produce an accurate assessment of bladder pressure during voiding using the condom catheter technique. [20]

In 2004, the technique was reported to have a reproducibility comparable to that of invasive pressure-flow studies in an interim analysis of the first 730 patients enrolled in a study of changes in urinary bladder contractility secondary to benign prostatic hyperplasia. [21] In 618 (94%) of 659 eligible participants, one condom pressure measurement was completed; two measurements were done in 555 (84%). The maximum condom pressure ranged from 28 to 228 cm H₂O (mean 101, SD 34). A difference between the two pressures of less than ±21 cm H₂O was found in 80%. The mean difference was -1 cm H₂O (SD 18), significantly different from 0.

In the same year, the repeatability of the condom catheter technique was assessed in 457 volunteers and compared to that of the invasive pressure-flow technique in 397 comparable male patients. [22] The repeatability of the non-invasive method was found to be comparable to, or slightly better than, that of pressure-flow studies.

In 2006, the bladder volume dependency of the isovolumetric intravesical pressure measurement by the condom catheter technique was investigated. [23] In the 1,020 healthy subjects studied, it was concluded that the optimum bladder volume for isovolumetric pressure measurements, was 264 ± 122 mL (mean ± SD) and that measurements should be taken at or above this optimum volume. At volumes below the optimum volume, the pressure decreases by approximately 5% for each 10% of volume decrease. At bladder volumes smaller than 247 mL, pressure readings in 50% of subjects were suboptimal.

The same group in Rotterdam has also been exploring the measurement of perineal noise during voiding as a way of non-invasively quantifying male bladder outlet obstruction but the work has not yet progressed sufficiently beyond testing on models to determine the viability of this technique in vivo. [24, 25]

Both the penile cuff and condom catheter techniques show promise as non-invasive techniques to assess outlet obstruction in men. However, they are subject to some confounding factors and appear to give inaccurate results if the patient strains during the assessment. It remains to be seen where and if these measurements have a role in the routine clinical assessment of men with symptoms of bladder outlet obstruction.

**Conclusion (level 2)**

- Non-invasive measurements of pressure and flow in men by the penile cuff or condom catheter seem to be as clinically useful as the traditional invasive measurement of pressure and flow.

**Recommendation (grade B)**

- That non-invasive measurements of pressure and flow should be considered when the patient is not required to undergo an invasive assessment of the storage function of the lower urinary tract.
4. URETHRAL RETRO-RESISTANCE PRESSURE

In 2004, Slack et al described a ‘new clinical measure of urethral function’. [26, 27] In the measurement of urethral retro-resistance pressure (URP), a small meatal plug is inserted just inside the female urethra and saline is pumped into the urethra. The pressure in the system rises until it reaches a value sufficient to overcome the resistance offered by the urethra and the fluid then retrogradely flows into the bladder. The pressure required to achieve and maintain an open sphincter is taken to be a measure of urethral closure function. Whilst the technique is new in that modern technology is used to apply the head of pressure to the urethra and the measurement of opening pressure is automatically recorded, the basic principle behind the technique has its origins in 1923 when Bonney made a simple attempt to measure the efficiency of urethral closure. [28]

In his first paper, Slack et al studied 258 stress incontinent women with the URP technique and compared their values with incontinence severity. They also compared the URP measurements with those of maximum urethral closure pressure (MUCP) and valsalva leak point pressure (VLPP). They found that URP measurements correlated well with both MUCP and VLPP. They also found that URP measurements correlated with incontinence severity whereas neither MUCP nor VLPP did so. [26]

In the second study, Slack et al showed that the URP in a group of 61 women, without symptoms of urinary incontinence and who had negative standing stress tests, was significantly greater than the group of stress incontinent women who had been tested previously. [27] This study also provided some test-retest data which showed that URP measurements were consistent in individuals.

The authors concluded from both of these pieces of work that the technique of URP shows promise as a physiological urethral pressure measurement.

In 2006, Digesu et al carried out measurements of URP on 165 women with various urodynamic diagnoses. [29] Women with urodynamic stress urinary incontinence (USI) had significantly lower URP than women with competent urethral sphincters. Women with mixed urodynamic incontinence had values of URP intermediate between women with detrusor overactivity (DO) and those with USI. In the mixed group, URP mean values were not significantly different from those with DO and competent sphincters or those with USI.

There was no significant difference between mean URP values and different urinary symptoms. The authors concluded that whilst there are significantly different URP measurements between women with DO and those with USI, the URP is not a diagnostic tool.

In 2007, Tunn et al measured URP in 48 women with clinically and urodynamically proven SUI without prolapse before and after anti-incontinence surgery (colposuspension n = 8, tension-free vaginal tape n = 6, tension-free transoburator tape n = 34). They found that preoperative URP did not correlate with SUI in all women, had no predictive value, and did not correlate with the outcome of anti-incontinence surgery. However, they did find a positive correlation between URP and body mass index. [30]

In 2008, Roderick et al reported on URP and established measures of incontinence severity in 100 women with pure USI prior to and 3 months after the insertion of a midurethral tape. [31] They found mean URP bore no relationship to the severity of urine loss assessed by 24-hour pad loss. There was no correlation between URP and other measures of incontinence severity. Pre and postoperative URP was available in 73 women. Although 84.9% were objectively cured after surgery, pre and postoperative URP was not significantly different (62.7 ± 19.4 cm H2O vs 61.2 ± 20.4 cm H2O). They concluded that urethral retro-resistance pressure is not a useful measure of urethral function.

**Conclusion (level 2/3)**

- Urethral retro-resistance pressure measurements do not give any better information about urethral closure function than the urethral pressure profile or valsalva leak point pressure.

**Recommendation (grade B/C)**

- That urethral retro-resistance pressure measurements should be discouraged because equivalent information can be obtained from urethral pressure measurements made with conventional urodynamic equipment.

5. URETHRAL PRESSURE REFLECTOMETRY

In 2005, Klarskov et al reported on an in vitro study of pressure reflectometry; a novel technique for the simultaneous measurement of cross-sectional area and pressure in a collapsible biological tube. [32] A very thin, highly flexible 6 cm long polyurethane bag with a diameter of 5 mm when expanded was introduced into eight different test model cavities of known cross-sectional areas in the range of 4-16 mm². The cross-sectional area was measured by acoustic reflectometry while pressures of 10-200 cm H2O vs 61.2 ± 20.4 cm H2O. They concluded that urethral retro-resistance pressure measurements should be discouraged because equivalent information can be obtained from urethral pressure measurements made with conventional urodynamic equipment.

422
clinical use in the range of 4-16 mm$^2$ and at pressures from 10 to 200 cm H$_2$O.

In 2007, Klarskov and Lose used the technique of urethral pressure reflectometry (UPR) to assess the female urethra. [33] Cross-sectional area of the urethra was measured during inflation and deflation of the thin bag placed in the urethra using step-wise pressure changes within the range 0 to 200 cm H$_2$O. They showed that the technique was easy to carry out and that they could obtain measurements of opening and closing pressure, opening and closing elastance and hysteresis. They postulated that these parameters had the potential to provide more physiological information about the urethra than could be obtained from conventional urodynamic studies.

In the same year, Klarskov and Lose compared UPR with urethral pressure profilometry (UPP) in 143 women (105 patients and 38 healthy volunteers). [34] UPR was measured supine both while relaxed and during ‘squeeze’, and while upright and relaxed. UPP was carried out using the perfusion technique with the patient supine and relaxed. All the women were assessed twice with both UPR and UPP at the same setting (short-term reproducibility) and 17 patients were assessed with both methods on two different days (long-term reproducibility). The authors showed that UPR measured the same pressure as UPP but the UPR was more reproducible. With the patient relaxed the opening and closing pressure, opening and closing elastance and the hysteresis can be measured while supine and upright; while squeezing, the opening pressure and elastance can be measured.

In 2008, Klarskov and Lose measured UPR parameters in healthy and stress urinary incontinent (SUI) women and compared them with urethral pressure parameters obtained by the perfusion technique. [35] The study included 30 SUI women and 30 volunteers (23 “continent” and 7 “nearly continent”). The women were examined in the supine position both while relaxed and during squeezing, and upright position and the following UPR variables were measured; opening and closing pressure, opening and closing elastance, hysteresis (absolute) and hysteresis (percent). UPP was carried out with the women supine while relaxed and during squeezing. The maximum urethral pressure (MUP) and maximum urethral closure pressure (MUCP) were obtained. They showed that all parameters except the hysteresis (percent) were significantly decreased in the SUI group compared to the volunteers. The squeeze opening pressure increased in all women compared to the resting condition, while MUP and MUCP during squeeze increased in 78% and decreased in 22%. The separation between the continent and SUI women was better using the resting and squeezing opening pressure than the corresponding UPP parameters. They concluded that UPR is a clinically reliable technique, which provides sound physiological parameters. The resting and squeezing opening pressures separate SUI from continent women better than the UPP parameters. They also postulated that UPR parameters have the potential to provide a pathophysiologic subdivision of SUI and other dysfunctions.

**Conclusion (level 3)**

- Measurement of opening pressure from urethral pressure reflectometry appears to have more power to separate women with stress urinary incontinence from those with normal urinary control when compared to continent women.

**Recommendation (grade C)**

- That further studies are undertaken to investigate the clinical usefulness of this technique.

---

**C. URODYNAMICS: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE**

### I. REPRODUCIBILITY OF FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS

#### 1. INTER-OBSERVER, TEST-RETEST AND PRACTICE VARIATION

When different investigators judge urodynamic traces together with written clinical information in women, there is agreement between them regarding the final clinical diagnosis in about 80% of cases. In other words there is, depending on the diagnosis, some disagreement in 20% of cases when urodynamics is judged in this manner. [36].

A few studies have concluded that there is good inter and (short time) intra–rater reliability. In a single centre series of 621 urodynamic pressure flow tracings of female patients, small average differences between analysis parameters were observed by various investigators, which was interpreted as good interobserver agreement. [37] Inter-observer variability has also been tested in other ways. In a study where 4 experienced practitioners, evaluated 17 pediatric urodynamic datasets, they failed to agree on aspects of detrusor function, including DO, in a quarter of the cases. [38] This result is reminiscent of a similar study of the interpretation of urodynamic recordings of male voiding function. [39]

In a survey to determine the variation in urodynamic...
practices in the United Kingdom 100 questionnaires were sent to units known to be performing urodynamic investigations. There was a significant variation in practices with only 51% of units having a protocol for what tests should be performed, under what circumstances and how. [40]

Standardisation of urodynamic variables may result in a greater consistency of diagnosis, allowing easier comparisons of treatment regimes and outcomes, and is the conclusion of studies of this kind and reviews. [41, 42].

In a review to examine the best position during cystometry to demonstrate DO and reproduce the overactive bladder (OAB) symptoms, 16 relevant studies with good consistency were analysed. All but two showed a clear effect, with a higher incidence of DO in the vertical position (sitting or standing) or onset of DO when changing to a vertical position. Performing the UDS in a supine position would have missed a large proportion of DO diagnoses ranging from 33% to 100%. The authors noticed a substantial practice variation in position during urodynamic investigation and demanded standardisation. [43]

2. SHORT-TERM (WITHIN-SESSION) REPRODUCIBILITY

A number of authors have investigated the within-session reproducibility of cystometric measurements. Because such measurements are conducted within a short period of time, the possibility that the first measurement influences the second for example through a direct effect on the mechanical properties of the bladder (hysteresis and/or viscoelasticity) has to be considered.

Brostrom et al [44] examined 30 healthy women with a mean age of 52 years, performing 2 consecutive medium fill rate (50 mL/min) cystometries in a single session. The volumes at first desire to void (FDV) and normal desire to void (NDV) increased significantly from the first to the second measurement, by 34 and 51 mL respectively. The maximum bladder capacity showed no significant change. The proportion of these healthy subjects who showed DO decreased from 4/30 (13%) in the first cystometry to 1/30 (3%) in the second but this was not statistically significant.

In a similar study [45] of short-term repeatability in 31 female patients aged 14-74 years, two consecutive cystometries were performed with body temperature liquid at a rate of 50 mL/min. On the first cystometry, FDV occurred at a median volume of 112 mL (range 26-503 mL). The cystometric capacity had a median value of 150 mL, with a range from 39-633 mL. (These values may be compared with the normal values in Table 3). The volume at FDV increased by 46 mL from the first to the second cystometrogram, while the cystometric capacity increased by 35 mL. These changes are similar to those seen in normal volunteers, but, as the authors point out, they are not clinically important because they are much smaller than the random variability within subjects, as measured by the 95% confidence limits of ±130 and ±106 mL respectively.

Chin-Peuckert et al [46] examined the variability between two consecutive cystometries in 32 male and 34 female children with a mean age of 7. Most suffered from spinal dysraphism. A smaller number showed DO on the second study than on the first (p<0.05), and similarly the volume at which DO was first observed was larger on the second study (p<0.05). Interestingly, these results are similar to those obtained in children without overt neuropathy.[47]

Hess et al [48] did not perform repeated cystometries, but first measured the bladder pressure “as is” at whatever volume was in the bladder initially, in 21 men and 1 woman with ‘neurogenic bladder’. They then drained the bladder and refilled to the same volume and again measured the pressure. The second “cystometric” pressures were higher than the initial ‘physiological’ ones by approx 6 cm H2O (p = 0.01), although there was a strong correlation between them.

In another study where fifty consecutive individuals with spinal cord injury had 2 trials (trial 1 and trial 2) of UDS done 5 minutes apart, differences in maximum cystometric capacity, opening pressure, maximum detrusor pressure, volume voided, and post void residual (PVR) volume were evaluated. The variation observed was ± 100-150 mL for the volume parameters and ±10-20 cm H2O for the mentioned pressure parameters. [49]

Sixty men with LUTS and 35 with neurogenic bladders after spinal cord injury (SCI) were assessed. Symptom scores and uroflowmetry were obtained and filling and pressure-flow cystometry were carried out three times in succession. In men with LUTS, a significant decrease in the number and pressure of involuntary detrusor contractions (IDC) in consecutive cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. In men with SCI, cystometric variables and DO remained consistent over sequential studies. [50].

Twenty asymptomatic women with a mean age of 41.8 years (30-55) agreed to undergo a urodynamic evaluation, repeated immediately without removing the catheters (a two-fill and void study). [51] Sixteen women of this cohort returned for an identical assessment 1-5 months later. Immediate and short-term repeatability of UDS parameters was assessed. The short time variation was ± 5 ml/s for Qmax and ± 10 cm H2O for PdetQmax. Voided volume and first sensation of filling (FSF) differed ±50 mL in the test retest situation. The authors noted that the variation of parameters in these healthy women was larger than observed in other studies with patients.
3. INTERMEDIATE-TERM REPRODUCIBILITY

Homma et al [52] found that, in 30 patients with DO, repeat cystometry carried out 2-4 weeks after initial testing showed a consistent shift toward normal. Bladder volumes increased by 10-13% (p<0.01), while DO disappeared in 10% of subjects and decreased in amplitude by an average of 18% in the remaining cases. The random variability of cystometric capacity was ± 57 mL (95% CI).

4. LONG-TERM REPRODUCIBILITY

Sørensen et al [53] investigated 10 healthy females (mean age 34 years), twice at an interval of 2 years. They carried out measurements in both supine and sitting positions. FSF occurred at a mean volume of 378 mL supine and 354 mL sitting, with intra-subject variability over two years as quantified by the standard deviation (SD) of 76 and 100 mL (SD) respectively. Maximum capacity was 512 mL supine and 502 mL seated, with intra-subject SD of approximately 75 mL in both cases. Inter-subject SD's were a little larger: 76-144 mL. No significant differences in volumes or compliance over two years could be demonstrated (Table 2).

Summary

In patients and in healthy volunteers, if cystometry is repeated either during the same session or within about 4 weeks, the bladder volumes at which various sensations are felt and the bladder capacity tend to increase by 30-50 ml, while the proportion of traces showing DO tends to fall. These systematic changes are fairly small in comparison with the random within-subject variability, which has an SD of about 50-60 mL.

Conclusions (evidence level 2)

- A number of studies have reported test retest variation of ±10-15% for various parameters (volume, pressure or flow) and observations; this can be regarded as the physiological variation of urodynamic testing.
- Various studies have demonstrated clinically relevant practice variation and inter-rater/observer variation.

Recommendations (grade B)

- The committee recommends that investigators and clinicians take into account the inherent physiological variability of urodynamic testing.
- The committee recommends investigators and clinicians evaluate the ‘representativity’ of the tests (which is an evaluation based on the patient’s perception as to how well the tests have reproduced their usual lower urinary tract function) and the committee recommends that examiners strive towards maximal representativity.

(SD) Key to symbols: VDO = volume at which DO occurs; Δ = increase from test 1 to test 2.
• The committee recommends persistent attention to the standardisation of techniques and interpretation of results, especially to reduce inter-practice variation and inter-observer variability.

**Topics for research**

• The committee suggests further consideration of standardisation of urodynamic tests, procedures and evaluation, especially to reduce inter-practice variation.

• The committee suggests intensive dissemination of up-to-date standards and careful training of urodynamic investigators and suggests evaluation of the effect of these standards and training on health care quality.

Total DO 20/252 = 8% Key to symbols: ± = SD; (xxx-yyy) = interquartile range; xxx-yyy = 95% confidence interval. All volumes are in ml
is no evidence from the table that these variations are associated with differences in filling rate, infusate temperature, or patient position. It appears that the sensations themselves are ill-defined and inadequately standardised.

Wyndaele et al [54] examined 50 volunteers. The bladder was filled at 30 mL/min with body temperature saline. For males (n=18; mean age 22 ± 3 years), FSF occurred at 222 mL ± 151 mL; FDV occurred at 325 mL ± 140 mL; and strong desire to void (SDV) occurred at 453 mL ± 94 mL, and this was taken as maximum capacity. For females (n=32; mean age 21 ± 2 years) FSF occurred at 176 ± 96 mL; FDV at 272 mL ± 106 mL; and SDV at 429 mL ± 153 mL. DO was observed in 7/50 (14%) of these normal volunteers. The group also published a study with symptom free ‘middle-aged’ female volunteers. Of their volunteers a substantial number was excluded because of asymptomatic abnormalities. The remaining had an average capacity during cystometry of 586 mL (sd 193 m) with 258 mL and 1092 mL as extremes. [63].

In 17 healthy subjects, reported in another study, with a mean age of 24 years, but a wide age range, FSF occurred at a mean volume of 104 ± 57 mL; FDV occurred at 172 ± 66 mL; NDV occurred at 294 ± 96 mL; strong desire occurred at 263 ± 93 mL; and DO was observed in 3 of 17 subjects (18%) on conventional cystometry in the seated position. The filling rate was 35 ml/min. On ambulatory monitoring the proportion showing DO rose to 69% (Table 4).

Fifty-seven postmenopausal women: 30 continent and 27 with SUI underwent urodynamic investigation in another small study. The incontinent women showed lesser bladder capacity at FDV, as well as decreased urinary volume. MUCP was lower in the patients in relation to the continent women. Other differences between the normals and the incontinent women were not observed. [64].

Robertson [65] reported on 11 male and 6 female healthy asymptomatic volunteers, age range 22-72 years, examined by conventional 20ºC saline filling cystometry and by ambulatory monitoring. In females: the ‘filling volume’ (presumably equivalent to maximum cystometric capacity) was: 342 mL median (269-471 mL IQR) at 50 mL/min; and 475 mL median (400-600 mL IQR) at 100 mL/min. In males it was: 500 mL median (345-562 mL IQR) at 50 ml/min; and 500 mL median (390-790 mL IQR) at 100 mL/min. DO was observed in 2/12 volunteers (17%) during filling cystometry at 50 mL/min; there was none at a filling rate of 100 mL/min (which preceded the 50 ml/min filling). During ambulatory monitoring DO was seen in 6/16 subjects (38%). The median volume voided during ambulatory monitoring was markedly smaller than the filling volume on conventional cystometry (compare Tables 3 and 4).

Sørensen et al [58] examined 10 younger women (mean age 34 years, range 29-46 years) at 3 points of the menstrual cycle, filling the bladder with body temperature fluid at 60 ml/min. Because the variables showed little systematic variation during the cycle, average values are given here. FSF occurred at 347 mL ± 101 mL (SD) supine and 357 mL ± 126 mL seated. MCC was 482 mL ± 103 mL, supine and 491 mL ± 147 mL seated. No DO was observed. The same authors [57] investigated 12 healthy post-menopausal females, mean age 59 years, using similar parameters. The means of 2 studies showed: FSF, supine, at 396 mL ± 163 mL (SD); and sitting at 331 mL ± 168 mL. MCC, supine, at 551 mL ± 223 mL; and sitting at 489 mL ± 196 mL. They reported no DO.

In 2004, Hosker reported on the urodynamic findings of 72 healthy female volunteers (mean age 41.4 ± SD 10.1 years and mean parity 2.3 ± 1.6) who formed the control group for a study of urethral pressures in women with urodynamic stress incontinence. Cystometry was performed in the supine position with saline at body temperature filling the bladder at a rate of 100 mL/min. The mean PVR on catheterisation was 11 ± 13 mL. The mean FDV was 304 ± 116 mL and the mean MCC was 543 ± 94 mL. He reported no DO. [61]

Twenty-four women without a history of frequent urgency and without DO (mean age 50.2 years, range 22-80 years), including 7 pre- (29.2 years), 7 peri- (48.8 years), and 10 postmenopausal (66.0 years) women were studied with uroflowmetry and video urodynamics to determine normative data for LUT.

427
function in asymptomatic continent women without DO across the age span. For all subjects, median maximum single voided volume in bladder diary was 500 mL and median MCC was 580 mL. SDV was reported at 287, 366, and 425 mL for pre-, peri-, and postmenopausal groups, respectively. The maximum flow rate was 25, 32, and 23 mL/sec in uroflowmetry and 23, 24, and 18 mL/sec during the pressure-flow study, respectively. Median PVR was below 20 mL in all groups. At maximum flow rate subjects voided with detrusor pressures of 29, 26, and 24 cm H2O, respectively and maximum urethral closure pressure was 94, 74, and 42 cm H2O, respectively. [66].

Heslington and Hilton [59] examined 22 asymptomatic healthy female volunteers, performing conventional cystometry and ambulatory study in a random order. DO was observed in 18% on conventional cystometry and 68% on ambulatory monitoring.

As indicated above, most studies of ambulatory monitoring in healthy subjects have revealed high percentages with DO (typically of modest amplitude [55, 67]). However, Salvatore et al [62] by using 2 bladder catheters simultaneously and only verifying DO if it was shown by both, suggested that some of this apparent overactivity was a measurement artifact, and that 90% of a group of 26 healthy women showed no DO on ambulatory monitoring.

Thirty healthy males aged 21-32 years volunteered for an ambulatory urodynamic 24 h investigation with a suprapubic catheter to study natural fill urodynamics. Thirty healthy males aged 21-32 years volunteered for an ambulatory urodynamic 24 h investigation with a suprapubic catheter to study natural fill urodynamics during normal and increased fluid intake. The recorded micturition data were: frequency (f), voided volume (VV), voiding time, maximum flow rate (Qmax) and time to Qmax. The number of sensed and not-sensed detrusor contractions, and their duration and time in relation to voiding were also recorded. During the recording day subjects were randomised to normal (30 mL/kg body weight per day) or larger (60 mL/kg body weight per day) fluid intake. There was a larger urine production and an increased voiding frequency in the fluid-loaded group (p<0.0001). The detrusor pressure (PdetQmax) was significantly higher in the fluid-loaded group (73 cm H2O, range 57-94) than in the normal fluid intake group (60 cm H2O, range 45-86) (p=0.003).

No other urodynamic data differed significantly between the two groups. Ambulatory urodynamics in normal young men showed a large interindividual variation. Detrusor contractions during filling were frequently recorded, and premicturition contractions were consistently found. The data found in this study were similar to previous home flow recordings in the same group. [68]

In a retrospective study of 186 selected investigations the influence of autologous urine production during filling cystometry on total bladder volume was observed. Mean filled volume (external infusion plus autologous urine production) was 346 ± 152 mL, but mean real bladder capacity (voided volume + residual urine) was 391 ± 170 mL. In all patients, 14% extra urine was produced due to autologous urine production (mean rate, 6.1 mL/min). In 42% of the investigations, the real bladder capacity was more than 110% of the infused volume. In 18% of the patients, the contribution of natural bladder filling was more than 25% of the infused volume. [69]

Urodynamic tests were, in another study, conducted on 39 asymptomatic male volunteers with a mean age of 25.8 years (range 21 to 31) and mean weight of 75.5 kg. (range 63 to 95) to examine the pressure-flow relationship and obtain evidence to support the hypothesis that fluid consumption has a role in detrusor voiding function. Volunteers were divided into 2 groups according to water consumption regimen of 30 mL/kg daily (17 patients, group 1) and 60 mL/kg daily (12, group 2). Bladder pressure was monitored via a suprapubic catheter and abdominal pressure was measured via a rectal balloon using an ambulatory system with an average duration of 20.5 hours. Doubling of water consumption increased urethral opening pressure from 51.2 ± 3.2 to 61.5 ± 5.1 cm H2O (p<0.05), maximum detrusor pressure from 58.9 ± 4.5 to 70.0 ± 6.2 cm H2O (p<0.01) and contractility from 15.4 ± 1.4 to 17.7 ± 1.4 W/m². There were no significant differences due to water consumption in maximum flow rate (24.4 ± 1.4 to 25.2 ± 1.8 mL/s) or bladder capacity (286 ± 20 to 329 ± 15 mL) but a significant increase in the number of micturitions from 5.8 ± 0.5 to 9.8 ± 0.5 per day (p<0.001) proportional to water consumption. [70]

2. COMPLIANCE

Compliance is the ratio of a change in volume measured relative to the corresponding change in pressure. Usually compliance is calculated over the change in volume from an empty bladder to that at MCC.

In 17 healthy subjects, using a filling rate of 35 mL/min, [55] the range of compliance values was very wide (range = 11-150 mL/cm H2O; mean ± SD = 46 ± 40 mL/cm H2O). Such a mean value implies only a small rise in pressure on filling (a few cm H2O), consistent with a high compliance. Sørensen et al [53] reported similar mean values for compliance in a group of healthy females: 62 mL/cm H2O initially and 58 mL/cm H2O on re-examination 2 years later. Even higher values of compliance were reported by Hosker (range = 31-800 mL/cm H2O; mean ± SD = 124 ± 150 mL/cm H2O) in 72 healthy females (age 25-75 years) and these reproduced the wide range of values already published. [61]

The results were comparable in elderly, peri and post menopausal women. [66]. In another selected group of healthy, middle aged, volunteers compliance was ‘high’ on average, however with a large variation. [63]
Similarly, Robertson showed that in 17 healthy male and female volunteers, the median detrusor pressure rise on conventional filling cystometry was 5 or 6 cm H\textsubscript{2}O at filling rates of 50 and 100 ml/min respectively. [65] On ambulatory monitoring the median pressure rise was 0 cm H\textsubscript{2}O however, a significantly smaller value.

Compliance cannot only be quantified in the units of ml/cmH\textsubscript{2}O but also as a dimensionless number measured from empty to MCC. Compliance increases with age (because bladder capacity increases with age). The dimensionless value of compliance presents a value of which is independent of age. This is especially relevant in children when intra- and inter-individual test (retest) comparisons are made. [71]

Consistently, among 22 healthy female volunteers, conventional cystometry and ambulatory study performed in random order showed a significantly larger detrusor pressure rise on conventional filling as compared with ambulatory studies. [59]

Although these figures show that conventional filling cystometry provokes higher pressure increase during filling than ambulatory monitoring with natural filling of the bladder, this is not necessarily a disadvantage because it may unmask abnormal compliance.

Robertson [65] reported cystometric variables for 6 patients with “low-compliance bladders” due to neuropathy. Conventional cystometry showed pressure rises of 18 (± 7) and 46 (± 13) cm H\textsubscript{2}O during bladder filling at rates of 20 and 100 mL/min respectively, but the pressure rise during natural (ambulatory) filling was much smaller (in fact, hardly distinguishable from normal): 6 (± 4) cm H\textsubscript{2}O. The corresponding compliance values were 8 (± 2) and 6 (± 3) mL/cm H\textsubscript{2}O for conventional cystometry (abnormally low), but 114 (± 32) mL/cm H\textsubscript{2}O for natural filling (a normal value). [67]

### 3. NORMAL SENSATIONS AND BLADDER CAPACITY - SUMMARY

Table 3 shows the striking variability from centre to centre: FSV for example occurs at about 100 ml in one centre but at about 350 ml in another, a value large enough to provoke a strong desire to void in the first.

The bladder capacity is somewhat less variable from centre to centre, its mean varying from 340 to 570 mL. Apart from this inter-centre variability, the inter-subject variability of all the parameters is also substantial, with an SD of about 100 mL in order of magnitude. Some of this variation represents genuine differences between subjects, but it should be noted that the within-subject variability is also quite large, in order of magnitude 50 mL (Table 2).

As a rule of thumb in healthy adult subjects, and omitting some of the more inconsistent values, FSF occurs at about 170-200 ml, FDV or NDV (the ICS makes no distinction [4]) at 250 ml, and strong desire to void at about 400 ml; MCC is about 480 ml. It is interesting that the mean voided volume on ambulatory monitoring falls between FSV (on cystometry) and FDV/NDV.

Thus, in daily life, the bladder is usually emptied long before a strong or even a “normal” desire to void would be felt on cystometry, although much more can be held if voiding has to be postponed. Correspondingly, there is a discrepancy in bladder capacity between daily life and urodynamic study, also depending on the method of measurement (uroflowmetry, voiding diary or cystometry).[72]

### 4. DETRUSOR OVERACTIVITY IN NORMAL SUBJECTS - SUMMARY

DO is shown during conventional cystometry by up to 17% of normal subjects with a mean percentage of about 8% (Table 3). The percentage is much higher (up to 69%, see Table 4) on ambulatory studies, although one group disputes this.

DO can be observed during urodynamic testing, in healthy subjects (without the symptoms that are usually associated with OAB) which indicates that the observation of ‘detrusor overactivity’ should not always be interpreted as ‘synonymous with pathology that demands treatment’.

**Conclusions (evidence level 2)**

- Various studies have been helpful to reveal normal values and test retest variation of urodynamic parameters in healthy volunteers.
- There is some evidence that evaluation of filling sensation may be different between laboratories, (thus: ‘may be observer dependent’), making data exchange as well as generalisation and interpretation of published data difficult.

**Recommendations (grade B)**

- The committee recommends that investigators and clinicians bear in mind the results of urodynamic testing in healthy persons and to recognise ‘normal’ test-retest variation as well as the differences and/or variations between ‘usual LUT behaviour’, ambulatory monitoring and office urodynamic testing.
- The committee suggests investigators should be sufficiently aware of the normal variation, and normal values of urodynamic studies.
- The committee recommends further standardisation and a practical objective means of recognising and recording the parameters relevant to sensation during bladder filling.
5. INFLUENCE OF CATHETER ON VOIDING

A urodynamic database of 600 consecutive women referred for the evaluation of voiding symptoms was reviewed to examine the effect of a 7F transurethral catheter on flowrate. Before urodynamic, all patients voided privately using a standard toilet and free flow was recorded. Only 100 patients who voided similar volumes varying by less than 20% on the free and pressure flow studies were included. In each voided volume category and urodynamic diagnosis, pressure-flow parameters were significantly different from the equivalent free flow parameters in all but 4 cases. Specifically the maximum flow rate was significantly less and flow time was significantly longer on pressure versus free flow studies (each p <0.01). An intermittent flow pattern was more common on pressure than in free flow measurements (43% versus 9%). [73]

Women between the ages of 30 and 70 years, without LUT complaints and without a history of surgery for urinary incontinence, were recruited to prospectively examine the effect of a 6F urethral catheter on the urinary flow rate in healthy women without LUT symptoms. After a free flow rate, cystometry and pressure-flow studies were performed twice using a 6F urethral catheter. The maximum flow rates during the first and second studies were compared with one another and with the nonintubated values. In the 20 volunteers (mean age 42 years), the mean nonintubated flow rate was 23 mL/s. With a 6F urethral catheter in place, the women had a mean maximum flow rate of 16 mL/s on the first study and 15 mL/s on the second. A significant difference was demonstrated between the free and intubated maximum flow rates for both the first (p = 0.0006) and the second (p = 0.0001) study. No significant difference was detected between the two intubated maximum flow rates (p = 0.262). [74]

The impact of three different sized (4.5-, 6- and 7F) catheters on pressure-flow studies was studied in 60 women undergoing urodynamic evaluation for LUT symptoms, divided into two groups (A and B) of 30 women each. The patients underwent non-invasive free-flow uroflowmetry with determination of PVR. In group A the two consecutive pressure-flow studies were performed using a 4.5F catheter once and a 6F catheter once; in group B the two consecutive pressure-flow studies were performed using a 4.5F catheter once and a 7F catheter once. The maximum and average flow rate in all pressure-flow studies performed were significantly lower than the equivalent free-flow parameters and the flow time was significantly longer for all pressure-flow versus free-flow studies. Furthermore, there was a significantly larger PVR for pressure-flow than for free-flow measurements. There was no significant difference in maximum flow rate, average flow rate and flow time between 4.5- and 6F pressure-flow studies (A). However, there was a statistically significant difference between 4.5- and 7F pressure-flow studies (B) in those uroflowmetry parameters. Detrusor pressure at maximum flow (p_{detQmax}) and maximum detrusor pressure (p_{detmax}) in group A did not show statistically significant differences between 4.5- and 6F pressure-flow studies whereas in group B, p_{detQmax} and p_{detmax} were significantly different between 4.5- and 7F pressure-flow studies. [75].

Conclusion (evidence level 3):

- There is evidence that, in general, flow is reduced when voiding with a urodynamic catheter in the urethra and that this reduction is partially caused by the size of the catheter.

Conclusion (evidence level 4):

- It is also the opinion of the committee that single catheters 6F incorporating both a filling channel and a pressure-sensing channel should be used for intravesical pressure measurement during cystometry (i.e double lumen catheters in the case of using fluid filled pressure lines). This is because removal of a separate filling catheter just before voiding may displace the pressure sensor and that movement of catheters within the urethra are likely to interfere with the representativity of lower urinary tract function during micturition.

Recommendations (grade B)

- The committee recommends that investigators interpret pressure-flow-voiding parameters and the subsequent post void residual together with the uncatheterised (and representative) voiding parameters.

- The committee suggests the ‘standard’ use of, as thin as possible, ‘one-catheter-systems’ for filling and pressure recording during urodynamic testing.

III. REPRODUCIBILITY, RELIABILITY AND NORMAL VALUES OF URETHRAL PRESSURE MEASUREMENTS

1. NORMATIVE AND COMPARATIVE DATA FOR MAXIMUM URETHRAL CLOSURE PRESSURE

Table 5 shows values of MUCP that have been obtained by different authors in normal (or, at least, without urodynamic stress urinary incontinence) and abnormal female populations. It has several striking features. The first is the between-centre variability in
the values reported, with mean MUCP varying from 36 to 101 cm H2O in non-stress-incontinent subjects. The second is the large between-subject SD reported in most studies (from 10 to 52 cm H2O). The third is that, in spite of this variability, in every study the mean MUCP was lower in stress-incontinent patients than in non-stress-incontinent women, sometimes significantly so and sometimes not. Although, some of the variations shown in the table are the result of different patient populations, a weighted averaging of the mean values suggests that a normal MUCP is about 54 ± 25 cm H2O. In stress-incontinent women the corresponding figures are 39 ± 24 cm H2O. Clearly there is so much overlap that this test can hardly be useful for diagnosis [90] (see section D.I.2.b - severity of stress urinary incontinence).

Eighty primiparous women with self-reported new stress incontinence 9-12 months postpartum were compared with 80 primiparous continent controls and 80 nulliparous continent controls to identify impairments specific to stress incontinence. MUCP (± SD) in primiparous incontinent women (62.9 ± 25.2 cm H2O) was lower than in primiparous continent women (83.9±21.0) who were similar to nulliparous women (90.3 ± 25.0). This lower MUCP followed by ultrasound assessment of vesical neck mobility on coughing was the measure most associated with de novo stress incontinence after first vaginal birth. [91]

Studies providing normative data for men are scant, but there are some data on the UPP in normal males.[92, 93].

2. RELIABILITY OF URETHRAL PRESSURE VARIABLES

In clinical practice, use of a fluid-perfusion technique to measure resting urethral pressure profile parameters such as MUCP yields an SD that ranges from 3.3 to 8.1 cm H2O. On average the SD is approximately 5 cm H2O (95% confidence limits ± 10 cm H2O) or ± 5%. With a microtip transducer technique the SD varies between 3.3 and 16.5 cm of water, which means that the 95% confidence limits may be as large as ± 33 cm H2O. The coefficient of variation when using the microtip transducer technique has been reported to be 17% (95% confidence limits ± 34%).
In one study using fluid perfusion the coefficient of variation of MUCP varied from 3% to 11% (95% confidence limits 6% - 23%). [94]

Another, comparative study between fluid-filled and microtip pressure transducers observed that MUCP obtained from the fluid-filled catheter was significantly higher than that obtained from the microtip catheter. However, the authors also concluded that the use of the double-lumen fluid-filled catheter for the measurement of MUCP can be considered a reliable technique since its reproducibility is as good as that of the microtip catheter. [95]

A significant difference between MUCP values recorded by microtransducer versus fiberoptic catheter systems has also been observed. Significantly lower mean MUCP's were recorded by the fiberoptic system than by the microtransducer system. No significant difference was however observed between these two systems in measurement of VLPP. [96]

As mentioned earlier, the performance of air-charged catheters in measuring MUCP has been shown to be comparable to microtransducers in the measurement of maximum urethral closures pressure in a non-randomised study. [9] However, there was a difference in FUL which was attributed to the different diameters of the two catheters.

In 2008, Zehnder et al carried out a randomised comparison of these air-charged catheters with microtip catheters in 64 women and found that the air-charged catheter was as least as reliable as the microtip for measuring both MUCP and FUL. However, they found that the air-charged catheter gave a higher reading of both parameters compared to the microtip device. [10]

3. AGING

It is well established that in women the UPP changes with age. A recent study of 255 women, ages 20-77 years, without DO, overt neuropathy or pelvic or urinary incontinence surgery, confirmed that the MUCP is negatively associated with age ($r = -0.489, P < 0.0001$). [97] This study was not a randomised trial but one that used a convenience sample of patients.

4. OTHER PARAMETERS AFFECTING THE MEASUREMENT OF URETHRAL CLOSURE PRESSURE

The 2002 ICS standardisation report relating to urethral closure pressures shows that the value of MUCP is not only dependent on the type of catheter used but also its orientation within the urethra, the degree of bladder fullness and the position of the patient. [98]

Conclusions (evidence level 2)

- Various studies have shown considerable test-retest variation of all urethral pressure measurements or parameters.
- Various studies have shown that normal and pathological values of urethral pressure parameters are largely overlapping.
- Various studies have shown that urethral pressure (s) (parameters) are affected by age.
- Studies have shown that urethral pressures depend on patient position, volume of fluid in the bladder and position of the patient.
- Studies have shown that urethral pressures depend on the pressure recording catheter used and, sometimes, its orientation within the urethra.

Recommendations (grade B)

- The committee recommends that investigators and clinicians recognise the poor sensitivity and specificity of urethral pressure measurements and their ‘normal’ test retest variation.
- The committee does not recommend urethral pressure measurement as the only urodynamic test in patients with incontinence.
- The committee recommends that the clinical relevance of urethral pressure measurements, when performed, is judged in relation to other urodynamic tests (such as cystometry) and to the clinical examination.

IV. LEAK POINT PRESSURE

1. INTRODUCTION

The detrusor pressure or the intravesical pressure ($P_{det}$ or $P_{ves}$) at which involuntary expulsion of urine from the urethral meatus is observed is the leak point pressure (LPP). The rise in bladder pressure causing leakage may originate either from the detrusor (caused for example by the filling of a low-compliance bladder) or from an increase in the abdominal pressure. Thus there are two different leak point pressures – the detrusor LPP (DLPP) and the abdominal LPP. The abdominal pressure increase during the latter is produced voluntarily by coughing (CLPP) or by Valsalva (VLPP).

LPP is not consistently defined throughout the reports in literature and we have not found any standardisation (report) of the technique. Any comparison of findings between studies is hindered by this.

The elements which could be standardised include: 1) the basic definition of LPP (baseline value of pressure; route of measurement – urethral or rectal), 2) whether Valsalva or cough is used to produce leakage, 3) the technique to confirm urine loss, 4) location of catheter, and shift in location on cough or strain, 5) calibre of catheter (if transurethral) 6) type...
of pressure sensor 7) the volume in bladder, 8) the rate of prior bladder filling and 9) patient position. [90].

2. RELIABILITY OF LEAK POINT PRESSURE MEASUREMENTS

a) Diagnosis

In a study that recruited 168 patients it was seen that women who demonstrate urodynamic SUI at lower bladder volumes do not report greater bother from incontinence than women who leak at higher volumes. The authors concluded that leakage severity ‘quantified’ by this urodynamic method, is not an adequate reflection of incontinence related quality of life and or subjective incontinence severity. [99] Another study confirms these observations. [100]

A total of 200 women with SUI were clinically evaluated and underwent urodynamic study to determine the correlation between VLPP and the UPP. A progressive correlation of VLPP with MUCP was found when UPP was performed at 50 mL (r = 0.305, p < 0.0001), at 250 mL (r = 0.483, p < 0.0001) and at maximum bladder filling (r = 0.561, p < 0.0001). The authors concluded that there is a significant correlation between MUCP and VLPP. [101] Another prospective study in 109 patients assessed the relationship between CLPP and VLPP with SUI (n=61; 56%), DO (n=21; 19%) or a combination of these (n=27 25%). More women with SUI leaked during CLPP than during the VLPP; fewer women with DO leaked during CLPP and more during the VLPP. [102] LPP’s are reported to be dependent on patient position; being lower in the standing position as compared to supine position. [103] Another study with the goal of determining the effect of position on UPP seems to have been troubled by ‘poor test retest reproducibility’ in the standing position. [104]

Two studies, one with 369 patients including some without incontinence and another study with 65 female patients with incontinence stratified into groups with various LPP’s; various grades of urethral (hyper-)mobility and various grades of incontinence severity have been performed. Both studies were unable to find strong ‘urodynamic’ discriminators for the type or severity of incontinence and concluded that all values overlapped. Patients with SUI can be characterised by LPP and change in the urethral angle and or mobility, although these variables do not always define discrete classes. [105, 106]

The results of these studies basically confirm the earlier conclusion in an expert review: ‘It is not apparent that either LPP measurement or UPP can accurately predict which patients will achieve the best outcome of surgical treatment for SUI. Other parameters assessed during urodynamic evaluation might provide prognostic information regarding the risk of voiding dysfunction postoperatively and the possibility of persistent urgency-related leakage following surgery, though not directly predict cure.’ [107]

b) Treatment

Can any value of LPP (vValsalva or cough) and/or UPP help in the selection of treatment for patients with SUI? This question has been addressed by various investigators.

In a retrospective cohort analysis of 3-month outcomes in 145 subjects (TOT = 85; TVT = 60) it was observed that relative risk of postoperative urodynamic SUI 3 months after surgery in patients with a preoperative MUCP of ≤ 42 cmH2O was 5.89 (1.02 to 33.90, 95% confidence interval) when TOT was compared with TVT tape. [108]

The value of urethral hypermobility, MUCP and urethral incompetence in the diagnosis of SUI was evaluated in 369 women with clinical symptoms suggestive of SUI without symptoms of bladder overactivity. The cohort was divided into 2 groups according to continence or incontinence status. Continent and incontinent patients differed with regards to urethral incompetence and hypermobility (each p < 0.0001). Incontinent patients had a greater probability of a higher grade of each factor. MUCP was significantly lower in the incontinent group (p < 0.001). [106]

A prospective study assessed the difference in measured urethral function before and after TVT procedure. Twenty-three (65.7%) of 35 consecutive women had a preoperative diagnosis of intrinsic sphincter deficiency (ISD) as defined by MUCP < 20 cm H2O and/or VLPP < 60 cm H2O. Subjective and objective success rates were 91% and 83%, respectively. The mean change in MUCP was -1.3 cm H2O (95% CI -5.9, 3.3), whereas the pressure transmission ratio increased 15.7% (95% CI 5.0, 26.3%). The mean decrease in straining urethral angle was 16.3 degrees (95% CI -23.9 degrees, -8.7 degrees). Cured subjects, demonstrating hypermobility preoperatively, continued to do so postoperatively. The effectiveness of the TVT did not appear to depend on a clinically significant change in the straining urethral angle. [109]

A total of 221 women 29 to 80 years old (mean age 55.2) were included in a later study to evaluate the outcome of the TVT procedure for SUI with low VLPP. Mean follow-up was 10.5 months (range 6 to 52). Patients were divided into 61 with low (<60 cm H2O) and 160 with higher (>60 cm H2O) VLPP. The overall cure rate was significantly lower in patients with low vs higher VLPP (82.0% vs 93.1%, p = 0.013). In women with low VLPP, multivariate analysis indicated that urge symptoms and low MUCP were independent factors for treatment failure (OR 15.12, 95% CI 1.90 to 120.61, p = 0.010 and OR 0.92, 95% CI 0.86 to 0.99, p = 0.018, respectively). [110]

174 consecutive patients who underwent a distal polypropylene sling procedure for the treatment of SUI were prospectively evaluated and reported in a slightly earlier study. The group was divided by VLPP
into group 1: 60 patients who did not leak on urodynamics, group 2: 27 patients with VLPP > 80 cm H2O, group 3: 71 patients with VLPP 30 to 80 cm H2O and group 4: 16 patients with VLPP < 30 cm H2O. Mean follow-up was 14.7 months (range 12 to 30) and mean patient age was 62 years (range 32 to 88). The groups were well matched before surgery with respect to age, number of previous surgeries, and severity of SUI symptoms and urge incontinence. The percentage of patients who were cured or improved was similar among groups. After surgery there was no statistical difference among patient mean self-reported symptoms of or bother from SUI or urge incontinence. The distal urethral polypropylene sling provides similar symptom improvement in all patients regardless of preoperative VLPP. LPP is helpful in the diagnosis of SUI but appears to be of minimal benefit in predicting the outcome of the distal urethral polypropylene sling procedure. [111]

A later study reported that neither MUCP nor LPP were good predictors of post-operative stress incontinence but, because this was not the primary outcome measure of this study, there may not be adequate power to make this a definitive conclusion. [112]

c) Within-patient variability

McGuire and coworkers [113] found a SD of 5.4 cm H2O yielding a true 95% confidence interval of 89-111 cm H2O. In another study where the microtip transducer technique was used the true value was found to vary between 72 and 128 cm H2O in the standing position and between 61 and 139 cm H2O when semirecumbent. [103]

The committee has found no reports on inter-observer variability.

Conclusions (evidence level 2/3)

- Different definitions and techniques to determine (urine) leak point pressure exist.
- Various studies have demonstrated a weak association of abdominal leak point pressures and the patient experienced or measured severity of incontinence.
- Studies have shown that the ‘isolated’ parameters from abdominal leak point pressure measurements are not extremely helpful as predictors of success for TVT, TOT or suburethral sling treatment of patients with stress urinary incontinence.

Recommendations (grade B/C)

- The committee does not recommend leak point pressure measurement as a single urodynamic test in patients with urinary incontinence.
- The committee recommends that the result of abdominal leak point pressure measurements, when performed on patients with urinary incontinence, should be judged in relation to other urodynamic tests such as cystometry and to the clinical examination.
- The committee considers detrusor leak point pressure in patients with neurogenic lower urinary tract dysfunction a relevant parameter. This is discussed in section III (neurogenic lower urinary tract dysfunction) and in section IV (patient evaluation: children).

V. DIAGNOSTIC PERFORMANCE OF FILLING CYSTOMETRY AND AMBULATORY MONITORING

1. SENSITIVITY AND SPECIFICITY OF FILLING CYSTOMETRY IN OVERACTIVE BLADDER SYNDROME WITH OR WITHOUT URGENCY INCONTINENCE

a) Detrusor overactivity incontinence

Table 6, reproduced from the second Consultation[2] shows that some authors have found quite high positive sensitivity, specificity and predictive value of symptoms for urodynamic SUI. Specificity, sensitivity and predictive value of symptoms were less for detrusor overactivity incontinence (DOI) or ‘mixed symptoms’ of urinary incontinence.

Van Waalwijk van Doorn et al [122] made careful tests of the sensitivity and specificity of non-ambulatory urodynamic observations (a) for any urinary incontinence and (b) for urgency urinary incontinence (UUI). Among 348 women of mean age 41 years with symptomatic urinary incontinence, urodynamics demonstrated incontinence in only 164, a sensitivity of only 164/348 = 47%. For a similar group of men of mean age 44 years the corresponding figures were 31/83 = 37%. In a similar group of 102 female patients with voiding complaints but without symptoms of urinary incontinence, urodynamics revealed no incon- tinence in 96/102, a specificity of 94%. For men the corresponding figures were 71/75 = 95%.

Among 154 female patients (in the same study [122]) in whom urodynamics reproduced urinary incontinence, the observation of pure DOI had a sensitivity of 25/28 = 89% for symptomatic pure urgency incontinence; its specificity was 103/126 = 82%; and its negative predictive value was 97%. However, the positive predictive value was only 25/48 = 52%. In large part this low value was due to a group with mixed symptoms who revealed DOI on urodynamics.
Taking account of the patients with mixed symptoms does not however improve the overall agreement between symptoms and urodynamic findings, because nearly half of them proved to have isolated urodynamic stress urinary incontinence on urodynamics. Similar findings for stress urinary incontinence are discussed in section D.I.2.

Griffiths et al [123] examined 100 older men and women, median age 79.5 years, with urinary incontinence proven on 24-hour monitoring. The type of urinary incontinence was believed to be DO in the majority. During filling cystometry (room temperature fluid, filling rate 60 mL/min, supine and seated) urinary incontinence was not demonstrated in 32%; i.e. the sensitivity of conventional urodynamics for DO with incontinence was 67% in this study.

b) Detrusor overactivity alone

The sensitivity, specificity and predictive value of symptoms for DO, given in a review of papers quoted in the third ICI [124] are shown in Table 7. (Note that this sensitivity and specificity are equal to the positive and negative predictive values of DO for corresponding symptoms.)

In spite of the wide variations shown in Table 7, all authors agree that the correlation between symptoms and DO is modest; underlining the necessity of urodynamic testing to obtain an objective diagnosis.

Van Brummen et al [143] examined the sensitivity of DO, observed during conventional cystometry, for UUI. They examined 95 women, with OAB, symptomatic stress urinary incontinence, and/or prolapse. Symptoms were assessed by a bladder diary and conventional filling cystometry was performed (sitting, fill rate 60 mL/min). Urinary frequency, urgency and UUI had similar associations with the cystometric observation of DO (Table 8). Among patients with one of these symptoms, DO was not observed in 77-81%: i.e., there were large numbers of ‘false positive symptoms’.

In another study 171 women were recruited. These women were assessed with an OAB scoring system to help discriminate between USI and DO. The scoring system had a sensitivity of 79%, a specificity of 78% and a positive predictive value of 73% to identify DO. Investigators suggested that the scoring system could be applicable in primary care. [144]

In a similar study the accuracy of a urinary incontinence questionnaire in the diagnosis of various types of urinary incontinence was classified according to the results of multichannel urodynamic testing. Using a urinary incontinence questionnaire consisting of 12 urinary symptoms questions 129 women with symptoms of urinary incontinence were interviewed. Of the 12 questions, only three questions (two SUI symptoms and one OAB symptom) were significantly associated with the urodynamic diagnoses of urodynamic SUI or DO. The sensitivity and specificity of the questions was relatively low leading to the author’s conclusion that symptoms of urinary incontinence were not sufficient to predict types of urinary incontinence and the suggestion that urodynamic testing is essential in the diagnosis and management of female urinary incontinence. [145]

In a study to determine the prevalence and associations of ‘sensory urgency’ in comparison with DO 592 women, attending for an initial urogynecological / urodynamic assessment, took part. The group was separated into those having ‘sensory urgency’; relevant symptoms, without urodynamic DO

STV = sensitivity, SPT = specificity, PPV = positive predictive value

* = predictive values are for type II SUI (i.e. with hypermobility)
or those with DO. The only difference in the clinical profile between to groups was increased prevalence of the symptom of UUI. The authors concluded that sensory urgency and DO appear to be part of the same clinical spectrum of bladder dysfunction. [146]

Looking just at the association between DO and UUI [44, 143], there was again a substantial number of ‘false positive symptoms’ – subjects with UUI but no DO. Correspondingly the specificity and negative predictive value of DO were found to be low, in these studies (15/67 = 22%; 27/79 = 34%).

To determine and compare the urodynamic characteristics in patients with OAB and patients with OAB plus SUI (OAB+SUI), 120 patients (60 each in OAB and OAB+SUI groups) underwent detailed history, physical examination, complete urodynamic investigation and 20-minute pad test. FDV, SDV, urgency, and the percentage of urodynamic SUI were larger in the OAB+SUI group and FUL, MUP and MUCP were significantly lower in the OAB-SUI group than those in the OAB group (P <0.03). [147]

c) Detrusor overactivity and overactive bladder syndrome

Digesu et al [148] reported a retrospective review of 4500 women aged 22-73 years. Neurological disorders were excluded. As shown in Table 8, this study highlights that there are not only a substantial proportion of ‘false positive symptoms’, but also a large number of ‘false negative symptoms’; patients with DO but without OAB symptoms. The sensitivity and specificity of DO for OAB (symptoms) were 457/843 (54%) and 2473/3657 (68%) respectively, while its positive and negative predictive values -with symptoms referred to as the ‘golden’ standard- were 28% and 86% respectively.

Sekido et al [149] retrospectively reviewed the urodynamic examination of 139 adult patients (12 males and 38 females) and looked into the correlation between detrusor function (FSF, MCC, compliance) and DO versus symptoms of uncomplicated OAB. 75% of male patients with OAB symptoms had DO on cystometrogram in supine position and only 36.8% female patients.

</table>
In a retrospective study with 1,626 women with symptoms of mixed urinary incontinence were divided into stress predominant or urgency predominant symptoms; or equal severity of stress and urgency on the basis of the most severe symptom scored on the King’s Health Questionnaire. The frequency of different urodynamic diagnoses for the all women in each of the above groups was calculated. In this study 29% (464/1,626) had stress predominant symptoms, 15% (248/1,626) had urgency predominant symptoms and 56% (912/1,626) had equal severity of urgency and stress symptoms. On urodynamics 42% (665/1,626) had pure urodynamic stress incontinence (USI), 25% (414/1,626) had pure DO, 18% (299/1,626) had both DO and urodynamic SI and 15% (248/1,626) had normal urodynamic studies. In those with stress predominant symptoms, 82% had USI; in those with urge predominant symptoms, 64% had DO. The urodynamic diagnoses were significantly different for the different balance of symptoms (p<0.05). In women with equal severity of urgency and SUI, 46% had DO while 54% had USI. The relative severity of symptoms from a symptom questionnaire distinguishes between different urodynamic diagnoses. [151]

In a study 1457 adult males and females were retrospectively selected based on OAB syndrome symptoms to determine how well the symptoms of OAB syndrome correlated with urodynamic DO using ICS definitions. A better correlation in results between OAB symptoms and the urodynamic diagnosis of DO was observed in men than in women. Of men 69% and 44% of women with urgency (OAB dry) had DO, while 90% of men and 58% of women with urgency and UUI (or OAB wet) had DO. SUI seems to have accounted for the decreased rates in women since 87% of women with UUI also had the symptom of SUI. The ICS definition does not specify what constitutes abnormal voiding frequency. Analysis of results showed that increasing voiding frequency did not have any effect on increasing the accuracy of diagnosis of DO except in women with 10 or more daytime micturition episodes. The authors concluded that the bladder is a better and more reliable witness in men than in women. [152]

The association between urinary symptoms and the urodynamic diagnoses of DO and USI was calculated to describe the relationship between symptoms reported in a self-completed postal questionnaire and urinary disorders based on urodynamic investigation. The study population was selected from women aged 40 years or over living in the community, who responded to a postal questionnaire. Four hundred eighty-eight women completed urodynamic investigation; 29.1% (142/488) were found to have DO, 33.6% (164/488) USI, 20.7% (101/488) mixed incontinence, and 16.6% (81/488) no urodynamic abnormality. SUI and UUI were included in the risk model for USI. SUI reported monthly or more was associated with more frequent diagnosis of USI, and UUI reported weekly or more with less frequent diagnosis of USI (STV: 76.9%; SPT: 56.3%; PPV: 67.8%). Strong or overwhelming urgency, urinary incontinence monthly or more, and nocturia once a night or more were all significantly associated with an increased diagnosis of DO. Reporting of SUI monthly or more reduced the risk of DO (STV 63.1%; SPT 65.1%; PPV 63.1%). The conclusion was that a postal urinary symptoms questionnaire was able to predict urodynamic diagnoses with moderate accuracy. [153]

One hundred and fourteen women attending a tertiary urogynaecology clinic were included in a randomised crossover study to either an initial interview-assisted questionnaire in the clinic with a follow up postal questionnaire or an initial pre-outpatient questionnaire followed by an interview-assisted questionnaire at the clinic visit. Question responses were compared with urodynamic diagnoses. With an interview method, only severity of incontinence was significantly associated with DO (p = 0.012). With self-completion, severity of nocturia (p < 0.05), urgency (p = 0.003), UUI (p = 0.003), leakage without warning (p = 0.035) and incomplete voiding (p = 0.01) were significantly associated with detrusor activity. On interview the symptom of SUI (p = 0.002) and use of pads (p = 0.011) were significantly associated with a diagnosis of USI. Severity of SUI (p < 0.001), frequency of leakage (p = 0.004), use of protection (p < 0.018), nocturnal incontinence (p = 0.002) and quantity of leakage (p < 0.05) on self-completion were strongly associated with diagnosed USI. There was no

Hyman et al [150] examined 160 men, mean age 61 ± 15 years, without neuropathy but with symptoms “suggestive of DO.” They observed DO in 68%, suggesting a sensitivity of 43% for OAB symptoms. DO was seen more often with UUI than with symptoms of frequency, urgency, nocturia, suggesting a rather higher sensitivity for UUI.

The association between urinary symptoms and the urodynamic diagnoses of DO and USI was calculated to describe the relationship between symptoms reported in a self-completed postal questionnaire and urinary disorders based on urodynamic investigation. The study population was selected from women aged 40 years or over living in the community, who responded to a postal questionnaire. Four hundred eighty-eight women completed urodynamic investigation; 29.1% (142/488) were found to have DO, 33.6% (164/488) USI, 20.7% (101/488) mixed incontinence, and 16.6% (81/488) no urodynamic abnormality. SUI and UUI were included in the risk model for USI. SUI reported monthly or more was associated with more frequent diagnosis of USI, and UUI reported weekly or more with less frequent diagnosis of USI (STV: 76.9%; SPT: 56.3%; PPV: 67.8%). Strong or overwhelming urgency, urinary incontinence monthly or more, and nocturia once a night or more were all significantly associated with an increased diagnosis of DO. Reporting of SUI monthly or more reduced the risk of DO (STV 63.1%; SPT 65.1%; PPV 63.1%). The conclusion was that a postal urinary symptoms questionnaire was able to predict urodynamic diagnoses with moderate accuracy. [153]

One hundred and fourteen women attending a tertiary urogynaecology clinic were included in a randomised crossover study to either an initial interview-assisted questionnaire in the clinic with a follow up postal questionnaire or an initial pre-outpatient questionnaire followed by an interview-assisted questionnaire at the clinic visit. Question responses were compared with urodynamic diagnoses. With an interview method, only severity of incontinence was significantly associated with DO (p = 0.012). With self-completion, severity of nocturia (p < 0.05), urgency (p = 0.003), UUI (p = 0.003), leakage without warning (p = 0.035) and incomplete voiding (p = 0.01) were significantly associated with detrusor activity. On interview the symptom of SUI (p = 0.002) and use of pads (p = 0.011) were significantly associated with a diagnosis of USI. Severity of SUI (p < 0.001), frequency of leakage (p = 0.004), use of protection (p < 0.018), nocturnal incontinence (p = 0.002) and quantity of leakage (p < 0.05) on self-completion were strongly associated with diagnosed USI. There was no
association between the symptoms of urgency or UUI, and USI. No symptom had a high enough specificity and sensitivity to replace urodynamic testing however, postal questionnaire responses had a better relationship with urodynamics, for USI and for DO, than interview-assisted questionnaire responses. [154]

Conclusions (evidence level 2)

- Many studies have shown the weak correlation between symptoms and the result of urodynamic investigation, especially cystometry, in patients with incontinence.
- The correlation of the symptom ‘stress incontinence’ (expressed, or questioned) with the result of urodynamic investigation is somewhat better than the correlation of urgency or urgency incontinence (expressed, or questioned) with urodynamic investigation.
- The committee concludes that especially when frequent voiding, urgency and/or urgency incontinence is part of the symptom complex of patients with incontinence, urodynamic investigation is of value to obtain an objective diagnosis.
- Taking into account the variation between various institutes and the test-retest variation, the committee considers it relevant that investigators and clinicians judge the individual representativity of the results of the performed tests by comparison with the patients’ symptoms.

Recommendations (grade B)

- The committee recommends urodynamic testing in patients with incontinence when an objective diagnosis is warranted. This is commonly the case when symptoms do not exclusively direct to stress incontinence, or when (for all types of incontinence) conservative measures have not been successful, or when relevant comorbidity exists or relevant previous surgery is performed.
- The committee recommends interpretation of the results of the complete urodynamic testing in relation with the symptoms, the clinical (or other) examinations and with the voiding diary in all patients.

**d) Distinguishing or defining characteristics of detrusor overactivity**

Several groups have attempted to find characteristics of DO that may distinguish incontinence with different aetiologies, or incontinence of different severity.

One group [155, 156] examined 132 patients with OAB symptoms (with and without neurological disease) by videourodynamic. Based on the characteristics of their involuntary contractions, patients were divided into 4 categories: type 1 - no evidence of involuntary detrusor contractions on videourodynamic; type 2 - involuntary detrusor contractions present, and patient aware and able to abort them; type 3 - contractions present, patient aware and able to contract the sphincter (judged from the videourodynamic) but not to abort contractions; and type 4 - contractions present and patient unaware but unable to contract the sphincter or abort contractions. There was no significant relationship between category and severity of symptoms as judged by voiding frequency, functional bladder capacity, or pad test. The authors concluded that the characteristics of the involuntary contractions were not distinct enough to aid in differential diagnosis, but that the ability to abort DO and stop incontinent flow might have prognostic implications, especially for the response to behaviour modification, biofeedback training, and pelvic floor exercises.

Cucchi et al [157] looked into detrusor contraction strength, detrusor contraction velocity and contraction sustainability. In this retrospective review the authors separated male patient into three groups; Group 1 had no neurogenic DO, with urgency and UUI. Group 2 was similar to group 1 but did not have urgency before involuntary contractions and Group 3 consists of “normal” men. They found that detrusor contraction velocity was different in the group with urgency versus no urgency or normal, implying that this may be an underlying mechanism for urgency.

Defreitas and coworkers [158] examined three groups of patients: group 1, men with LUTS and no known neurological condition with DO (n = 22); group 2, men with Parkinson’s disease and LUTS (n = 39); and group 3, women with Parkinson’s disease and LUTS (n = 18). Patients with Parkinson’s disease had a significantly lower median volume at first detrusor contraction than those with non-neurogenic DO. The percentage of group-1 patients with UUI was significantly lower than that found in the other two groups (9% versus 54% and 56%, p <0.001 and 0.002, respectively). No statistically significant correlation between the duration or severity of Parkinson’s disease and urodynamic parameters was found. The distinction between Parkinson’s disease proper and multiple system atrophy, which appears to be important with regard to bladder dysfunction,[159] was not made in this study.

In the study cited above, [150] 160 older men without neuropathy but with symptoms “suggestive of DO” were examined. DO was seen more often with UUI than with symptoms of frequency, urgency and nocturia. The bladder volume at which DO was observed tended to be lower in those with UUI and frequency and/or urgency than in the rest (p = 0.07). The prevalence of DO was similar in men with and without bladder outlet obstruction (BOO).
Ockrim et al [50] compared the variability of DO in men with LUTS to that in men with SCI by sequentially repeating urodynamic studies three times. They observed a significant decrease in the number and amplitude of involuntary detrusor contractions in the 60 patients with non-neurogenic LUTS whilst in the 35 SCI patients, the urodynamic variables remained the same over the subsequent studies.

The urodynamic characteristics of DO in women with multiple sclerosis (MS) (n = 54) were compared with the involuntary contractions found in women with LUTS and DO (n = 42) in a retrospective study. Among other parameters, the amplitude of the first involuntary contraction, maximum detrusor contraction, and threshold volume for the first involuntary contraction were evaluated. The amplitude of the first involuntary contraction was statistically greater in the patients with MS and DO compared with patients with DO (28.3 versus 20.5 cm H2O, p = 0.003), as was the maximum detrusor contraction (46.4 versus 30.8 cm H2O, p = 0.002). The threshold volume for DO was greater among patients with neurogenic DO (186.8 versus 150.5 mL, p = 0.037), which was likely to be secondary to the elevated PVR volume noted among patients with MS (p = 0.049).

The authors concluded that additional investigation is required to determine whether these differences are due to neurogenic influences directly on the detrusor muscle through aberrant innervation or by other mechanisms. [160]

Miller et al [161] suggested that functional bladder capacity was smaller in those with more severe incontinence as judged from the voiding diary in a study to evaluate quantification of DO.

**Conclusions (evidence level 2)**

- Studies have not been able to show relevant differences in patterns or characteristics of detrusor overactivity when the cause of overactivity is neurogenic or idiopathic.
- Various studies have not been able to reliably quantify the severity of detrusor overactivity, in a clinically or scientifically applicable way.

**Recommendation (grade C)**

- The committee recommends that neither the cause (neurogenic or idiopathic) nor the severity of detrusor overactivity is diagnosed on the basis of parameters from urodynamic investigation (cystometry).

**Topics for research**

- The committee recommends further evaluation and development of objective parameters for assessing the treatment outcome of detrusor overactivity.

- The committee recommends the development of an objective and cystometry-based detrusor overactivity severity scale.

**e) Provocative manoeuvres**

Some studies have shown that 50% of DO occurs during supine cystometry without provocation and that the remaining 50% is revealed by posture change, standing cystometry, on provocation by cough, or on catheter removal. [162-164].

Awad and McGinis [125] observed DO in 30% of female patients in the supine position versus 61% in the standing position. A systematic review of the literature by Al-Hayek et al [43] concluded that supine cystometry failed to detect a significant percentage of patients with DO.

Webster et al [165] found that in 52% of women with DO, provocation by fast filling in the standing position, and with exercises such as coughing, was required to reveal it. Investigative technique, in particular the inflation of a balloon in the proximal urethra [166] or the instructions given to the patient, [167] affects the frequency of the observation of DO.

Choe et al [168] systematically examined which manoeuvres were most provocative of DO. In 134 women with symptomatic UUI they performed gas (CO2) cystometry. Six provocative manoeuvres were performed consecutively to evoke DO, including lying supine, rising to a seated position, walking toward the bathroom, handwashing, coughing and sitting on the toilet with instructions not to void. By filling to maximum capacity and performing these manoeuvres in 2 different orders, they were able to demonstrate DO in 76/134 subjects (67%). Sitting on a toilet with a full bladder and with the instruction not to void was the most provocative manoeuvre, responsible for revealing DO in 52 of the 76 (68%). Handwashing was a distant second, revealing overactivity in 15 of the 76 (20%). Other manoeuvres revealed very little DO.

An extreme provocative manoeuvre is the bladder cooling (ice water) test advocated by Geirsson et al.[169]. The empty bladder is filled with water at a temperature of less than 10 oC. This stimulates C-fibers that normally carry afferents from receptors sensitive to temperature and pain. In infants, stimulation of these receptors can initiate a detrusor contraction, but this response is normally lost at ages over 5 years. The bladder cooling test stimulated detrusor contraction (neurogenic DO) in 91-97% of patients with traumatic upper motor neuron lesion, but in only 47% of those with presumed idiopathic DO. Detrusor contraction was not observed in any patient with a lower motor neuron lesion or pure (urodynamic) SUI. Thus the bladder cooling test is highly sensitive for neurogenic DO, and highly specific for DO in general.
The bladder cooling reflex, elicited by the ice water test (IWT) was performed in patients with painful bladder syndrome (PBS, n = 17), idiopathic DO (IDO, n = 22), neurogenic DO (NDO, n = 4) and SUI (as controls, n = 21). The IWT was performed by intravesical instillation of cold saline (0 - 4 degrees C). A positive IWT was observed in IDO (27.3%) and NDO (100%) patients, but was negative in all PBS and all control patients. Thirteen (76.5%) PBS patients reported pain during the IWT, with significantly higher pain scores during ice water instillation compared to the baseline (p = 0.0002), or equivalent amount of bladder filling (100 mL) with saline at room temperature (p = 0.015). [170]

A total of 114 patients >50 years, with an International Prostate Symptom Score (IPSS) >8 and Quality of Life (QoL) >2, were evaluated by complete urodynamic workup and IWT to investigate whether DO and/or the response to the IWT were related to nighttime urinary frequency. The DO-positive IWT responders had a significantly higher bladder outlet obstruction index (BOOI) than did the DO-positive IWT nonresponders and the DO-negative IWT nonresponders. The DO-positive IWT responders had significantly more frequent nocturia and smaller nighttime maximal and minimal voided volumes than did the DO-negative IWT nonresponders without any difference in the nocturnal voided volume. The patients with nocturia two or more times had a significantly larger nocturnal voided volume and smaller nighttime minimal voided volume than the patients with nocturia less than two times. The incidence of DO-positive IWT responders had significantly greater among the patients with nocturia three or more times than that among those with nocturia less than three times. The authors concluded that high grade BOO leads to development of C-fibre reflex activity. [171]

**Conclusions (evidence level 2)**

- A systematic review concludes that more detrusor overactivity is seen when the patient is in the sitting position during cystometry, when compared to the supine position.

- There is some evidence that moving to a toilet, and also handwashing, is a strong provocative of detrusor overactivity.

- Evidence suggests that ice water cystometry can be applied to elicit detrusor overactivity in patients with neurogenic lower urinary tract dysfunction and that a detrusor contraction during filling with ice water can be interpreted as a sign of pathologic (existing only in patients with relevant neurology) C-fibre reflex activity. It has however also been shown in this regard that false-negative tests do occur.

**Recommendations (grade B)**

- The committee recommends that the results of provocative cystometry are interpreted in view of patients' symptoms and to bear in mind the representativity of the results obtained.

- The committee recommends that the position of the patient during filling cystometry is taken into account because it can influence the demonstration of detrusor overactivity. Repeating the cystometry in a different position can be helpful when it is deemed clinically necessary.

**2. AMBULATORY URODYNAMICS: SENSITIVITY AND SPECIFICITY**

Ambulatory urodynamics is performed in an effort to capture more realistic or more physiological observations, especially of incontinence episodes. Thus, similar to provocative manoeuvres, it is an attempt to increase sensitivity by providing a longer time for overactivity to manifest itself. The authors of a review article [172] concluded that ambulatory monitoring detects more actual incontinence than conventional cystometry.

Radley et al. [173] found that ambulatory monitoring revealed DO in 70/106 women with symptoms suggestive of DO (twice as many as conventional cystometry with provocation by handwashing), and that it detected DOI in 40 of the 70. The observation of DOI was correlated with symptom severity, but it was not clear how many women complaining of UI showed DOI. Therefore the sensitivity is unknown.

**3. THE ADJUNCT USE OF IMAGING AND EMG**

Videourodynamics is an investigation where cystometry is carried out simultaneously with imaging (usually x-rays) of the lower urinary tract. This can be useful in the management of some patients; particularly children and neurogenic patients and is briefly discussed in the relevant sections. There is a fuller discussion of videourodynamics in the chapter on Imaging, Neuropohysiologie and other tests.

Another adjunct to cystometry is the simultaneous measurement of muscle activity using EMG. Most frequently this is used in the investigation of neurogenic patients and often surface electrodes are placed on the perineum to detect general striated muscle activity. Amongst other uses, failure of the urethra/pelvic floor to relax and detrusor sphincter dyssynergia can be theoretically detected during voiding using this technique. Unfortunately, it is technically difficult to ensure a good quality EMG signal from the appropriate muscle during this procedure and there have been no publications in at least the last 20 years investigating the benefits of combining EMG with cystometry.
1. PREDICTION OF TREATMENT RESPONSE

a) Filling cystometry

The authors of a review of papers from 1980-2000 [124] (see Table 9), concluded that "it is not possible to correlate the results of urodynamic tests with the effects of non-invasive therapy."

Consistent with the table, Malone-Lee et al [177] reported on 356 female patients with OAB symptoms. On urodynamics, 266 showed DO. There was no significant difference (between those with and without DO) in treatment outcome after 6-8 weeks of oxybutynin and bladder retraining.

On the other hand, previous reviews have concluded that women with incontinence and DO respond less well to surgery for SUI than those without DO. [2] Friis et al [178] conducted a blinded prospective study to evaluate the usefulness of urodynamic examination compared to clinical diagnosis. The study showed that when urodynamic examination was added to the preoperative planning of treatment for female urinary incontinence a more beneficial cure rate was found if the patient was treated in accordance with the urodynamic findings. However, the patient material is small and the power of the study is weak.

A retrospective study has shown that a careful minimal evaluation may be adequate to identify ISD, predict postoperative voiding difficulties and maximise surgical outcomes. [179]. A Cochrane review concluded that current evidence is insufficient to demonstrate a clear improvement in clinical outcomes as a result of performing urodynamic studies. [180].

In men, fewer studies have been done. Golomb et al [181] examined whether preoperative urodynamic examination allows us to predict the risk of incontinence after radical prostatectomy. A small group of 20 patients underwent radical retropubic prostatectomy for prostate cancer. Urodynamics showed DO in 12/20 pre-operatively. 5 of these 12 suffered from UII post-operatively. The positive predictive value of preoperative DO for post-operative incontinence was thus only 42%.

In a literature overview of the diagnostic and therapeutic value of urodynamic investigations in patients undergoing prolapse surgery, the reviewers found a large heterogeneity of results. ‘Occult’ SUI showed large variation between studies and de novo DO after TVT as adjunct to prolapse surgery was observed in inconsistent and unpredictable percentages. It was impossible to estimate the predictive value of urodynamic testing on the basis of this review and prospective studies were demanded. [182] A later clinical study confirmed this view. [183]

A study presented a decision-analytic model that evaluated the cost-effectiveness of basic office evaluation before surgery in women with prolapse and SUI symptoms and contrasted it with that of urodynamic testing. Costs were obtained from the Federal Register; effectiveness of treatment for urinary incontinence was based on the published literature. The strategies of basic office evaluation and urodynamic testing had the same cure rate of urinary incontinence (96%) after initial and secondary treatment. Under baseline assumptions incremental cost-effectiveness (cost for single extra cure of urinary incontinence) of urodynamic testing was $328,601.

According to sensitivity analyses, basic office evaluation was more cost-effective than urodynamic testing when the prevalence of pure DO was <8% or when the cost of urodynamic testing was >$103. The analysis concluded that urodynamic testing before surgery in women with prolapse and SUI symptoms is not cost-effective relative to basic office evaluation. [184]

b) Ambulatory monitoring

Brown and Hilton [185] used conventional and ambulatory urodynamic monitoring to study the incidence of DO before and after colposuspension. They showed that preoperative ambulatory monitoring was unable significantly to predict which patients would suffer from urgency postoperatively, or even which women would demonstrate DO post-surgery. Another paper addressed specifically the effect on clinical management of doing ambulatory urodynamics.[186] In this retrospective chart review of 71 women there were technical difficulties in 30/71 ambulatory studies although only 2 were not interpretable. 32/71 women showed DO and were nearly all treated with medication. Among the remainder without DO fewer received medication. However, fewer than half of those who received medication improved. The authors concluded that ambulatory urodynamics was not very helpful in deciding on management.

Conclusions (evidence level 2/3)

- Various studies have shown that the result of urodynamic investigation does not perfectly predict the outcome of relevant treatment in all patients; neither in patients with urodynamic detrusor overactivity nor in patients with urodynamic stress incontinence and also not in patients with a ‘double’ urodynamic diagnosis.
- A retrospective study with subsequent health economic modelling has shown that in patients with ‘pure symptoms of stress incontinence’ urodynamic testing might not be cost effective.

Recommendations (grade B/C)

- The committee recommends that the result of urodynamic investigation is applied to ‘optimise’ treatment strategy without attributing perfect specificity to the result of treatment, in an individual patient.
- The committee recommends that the cost effectiveness of urodynamic testing is taken into account when discussing the necessity of urodynamic investigation.

Topics for research

- The committee suggests that large multicentre (‘national’) prospective studies might be of help to better understand the cost-effectiveness of high quality urodynamic testing in health care quality for patients with incontinence.
incontinence and urgency urinary incontinence remains to be established, as does the significance of the corresponding urodynamic observations such as USI, DOI and DO. However it should be noted that besides their diagnostic potential, urodynamic investigations can contribute qualitative and quantitative information about the underlying or coexisting pathophysiology.

In the following paragraphs the committee discusses clinical application of urodynamic tests in patients with signs or symptoms of incontinence. Firstly women with stress incontinence, followed by women with overactive bladder symptoms with incontinence.

2. STRESS URINARY INCONTINENCE

a) Pathophysiology of stress urinary incontinence

There is a clear need to better understand the pathophysiology of stress urinary incontinence. Neither the clinical nor the pathophysiological value of classification into types 0-III,[189] or of distinguishing between hypermobility and ISD, has ever been documented in prospective studies. Clinically, ISD has been defined as "... sphincter weakness..." because "...the urethral sphincter is unable to coapt and generate enough resistance to retain urine...".[190] However, this clinical term has never been conceptualised into sound urodynamic parameters. Conventional static urethral parameters such as MUP or MUCP, or cough profile parameters such as pressure transmission ratio and LPP have been shown to be of limited value to characterise the extent and the type of urethral dysfunction.[90, 191] Thus conventional urethral pressure profile parameters do not consistently provide reliable pathophysiological information. One study suggests that urethral elastance may be a more useful variable to characterise intrinsic sphincter deficiency.[192]

b) Severity of stress urinary incontinence

There is no consensus on how to measure the severity of SUI clinically or urodynamiically. Severity can be expressed on the basis of simple clinical measures such as questionnaires, or on a bladder diary or on pad weighing tests. A review concludes that static urethral pressure profilometry parameters such as MUCP or cough profile parameters such as pressure transmission ratio cannot be used to characterise the severity of incontinence.[90]. One review suggested that abdominal LPP measurement might be a useful tool to quantify urethral dysfunction associated with SUI.[191]

However, other studies have found no correlation between leak point pressures and the severity of urinary incontinence as measured by bladder diaries and quality of life instruments. [100, 193-195] Leak point pressures are also limited as a diagnostic tool by the lack of standardisation of the technique. [196]

A total of 221 women, 29 to 80 years old (mean age 55.2), were included in a prospective TVT treatment study, performed mostly using local anesthesia with a mean follow-up of 10.5 months. Patients were divided into 61 with low (less than 60 cm H2O) and 160 with higher (60 cm H2O or greater) VLPP. Cure of incontinence was defined as an absent subjective complaint of leakage and absent objective leakage on stress testing. The overall cure rate was significantly lower in patients with low vs higher VLPP (82.0% vs 93.1%, p = 0.013) and, in women with low VLPP, multivariate analysis indicated that urgency symptoms and low MUCP were independent factors for treatment failure (OR 15.12, 95% CI 1.90 to 120.61, p = 0.010 and OR 0.92, 95% CI 0.86 to 0.99, p = 0.018, respectively). This led to the conclusion that women with urgency symptoms and low MUCP should be considered to be at high risk for failure after the TVT procedure. [110]

The role of preoperative VLPP in predicting the outcome of the distal polypropylene sling procedure for the treatment of SUI was prospectively evaluated in 174 consecutive patients, divided by VLPP into group 1 (60 patients who did not leak on urodynamics), group 2 (27 patients with VLPP >80 cm H2O), group 3 (71 patients with VLPP 30 to 80 cm H2O) and group 4 (16 patients with VLPP <30 cm H2O). Mean follow up was 14.7 months and mean patient age was 62 years. The distal urethral polypropylene sling provides similar symptom improvement in all patients regardless of preoperative VLPP. VLPP is helpful in the diagnosis of SUI but appears to be of minimal benefit in predicting the outcome of the distal urethral polypropylene sling procedure. [111]

In a review of recent reports and controversies concerning the use of LPP testing and urethral pressure profilometry prior to surgical treatment for SUI, it was concluded that there remains no clear consensus as to whether this testing enhances surgical outcome of SUI treatments by improving case selection or altering the surgical approach based on study findings. The reviewer found little evidence to suggest that patients with more severe forms of USI on urodynamic testing fare more poorly after the most commonly offered surgical treatment than those with less severe forms. However urodynamic testing may aid in identifying the group of women who appear to be at higher risk of voiding dysfunction following incontinence surgery. [107]

A total of 200 prospectively selected women with stress urinary incontinence (SUI) were clinically evaluated and underwent urodynamic study to determine the correlation, as well as the influence of bladder volume, between VLPP and UPP in urody-namically selected patients with USI. A progressive correlation of VLPP with MUCP was found when UPP was performed at 50 mL (r = 0.305, p <0.0001), at 250 mL (r = 0.483, p <0.0001) and at maximum bladder filling (r = 0.561,
A total of 655 women with stress predominant symptoms underwent a standardised assessment before sling or Burch procedure. Weak to moderate correlations were observed between Medical, Epidemiological and Social Aspects of Aging Questionnaire, incontinence episode frequency, pad weight, Incontinence Impact Questionnaire and Urogenital Distress Inventory. On the other hand, VLPP correlated poorly with all variables measured. The sensitivity and specificity of the supine empty bladder stress test to predict intrinsic sphincter dysfunction were 49% and 60%, respectively. Urinary incontinence severity measures correlated moderately with each other at best. VLPP did not correlate with measures of severity and quality of life. The supine empty bladder stress test did not demonstrate a clinically significant association with other severity measures. [100]

From a total of 168 women, the 31% that demonstrated SUI at lower bladder volumes (100 ml) did not report greater bother from incontinence than the 35% women who leak at higher volumes (>400 ml). The Urogenital Distress Inventory, Incontinence Impact Questionnaire, and also the MUCP and VLPP were similar in the groups. Among the 116 patients who had a sling procedure, USI persistence did not differ according to the volume at which USI occurred (p=0.72). The authors concluded that ‘bladder volume when leaking’ during a urodynamic study is not an adequate reflection of incontinence related quality of life. [99]

Most retrospective studies show higher failure rates after surgery in women with low MUCP (often defined as MUCP ≤ 20 cm H2O at MCC [90]). Other urethral closure pressure cut-points have been suggested as predictive of failure with transobturator versus retropubic midurethral slings in recent retrospective trials, but no prospective, randomised studies have been done to validate these observations.[108, 197] However, other investigators have shown that a low MUCP is not an efficient predictor of surgical failure.[187] In a recent prospective, randomised trial of women undergoing either Burch retropubic urethropexy or bladder neck slings, LPPs were not found to be predictive of surgical outcome for SUI. [198] Nevertheless, there are data to suggest that LPP may be a sensitive indicator of changes in incontinence status, reflecting treatment effect.[191]

The value of urethral hypermobility, MUCP and urethral incompetence was analysed in a study with 369 women with symptoms suggestive of SUI without symptoms of DO. Continent and incontinent patients differed with regards to urethral incompetence and hypermobility (each p <0.0001).

Incontinent patients had a greater probability of a higher grade of each factor. Even after adjusting for the older age of incontinent patients by ANCOVA, MUCP was significantly lower in the incontinent group (p <0.001). The best univariate optimised cutoff point for discriminating continence from incontinence was obtained with urethral incompetence greater than grade I. [106]

To compare the success rates of Burch colposuspension in relation to a VLPP cutoff level of 60 cm H2O and to examine other predictive factors for ISD, such as MUCP and FUL, in an attempt to define the urodynamic contraindications to Burch colposuspension 79 patients eligible for continuous postoperative follow-up were enrolled in a prospective study. The mean age was 58 ± 10 years, mean parity was 3.71 ± 4.

The success rates in 2 groups, VLPP ≥ 60 cm H2O (n=55) and < 60 cm H2O (n=24) were 94.55% and 91.67%, respectively, demonstrating no statistical significance (p > 0.05). On post-hoc analysis a VLPP level <60 cm H2O was not found to represent an absolute contraindication to Burch colposuspension, provided that other parameters, such as MUCP and FUL, are within acceptable ranges. [199]

Conclusions (evidence level 2/3)

• Various studies have shown conflicting results regarding the association of incontinence severity and urethral function tests (leak point pressures and urethral closure pressures)

• It is the opinion of the committee that contemporary urethral function tests are only modestly suited to judge the severity of incontinence or to further 'subcategorise' patients with stress (predominant) incontinence.
**Recommendations (grade B/C)**

- The committee recommends that urethral function measurements of leak point pressures and urethral closure pressures are not used as a single factor to grade the severity of incontinence.
- The committee recommends caution with the prediction of the outcome of any surgical treatment on the basis of contemporary urethral function tests.

**Topics for research**

- The committee suggests further studies with the aim to better understand urethral closure function and dysfunction, in relation to treatment for stress incontinence or stress predominant symptoms.

**c) Aspects of urodynamic studies relevant to therapy for stress urinary incontinence**

In a systematic meta analysis (only) 129 (out of 6009) studies were relevant for inclusion using the Quality Assessment of Diagnostic Studies (QUADAS) tool to identify and synthesize studies of diagnostic processes of urinary incontinence and to construct an economic model to examine the cost-effectiveness of simple, commonly used primary care tests. A clinical history for diagnosing USI in women was found to have a sensitivity of 0.92 and specificity of 0.56 and for DO a sensitivity of 0.61 and specificity of 0.87. For validated scales, question 3 of the Urogenital Distress Inventory was found to have a sensitivity of 0.88 and specificity of 0.60. Seven studies compared a pad test with multichannel urodynamics; however, four different pad tests were studied and therefore it was difficult to draw any conclusions about diagnostic accuracy. Of the four studies comparing urinary diary with multichannel urodynamics, only one presented data in a format that allowed sensitivity and specificity to be calculated. Their reported values of 0.88 and 0.83 suggest that a urinary diary may be effective in the diagnosis of DO in women.

Examination of the incremental cost-effectiveness of three primary care tests used in addition to history found that the diary had the lowest (best) cost-effectiveness ratio of between £35 and £77 per extra unit of effectiveness (or case diagnosed). Imaging by ultrasound to determine leakage was found to be effective in the diagnosis of USI in women, with a sensitivity of 0.94 and specificity of 0.83. The report found that a large proportion of women with USI can be correctly diagnosed in primary care from clinical history alone. On the basis of diagnosis, the diary appears to be the most cost-effective of the three primary care tests (diary, pad test and validated scales) used in addition to clinical history. The authors thought that ultrasound imaging may offer a valuable alternative to urodynamic investigation and that the clinical stress test is effective in the diagnosis of USI. However, they also conceded that if a patient is to undergo an invasive urodynamic procedure, multichannel urodynamics is likely to give the most accurate result in a secondary care setting. [200]

In 2006 in the UK, the National Institute of Health and Clinical Excellence (NICE) issued guidelines that urodynamics was recommended before surgery for urinary incontinence only if there is a clinical suspicion of DO or, if there has been previous surgery for stress incontinence or anterior compartment prolapse or, if there are symptoms suggestive of voiding dysfunction. [201] In other words, urodynamics is not routinely recommended for women before surgery for a ‘clearly defined clinical diagnosis of stress urinary incontinence’. This was a recommendation founded on expert opinion collated by a modified Delphi process. However, a study in 2008 by Agur et al casts some doubt on the wisdom of this recommendation. [202] In their tertiary centre, patients are referred with lower urinary tract symptoms. Information is collected and entered into a computer database at the time of history taking and before conducting urodynamic tests. The database was used retrospectively to identify women aged 18-80 years who had multichannel cystometry for urinary incontinence over a 17-year period (1 January 1990 to 31 December 2006). To apply the NICE criterion of a ‘clearly defined clinical diagnosis of pure SUI’, strict selection criteria were used to identify patients with pure SUI. The reliability of the patients’ history in predicting ‘pure’ USI in patients with ‘pure’ SUI was investigated. They found that only 324/6276 (5.2%) women had pure SUI; moreover, a quarter of those with pure SUI symptoms ultimately had urodynamic diagnoses other than USI, that could affect the outcome of continence surgery. They concluded that only a small group of women fulfil the NICE criteria of pure SUI and it seems inevitable that even with these strict criteria, a woman can go forward to a surgical procedure with potentially important urodynamic findings unaddressed.

**Conclusion (evidence level 1)**

- It is concluded in a model study, based on a selected retrospective cohort, that urodynamic testing is not cost effective in the primary health care setting for women with predominant stress incontinence symptoms. It is also shown that in the referred population, urodynamic investigation is the most accurate way to obtain an objective diagnosis in patients with predominant stress urinary incontinence symptoms.

**Conclusion (evidence level 3)**

- Symptoms of pure stress urinary incontinence do not always exclude other abnormalities of lower urinary tract function.
**Recommendation (grade A)**

- The committee recommends that the cost effectiveness of urodynamic testing is kept in mind when discussing 'cost and gain' of the various methods of diagnosis for urinary incontinence, in relation to the method of treatment.

**Recommendation (grade B)**

- The committee recommends urodynamic studies are carried out in all women prior to surgical intervention for stress urinary incontinence.

**Topic for research**

- The committee suggests that a well-designed, multicentre study should address the question as to whether women with symptoms of pure stress urinary incontinence are more at risk of failure from surgical treatment of their incontinence without pre-operative urodynamics or have more adverse events following surgery without pre-operative urodynamics than women who have pre-operative urodynamic studies.

**d) Prediction of failure of surgery**

Most retrospective studies show higher failure rates after surgery in women with low maximum urethral closure pressure (often defined as MUCP ≤ 20 cm H2O at maximum cystometric capacity). [90] Other urethral closure pressure cut-points have been suggested as predictive of failure with transobturator versus retropubic midurethral slings or pubovaginal slings in recent retrospective trials, but no prospective, randomised studies have been done to validate these observations. [108, 197, 203] When used together, Kilcarsian and colleagues found low urethral closure pressure and low leak point pressures to be predictive of failure after in situ vaginal wall slings in 58 women. The success rate was 65% in women with VLPP < 50 cm H2O and MUCP < 30 cm H2O but it was 91% in those with VLPP > 50 cm H2O and MUCP > 30 cm H2O (p< 0.05). [204] Clemons and LaSala showed that combining low urethral closure pressure and the absence of urethral hypermobility was predictive of surgical failure after a tension-free vaginal tape procedure. They found that an MUCP ≤ 15 cm H2O resulted in only a 60% cure rate after TVT with an odds ratio of 6.3 for failure (p= 0.03). The absence of urethral hypermobility, defined as a straining angle of ≤ 35°, was associated with a cure rate of 50% with an odds ratio of 7.7 (p= 0.02). When the 2 factors were combined the cure rate was only 17% (p< 0.001). [205]

However, other investigators have shown that a low MUCP is not an efficient predictor of surgical failure. [187, 206] In a recent prospective, randomised trial of women undergoing either Burch retropubic urethropexy or bladder neck slings, leak point pressures were not found to be predictive of surgical outcome for stress urinary incontinence. [198]

Leak point pressures have not been found to be predictive of surgical outcomes following bone-anchored suburethral slings, transobturator and retropubic midurethral slings. [111, 193, 207-209]

Urethral retro-resistance pressure has also been studied as a potential predictor of surgical success. However, Tunn et al failed to show any predictive value of this measurement for surgical success with colposuspension, retropubic midurethral slings and transobturator midurethral slings. [30]

Ward and colleagues carefully examined the impact of urodynamic testing on decision-making and treatment recommendations in incontinent women. They found that the probability that urodynamics would alter recommendations for medical treatments was 27% and 46% for surgical treatment. Clinicians believe that there is value to adding multichannel urodynamics studies to history, physical examination, bladder diary, assessment of urethral hypermobility, cough stress test and post-void residual urine measurement. [210]

**Conclusion (evidence level 2)**

- Leak point pressures do not appear to correlate with success rates of colposuspensions, transobturator and retropubic midurethral, bone-anchored suburethral slings

**Conclusion (evidence level 3)**

- There is some evidence that low urethral closure pressures are associated with poorer success rates of retropubic and transobturator midurethral, vaginal wall and transvaginal bone-anchored slings.

**Recommendation (grade B/C)**

- The committee recommends that measurements of urethral function (leak point pressures and urethral closure pressures) are not used to reliably predict the likelihood of success after surgical treatment for stress incontinence. However, the values of urethral closure pressure may provide some guidance in this respect.

**e) Voiding difficulties after surgery**

Surgery for SUI may lead to voiding difficulties. [211] At this time risk factors (including urodynamic risk factors) for delayed resumption of voiding are not well defined. The type of surgery clearly plays a role: retropubic midurethral slings have been found to be less obstructive than Burch colposuspensions [212]
and transobturator midurethral slings appear to be less obstructive than the retropubic midurethral slings [213]. One major problem is that at the moment there is no clear urodynamic definition of obstruction or detrusor underactivity in women. It has been reported that low maximum flow rates (< 20 mL/s) [214] or “inadequate contraction strength” defined as pdet <15 cm H2O during voiding (but note that this low pdet frequently signifies a low urethral resistance, and not necessarily a weak detrusor contraction), or significant use of the Valsalva manoeuvre when voiding, are associated with postoperative voiding difficulties.[215-217] Wheeler et al found that maximum flow rates were the best predictor of passing an initial voiding trial after retropubic and transobturator midurethral slings in multivariate analysis of 89 women (p=0.0002). [218] Similar findings were noted by Gravina and colleagues. [219] The possibility exists that, in women who do not use their detrusor during voiding, detrusor contractility may be assessed preoperatively by mechanically interrupting the flow (“Stop test”). [220, 221]

Shukla and colleagues found no urodynamic factors that were predictive of postoperative voiding difficulty following tension-free vaginal tape procedures despite a trend toward long term voiding difficulties in those with lower average flow rates in a multivariate regression analysis of 411 patients (p= 0.12). [222]

Dawson et al showed a significant relationship between the centile score for average flow rates and the risk of voiding dysfunction and the need for intermittent self-catheterisation on multivariate analysis after tension-free vaginal tape procedures in 267 women (p=0.029). [223]

**Conclusion (evidence level 3)**

- Current test methods have not been able to reliably predict patients who will develop voiding difficulties after surgery for stress incontinence.
- However, average and maximum flow rates may be useful in predicting post-operative voiding dysfunction and retention following retropubic and transobturator midurethral slings.

**Recommendation (grade C)**

- The committee recommends that patients are informed that it is difficult to predict who will develop voiding difficulty following surgery for stress incontinence. However, poor pre-operative maximum and average flow rates are more likely to result in voiding problems following retropubic and transobturator midurethral slings.

**f) Postoperative urgency**

The preoperative symptoms of UUI and urgency, and the urodynamic observation of DO, have each consistently been shown to be associated with poorer surgical outcome in patients with mixed urinary incontinence. Several studies where the amplitude of DO was graded have shown that the risk of persistent urgency was more closely associated with high-pressure DO (pdet ≥ 25 cm H2O) than low-pressure DO.[224-226] Consequently cystometry may allow a more precise selection of patients who respond well to surgery despite concurrent urge symptoms. The success rate after anti-incontinence surgery in patients with low-pressure contractions seems to be similar to the success rate in those without DO, [224-227] but the success rate in women with high-pressure contraction is less than 50%.[224-227]

On the other hand preoperative urgency symptoms resolve in a substantial proportion of patients (50-65%).[228-230] One untested hypothesis is that surgical correction of the bladder outlet may prevent ingress of urine into the proximal urethra (which if it occurs, may induce DO in some patients).[231-234]

De novo UUI has been reported to occur in 10-20% of patients after surgery.[211] There is scant information on clinical or urodynamic risk factors; possibly the type of surgery plays a role. A recent retrospective trial suggested that the incidence of de novo UUI was higher in bladder neck slings than in retropubic midurethral slings which were also associated with more de novo UUI than transobturator midurethral slings [213]. It should be remembered however that de novo DO may merely represent DO that was missed preoperatively.

**Conclusions (evidence level 2)**

- Current test methods have been unable to reliably predict which patients will develop de-novo urinary urgency (OAB syndrome) after surgery for stress incontinence.
- Post hoc evidence suggests that procedures which are more ‘obstructive’ produce a higher chance of de novo urinary urgency (OAB-syndrome).

**Recommendation (grade C)**

- The committee recommends that patients with stress incontinence are informed that the chance of developing urinary urgency (OAB-syndrome) following surgery is largely unpredictable.

**Topics for research**

- The committee suggests further work to evaluate predictors of voiding difficulties or urinary urgency after contemporary (moderately invasive) treatments of stress incontinence (e.g. trans-obturator or trans-vaginal tapes).
g) The role of urodynamic studies in predicting occult stress urinary incontinence in women due to be treated for pelvic organ prolapse

Because 11 to 22% of continent women undergoing vaginal repair for a large cystocele develop SUI following surgical repair,[235, 236] it would be helpful to devise methods to evaluate patients who are at risk for this complication.[237] Women with severe pelvic organ prolapse may develop incontinence symptoms when the prolapse is reduced; this is frequently named ‘occult’ SUI. Voiding difficulty and bladder outlet obstruction may coexist with occult SUI; all may be associated with pelvic organ prolapse, and all may be altered if the prolapse is reduced during urodynamic testing.

The overall incidence of occult SUI was 25% when videourodynamic testing was performed with and without pessary support of the bladder base during stress manoeuvres.[238]

In a small group of patients with severe genitourinary prolapse, occult incontinence was found in 59%, and about 20% (4/22) were reported to demonstrate stress pressure profiles suspect for SUI after pessary placement.[239] However, it should be remembered that stress UPPs are not particularly reliable measurements. A special technique (Scopette, Birchwood Lab) for reducing prolapse during multichannel urodynamics revealed a 56% incidence of low-pressure urethra (possibly related to ISD, but see caveats regarding UPPs above) and an overall incidence of occult SUI of 83% in women with massive pelvic organ prolapse but without clinical urinary incontinence.[240]

As expected, urethral hypermobility is correlated with the degree of prolapse.[241] Surprisingly, so too is DO (revealed by prolapse reduction), although impaired detrusor contractility and ISD were not significantly associated with prolapse in this one study.

The literature thus emphasises the importance of urodynamic assessment with prolapse reduction to assess potential occult SUI and possibly DO.[184, 237, 238, 242] However, although occult SUI is revealed in a high proportion of cases with severe prolapse, there seem to be no studies assessing reproducibility, a particularly important point since the technique of reduction is variable and non-standardised.

Many different tests (e.g. pessary test, speculum test) have been used to document occult SUI. In many studies they are positive in 50–77% of patients (which, arguably might be overestimating the risk). In various papers the Pereyra and Kelly procedures have been used prophylactically but there is no documentation that they reduce the risk of postoperative incontinence.[243-245] A prospective controlled study[246] showed that the pessary test was positive only in 50% of incontinent women and was falsely positive in 72%. Another study[219] concluded that urodynamic testing before a pelvic organ prolapse operation was not cost-effective.

More recently in 2008, the CARE trial in the United States examined 322 stress-continent women with stages II-IV prolapse who underwent standardised urodynamics. Five prolapse reduction methods were tested: two at each site and both were performed in each subject. Clinicians were masked to urodynamic results. At sacrocolpopexy, participants were randomised to Burch colposuspension or no Burch colposuspension (control). Preoperatively, only 12 of 313 (3.7%) subjects demonstrated USI without prolapse reduction. More women leaked after the second method than after the first (22% vs. 16%; p = 0.012). Preoperative detection of USI with prolapse reduction at 300ml was found with a pessary in 6% (5 of 88); with manual vaginal elevation in 16% (19 of 122); with forceps in 21% (21 of 98); proctoswabs in 20% (32 of 158); and with a speculum in 30% (35 of 118). Women who demonstrated preoperative USI during prolapse reduction were more likely to report postoperative SUI, regardless of concomitant colposuspension (controls 58% vs. 36% (p = 0.04) and Burch 32% vs. 21% (p = 0.19). [247]

Conclusions (Evidence level 1)

• Various studies have shown that symptoms of stress incontinence can appear after surgery for prolapse.

• There are a variety of methods to uncover ‘occult stress urinary incontinence’ in women with vaginal prolapse. However, they all have different sensitivities and this makes comparison of results difficult. Standardisation of these tests in clinical practice may be beneficial.

• Various studies have shown that concomitant procedures to address possible stress incontinence developing after prolapse surgery (with or without simultaneous urodynamic testing) are not reliable in preventing its occurrence.

Recommendation (Grade B)

• The committee recommends that patients with vaginal prolapse are informed about the relative unpredictable chance of developing stress incontinence after surgery for that prolapse.

3. URGENCY URINARY INCONTINENCE
a) Pathophysiology and severity of urgency urinary incontinence

It remains unclear if the chronological sequence of bladder and urethral pressure changes may distinguish between ‘true’ (idiopathic?; originating in the detrusor?)
DO and ‘secondary’ DO. Secondary DO might be due to bladder outlet relaxation and ingress of urine into the proximal urethra followed by a micturition reflex. [248]

No statistically significant relationship between the various cystometric variables and reported symptom severity has been established.

b) Prediction of treatment response

Urgency and UUI or OAB syndrome are poorly associated with the urodynamic observation of DO, as discussed previously. The positive predictive value of OAB (urgency usually accompanied by frequency and nocturia with or without UUI) for urodynamically determined DO is only around 50%. [148] On the other hand DO is reported in 10-69% of asymptomatic female volunteers, depending on the definition and type of cystometry. [55, 59, 65, 162, 187, 249] This makes it impossible to use urodynamic investigation (cystometry) to predict the outcome of treatment for UUI.

Studies on voiding difficulties or de novo SUI or combined incontinence (as a consequence of increased capacity because of treatment for UUI) have not been published.

Conclusions (level 2/3)

- Various studies have concluded that the association between overactive bladder symptoms and detrusor overactivity during urodynamic investigation is weak.
- Various studies have concluded that the prediction of treatment - for overactive bladder symptoms - response on the basis of the characterisation or quantification of detrusor overactivity during urodynamic investigation is impossible.

Recommendation (Grade B/C)

- The committee recommends that investigators and clinicians discuss with patients with detrusor overactivity that neither quantity nor specific characteristics of detrusor overactivity predicts the response of any of the therapeutic approaches.

Topics for research

- The committee suggests further studies to find predictors of response on treatment for patients with overactive bladder syndrome.
- The committee suggests further studies to find urodynamic predictors of response for patients with overactive bladder without detrusor overactivity.

4. RECOMMENDATIONS FOR URODYNAMIC STUDIES IN WOMEN WITH URINARY INCONTINENCE

a) Recommendations for clinical practice:

1) The committee recommends non-invasive urodynamics (voiding and incontinence diary, PVR, and possibly uroflowmetry) for all patients with incontinence.

2) The committee finds that invasive urodynamic studies are not necessary prior to treatment in situations where the type of urinary incontinence is clear and there are no complicating factors and planned treatment is reversible. The committee provides the following examples:

- uncomplicated symptoms of SUI with normal bladder diary, normal flowmetry and without relevant PVR. (Symptomatic pure SUI with no symptoms or signs of voiding difficulties), for treatment by, for example, pelvic floor muscle training.
- uncomplicated symptoms of UUI with a bladder diary in accordance with these symptoms, with normal flowmetry and without relevant PVR. (symptomatic pure UUI with no symptoms or signs of voiding difficulties), for treatment by, for example, bladder training.

3) The committee recommends that, whenever surgical intervention is planned, whenever there is doubt about the pathophysiology, or about whether the incontinence is uncomplicated or not, then invasive urodynamics should be performed in order to provide the knowledge on which rational treatment decisions or prognosis can be based. The investigation should be tailored to the individual patient; typically this means that it will be a comprehensive examination of multiple aspects of storage and voiding function, and not just of the incontinence itself.

4) The committee suggests for research:

- to study new or existing urodynamic tests and parameters which have a sound technical and physiological basis
2) The committee recommends that no new therapy should be introduced without extensive urodynamic testing of all accessible aspects of its effect on LUT function and dysfunction.

II. PATIENT EVALUATION: MEN

1. INTRODUCTION

Although the incidence of urinary incontinence in men is generally regarded as much lower than in women, this is not necessarily true for all patient groups, especially when dealing with the elderly (see section D.V, Patient evaluation: Frail elderly). In both sexes those who lose urine, whatever the cause may be, increase in number with advancing age.[250] In this section the characteristic pathologies that lead to incontinence in men are discussed from the point of view of urodynamic testing. Although urinary incontinence related to benign prostatic obstruction (BPO), BOO or to (radical) prostatic surgery is most frequently encountered, other important pathological conditions such as nocturnal enuresis and post-micturition dribbling are also clinically relevant.[2, 251]

This section is organised according to the suspected origin or cause of incontinence or related LUTS, reflecting the very varied aetiologies responsible for the condition in men.

2. LOWER URINARY TRACT SYMPTOMS RELATED TO BLADDER DYSFUNCTION MAINLY DETRUSOR OVERACTIVITY AND BLADDER OUTLET OBSTRUCTION

LUTS are fairly common among men of 50 years and over. Incontinence is not usually prominent but, if it is present, urodynamics can be helpful to establish the underlying vesical/urethral dysfunction, in particular, DO and/or BOO. Coexistence of BOO and DO increases with age and with the degree of BOO. [252, 253]

Non-invasive investigations such as uroflowmetry and measurement of PVR are easy to perform, but even in simple situations can only give clues to the underlying pathology. Low Q_max on uroflowmetry cannot distinguish BOO from the poor detrusor contractility. [254] There is also a significant variation in Q_max in repeated tests [255]. Moreover, since elderly people often suffer from co morbidities – e.g. insidious neurogenic ailments such as Parkinson’s disease, multiple sclerosis, cerebrovascular disease or diabetes mellitus – invasive urodynamic tests are frequently necessary to finalise the diagnosis and plan any intervention, especially if surgical treatment is considered.

The role of urodynamics and DO in predicting treatment outcome still remains controversial. Aboseif et al compared 92 men with and without DO on pre-operative urodynamics before radical prostatectomy.

They found, after one year, a significantly higher incidence of incontinence (39% v/s 3%) in patients with pre-operative DO compared to those without pre-operative DO. [256]

Similarly, Seki et al in a retrospective study of 384 patients who had undergone transurethral resection of the prostate (TURP) for symptomatic benign prostatic enlargement (BPE), showed after one year from IPSS and QoL that the baseline DO negatively affected outcome. [257]

Monoski et al found in 40 men who underwent photoselective laser vaporisation prostatectomy (PVP) for ‘BPH’ and retention that the presence of DO in patients on pre-surgery urodynamics is associated with significantly more storage symptoms requiring twice as likely anticholinergics treatment than the patient without DO. No specific distinction was given to incontinence. [258]

On the other hand, Kleinhans et al concluded (44 patients) that preoperative DO did not correlate to any of the post surgical incontinence eight months after radical prostatectomy. [259]

In 1999, Golomb et al also concluded that there was no significant association between pre-operative DO and post-operative incontinence. [181]

Urodynamics may also be useful for selecting candidates for new, emerging treatments. For example, Vandoninck et al. [260] used urodynamics to evaluate patients with OAB symptoms who were to be treated with percutaneous tibial nerve stimulation. Overall, the objective and subjective success rates of stimulation were 56% and 64%.

The treatment abolished DO only in a few cases and subjects without DO at baseline were 1.7 times more likely to preferably respond to percutaneous tibial nerve stimulation than those with DO.

a) Recommendations for urodynamic investigation in those with LUTS with incontinence related to bladder dysfunction mainly detrusor overactivity and bladder outlet obstruction

Patients with symptoms suggestive of non-complicated bladder outflow obstruction (BOO) on the basis of prostate enlargement without incontinence, need prostate size assessment, urinary flow study, PVR measurements, (International Prostate) Symptom Score and 24 hour frequency-volume charts prior to intervention, but do not always need to be investigated with invasive urodynamic study. [261-263]
Men with incontinence and a suspicion of other LUT dysfunction form a much more restricted group with complicated, disparate, and uncertain diagnoses. In some the incontinence may be an initial symptom; in others it may follow treatment (see the following section on post-prostatectomy incontinence).

Recommendation (Grade C)

- Evidence that urodynamics improves outcome is limited, but nevertheless the committee recommends that all such patients should receive a complete urodynamic evaluation in order to understand the problem that is to be treated and that surgeons should plan surgical interventions only after scrutinising the lower urinary tract by urodynamics.

3. POST-PROSTATECTOMY INCONTINENCE

a) General

After prostatectomy a noticeable number of patients suffer from urinary incontinence. The reported incidence following surgery varies widely depending on patient age, bladder function, definition or degree of urinary incontinence, benign or malignant prostatic disease and the type of surgery. Approximately 10-14% of patients, 2-5 years after radical prostatectomy complain of incontinence. [264] A prospective survey study on 1201 patients and 625 partners on outcome after treatment for prostate cancer showed that urinary incontinence was at its worst by 2 months after surgery and then improved in most patients. Factors that were associated with worse incontinence were an older age, black race, and a high PSA score at diagnosis. Patients in the brachytherapy group reported significant deterioration in ‘urinary irritation’ or obstruction and incontinence as compared with baseline (p<0.001). Incontinence after brachytherapy was reported by 4 to 6% of patients at 1 to 2 years after treatment. [265]

Understanding of prostato-vesical anatomy and the pelvic floor, and meticulous surgical technique, are of prime importance in preventing these distressing symptoms. Urodynamic studies can establish the aetiology and provide a rational basis for treatment by determination of the type of LUT dysfunction(s).

Kondo et al [251] have analysed the aetiology of urinary incontinence following surgery for ‘benign prostatic hyperplasia (BPH)’ or prostatic cancer using accumulated data from 573 patients reported in 8 articles from 1978 to 1997. Urodynamic studies suggested that the most common aetiology was sphincter weakness (causing USI), present in 34% of patients, followed by sphincter weakness plus DO in 33%, and DOI alone in 26%. Other aetiologies including low compliance and urethral stricture were responsible for the remaining 7% of patients with incontinence after surgery for BPH. Thus, although sphincter weakness was present in two-thirds of patients, a blanket assumption that it is the only cause of incontinence would be wrong in two-thirds. Clearly urodynamic testing is needed for diagnosis, and perhaps to choose treatment.

b) TURP, Open Prostatectomy and Thermal Treatments

Approximately 1% of patients who have undergone TURP suffer from post-prostatectomy incontinence.[266] Is urodynamics required prior to treatment? Das et al. [263] performed holmium laser resection of the prostate in 100 men patients for management of LUTS without performing any urodynamic studies except for a urinary flow rate. Their follow-up study 2 years later revealed that persistent incontinence remained in only 1, who required pads, and that the IPSS and maximum flow rates improved from 21.6 to 6.8 points and from 7.5 to 21.6 mL/s, respectively. This report does suggest that if patients are appropriately selected, post-operative urinary control is quite satisfactory, leaving only about 1% of cases with urinary incontinence. This implies that the role of urodynamic investigation in preventing post-operative incontinence before laser resection of the prostate may be marginal.

Kuo [267] urodynamically evaluated 185 men aged from 55 to 91 with a mean of 75 years who had had variable LUTS after TURP and had been refractory to conventional treatments. He found that urinary incontinence was present in 74 patients (40%) and that BOO and DO with impaired contractility (DHIC) were the most common findings associated with post-prostatectomy incontinence, followed by DO. Since these diagnoses imply quite different treatments, urodynamic investigation has an important role.

Conclusions (evidence level 3)

- Retrospective studies have shown that urodynamic tests cannot predict stress urinary incontinence or detrusor overactivity (with or without incontinence) after surgical treatment for benign prostatic obstruction.
- Studies have shown that urodynamic tests clearly identify the aetiology of urinary tract dysfunction after surgical treatment for benign prostatic obstruction however the predictive value towards the effects of subsequent treatment is unknown.

Recommendations (Grade C)

- The committee recommends urodynamic testing when patients have signs and/or symptoms of lower urinary tract dysfunction after surgical treatment for benign prostatic obstruction; particularly if further surgical or invasive treatment is planned.
c) Radical Prostatectomy and Radiotherapy

i) Is (invasive) urodynamic investigation of incontinence after radical prostatectomy necessary?

Radical retropubic prostatectomy for prostatic cancer results in much higher incidence of post-prostatectomy incontinence than TURP. In physician-reported studies, the incidence of total incontinence is a few percent and the incidence of SUI requiring some degree of protection is about 10%. [268] In studies based on patient self-report, however, the incidence of any degree of incontinence is 66% and the incidence of pad use is 33%. [269] One of the main determinants of prevalence is the time following surgery, since continence is regained after radical prostatectomy over the first year in many patients. [270] Continence after radical prostatectomy depends on minimizing the injury to the striated urethral sphincter and the use of well-designed surgical techniques. [271]

Patients who undergo a nerve-sparing radical prostatectomy appear to have a better chance of achieving continence than those undergoing standard radical prostatectomy. [272] Recent enhancements to the nerve-sparing prostatectomy may preserve external sphincter function and shorten the time to achieve post-operative continence. [272]

Castille et al prospectively assessed 229 men who were scheduled to undergo radical retropubic prostatectomy with preoperative urodynamics in an attempt to help physiotherapists predict postoperative incontinence. [273] They observed that all men diagnosed as having DO or BOO were incontinent 6 weeks after operation but had improved 4 months later. They stressed that DO and BOO in those undergoing radical retropubic prostatectomy are significant risk factors for postoperative incontinence, although only for a short period of time. Thus the role of pre-operative urodynamics is limited.

Groutz et al [274] evaluated 83 men of mean age 68 years, who were consecutively referred for persistent urinary incontinence following radical retropubic prostatectomy. They reported that USI was the most common urodynamic finding (73 patients, 88%), followed by DO in 6, BOO in 1, impaired detrusor contractility in 1, and normal findings in 2. Of 73 men diagnosed as having USI, 27 suffered from pure urodynamic USI, and the remaining 46 had concomitant bladder disorders such as impaired detrusor contractility (22 men), BOO (14 men) or DO (10 men). The authors reported that 25 of the 83 men had what they called “low urethral compliance”. This non-standard term expressed the fact that there was a difference of more than 10 mL/s between maximum free uroflow and maximum invasive (pressure-flow) uroflow. This term is not recommended, however, as it implies a cause for these observations that may not be correct.

Huckabay et al suggested a urodynamic protocol with video-urodynamics for patients with persistent incontinence after radical prostatectomy. They evaluated 60 men and found that twenty-four (40%) men had DO with 8 (13%) also having DOI. Only one patient had impaired bladder compliance. All men had USI, but 21 (35%) men demonstrated it only after removal of the urethral catheter. For men leaking with and without the urethral catheter, the respective abdominal leak point pressure (ALPP) was significantly different, 86.3 and 67 cmH₂O, respectively (p = 0.002). The men who leaked only in the absence of the urethral catheter had significantly higher ALPP measurements, p < 0.001. After reclassification using the fluoroscopic images of the bladder outlet and free Qmax, only 13.3% patients were obstructed. [275]

McCallum et al [276] reported that 21 of 180 men who had been treated for incontinence following radical prostatectomy still remained incontinent 2 years later. Sixteen of the 21 were evaluated, and half had USI together with UUI or decreased bladder compliance. The authors emphasised that SUI was one of the predominant symptoms but that co-morbid detrusor dysfunction had to be taken into consideration, as well as ISD, in order to properly treat persistent post-prostatectomy incontinence.

There was a very interesting study reported by Noguchi et al in 2006. [277] They evaluated a standard versus modification technique of radical prostatectomy in which the anterior attachment of the puboprostatic ligament to the pubic bone is preserved, to which the newly created vesico-urethral anastomosis is suspended. Three months after surgery ALPP, functional urethral length (FUL) and maximal urethral pressure were measured. The “suspension” group had a significant better continence rate and significantly higher ALPP.

On the other hand Twiss et al. based on study 29 men with incontinence after radical prostatectomy, concluded that ALPP is a relatively poor predictor of incontinence severity and, therefore, has limited clinical value in the urodynamic evaluation of post-prostatectomy incontinence. [278]

i) Is (invasive) urodynamic investigation of incontinence after radiotherapy necessary?

There are few manuscripts reporting the effects of radiotherapy in those with prostatic cancer, and even fewer discussing the place of urodynamics. [279, 280]

Henderson et al. [281] assessed the clinical role of urodynamics in the selection of prostate cancer patients for brachytherapy with a minimum dose of 145 Gy. One hundred consecutive patients were assessed after implantation. Prior to the treatment an unselected group of 57 of the 100 patients had been evaluated urodynamically: normal detrusor function (no DO) was found in 48 and DO in 9. No patients had
permanent urinary incontinence and 2 required surgery for BOO. Acute urinary retention developed in 7 patients, clean intermittent catheterisation was utilised by 27, and 89% of patients had a deterioration in their LUTS with the worst symptoms 6 weeks after implantation. They found that those who post-operatively had acute retention or preferred to utilise clean intermittent catheterisation had either larger prostatic volumes (> 35 mL) or were urodynamically obstructed. Consequently they concluded that urodynamics might have an important role in the selection of treatment for men with early prostate cancer, in particular to improve the outcome of brachytherapy.

In another study Beekman et al found in 204 patients that high PVR (> 100 mL) is associated with slower resolution of voiding symptoms, prolonged (more than 3 days) catheter dependency, and increased postbrachytherapy surgical intervention for BOO. [282]

Also Wehle et al suggested that the combination of urinary flow rate, prostate volume, postvoid residual urinary volume, and the American Urological Association symptom score can help identify patients with underlying voiding dysfunction. Urinary flow rate was a statistically significant predictor of genitourinary tract morbidity after brachytherapy for localised prostate adenocarcinoma. [283]

Overall there is a weak evidence to support urodynamic evaluation before radiotherapy for cancer of the prostate

**iii) Artificial urinary sphincter and male sling**

Gomha and Boone [284] treated 86 patients who were incontinent following surgery with implantation of an artificial urinary sphincter (AUS) and assessed whether or not prior radiation affected surgical outcomes in those who had or had not had radiotherapy. The aetiology of the urinary incontinence in group I (without radiation) was radical prostatectomy in 55 patients, TURP in 2, orthotopic ileal reservoir in 1; in group II (with radiation) the aetiology was radiation with salvage prostatectomy in 5, adjuvant radiotherapy after radical prostatectomy in 20, and radiotherapy and TURP in 3. Urodynamic study prior to artificial sphincter implantation revealed that DO was much more prevalent in group II (radiation, 26%) than in group I (no radiation, 5%), a significant difference (p = 0.04). In spite of this, post-operative urgency with or without urgency incontinence was found in similar proportions of the 2 groups (47% of group I and 43% of group II), and similar proportions were 0 to 1 pad a day to protect against their incontinence (60% and 64% respectively). Thus pre-operative urodynamics did not predict outcome.

Similarly, Thiel and co workers concluded that patients with incontinence post RP and DO, low compliance, decreased MCC and FSF have the same outcome after AUS implantation. [285] This was a retrospective review of 86 patients. Obviously, there could have been a selection bias in the study and the more severe cases could have been excluded from surgery.

However Ullrich & Comiter evaluated urodynamically 22 patients at a mean of 25 months after a male sling procedure and found that patients with postoperative retrograde leak point pressure < 50 cm H2O and DO are associated with increased pad use and bother. [286]

**d) Recommendations for urodynamics in those having post-prostatectomy incontinence**

Sphincter weakness, BOO, DO and mixed incontinence are significant aetiological factors contributing to post-prostatectomy incontinence.[251, 267, 276] These parameters can be only identified by urodynamics, which is considered by most.[284, 287, 288] but not all, [289] to be one of the main tools for investigating this type of incontinence. In brachytherapy for prostate cancer, urodynamics may have some value for predicting which men might develop acute urinary retention or might require intermittent catheterisation after treatment.[281]

**Conclusions (evidence level 3)**

- Retrospective studies have shown that urodynamic tests cannot predict lower urinary tract dysfunction after surgical treatment for prostatic carcinoma.
- There is weak evidence to support urodynamic evaluation before radiotherapy for cancer of the prostate
- Studies have shown that urodynamic tests clearly identify the aetiology of urinary tract dysfunction after surgical or radiotherapeutic treatment of prostatic carcinoma however the predictive value towards effect of subsequent treatment is unknown.

**Recommendations (grade C)**

- The committee recommends urodynamic evaluation before radiotherapy for cancer of the prostate.
- The committee recommends urodynamic testing when patients have signs and/or symptoms of lower urinary tract dysfunction after treatment of prostatic carcinoma; particularly if surgical or invasive treatment is planned.

**Topics for research**

- The committee suggests research to find predictors for lower urinary tract dysfunction after treatment for benign prostatic obstruction or for prostatic carcinoma.
- The committee suggests research to improve
4. NOCTURNAL ENURESIS AND PARKINSON'S DISEASE RELATED TO MALE INCONTINENCE

Several ailments or pathological conditions have been reported to be closely associated with male incontinence, e.g., neurological diseases, prior radiotherapy, neurogenic DO, diminished bladder compliance, nocturnal enuresis, post-micturition dribble and terminal dribbling. [251]

a) Nocturnal enuresis

Nocturnal enuresis in adult males is rather rare. Sakamoto and Blaivas reported important and interesting observations based on data of over 3000 patients referred for the evaluation of LUTS. [288] They found that 8 of 3277 patients (0.02%) had adult onset nocturnal enuresis without daytime enuresis. All these patients were male, with a mean age of 63 years (48 to 80 years) and all suffered from BOO with mean maximum urinary flow rate 8.5 mL/s, mean IPSS 12.6, and mean PVR urine 350 ml (50 to 489 ml). The authors identified hydronephrosis in 5 of the 8 patients, a bladder diverticulum in 3/8, VUR in 4/8 and low bladder compliance in 4/8. Five of the 8 underwent TURP resulting in improved symptoms. Thus BOO is one of the distinct pathologies that can provoke nocturnal enuresis with variable LUTS, but it is not the only pathological factor. For example, Hunsballe [290] found more delta activity in electroencephalography among adult primary enuretics compared to normal controls. Therefore, invasive urodynamics may be justified in such patients, because it is the only way of reliably identifying BOO.

Another factor contributing to nocturnal enuresis is the presence of a neobladder. Nocturnal enuresis plagues nearly 28% of such patients. Indeed, 25 of 30 patients (83%) who underwent the Stanford pouch ileal neobladder had nocturnal enuresis 1 year later. [291] Patients older than 65 years are at greater risk because of the physiological increase in LUTD nocturnal diuresis associated with aging. An orthotopic neobladder produces variable LUTD including both failure to empty the bladder and failure to store urine. The urodynamic behavior depends on the type, length, and configuration of the bowel segment used. [292] There may be overdistension, elevated PVR, lack of sensation, reduced MUCP, or more frequent and higher-pressure DO. [293] The intestinal overactivity in a neobladder resembles bowel peristalsis. [294]

e-l-Bahnasawy et al studied urodynamically 50 enuretic men at least 1 year after a radical cystoprostatectomy and ileal neobladder and compared them to 17 men with only occasional enuresis and 50 men without enuresis after similar surgery. Both enuretic groups had significantly higher residual urine volumes, pressure at mid-capacity and at maximum enterocystometric capacity, amplitude of involuntary contractions, and lower compliance than continent men. Men with occasional enuresis also had a significantly higher frequency and duration of involuntary contractions than continent men. Men with persistent enuresis had significantly lower average and maximum urinary flow rates than continent men, and significantly lower functional urethral length and maximum urethral pressure. [295]

Urodynamic investigation is important to establish the diagnosis and select treatment, although one group suggested that bed wetting could be simply alleviated by waking up at least twice per night to void. [291] Stroke is a common and well-known cause of enuresis and LUTD in the older population. The predominant symptoms are urinary frequency, urgency and UUI (including night-time incontinence) while DO is the most common finding on urodynamics. [296] In patients after a stroke, incontinence (or LUTD in general) is a serious threat for quality of life. [297] Because DO in patients with LUTD is so prevalent, conservative or pharmacologic treatment is often instituted without prior urodynamic investigation, even though the size and the site of the stroke do have an influence on urological findings. [298] Simple tests such as uroflowmetry and, especially, PVR urine assessment (by ultrasound) are however useful since elevated residual urine is to be expected in a significant amount of these patients and its evaluation can improve caregiving and quality of life. [299, 300] Cystometry has limited value: the prevalence of DO in older people is quite high even in the absence of stroke (perhaps 10% in women and 25 to 35% in men). Therefore the observation of DO alone is not definitive, while the observation of DOI merely confirms what one would suspect in any case.

b) Parkinson's disease

Parkinsonian diseases are known to significantly influence bladder function (see section D.V.6). LUTS may be the first sign, especially nocturia in male patients. Large capacity bladder (when discovered during urodynamic testing for LUTS) may also be a sign of Parkinsonism. [301-304]

DOI is common in patients with Parkinsonism, [158] but urodynamic findings differ in different diseases of this group. [305] In multiple system atrophy for example – as opposed to Parkinson’s disease – PVR urine volume > 100mL, detrusor-sphincter dyssynergia, or EMG evidence of internal or striated sphincter denervation are common. Such findings, especially (large) residual urine, may influence the choice of treatment. If there is residual urine, invasive pressure-flow studies may be indicated, particularly to diagnose...
or rule out BOO and or to confirm detrusor underactivity or dyssynergy.

Defreitas et al carried out a retrospective review of the urodynamic results in men with DO due to BOO (22 patients) and compared them to men (39 patients) and women (18 patients) with Parkinson’s disease. Patients with Parkinson’s disease had a significantly lower median volume at first detrusor contraction than those with non-neurogenic DO. The percentage of urgency incontinence was significantly lower in patient without Parkinson’s disease than in men and women with it (9.1% vs 53.8% and 55.6%). No statistically significant correlation between the duration or severity of Parkinson’s disease and UDS parameters was found. [158]

c) Recommendations for urodynamic investigation for men suffering from nocturnal enuresis or Parkinson’s disease

Conclusions (level of evidence 2/3)

- Nocturnal enuresis in adult males is rare but problematic, and it is associated with many possible aetiologies.
- Nocturia, nocturnal enuresis or lower urinary tract symptoms may be a first or an early sign of Parkinsonism in elderly male patients.
- Lower urinary tract dysfunction in patients with Parkinsonism can be the result of detrusor overactivity, (benign prostatic) bladder outlet obstruction, dyssynergic voiding or post void residual urine or any combination thereof.

Recommendations (grade B/C)

- The committee recommends that urodynamic evaluation should be conducted in all cases of nocturnal enuresis in adult males
- The committee recommends that urodynamic evaluation should be performed in patients with Parkinsonism. There should be flowmetry and postvoid residual assessment in all cases and invasive testing when abnormalities are observed in flowmetry and postvoid residual assessment.
- The committee suggests that investigators should be alert for large capacity bladder and/or detrusor underactivity (or large residual without significant bladder outlet obstruction) because it is a first or early sign of Parkinsonism.

5. POST-MICTURITION OR TERMINAL Dribbling

There are no recent manuscripts on post-micturition dribble or terminal dribbling involving urodynamics.

In 1996, Reynard et al determined the prevalence of the symptom of terminal dribbling from a symptom questionnaire completed by 165 men presenting with LUTS. Objective evidence of terminal dribbling during voiding was assessed from uroflow recordings and prostate volume was measured by transrectal ultrasonography. Combined pressure-flow studies were performed to determine the presence or absence of BOO. They found that there was relatively poor agreement between the symptom of terminal dribbling and objective evidence of its presence; 48% of the patients who reported terminal dribbling most or all of the time showed no objective evidence of terminal dribbling on uroflowmetry.

The symptom of terminal dribbling was not significantly related to the presence of BOO (p = 0.74). However, objective evidence of terminal dribbling on uroflow traces was significantly related to BOO (p < 0.001) and those patients with objective evidence of terminal dribbling had higher values of URA (median 39 compared with 28 cmH2O). Objective terminal dribbling had a specificity of 92% and positive predictive value of 88% for the presence of BOO.

Neither the symptom of terminal dribbling nor objective evidence of its presence were significantly related to prostatic enlargement. The authors concluded that while the symptom of terminal dribbling is probably not related to BOO or prostatic enlargement, objective evidence of terminal dribbling on flow curve recording is fairly specific for BOO and as such, its presence could potentially be of value in the assessment of men with LUTS. [306]

Recommendation (grade C)

- When a complaint of terminal dribbling is objectively identified in the urinary flow curve, urodynamic studies may be indicated to verify or rule out the presence of bladder outlet obstruction or urethral pathology.

III. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

1. INTRODUCTION

Neurogenic incontinence may express itself as UUI, ‘reflex incontinence’, ‘overflow incontinence’ or SUI. UUI and SUI have already been reviewed in this present chapter. ‘Reflex’ and ‘overflow incontinence’ are terms not currently recommended by the International Continence Society but they will be discussed below, together with other relevant topics for this group of patients which are not covered elsewhere in this chapter.
2. WHAT IS USUALLY EVALUATED?

Because not all patients with neurogenic conditions develop typical urinary symptoms or urodynamic findings, a specific understanding of the dysfunction in each individual is an absolute prerequisite for the correct choice of therapy.[307-309] The aim is to describe the (dys)function of the bladder, the urethra and the pelvic floor, their coordination during filling and voiding, and their influence on other pathological conditions (e.g. autonomic dysreflexia) or organ systems (e.g. renal function). Except in a few diseases where empirical, conservative therapy can safely be instituted, or where LUT dysfunction is predictable (e.g. post-stroke), urodynamic investigation is required to provide the understanding of the situation on which rational treatment must be based. Even when empirical therapy is instituted without urodynamics, the progress of the patient must be carefully reviewed to determine whether urodynamics is needed after all.

Because many patients with neurological conditions show anatomical abnormalities that involve the LUT, or detrusor-sphincter dyssynergia (lack of coordination) that can be demonstrated easily by imaging, comprehensive videourodynamics is the test of choice.[307-311]

3. SPECIAL TESTS

The ice water (bladder cooling) test is sometimes used in an attempt to identify neurogenic DO (see section C.V.1.e: provocative manoeuvres).

The carbachol test is intended to reveal supersensitivity to muscarinic agents following neurological decentralization, typically in bladders in which a voiding reflex cannot be demonstrated.[312] A subcutaneous injection of a muscarinic agonist (0.25 mg carbachol or bethanechol) is given and the detrusor pressure is monitored for 30 min or until it rises to over 20 cm H2O. The test is considered positive if the detrusor pressure increases above 20 cm H2O.[313] Results published more than 20 years ago report detrusor decentralisation in a variable proportion of patients with a positive carbachol test (from as few as 50% up to as many as 98%).[312, 314, 315] Thus in some hands (though not in all) it does not have a very good diagnostic performance and as a result it has fallen out of favour. An attempt to use it to help predict the results of sacral neuromodulation proved unsuccessful.[316]

4. NEUROGENIC DETRUSOR OVERACTIVITY

INCONTINENCE (‘REFLEX INCONTINENCE’)

DO of neurogenic origin is frequently observation in association with neurological disease, and often leads to actual leakage, i.e. incontinence. Observed on urodynamics, this type of incontinence should be termed neurogenic DOI. The corresponding symptom is variable: if the DO is accompanied by sensation (desire to void) it might be termed UUI; frequently however any sensation is absent and so the term urgency incontinence is misleading. For this reason the term ‘reflex incontinence’ was introduced,[4] implying automatic filling and emptying of the bladder without sensation or control. This term is no longer recommended.[5]

5. DETRUSOR-SPHINCTER DYSSYNERGIA

Neurogenic DO is often accompanied by detrusor-sphincter dyssynergia: a neurogenically determined failure of coordination of detrusor and urethra. The failure of the urethral sphincter to relax, when the detrusor contracts, causes a functional urethral obstruction which may not only hinder bladder emptying, but may also permit the development of high detrusor pressures. If high pressures are present for prolonged periods in daily life, renal function may be endangered (see the following subsection on “overflow incontinence”).

6. ‘OVERFLOW INCONTINENCE’

‘Overflow incontinence’ is another term that is no longer recommended.[4] It means continual leakage from a constantly overdistended bladder.[4] The presenting symptom is usually characterised by continual small amounts of incontinence, exacerbated by increased abdominal pressure, together with an inability to empty the bladder by voiding.

On urodynamics the usual corresponding observation is a bladder with low compliance and little or no detrusor activity; as the bladder is filled the detrusor pressure rises because of the poor compliance, until it reaches a value sufficient to open the urethral sphincter. Dribbling leakage then ensues. Clinically, the most important variable is believed to be the detrusor pressure at which leakage occurs, the detrusor leak point pressure (DLPP). If this pressure is elevated, and if similar pressures are attained during continual leakage in daily life, then renal function is endangered because the constantly high detrusor pressure hinders outflow from the ureters. Conventionally, DLPPs of 40 cm H2O or more are believed to be unacceptable. There is evidence (mostly from pediatric studies) that upper urinary-tract deterioration is more probable when DLPP is elevated. [317-319] However, the evidence for a cut-off at 40 cm H2O seems less clear.

7. REPRODUCIBILITY AND RELIABILITY OF TESTS

Since many patients with neurogenic dysfunction of the LUT have severe subpontine neuropathy, the influence of the emotional (limbic) nervous system on lower-tract function is reduced or eliminated; thus, urodynamic observations may be less variable and more reliable than those made in individuals with an intact nervous system. Nevertheless, the test
conditions (e.g. the rate of filling the bladder) do influence the results, and should be chosen carefully.[2]

8. DOES URODYNAMIC TESTING IMPROVE CLINICAL OUTCOME?

The aims of therapy for neurogenic lower urinary tract dysfunction are to achieve the most nearly physiological filling and voiding conditions [307-309] as well as a management situation acceptable to the patient in daily life. Long periods of elevated detrusor pressure during bladder filling or (abnormally prolonged) voiding put the upper urinary tract at risk [317-319] (Level of evidence 3). The primary aim of therapy in patients with such problems is conversion to a low pressure bladder during filling,[307, 309] even if this leads to incomplete emptying. Adequate therapy depends on whether the detrusor is overactive or has reduced compliance, and only urodynamics can answer those questions unequivocally. Timely and adequate diagnosis is of paramount importance for the patient's quality of life.[308, 309, 320, 321] Urodynamic investigation is essential for checking the efficacy of treatment and in following up any sequelae of the disease and its management. Kabay et al [322] used urodynamics to evaluate acute Posterior Tibial Nerve Stimulation in patients with MS. Stimulation improved volume at the first involuntary detrusor contraction and MCC. It remains however unclear if this translates to clinical improvement.

Conclusions (evidence level 3)

- Urodynamic testing improves clinical outcome in patients with continually elevated detrusor pressures.
- In many other types of neurogenic dysfunction rational treatment is impossible without the knowledge that invasive urodynamic testing provides.

Recommendations (grade B/C)

- The committee recommends that patients with suspected neurogenic dysfunction of the LUT should receive comprehensive urodynamic evaluation, including videourodynamic if possible, to establish the state and function of the lower tract.
- The committee recommends that anorectal function should be evaluated in addition to urinary function (see section F on Anorectal physiology studies).
- The committee recommends that urodynamic testing in this group of patients should be done in specialised centres by trained and certified personnel.

Recommendations for research:

1. Comprehensive urodynamic testing should form an essential part of the evaluation of new therapies such as botulinum toxin injection or intravesical instillation of capsaicin analogs.
2. New types of urodynamic study need to be developed to delineate more precisely the types of neurogenic dysfunction that arise from supraspinal abnormalities of the lower urinary-tract control system, which up to the present have been neglected.

IV. PATIENT EVALUATION: CHILDREN

1. INTRODUCTION

The indications for urodynamic evaluation in children in this section have been set out on neurological, anatomical and functional lines, with the types of studies to be performed being based on the underlying pathological conditions rather than on the presenting symptoms. The findings, efficacy and reliability of urodynamic studies for each of these conditions will be discussed.

Many of the conditions for which urodynamics is employed in children involve anatomical and neurological abnormalities, in which LUT dysfunction is variable, complicated, and unpredictable. Urodynamic testing is used to establish as clearly as possible the baseline situation, so that changes as a result of treatment and/or growth can be assessed, and some guidance is obtained in the choice of treatment (although the result of urodynamic testing may not necessarily be the deciding factor). Here, therefore, perhaps more clearly than in any other patient group, the aim of urodynamic studies is surely to provide objective knowledge about LUT function and dysfunction as well as to provide understanding to the care-giver and to the patient (and her or his parents).

Of course, it is still important that the tests used should be relevant, reliable and reproducible in the patient population considered, and the evidence for this will be discussed in the following paragraphs.

2. NEUROGENIC BLADDER DYSFUNCTION

a) Myelodysplasia

For the last 20 years initial urodynamic studies very early in the neonatal period have been recommended for children with myelodysplasia, the basis being that they help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture.[323]. DO on cystometry, detrusor underactivity during voiding, detrusor-sphincter dyssynergia (usually established on the basis of surface EMG), DLPP, and
PVR are the key elements of a detailed urodynamic study that need to be considered.[324, 325]

In an exhaustive review of the efficacy and reliability of urodynamic studies in newborns with myelo-dysplasia [326], of 24 studies analysed, 13 focused on EMG activity of the striated urethral sphincter or pelvic floor, 7 on bladder compliance and 2 on cystometric technique. Twenty-one studies were at level of evidence 4, 2 were at level 3 and 1 was at level 1. Nine of the 24 studies were performed at international sites and the remainder within the United States. The urodynamic patterns of normal detrusor function (66%), acontractile detrusor (33%), DO (57%), and detrusor compliance, as well as detrusor-sphincter synergy (21%), dyssynergia (37%) and sphincter denervation (60%) were similar, with little variability across comparable studies.

van Meel et al have shown that repeating the Ice Water Test (IWT) will increase its positivity. Combining the IWT and electrical perception threshold (EPT) will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurological cause of the dysfunction in children with idiopathic DO. The IWT was positive in 46% patients with relevant neurological abnormalities if used once, this percentage became 86% when the IWT was repeated. In patients without neurological abnormalities, one IWT was positive in only 7% and when repeated, the positive test rate increased to 24%. The EPTs were not significantly different between the neurologic and nonneurologic patients with a positive IWT, except after the third instillation. In those with negative IWTs, the EPTs were significantly different between the neurologic and nonneurologic patients, independent of the number of IWTs done. [327]

Bladder capacity was studied in a group of 506 myelodysplastic children [328] and found to conform to the formula: capacity in mL = 24.5 x (age in years) + 62. This formula for the increase in bladder size with age is 20% less steep than published age-related bladder capacities in neurologically normal children [329, 330] (e.g. 30 x age + 30). However, those children who did not have DO had a bladder capacity similar to normals. Because neurological impairment affects detrusor compliance, cystometric filling rates also influence measured capacity and compliance as noted in 3 studies that addressed this issue.[328, 331, 332]. The lower the filling rate the greater the compliance and the larger the capacity.

Bladder augmentation alone without simultaneous antireflux repair is usually sufficient for the resolution of pre-existing vesico-ureteral reflux (VUR) in children with neurogenic dysfunction. A retrospective study by Juhasz et al in 2008 suggested that the various GI segments used for augmentation have no effect on the urodynamic results and the resolution of VUR. [333]

On the basis of a retrospective review of single centre data, that also included results from other centres and multicentre studies, intravesical electrotherapy was considered effective in improving bladder capacity without deterioration of compliance and without 'new onset' DO. Of the 372 patients 77% had a 20% or greater increase in bladder capacity after treatment. In this subset of patients, bladder storage pressure at capacity was below the 'critical level' of 40 cm H2O in 75%. Of the 17% of patients who had no change in bladder capacity 81% had normal bladder storage pressures after treatment. Bladder sensation developed and was sustained in 62% of patients. [334].

Rendeli et al retrospectively assessed the usefulness of urodynamic testing to determine the optimal timing of neurosurgery and to evaluate the evolution of bladder function in children with lipomeningocele. All patients underwent urodynamic testing preoperatively and during extended followup (mean 6.5 years, range 3 to 12). Bladder capacity and mean DLPP improved in all groups but particularly in children who had had neurosurgical treatment within the first year of life. At the end of the study mean bladder capacity was 420 cc in patients operated before the age of 12 months, 300 cc in those operated between 2 to 36 months old and 260 cc in those who were older than 36 months at the time of surgery (p <0.01). Mean DLPP was 37, 54 and 55 cm H2O in these groups respectively (p <0.01). At the latest followup, 65% of patients in the youngest group had improved urodynamic parameters compared to 33% of those 12 to 36 months old and 28% of those older than 36 months. Urodynamic evaluation and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele, and in diagnosing the onset of tethered cord. [335]

Six studies evaluated the relationship between level of the neurological lesion (on clinical examination) and LUT function but none could predict a specific urodynamic pattern based on the level of the lesion. Sacral level lesions can be associated with an upper motor neuron urinary tract ‘urodynamic pattern’ just as readily as the expected lower motor neuron findings.[336] Similar findings have been noted for children with thoracic or high lumbar level lesions where the incidence of sacral reflex sparing is 54%. [337]

Approximately 90% of children born with spina bifida will have a normal upper urinary tract at birth. Over time many children who have not received proactive urological care develop upper and/or LUT deterioration. The deterioration is an acquired phenomenon secondary to the development or progression of various LUT hostility factors such as neurogenic DO, poor bladder compliance, detrusor-sphincter dyssynergia and/or high LPP from denervation fibrosis.
[323-325, 338] Despite the fact that only one study was at level 1, all urodynamic studies corroborated their reliability by reporting that the prediction of upper urinary tract deterioration on the basis of urodynamic testing is possible with 90% accuracy.

In 2006, Wang et al calculated a urodynamic risk score including a DLPP of >40 cmH2O, a bladder compliance of <9 mL/cmH2O and evidence of-acontractile detrusor. They postulated that the selective use of urodynamic variables might be valuable for predicting the risk of upper urinary tract dilatation in children with neurogenic bladder-sphincter dysfunction. They found that decreased bladder compliance, increased DLPP and acontractile detrusor are the main urodynamic risk factors, and they reciprocally increase the occurrence and grades of upper urinary tract dilatation. The grades of renal dilatation are compatible with increases in relative unsafe cystometric capacity and the calculated urodynamic risk score [338] Severe bladder trabeculation in incontinent children with neurogenic LUT dysfunction is reported to be associated with bladder outlet obstruction. [339]

Not all authors consider that prophylactic (high pressure prevention) treatment is beneficial, but all recommend periodic cystometry when new onset hydronephrosis, VUR or urinary incontinence develops, the latter in children on a continence program already (i.e. clean intermittent catheterisation and/or drug therapy).[340, 341] When new onset urinary incontinence not related to urinary infection nor easily treated by increasing current treatment regimens occurs, one study has shown that repetition of cystometry, urethral pressure profilometry, and EMG measurements, is helpful in management [342].

When incontinence develops in spite of strict adherence to bladder and bowel continence programs, or when changes occur in leg function or sensation, or when the child experiences back pain or increasing scoliosis, a change in neurological impairment might be expected. If striated urethral sphincter EMG is assessed periodically during the first 3 to 6 years of life and then periodically throughout puberty, changes in pelvic floor or urethral sphincter innervation can indicate changes in neurological and LUT function. Bearing this in mind, 4 studies, noted that a considerable number of myelodysplastic children (40% to 61%) regardless of their neurological level have progressive neurological deficits as they grow up and reach puberty.[336, 343-345] Two of these studies noted changes particularly early in infancy, while a third study noted changes throughout childhood. Thus, most clinicians agree that myelodysplasia is a dynamic disease process which changes as the child grows and that warrants constant vigilance of both the neurological picture and lower urinary tract function. Although its efficacy has not been proven, it is recommended that a cystometrogram/EMG be repeated 3 months following any neurosurgical intervention to correct a tethered cord, or spinal surgery to repair increasing scoliosis, for this provides a new baseline for comparison should further spinal cord tethering take place after corrective surgery.

In 2006, Schulte-Baukloh et al evaluated prospectively the efficacy and tolerability of propiverine for treating neurogenic DO in children. Twenty children with neurogenic DO due to an upper motor neurone lesion were enrolled (17 had myelomeningocele). In the urodynamic examination, the mean (SEM) volume at first detrusor activity increased from 103.8 (21.3) to 174.5 (33.7) mL (p<0.005) after 3-6 months of propiverine treatment, maximum detrusor pressure decreased from 52.5 (7.9) to 40.1 (6.2) cmH2O (p<0.05), maximum cystometric bladder capacity increased from 166 (28.8) to 231.9 (34.8) mL (p<0.005), and bladder compliance improved from 11.2 (2.8) to 30.6 (9.7) mL/cmH2O p<0.01. The incontinence score (scale 0-3) improved from 2.4 (0.2) to 1.6 (0.3) (p<0.05). [346]

Several studies that evaluated the urodynamic result of bladder augmentation have been published. Significant increase in bladder capacity and compliance were achieved and maintained in the long term. Median preoperative compliance was 1.6 mL/cm H2O and an increase of 762.5% was observed during followup. [347]

Renal transplantation in patients with myelodysplasia is a challenging issue. LUT dysfunction carries increased risks for the grafted kidney. Careful diagnosis and surveillance of LUT function by urodynamic evaluation is essential to optimise these outcomes. Recent publications suggested that renal transplantation is a safe and effective treatment modality in patient with myelodysplasia. Videourodynamic tests were performed on all patients preoperatively as well as postoperatively. Augmentation cystoplasty was required in a proportion of children to achieve a low-pressure reservoir with adequate capacity. [348-350]

\textbf{b) Occult spinal dysraphism}

Several series characterising the preoperative urodynamic evaluation of children with occult spinal dysraphisms have documented abnormalities in striated urethral sphincter function (denervation and/or detrusor-sphincter dysynergia) in 20 - 35% of babies under 2 years of age with normal neurological examinations; thus emphasising the need for urodynamic testing in these children.[351-356]. Six reports in older children revealed a greater correlation (70 – 90%) between an abnormal neurological examination and the likelihood of finding an abnormality on urodynamics. [351, 355-359] A few studies demonstrated that between 10% and 20% of patients experience a loss in function immediately postoperatively (most of whom had abnormal LUT
function preoperatively), and a variable number, usually inversely related to age, have improved sacral cord function on postoperative assessment 3 or more months after surgery.[351, 353, 357-359] Two studies, both retrospective, revealed an efficacious response in EMG activity, with stabilisation or improvement in up to 60%, on postoperative urodynamic assessment when the dysraphic state was corrected before 2 years of age.[351, 357] When children were first operated on after 2 years of age, 2 urodynamic reports documented an additional 25 to 35% with progressive changes in urethral sphincter function with axial growth, very few of whom had a detectable change on physical examination.[352, 357]

In a small prospective study in 2008, it was observed that children with open spina bifida, as compared to closed dysraphism, tended to have more bladder dysfunction as exemplified on clinical history and urodynamic assessment. Before neurosurgical closure of the defect, history indicated that the bladder was involved in 14 of the 25 children. Six of the 10 cases with an open spina bifida showed clinical involvement of the bladder as compared to 8 of 15 with a closed pattern. Urodynamic studies showed evidence of bladder dysfunction in 19 children. Of 10 with a meningocele, there were abnormal urodynamics in 9 as compared to 10 of 15 with closed dysraphism. Follow up urodynamic studies showed improvement in 9 of 20 children 3 of 7 with a meningocele and 6 of 13 with closed dysraphism. The authors concluded that a preoperative urodynamic study helps to identify severity of bladder dysfunction in clinically overt cases and also identifies subtle bladder dysfunction in clinically silent cases. Evaluation after operation tends to show better outcome in children with closed dysraphism. The study also identifies deterioration in some patients with seeming clinical improvement. [356]

In 2007, Abrahamson et al studied the urodynamic findings in a consecutively treated population of children with myelomeningocele after untethering of the spinal cord. Severe bladder dysfunction was defined as detrusor pressure at MCC > 40 cm H2O and/or amplitude of DO in the range 20 - 40 cm H2O, moderate dysfunction as detrusor pressure at MCC in the range 20 - 40 cm H2O and/or amplitude of DO in the range 20 - 60 cm H2O, and mild dysfunction as detrusor pressure at MCC < 20 cm H2O. After untethering, 35% of the patients experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward, and 90% of those who were stable preoperatively continued to be stable postoperatively. Therefore, regular evaluation of bladder function in children with myelomeningocele should be performed. [360]

**Conclusions (evidence level 2/3)**

- Retrospective and prospective studies have shown that the urodynamic diagnosis of DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms.
- Many retrospective and prospective studies have shown that urodynamic testing in patients (children) with meningomyelocele or (occult) spinal dysraphism reveals clinical relevant results with regard to detrusor storage function.
- On the basis of expert opinion, videourodynamic testing is preferable above urodynamic testing without video, however the exact advantage (eg in repeated investigation) is not substantiated.
- Various studies have shown that LUT function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and physical growth).
- No studies have been published that are a help to determine the optimum of timing and frequency of urodynamic follow-up.

**Recommendations (grade B/C)**

- Comprehensive urodynamic testing is advised in all patients with myelodysplasia or (occult) spinal dysraphism.

**Recommendations (grade C)**

- Videourodynamic testing should be considered in children with myelodysplasia or (occult) spinal dysraphism.
- Timing and technique of urodynamic testing in patients with myelodysplasia or (occult) spinal dysraphism should be selected on an individual basis.
- To help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture initial urodynamic studies very early in the neonatal period are recommended for children with myelodysplasia or (occult) spinal dysraphism.
- The committee recommends that anorectal function or dysfunction is simultaneously evaluated with urinary tract function in children with myelodysplasia or (occult) spinal dysraphism (see section F on faecal incontinence).

**c) Sacral agenesis**

Sacro agenesis, absence of the lowermost vertebral bony segments, is a lesion that can be missed in infancy because of its subtle clinical manifestations,
with generally no loss of lower extremity motor and sensory function, and the non-progressive nature of its pathophysiology.[361, 362] Urinary and/or faecal incontinence usually manifest themselves at an older age when the child fails to toilet train on time. A careful physical examination noting flattened buttocks and a short gluteal crease is pathognomonic for the diagnosis. In 8 reports that provided enough data, urodynamic studies had been 90% accurate in delineating the neurological deficit, which cannot be predicted by the level of absent vertebrae,[354, 363-369] and in managing the incontinence and/or upper urinary tract abnormalities (i.e., hydronephrosis, VUR). These studies reveal that between 30 and 40% of these patients have an upper motor neuron type lesion with DO and an intact but dyssynergic sphincter, while 25 to 50% have signs of a lower motor neuron deficit with acontractile detrusor and denervation in the sphincter, and 15 to 20% have normal LUT function.[361, 363, 364] Tethered cord occurs in children without sacral anomalies as well as in those with low anorectal malformation. Mosiello et al [370] recommend evaluation of all patients using MRI. When MRI shows sacral or spinal cord anomalies, UDS should be performed. They recommend a noninvasive evaluation for all other children and urodynamics when neurogenic dysfunction is suspected. It is presumed that the neurological deficit associated with this entity is fixed because no study showed any progression of the neurological disorder with increasing age.

Various studies have shown that a proportion of children with sacral agenesis have dysfunction of the LUT and that the proportion of patients is the highest in the patients with concomitant relevant neurological abnormalities.

**Conclusion (evidence level 3)**

- Case series have shown that evaluation of lower urinary tract function in children with (partial) sacral agenesis reveals a substantial incidence of dysfunction.
- There is a small, however unknown, proportion of children with lower urinary tract symptoms where (otherwise subclinical) sacral abnormalities were ultimately discovered to be the cause of the problems.

**Recommendation (grade C)**

- Clinicians should consider urodynamic testing in children with sacral agenesis when clinical signs of LUT dysfunction or relevant neurological abnormalities exist.
- Clinicians must be aware that in children with lower urinary tract dysfunction, otherwise clinically silent sacral abnormalities might also exist.

**d) Spinal cord injury**

The rarity and variability of spinal cord injuries in children makes it difficult to propose any one treatment program unless the specific type of LUT function is known. [49, 371-373]. Even if the individual regains the ability to void spontaneously and empty his/her bladder, it is imperative to know the detrusor filling and emptying pressures. Even if the child is continent on clean intermittent catheterisation, it is important to measure detrusor compliance in order to determine the potential risk for hydronephrosis and VUR. [374] A poorly compliant bladder with or without elevated voiding pressures from detrusor-sphincter dyssynergia often leads to the development of hydronephrosis and VUR; when combined with urinary tract infection progressive renal failure is often the result. [375] Four studies extol the need for urodynamic studies once spinal shock from the initial injury wears off, to determine the presence of low filling and voiding pressures and the ability for complete emptying, for the reasons cited above. [376-379] All studies are retrospective and use historical controls for comparison.

A thoracic or cervical level injury may produce an upper motor neuron deficit leading to DO, poor compliance, high voiding pressures and incomplete emptying over time, secondary to detrusor-sphincter dyssynergia. [380-382] In the presence of elevated filling and voiding pressures, there is a 30% incidence of upper urinary tract deterioration. [318] Balanced voiding with pressures below 40 cm H2O in the absence of detrusor-sphincter dyssynergia ensures a stable upper urinary tract. [378]

Generao retrospectively studied 42 children with spinal cord injury. Patients were divided into 3 groups based on level of injury-cervical (10), thoracic (26) and lumbar (6). In the cervical group, safe bladder capacity was less than the expected capacity in 80% of patients but all patients undergoing multiple urodynamics had increasing capacity with time. In the thoracic group, 58% of patients had a safe bladder capacity less than expected and 76% of those undergoing multiple urodynamics had increasing capacity. In the lumbar group 50% of patients had a safe bladder capacity less than expected and 67% of those undergoing multiple urodynamics had increasing capacity. [373]

A cauda equina injury often leads to a lower motor neuron deficit of the striated sphincter that may not require any treatment whatsoever because the bladder empties readily at low pressure, but it probably necessitates medical and/or surgical therapy to achieve continence. Urodynamic studies are considered invaluable in describing LUT function and in efficaciously managing any dysfunction to maintain a healthy upper urinary tract and long-term survival with minimal morbidity. [375, 379, 383]
Urodynamic studies should be undertaken no earlier than 6 weeks after injury, to allow for the manifestation of the extent of the neurologic injury. [377]

Periodic reassessment of the bladder and sphincter function is appropriate up to 2 years after injury, due to the potential for change during that time

**Conclusion (evidence level 2/3)**

- Retrospective studies have shown that urodynamic testing of all children with spinal cord injury is relevant.
- Retrospective studies have shown that urodynamic testing of children with spinal cord injury results in diagnoses and treatment similar to adults with spinal cord injury.

**Recommendations (grade C)**

- The committee recommends that urodynamic testing in children with spinal cord injury is planned on an individual basis, but no earlier than 6 weeks after injury.

3. IMPERFORATE ANUS

Imperforate anus is classified as high, intermediate or low depending on whether or not the rectum ends above, at or below the levator ani muscle. In the past, imperforate anus repair for high lesions frequently resulted in urinary incontinence due to a pudendal nerve injury that often occurs from a perineal approach to bringing the rectum down to the anal verge.[392] With the advent of the posterior sagittal anoplasty this complication has been eliminated as a cause for subsequent urinary incontinence, although bladder neck incompetence may be a consequence of extensive mobilisation of the sigmoid colon which helps transfer the rectum to its final location. However, recent reports of spinal MRIs reveal a 35% incidence of distal spinal cord abnormalities in children with an imperforate anus.[393-395]

Wetting after definitive repair may be the result of stress incontinence through ineffective emptying ('overflow incontinence') and bladder underactivity or acontractility rather than sphincter injury. In 2005, Shimada et al reported on the reconstruction of cloacal anomaly in a consecutive series of 11 girls. The main clinical characteristic of bladder dysfunction was a failure to empty. [396] They could not define the exact aetiology, but iatrogenic injury from extensive dissection can lead to the higher risks of peripheral nerve damage.

In 2004, Warne et al prospectively studied the effect of surgical reconstruction by posterior sagittal approach and total urogenital mobilisation in either causing or worsening bladder dysfunction in new patients with cloacal anomalies. A comparable group of patients...
with anorectal malformation (ARM) were studied as comparative controls to assess the effect of posterior sagittal approach without urogenital surgery. Natural filling urodynamics via suprapubic catheter were performed in all infants at 0.2 to 9 months (mean 3) before surgical reconstruction. This assessment was repeated 6 to 24 months (mean 14.8) after surgery. A total of 10 patients with cloacal anomalies (5 with short [less than 3 cm] and 5 with long common channel [greater than 3 cm]) and 20 patients with anorectal malformation (ARM) were consecutively studied. At presentation bladder dysfunction was present in 9 of 10 patients with cloacal anomalies and in 12 of 20 patients with ARM. After surgery there was significant deterioration in bladder function in half of the cloacal group (5 of 10 patients, p = 0.04) and in 1 of 20 patients with ARM (p = 0.7). Of the 5 patients with cloacal anomalies who had deterioration of bladder function a urodynamic pattern of DO changed to detrusor underactivity in 4, all of whom had a long common channel at presentation. The authors concluded that patients with cloacal malformation have a high incidence of innate bladder dysfunction. However, surgical reconstruction by total urogenital mobilisation can cause further deterioration of bladder function, particularly in the group with a long common channel and urodynamic assessment is necessary to detect bladder dysfunction in these patients. [397]

The VATER or VACTERL association is a group of diverse abnormalities that include Vertebral bony, Anal atresia, Cardiac, Tracheo-Esophageal fistula, Renal and Limb anomalies. [321] Imperforate anus may occur as an isolated lesion or in conjunction with this association. Spinal cord pathology occurs in 38% of cases producing a picture of upper and/or lower motor neuron deficits to the LUT. [368, 394, 398-400] By combining the incidences in 3 studies it was found that the presence of an abnormal sacrum increases the likelihood of neurogenic LUT dysfunction to as high as 76% (38 of 50 children).[368, 398, 399] When the rectum ends above the levator ani muscle there is a much greater chance of neurogenic bladder dysfunction than when it ends below the pelvic floor [370, 398] and the older the child is at the time of urodynamic assessment the more likely he/she is to have abnormal LUT function. [400, 401]

In 2006, a prospective study was carried out on children with ARM prior to and following definitive procedure, using urodynamic evaluation. Among these 19 children 13 underwent re-evaluation after definitive surgery for ARM. Of the 19 children, 14 (73.7%) were cases of high ARM and 5 (26.3%) were cases of low ARM. Baseline evaluation done in 19 children revealed seven urodynamic patterns: Normal capacity, compliant without DO (21.1%) or with DO (5.3%); Normal capacity, poorly compliant without DO (5.3%) or with DO (10.5%); small capacity, compliant with DO (5.3%) or poorly compliant with DO (26.3%) and large capacity, compliant with DO (26.3%). Thirteen patients were evaluated post operatively also and in only 23% (3 of 13) was no change in urodynamic pattern observed. In the remaining 76.9% (10 of 13) some changes in urodynamic pattern were observed. The deleterious changes observed were appearance of DO in 30.8% (4 of 13), decrease in the bladder capacity in 23% (3 of 13) and decrease in bladder compliance in 15.4% (2 of 13). Only 9 of the 19 patients had normal urodynamics pre-operatively and post-operatively, and 3 more patients worsened. [402]

Mosięjewski et al recommends evaluation of all patients with ARM using MRI. When MRI shows sacral or spinal cord anomalies, urodynamics should be performed. They recommend a noninvasive evaluation for all other children and urodynamics when neurogenic dysfunction is suspected. [370]

The reliability and reproducibility of these findings among the various studies analysed confers an important role on videourodynamic studies as an integral part of the evaluation and management of these children: it has diagnostic accuracy; it provides a reason to explore any intraspinal abnormality to improve the child’s chances of achieving urinary and faecal continence; and it is useful as a basis for future comparison if incontinence should subsequently become a problem in children not undergoing early spinal cord exploration.

Conclusions (evidence level 3)

- Various studies have shown that a proportion of children with imperforate anus have primary or secondary dysfunction of the LUT, lower urinary tract innervation abnormalities or pelvic floor dysfunction.

Recommendation (grade C)

- Clinicians should consider urodynamic testing in children with imperforate anus when clinical signs of LUT dysfunction or relevant neurological abnormalities exist, before and or after reconstructive surgery.

4. ANATOMIC ABNORMALITIES

The use of urodynamics for evaluating anatomic lesions that affect the lower and, consequently, the upper urinary tract in children is still somewhat controversial. Essentially, the evidence consists of uncontrolled case series and expert opinions. Although many clinicians now feel its usefulness is beyond question.

a) Posterior urethral valves

Nowhere is the above controversy more obvious than in boys with posterior urethral valves. [403-405] Prior to the ready availability of urodynamics, persistent
upper urinary tract dilation was managed with bladder neck resection and/or striated urethral sphincter resection. By demonstrating the presence of detrusor underactivity or DO, urodynamic studies have helped explain the radiological findings of hydronephrosis that many of the children exhibited over time despite adequate valve ablation. These studies changed the focus from increased bladder outlet resistance to altered bladder function as the aetiology.

There are only two urodynamic reports prior to valve ablation. In one, DO was seen in 60%, poor compliance in 10% and normal function in 30%. In the other, all 46 patients had ‘bladder hypercontractility’ and comparable high maximum voiding detrusor pressures. At the end of followup (mean 4.5 years) in this second study, no patient in group 1 (22 patients who underwent simultaneous valve ablation and bladder neck incision at the 6 o’clock position) had ‘bladder hypercontractility’ or DO, and the mean maximum voiding detrusor pressure was 53 ± 15 cm H2O. In comparison, 9 patients in group 2 (24 patients who underwent simple valve ablation) had ‘bladder hypercontractility’, 6 had DO and the mean maximum voiding detrusor pressure was 87 ± 45 cm H2O (p < 0.01).

In a series of urodynamic studies after valve ablation, the type of bladder function found correlates with the time elapsed from surgery; DO is the predominant pattern initially but improvement is noted in both DO and compliance over time. In 2005, a series of 30 patients showed DO with single or multiple involuntary detrusor contractions in 60%, and small capacity, reduced bladder compliance in 40%.

Myogenic failure in conjunction with increasing capacity and poor emptying are primarily a later phenomenon, most likely secondary to increased urine production and decreased frequency of voiding with advancing age. Despite early valve ablation, a large proportion of boys treated for PUV have gradual detrusor decompensation and/or secondary bladder neck obstruction leading to obstructive voiding and ultimately detrusor underactivity or acontractility. VUR was, in a small and selected series, most commonly noted in boys with DO whereas hydronephrosis is most frequently seen with a poorly compliant bladder. The persistence of upper urinary tract changes is related to the bladder’s unresponsiveness to medical therapy for the DO and/or underactivity. Several studies have shown the predictability of the development of renal failure based on specific detrusor patterns seen on urodynamic evaluation; persistent poor compliance, high detrusor pressures and failure to adequately contract during voiding with increased PVR are the most likely causes of this progressive deterioration.

b) Bladder extrophy

Once the extrophied bladder is closed it may be difficult to determine how best to manage persistent incontinence, upper urinary tract dilation or VUR, whether to further improve bladder outlet continence function or whether to perform augmentation cystoplasty for a small capacity, poorly compliant bladder. In addition, as more children undergo complete primary repair of the extrophic bladder in the neonatal period the most concrete assessment of bladder function is via urodynamics. Only a few studies characterise the change in function following bladder neck reconstruction in patients with persistent incontinence; 20% show DO preoperatively versus 37% postoperatively, and compliance worsens in up to 50% after surgery. No studies are extant that have correlated incontinence with bladder capacity, compliance, DO and/or LPP.

c) Ectopic ureterocele

Urodynamic studies in babies with an ectopic ureterocele have shown that LUT function may be altered in as many as half the affected patients; 2 reports revealed that between 55 and 70% had a larger than normal capacity bladder for age with high compliance, and poor bladder emptying due to detrusor underactivity. In another multicentre analysis of 616 children with a variety of ureterocele types, investigators found only a 6% incidence of bladder dysfunction (all in children with an ectopic ureterocele) consisting of primarily DO; less than 1% had poor bladder emptying whereas the remainder had normal bladder storage function and complete emptying. In a recent study in 2007, voiding dysfunction was suspected in 23% of patients. Urinary incontinence and/or infection following surgical incision or excision of a ureterocele is likely to be secondary to the obstructive effects of the ureterocele directly on the bladder outlet and not to any surgical complication. Patients undergoing bilateral ectopic ureterocele repair are at increased risk for postoperative voiding dysfunction. Whether this risk is present preoperatively or is a result of trigonal surgery is unclear.

d) Vesicoureteral reflux

Recent evidence has confirmed that VUR may be a secondary phenomenon resulting from DO and not a primary anatomic abnormality at the ureterovesical junction in a significant proportion of children. There is growing evidence that DO may lead to VUR in a marginally competent ureterovesical junction mechanism.

This DO may be a natural phenomenon in the infant bladder, especially males (due to the presence of high voiding pressures and/or a learned dysfunction in older children who try to withhold voiding throughout the day). Several investigators have
shown that DO tends to resolve with increasing age. [434, 438, 441]

The bladder pressure at the onset of VUR, as determined by nuclear cystometrography, is a significant independent predictor of VUR resolution in children. The pressure at the onset of VUR was also highly predictive of spontaneous resolution (p = 0.0005). VUR occurring at greater pressures was more likely to resolve spontaneously, independent of the VUR grade or bladder volume at the onset of VUR. [442] VUR occurring at greater than 75% of predicted bladder capacity had a significantly higher resolution rate (p = 0.0005). In addition to grade, bladder volume relative to predicted bladder capacity at the onset of VUR appears to provide additional prognostic information regarding the likelihood of spontaneous resolution of primary VUR. [443]

Despite this finding, there is ample evidence in 4 studies to show that treating the DO and/or voiding dysfunction with anticholinergic agents leads to a faster rate of resolution of VUR (63 - 92% within 1 year) [444-446] than it might when the child is treated with antibiotics alone to prevent recurrent infection (25 - 54%). [447]

In this setting, history-taking about voiding habits [448] and urodynamics with cystometry and uroflowmetry to confirm the abnormal bladder and possibly sphincter function, become paramount to just treating the child with antibiotics and getting yearly voiding or nuclear cystograms. Urodynamic studies have confirmed the presence of DO and/or high voiding pressures in at least half the babies studied with high grades of VUR, whereas only 38% had totally normal function [436, 440, 449-452] Upper urinary tract damage is more likely to occur in children with abnormal bladder function as reported in 4 retrospective reviews.[441, 445, 451, 453].

In 2006, videourodynamic studies were performed in 40 patients. Dysfunctional voiding was present in 76% of the children with DO, in 73% of the children with VUR, in 63% of the children with urinary incontinence, in 77% of the children with episodic urinary tract infection, and in all of the children with diurnal enuresis. Compared to children without dysfunctional voiding, the voiding pressure was significantly higher in children with dysfunctional voiding (with VUR, 61 ± 30 vs. 25 ± 16 cm H₂O, p = 0.004; without VUR, 53 ± 24 vs. 25 ± 16 cm H₂O, p = 0.010). [454] In the 5 patients who had post-treatment urodynamic studies, biofeedback pelvic floor muscle training and treatment with an antimuscarinic agent effectively decreased detrusor pressure, increased bladder capacity and maximum flow rate, and reduced the grade of VUR.

Many clinicians treating patients with VUR advocate urodynamics to assess the LUT in children with high grade VUR, especially those who have incontinence, renal damage, or who are about to undergo surgery for VUR.[445, 455-457]

e) Urethral stricture

Urethral stricture disease in boys is rare, usually arising from a previously unsuspected straddle injury. Uroflowmetry can accurately predict the presence of a urethral stricture in 88% of affected males.[458-461] In a prospective study the voided volumes at first sensation of bladder fullness were significantly greater in hypospadias patients with urethral stenosis. They had bladder outflow obstruction and had decreased sensation of bladder fullness. The significantly decreased quotient of Qmax at greater and at smaller voided volumes could demonstrate a mild outflow obstruction. [462]

Because recurrence of a stricture is often both frequent and insidious, periodic urinary flow rates, analysing the maximum flow rate in relation to volume voided, may alert the clinician to early signs of renarrowing but efficacy of periodic flow rates has not been corroborated. [463] Uroflowmetry should be integral in the management of urethral stricture and complete urodynamic investigation is repeatedly required. [464]

Conclusions (evidence level 3)

- Many studies (case series) have demonstrated frequent urodynamic abnormalities - predominantly DO and reduced bladder compliance or large capacity bladder with impaired filling sensation - in children with posterior urethral valves, urethral stricture, ectopic ureterocele, VUR or bladder extrophy.

Recommendation (grade C)

- Clinicians should consider complete urodynamic testing, at least once, in children with posterior urethral valves, urethral stricture, ectopic ureterocele, VUR or bladder extrophy.

- Clinicians should consider regular uroflowmetry and postvoid residual urine in the management and follow-up of children with posterior urethral valves, urethral stricture, ectopic ureterocele, VUR or bladder extrophy.

5. FUNCTIONAL DISORDERS OF THE LUT

When assessing functional disorders involving the LUT in children, one must take into account the dynamics of the maturing nervous system, learned habits of elimination for bladder and bowel function and social influences that might modulate the child’s behaviour in a negative or in a positive manner.[465, 466]

a) Diurnal incontinence

Urodynamics has a limited place in diurnal (day and
night) incontinence. This condition is not considered worrisome before age 5 or 6. When older, most children without an (until then unsuspected) anatomic or neurological lesion should be dry.[467] Urinary incontinence in children can have many causes and history and clinical investigation are very important in this regard. Urinary incontinence can also coincide with dysfunctional voiding and or bowel elimination problems. [468, 469] Treating these elimination dysfunctions with behavioural modification, biofeedback training, drug therapy or intermittent catheterisation (CIC) [470] and/or antibiotics to prevent further urinary infection is necessary before considering urodynamics. [471] Uroflowmetry with a PVR urine determination and cystometry are however indicated; especially if the incontinence persists despite medical therapy. In one study of girls with recurrent infection without VUR two distinct patterns of dysfunction emerged in 80% of those studied, either DO with a normal urinary flow pattern and complete emptying, or a normal detrusor with an intermittent flow pattern and incomplete emptying. [472]

In boys with persistent day and night-time incontinence, voiding cystourethrography is warranted to determine the presence of different forms of bladder outlet obstruction that may be contributing to or coincide with the DO.[473]

Faecal incontinence in the absence of any anatomical or neurological deficit often affects LUT function and contributes to urinary incontinence in a number of ways. Constipation and faecal impaction have been shown to cause DO and a reduced functional bladder capacity.[474] Understanding and eliminating this possible aetiology can normalise LUT function. There is no need for urodynamic testing, before starting treatment for faecal impaction, in these cases. [468]

Persistent daytime and night-time incontinence in the absence of urinary infection and a normal bladder and bowel emptying regimen warrants cystometry, pressure-flow studies and a urinary flow rate. A meta-analysis, over 20 years, of 460 children with daytime incontinence evaluated with urodynamic studies reveals DO in 57% (261 of 460), dysfunctional voiding (failure to relax the sphincter mechanism) in 22% (34 of 152) and normal findings in only 14% (64 of 460). [436, 475-479] In recent studies, dysfunctional voiding was present in 76% of 40 children with DO. [454, 480] These findings are not gender-specific but are age-dependent, with most children outgrowing the abnormal findings by puberty. [476] Presumably normal children without day or night-time wetting do not have a pronounced degree of DO or dyssynergia but the evidence for this is lacking due to the paucity of studies in normal children.

Urodynamic testing has clearly improved our understanding of the aetiology of diurnal incontinence but no study has shown that urodynamic characterisation of any abnormality has improved the efficiency of treatment for these children.

b) Enuresis (nocturnal)

Night-time wetting (enuresis) is a condition that is common in children aged 5 years but which improves with time, so that less than 15% of pubertal boys and 5% of pubertal girls continue to be affected.[465-467, 481] Multiple causes for the persistent wetting, ranging from genetic factors, to maturational delays, to sleep disturbances, to social causes, to attention deficit disorders, to bladder and urethral dysfunction, to excess fluid intake, to abnormal vasopressin secretion and/or to constipation, have been implicated. [468, 482-489] Although in various cultures there may be social and familial pressures to resolve the condition before puberty, in western societies it is generally not necessary to conduct urodynamics until adolescence, to determine why the wetting has not abated. Urodynamic testing in 615 enuretic children with and without daytime symptoms has identified DO in 61%.[370, 490-494] In a prospective study, bladder volume and wall thickness index was calculated based on ultrasound studies and classified as thick (less than 70), normal (70 to 130) or thin (more than 130). 96% of the patients with an index of less than 70 exhibited DO on cystometry. [495, 496] In another prospective study 116 children with primary enuresis were evaluated and urodynamic abnormalities were seen in 80/116 (69%) patients namely DO 50/116 (43%), small bladder capacity 20/116 (17%), large bladder capacity 4/116 (3%), decreased bladder compliance 3/116 (3%) and detrusor sphincter dyssynergia 3/116 (3%). The combination of abnormal micturition history stating daytime urinary urgency or frequency or dysfunctional voiding symptoms like squatting and/or abnormal voiding charts could predict abnormal results of urodynamics correctly with sensitivity of 81% and specificity of 86%.[497]

When the children are divided into those with day and night-time incontinence (non monosymptomatic) versus those with just nocturnal wetting (monosymptomatic), the incidence of DO decreases from 64% to 35% in the latter group.[492, 493] In another prospective study comparing enuretics to age-matched non-enuretic controls, bladder capacity at night (enuretic capacity) was significantly less in those who wet versus those who did not.[498] Although the authors did not speculate on aetiology they felt that enuretics were less able to hold their urination than non-enuretics. Management should be directed at improving the child’s ability to withhold urination. Treating the non monosymptomatic child using antimuscarinic agents can be very effective (as high as 77% cure) with low recidivism rates when based on the findings of urodynamic testing.[484, 488, 499-503]
Conclusions (evidence level 2/3)

- Various studies show that treatment for children with functional incontinence (and of the, frequently associated, bowel elimination problems) can be initiated on the basis of history, clinical exam and uroflowmetry and postvoid urine assessment.
- Various studies, reviews and guidelines agree on the relevance of urodynamic testing in children with incontinence and nocturnal enuresis resistant to initial (conservative) treatment.

Recommendations (grade B/C)

- The committee recommends uroflowmetry and postvoid residual urine assessment (until -for the individual child- representative values are obtained) as screening and evaluation in all children with incontinence and nocturnal enuresis.
- The committee recommends complete urodynamic testing in children with incontinence and nocturnal enuresis resistant to conservative treatment, if invasive treatments are contemplated.

6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS

Often, differences in urodynamic parameters exist from one study to another or one year to the next. Chou et al provided reference ranges for “normal” variability in urodynamic parameters that can be considered as “no real change” from one study to the next. It was a retrospective chart review. Fifty consecutive individuals with spinal cord injury had 2 trials of urodynamic studies done 5 minutes apart. They established percentile ranges. Knowing these ranges of variability can be helpful in determining whether differences between filling trial 1 and filling trial 2 in a single study or year-to-year changes in urodynamic studies are significant or simply the normal variability of the urodynamic study. [49]

A reduced rate of filling, e.g. 10% of the expected bladder volume per minute, has been recommended in children to accurately determine detrusor compliance and functional bladder volume. [504] Some investigators advocate that infants should be assessed with much lower rates of filling or with natural filling cystometry. [505, 506] Several studies do show lower detrusor pressures under natural filling versus even slow filling rates during cystometry. [331, 332, 507] Even though the practicality of time management plays a role in a busy urodynamic laboratory, it is essential to perform urodynamic testing in a way that reveals what one considers clinically important. One study in particular [331, 332, 507] demonstrated that the intravesical pressure was lower when it was measured initially by catheterisation (before emptying the bladder) and then compared to the pressure at the same volume during the subsequent cystometrogram. Except for determining bladder volumes at specific pressures,[332] no study has shown that these differences are crucial in the management of children with LUT dysfunction. One study looked at the effect of the temperature of the instillate (25° versus 37.5° C) on measured detrusor pressures and found no significant differences in compliance. [46] van Meel et al have shown that repeating the Ice Water Test (IWT) will increase its positivity. [327]

The smallest dual-channel urethral catheter available should be used in children for the same reasons as specified for adults, although the measuring lumen must be large enough to measure pressures in a technically adequate manner. Although urethral catheters of moderate size do not always obstruct the urethra,[508, 509] or produce higher than the normal voiding pressures as measured with suprapubic tubes, it is prudent to employ the smallest calibre catheters that are practical when doing a cystometrogram that measures filling as well as voiding pressures. For very young infants it may be better to insert a suprapubic catheter placed under anaesthesia the day before the test to make the subsequent investigations more accurate [510, 511] but this has not been assessed with any precision.

Most children can undergo urodynamic studies without pre-medication; only the most agitated may require some degree of sedation. Even then, children should not be so heavily sedated that they cannot void around the catheter. However, there are no studies that show a difference in bladder filling pressure (whether related to compliance or to DO) in awake versus anaesthetised children.

In the previous consultation the recommendation was made that children should receive comprehensive urodynamic testing in a laboratory that is specialised in pediatric urodynamic testing with appropriately trained personnel.

Conclusions (evidence level 3/4)

- The committee concludes (on the basis of various studies to determine normal and test retest values for urodynamic testing in children) that within the limits also provided for adults, urodynamic testing in children is reliable and reproducible.
- Although it is plausible and considered useful to reduce filling speed and catheter size in relation to patient size, the exact values cannot be given and the influence of the transurethral catheter size on voiding is unknown.
Suggestions for research:

- The committee suggests that additional work is undertaken to establish normative values and reproducibility of urodynamic data, especially on voiding and voiding abnormalities, both in normal children and in well-defined groups of pediatric patients.
- The committee suggests that further integrated approaches to the diagnosis (and management) of children with anorectal (elimination) dysfunction in combination with lower urinary tract dysfunction are undertaken.

V. PATIENT EVALUATION: FRAIL ELDERLY

1. INTRODUCTION

Frail older patients are poorly represented in all studies, but especially those involving invasive interventions or medications, as they suffer from multiple impairments (eg poor mobility, cognitive impairment, renal failure) or conditions (heart failure, multiple medications) which tend to exclude them from research.

Elderly patients should not be considered differently from younger subjects simply because of their chronological age. LUT symptoms, especially storage symptoms, showed age-related alterations in the two sexes in the absence of any overt underlying disease, and bladder function in both sexes may be subject to a gender-independent aging process.[512] Urodynamic findings in the elderly tend to demonstrate DO, [513, 514] even in asymptomatic individuals. There may also be a reduction in bladder capacity, urinary flow rate and detrusor contractility.[515] Because of these changes the utility of urodynamics has to be judged against a different background in the elderly.

Older people age at different rates, with some developing a clinically recognised pattern of frailty [516, 517] characterised by impairments in a number of functions including physical activity, mobility, balance, cognition, nutrition and endurance. Such individuals tend to suffer multiple chronic medical conditions, take multiple medications, and are at risk of admission to hospital or a care home. [518, 519] They are also at greater risk of developing incontinence. As a group they are poorly represented in research studies. [519] These features need to be born in mind when considering the contributors to and investigation of incontinence. Limitations to care may also be appropriate in a frail older person who is nearing the end of their life [520] but appropriate intervention should not be denied on the basis of age. This is covered more fully in chapter on the Frail Elderly produced by committee 11.

Firstly, the invasive nature of conventional urodynamics becomes a more important factor in the old-old or frail elderly, who may be more vulnerable to any insult than younger people. For example, one study [521] showed that there was a significant association between age and the presence of asymptomatic bacteriuria before cystometry and between this bacteriuria and urgency (without DO) on cystometry. These results do not however support a policy of universal screening for bacteriuria before urodynamic investigation. Asymptomatic bacteriuria did not influence the urodynamic outcome except in patients with urgency (without DO); and the authors recommended that screening and treatment be considered individually in older women who are being investigated for storage symptoms. About 20% of this group of patients developed UTI (mostly asymptomatic) after the urodynamic investigation. The concept of ‘symptomatic’ is difficult in the frail elderly – for instance the development of delirium is a symptom of many conditions including UTI – but is not generally included in the outcome measures. This information should be included in the counselling before urodynamic investigation and should be incorporated into the patient information leaflet as part of good clinical practice. Unfortunately, there are few adequately powered studies (and none that we are aware of in this patient group) of the efficacy of antibacterial prophylaxis.

Secondly, given the multifactorial nature of incontinence in the elderly, [161] and the fact that there may be easily reversible causes or contributory factors, screening for these then conservative therapies are indicated initially.[522] Urodynamic examination is reserved for patients in whom conservative management has failed or has proved inadequate, who desire further attempts to correct or manage the incontinence, and who therefore need a detailed and objective diagnosis.

The place of urodynamics in the frail elderly with incontinence is therefore quite limited even in principle and, given that the number of studies seeking to establish its clinical utility is even smaller than in
younger adults, there is very little objective evidence for or against clinical urodynamics in this population group.

On the other hand, because of the changes in function that occur with age not only in the LUT, but in the neural system that controls it (or fails to control it), and also in other organ systems that may have an impact on urological problems, research urodynamics is essential to establish what these changes are, how they are related to other aging-associated changes, and how they may be reversed, so that there is a chance of developing new, more suitable therapies. Therefore, in academic centres at least, many geriatric patients should be examined so as to generate a steady stream of high-quality clinical urodynamic research, addressing mechanisms of disease and deterioration in all the main geriatric patient groups (including ‘normal aging’), and in the less common patient groups as well.

2. WHAT IS USUALLY EVALUATED

Among the frail elderly, incontinence is the paramount troublesome symptom in both men and women, with a steeply rising incidence after age 80.[523] The type of incontinence appears to be predominantly urge.[123, 514] SUI is relatively uncommon in men of any age (except post radical prostatectomy) and it seems to become gradually less common in women after the age of about 50, [523] for reasons that are incompletely understood.

a) Urgency incontinence

Urgency incontinence is usually the result of DO. (It is believed that occasionally it may be due to involuntary relaxation of the urethral sphincter mechanism, without a measurable detrusor contraction.[5]) Thus one possible reason to perform urodynamics might be to identify DO. The relevant test would be filling cystometry. There are reasons to question whether this is the best approach:

1. In straightforward urgency incontinence in the elderly, DO is highly probable, and it is not necessary to perform urodynamics to prove this before trying pharmacological or behavioral therapy. This is one of the reasons for the limited clinical role of urodynamics referred to above.

2. Because DO is only one contributor to urgency incontinence,[161, 524] not all individuals with DO are incontinent. In fact, DO is believed to be quite common in healthy older people who are apparently free of bladder symptoms of any kind. Thus it is important to look not just for DO, but for actual leakage caused by detrusor contraction - DOI.

3. Because only the more difficult or intractable cases are investigated with urodynamics, it is important to look for other coexisting LUT dysfunction, beyond simple DO.

4. As a group the elderly find hospital intervention more difficult to tolerate, and therefore urodynamics and even measurements of flow rates or PVRs on a single occasion are less reproducible.

Among the elderly, the most common type of DO is the ‘terminal’ pattern in which a single involuntary detrusor contraction occurs at the end of filling and leads directly to leakage (incontinence).[525][72] Quite frequently there is reduced bladder sensation also, so that the subject does not feel any sensation of bladder filling or the need to void until the contraction is about to take place.[526] and thus has very little warning of impending leakage. These characteristics are believed to have a neurological (cerebral) origin.[525, 526]

In elderly people, UUI frequently coexists with incomplete bladder emptying. Among men who have not had prostate surgery, urethral obstruction is a possible contributor to incomplete emptying. If there is no obstruction, and particularly in women in whom obstruction is rare, incomplete emptying is a sign of impaired bladder contractility.

The urodynamic abnormality underlying UUI with incomplete emptying (assuming no obstruction) has been named ‘DHIC’ (detrusor hyperactivity with impaired contractile function).[527] Its significance is that the standard pharmacological treatment of UUI – with antimuscarinics – may worsen bladder emptying and possibly cause urinary tract infection or even make the incontinence worse.

Thus the principal urodynamic tests that are done are:

1. Free uroflowmetry:
   a. may be useful as a screening test for obstruction or diminished detrusor contractility
      • A slow, prolonged or intermittent flow curve may indicate either urethral obstruction or diminished detrusor contractility; pressure-flow studies are required to distinguish between them

2. Measurement of PVR urine:
   a. to check whether anticholinergic (antimuscarinic) therapy is contraindicated because of a large residual
   b. to help identify DHIC

Observation of consistently elevated PVR thus has therapeutic consequences and so, among urodynamic investigations, measurement of PVR urine is important. Clinical experience suggests that faecal loading of the bowel is a common cause of poor bladder emptying in this group, but there are no studies to confirm this. Even if screening to rule out constipation has been carried out initially, this should be reconsidered in the presence of a large residual volume.
If a large amount of residual urine is found in the absence of faecal loading then incontinence associated with chronic overdistension or infection may be suspected, and intermittent catheterisation may be indicated. The measurement is included in the Resident Assessment Protocol (mandated for nursing homes by the US Congress) along with the stress test.[528] Even if screening to rule out constipation has been carried out initially, this should be reconsidered in the presence of a large residual volume.

If the PVR is small, significant infravesical obstruction or detrusor underactivity or acontractility is less likely, and a small dose of anticholinergic medication may be tried.

3. Filling cystometry:
   a. to demonstrate or rule out DO or – more importantly – DOI
   b. to identify the pattern of DO – terminal or phasic
   c. to identify reduced or normal bladder sensation

Cystometry is sometimes said to be an essential part of the diagnostic evaluation, both in defining underlying pathophysiology and directing treatment.[155] However, none of these aims (a.-c. above) have particular therapeutic importance except in difficult cases where initial therapy has failed and it is uncertain what the underlying problem is.

A small number of frailer older women are considered for operative intervention of SUI but as their risks are higher so should they have cystometry first, especially as pure SUI is so unusual in the frail elderly?

4. Pressure-flow studies of voiding:
   a. to identify or rule out prostatic obstruction (in men)
   b. to identify or rule out impaired contractility (reduced detrusor contraction strength)

5. Simple cystometry:

It is sometimes recommended that urodynamics in the elderly should be done by “simple cystometry” if cystometry is indicated and no equipment or referral is available.[529] The procedure needs only an open syringe attached to a single-lumen catheter, sterile water or saline and a tape measure. Fluid is infused by gravity at a pressure head of 15-20 cm H2O. Bladder capacity, sensation of filling and presence of a detrusor contraction or overactivity can be semiquantified. Pressure is measured by observing the height of the column of water. These simple measures can be carried out at the bedside and may be useful for disabled patients.[530-535] Simple cystometry, as compared with multichannel cystometry has a specificity of 75-79% and a sensitivity of 75-88% for the observation of DO.[530, 531] The accuracy can be improved by combining it with even simpler tests [531, 532] such as a stress test to exclude SUI.[536]

However the clinical significance of these findings is limited. DO is found in up to 50% of symptom-free elderly (and so it is not pathognomonic), while DOI is the most likely finding in incontinent frail elderly in any case.[123, 514, 527] Thus the test is performed only to rule out DO in a small subset of patients.

Furthermore, most of the studies recommending simple cystometry were conducted before the widespread availability of simple bedside bladder scans and before the high prevalence of detrusor hyperactivity with impaired contractility (DHIC) was recognised.[514] This dysfunction is the most common abnormality observed in the frail elderly population with incontinence.[514, 527] A total of 185 patients who had persistent LUTS after TURP were enrolled in one study, and the results revealed that a normal videourodynamic tracing was found in 9%, pure DO in 10%, low detrusor contractility in 19%, DHIC in 14%, poor relaxation of the urethral sphincter in 19%, and bladder outlet obstruction in 28%.[267] DHIC is easily misdiagnosed as a stable detrusor on simple cystometry,[536] because single-channel cystometry is less sensitive for detecting low-pressure detrusor contractions than multichannel recording. If a detrusor contraction coincides with a cough, the leakage may be regarded as the sign of a positive stress test.

By design, simple cystometry can at best recognise only DO, or DOI if actual leakage is recorded. There is no possibility of studying voiding dynamics. Furthermore, the checks on measurement quality that are part of conventional urodynamics are not available. Hence, because recognition of DO by itself has little therapeutic importance, and urodynamics in the elderly is reserved for difficult or intractable cases, it is more reasonable in such cases to conduct a full urodynamic examination of both filling and voiding phases, in which quality control can be maintained to eliminate artifacts, and the more relevant aspects of LUT behavior can be assessed, such as obstruction and reduced detrusor contractility.

b) Stress urinary incontinence

Among older men, SUI is almost entirely confined to post radical prostatectomy patients (see section D.II, Patient evaluation: Men). Among elderly women, pure SUI seems to be rare. Urodynamic testing usually follows the methods used in younger women. Frequently, it is difficult to perform an adequate examination because the patient is not able to produce a strong enough cough or Valsalva manoeuvre to cause leakage during testing, and cannot easily be examined in the upright position, which is the most likely posture to produce incontinence. On the other hand, it may be just such factors that make SUI uncommon in this population in the first place.

A weak urethral sphincter (intrinsic sphincter deficiency,
ISD) is a contributory factor to SUI. There is some evidence that a weak sphincter or inadequate sphincter control may contribute to the severity of UUI as well.\[155, 161\] Methods of assessing the sphincter include measurement of VLPP (difficult for the reasons stated above) and urethral pressure measurements. Unfortunately, urethral pressures diminish with age, whether or not there is SUI, and are not diagnostic.

3. EVIDENCE FOR REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC TESTS IN THE GERIATRIC OR FRAIL ELDERLY POPULATION

There is little published evidence about reproducibility and reliability in this patient population. Two groups have recently examined specific aspects of geriatric urodynamics which have some bearing on this topic. There is a little earlier evidence on the reproducibility of some parameters.

a) Filling cystometry

One group \[537\] sought urodynamic changes associated with behavioral and drug treatment of UUI in 105 ambulatory, nondemented, community-dwelling women, of mean age 67 years (range 55-91). Although oxybutynin and behavioral treatment were both effective, and although oxybutynin increased cystometric bladder volume at strong desire to void and bladder capacity, the authors were unable to demonstrate that the improvement in incontinence was related to the urodynamic changes observed – that is, that the changes mediated the improvement. One possible explanation for this negative result is that the urodynamic parameters measured show considerable variability, as in other patient groups (see sections C.I and C.II).

b) Post-void residual urine

Residual urine is believed to depend on the presence of bladder outlet obstruction (in men) as well as on detrusor underactivity (i.e. impaired contractility).\[538\] Thus, in a man, the presence of substantial residual urine (> 100 ml) in the absence of severe bladder outlet obstruction suggests that the increased residual urine is mainly due to a reduction in detrusor contractility, with bladder outlet obstruction making only a minor contribution. There may be an age-dependent decrease in contractility in both sexes.

Residual urine varies in a given individual for no known cause: recorded values wax and wane over time \[192\]. Significant daily variations have been observed in elderly patients of both sexes, with larger residuals (up to 40% greater) being measured in the early morning. Similar changes have been described in patients with bladder outlet obstruction or detrusor underactivity \[67, 539\]. No clear predictor of deterioration of residual urine volume or of complete urinary retention has been identified. Although the presence of faecal loading may be a significant factor, there is an absence of supporting evidence from formal studies.

c) Pressure-flow studies

Another group \[221\] compared consistency, reproducibility, and responsiveness of various methods of estimating detrusor contraction strength from pressure-flow studies. They retrospectively analysed urodynamic data on 84 females 53 years old or older, with UUI, who received either a titrated dose of antimuscarinic medication or placebo in a controlled trial. Data were gathered before and at the end of treatment. Three different variations of the stop test were compared. In a stop test, flow is prevented and the isovolumetric detrusor pressure attained is taken to be a measure of detrusor contraction strength. Flow may be stopped by a voluntary contraction of the urethral sphincter midway through voiding (voluntary stop test: often impossible in stress incontinent women); by blockage of the outlet by a balloon midway through voiding (mechanical stop test); or by attempted voiding against an outlet that is already blocked by a balloon (continuous occlusion).

The voluntary stop test yielded isovolumetric detrusor pressure values inconsistent with the other 2 tests (a mean and SD of 31 ± 16 cm H2O as opposed to 47 ± 26 and 49 ± 24 cm H2O). The mechanical and continuous occlusion tests gave very similar results that were highly correlated with one another (r = 0.87). Measurements pre- and post-treatment in the 20 women who received a placebo showed that the continuous occlusion test had the highest reproducibility (r = 0.9, p <0.01), followed by the mechanical (r = 0.7, p = 0.01) and voluntary (r = 0.7, p <0.01) stop tests. Treatment with oxybutynin decreased isovolumetric detrusor pressure by up to 6 cm H2O, but the decrease was statistically significant only for the continuous occlusion test.

The authors concluded that to assess detrusor contraction strength in elderly females with UUI either a mechanical stop test or a continuous occlusion test is acceptable but the continuous occlusion test has better reliability and more sensitively detects slight drug-induced changes. Again this study is on relatively young women, this time just ‘53 years and older’, once again demonstrating the lack of data in the elderly, let alone the frail elderly!

This work demonstrates that some urodynamic measurements in a geriatric population are quite reproducible, reliable, and responsive to the effects of treatment. This means that they may be useful for research, but are not necessarily clinically relevant. For example, there is no evidence that a weak detrusor contraction strength predicts poorer response to treatment with anticholinergic medication or surgery.
4. EVIDENCE THAT PERFORMING URODYNAMIC TESTING IMPROVES CLINICAL OUTCOMES IN THE GERIATRIC POPULATION

Few relevant studies have been published in this population. One publication [540] assessed the results of tension-free vaginal tape (TVT) for the treatment of SUI in 76 consecutive women more than 70 years old (median age 76 years). 31% (24/76) of the patients had OAB symptoms and 4 (3%) had proven DO controlled by anticholinergic therapy. All patients had preoperative multichannel urodynamic evaluation. At a mean follow up of 25 months, 67% of the patients were cured. Preoperative urgency symptoms were cured in 46% of the group. Among the failures, 14 (18%) had UUI, while “de novo” urgency without incontinence was noted in 21%.

Thus, this paper provides no clear evidence that preoperative urodynamics was able to predict the outcome of a popular SUI procedure in older women. It does show that post-operative difficulties may be due to urgency and UUI, which however could not be predicted from the tests performed preoperatively.

To summarise, there is no clear evidence that urodynamic testing improves clinical outcomes in the geriatric population.

5. THE PRACTICAL INDICATIONS FOR URODYNAMIC STUDIES AND WHICH TESTS ARE NEEDED

a) Post-void residual urine

Based on the above, there is general agreement that PVR urine measurement is indicated before treatment of incontinence either with anticholinergic medication or by SUI surgery. A consistently large residual urine certainly is a reason for caution and careful monitoring of bladder emptying, and may be a relative contraindication to such treatment.

b) Uroflowmetry

Uroflowmetry is a simple and noninvasive test. A normal uroflow without much residual urine probably rules out significant urethral obstruction or impaired contractility, but this finding is unusual in the elderly. Conversely, a poor uroflow is common in the elderly irrespective of sex, and although it cannot distinguish between obstruction and poor contractility, in either case there is a relative contraindication to anticholinergic therapy. Consequently, uroflowmetry (with residual urine measurement) may be a useful screening tool prior to instituting therapy.

c) Pressure-flow studies

A frequently asked referral question, in an older man who is incontinent, has an enlarged prostate, and is cognitively impaired or has a disease such as Parkinson’s disease or multiple system atrophy, is whether the incontinence is due to prostatic obstruction or to cerebral changes. If the former condition is present, then prostate surgery might be considered. As outlined above, prostatic obstruction is not usually the “cause” of UUI, which is typically multifactorial. However, there is weak evidence to suggest that, if the obstruction is urodynamically severe, then surgery may improve the incontinence. [541] If obstruction is equivocal or absent, then there is little point in performing surgery in an attempt to eliminate it. After screening with uroflowmetry and residual urine measurement, pressure-flow studies may be indicated in older men in whom obstruction cannot be ruled out and surgery is at least contemplated. See also discussion of Parkinson’s disease below.

6. THE URODYNAMIC PARAMETERS IMPORTANT IN VARIOUS GERIATRIC CONDITIONS

Recent papers have examined the urodynamics of Parkinson’s disease and related diseases. It is important to know the characteristic urodynamic features of these diseases, because a frequently asked clinical question is whether lower urinary tract dysfunction observed in an elderly male patient is due to such a disease or to BPE/BPO. Similar questions may sometimes arise in women.

a) Parkinson’s Disease

One group [158] found that men with presumed obstruction-related lower urinary-tract symptoms were less likely to have UUI (DOI) on urodynamics than men or women with Parkinson’s disease. DO due to Parkinson’s disease occurred at smaller bladder volumes than that in obstruction-related DO, although this finding was more pronounced in women than in men. The duration and severity of Parkinson’s disease were not related to the nature or severity of urodynamic abnormalities.

Another group [305] found that the majority of patients with Parkinson’s disease (72%) or multiple system atrophy (100%) had symptoms of urinary tract dysfunction. Neurogenic DO was more common in Parkinson’s disease (81% vs 56% in multiple system atrophy). Detrusor-external sphincter dyssynergia was seen only in multiple system atrophy (in 47%). Urethral obstruction (AG number or BOOI > 40) was more common in Parkinson’s disease than in multiple system atrophy. A weak detrusor (impaired contractility) was less common in Parkinson’s disease (66% of women and 40% of men) than in multiple system atrophy (71% of women and 63% of men). PVR urine volume > 100 ml was not observed in patients with Parkinson’s disease but was present in 47% of patients with multiple system atrophy.

Thus urinary tract dysfunction was prominent in both diseases but patients with Parkinson’s disease had
less severe dysfunction: primarily DO starting at small volumes and urethral obstruction. (Unfortunately these findings may make it difficult to distinguish from dysfunction associated with BPO). However, a PVR urine volume > 100 mL detrusor-striated sphincter dyssynergia, or an open bladder neck at the start of bladder filling are suggestive of multiple system atrophy. It has to be pointed out that multi system atrophy is diagnosed using other clinical criteria, and that residuals over 100 mL in frail older people are common.

**Recommendations (grade C)**

- As urinary incontinence in frail elderly people may be the result of a number of contributory factors, many of which are reversible by simple measures, such patients should be first evaluated by a clinician skilled in the care of older people before any invasive investigations or more potentially harmful medications are given.
- Post-void residual urine measurement by a noninvasive method is recommended before institution of pharmacological or surgical treatment of incontinence. It should be repeated to monitor the effect of such treatment.
- Uroflowmetry may be used to screen for voiding abnormalities prior to such treatment.
- Filling cystometry alone has limited value in this patient population. “Simple cystometry” is not recommended unless a urethral or suprapubic catheter is already present for management but still must be interpreted with care.
- Comprehensive urodynamics including, at a minimum, filling cystometry and pressure-flow study of voiding, is recommended in difficult and intractable cases that have not responded to behavioural or pharmacological therapy, and in whom further therapy is desired; and in complicated cases or cases with complicated comorbidity, where treatment is desired but the nature and aetiology of the urinary tract problems are unclear.
- If stress urinary incontinence is suspected, extra tests of urethral function and/or pelvic floor mobility may be useful, although stress urinary incontinence is not only less common than in younger patients but may be difficult to prove or rule out in this population.
- The committee recommends that comprehensive urodynamic testing be performed in specialised centres with a special interest in incontinence, by trained and certified staff who routinely perform urodynamic testing of any patients referred with suspected lower urinary tract dysfunction.
- To maintain adequate urodynamic expertise in this difficult-to-examine patient population, and to provide a background of ‘regular’ patients against whom specific patients can be judged, it is essential that such centres examine substantial numbers of frail elderly patients.

**Topics for research**

- Study of biological mechanisms of continence and incontinence in the frail elderly, especially those related to supraspinal control or lack thereof.
- Development and testing of treatments specific to the frail elderly.
- Establishment of the reproducibility and reliability of urodynamic measurements in the frail elderly.
- Investigation of the effect of faecal loading of the bowel on detrusor contraction, overactivity and residual volumes post micturition.
- The relationship between faecal incontinence and faecal loading in the absence of impaction.
Anorectal physiology studies (ARPS) incorporate a variety of measurements in the lower gastrointestinal (GI) tract which are intended to:

1. Aid diagnosis of anal incontinence
2. Quantify the effects of therapeutic intervention for anal incontinence
3. Aid prognosis of intervention to treat anal incontinence
4. Aid identification of continent individuals who are at risk of developing anal incontinence if they undergo surgery of the anorectum.

In many ways the lower GI tract is analogous to the LUT with the rectum (a reservoir for the storage and expulsion of faeces) being the analogue of the bladder and the anal canal (which acts as a valve to contain faeces within the rectum during storage and which acts as a tube to convey faeces away from the body during defaecation) being the analogue of the urethra.

Unlike the LUT which has to retain a substance of a fairly consistent viscosity to maintain continence (urine), the lower GI tract is not as simple in that the substance it is trying to retain for continence can have a wide range of textures (from “watery” to “hard”). Therefore, sphincters which might be adequate to maintain continence in the presence of hard stool may be totally inadequate when challenged with loose stool. This may well be a significant, confounding factor in measuring lower GI tract function but this has not been investigated with any great rigor.

There are simple ways of quantifying stool consistency [542, 543] which appear to be reproducible. [544] However, more objective measures also exist. [545]

The anal sphincters act as valves to contain faeces within the rectum until defaecation is convenient.
II. BASIC ANATOMY AND
PHYSIOLOGY

1. INTERNAL ANAL SPHINCTER

The internal anal sphincter is a continuation of the smooth muscle lining of the rectum and it is under autonomic control. A study in 1979 reported a 75% contribution of the internal anal sphincter to the closure of the anal canal at rest [546] but other workers demonstrated that it is responsible for around 85% of the resting tone in the anal canal. [547, 548] However, there is some evidence that the contribution may be only between 50%-60%. [549] What is known is that the external anal sphincter does contribute to resting pressure in the anal canal [550]; probably to varying degrees in individuals.

It has long been thought that poor internal sphincter function makes an individual more likely to suffer from passive anal leakage throughout the day and night. However Deutekom et al have shown that there is also an association of passive faecal incontinence with poor external sphincter function. [551]

2. EXTERNAL ANAL SPHINCTER

The external sphincter is voluntary, striated muscle. It is this muscle that an individual activates to maintain continence when a defaecation desire is experienced but it is inappropriate to do so. Poor external sphincter function makes an individual more likely to experience urgency when a defaecation desire is experienced and often incontinence can occur on the way to the toilet.

3. PUBLORECTALIS

There have been considerations in the past that puborectalis has a role in anal control. This part of the pelvic floor slings around back of the lower GI tract and creates the anorectal angle. During times of increased abdominal pressure it has been postulated that this angle creates either [552] or both [553] a “flap” valve or “flutter” valve effect to minimise the additional pressures challenging the sphincters. However, there is scant evidence to support the existence of either of these mechanisms. Bartolo in 1986 carried out work which showed that the presence of a “flap” valve mechanism was unlikely [554] and Bannister also confirmed this finding in the following year [555]

III. ANAL INCONTINENCE AND ANORECTAL PHYSIOLOGY STUDIES

Anal incontinence can result directly from poor sphincter function, altered rectal sensation, altered rectal compliance or recto-vaginal fistulae. Problems associated with the upper GI tract, which result in intestinal hurry and diarrhoea, can also directly lead to incontinence. Indirectly, anal incontinence can result from “overflow” due to poor evacuation. Incomplete defaecation may result from an anatomical problem such as rectocele but it can be a functional problem relating to poor rectal sensation, high rectal compliance, failure of the internal sphincter to relax during defaecation or the external sphincter actively contracting rather than relaxing during defaecation.

Anorectal physiology studies involve the measurement of sphincter function, rectal compliance and sensation and will be discussed in two parts. The first tests considered are those which measure parameters of lower GI tract function that can directly cause anal incontinence; these are termed tests relating to “primary incontinence”. After that, tests which measure parameters of lower GI tract function that can indirectly cause anal incontinence will be considered; these are termed tests relating to “secondary incontinence”

IV. TESTS RELATING TO PRIMARY INCONTINENCE

1. ANAL MANOMETRY

The most common way of assessing sphincter function is by anal manometry. Pressures are measured in the anal canal at rest, during voluntary contraction of the muscles and sometimes during Valsalva or cough. A variety of devices are used to carry out manometry including air-filled [556] and water-filled balloons, water-perfused catheters, catheter-mounted pressure transducers (also known as microtips and solid state catheters). [558] In 1983, Schouten and Vroonhoven described a simple system of anorectal manometry. [559] Even a simple tube system can give measurements of pressure in the anal canal. [560]

Devices for anal manometry can be single or multi-channelled with sensors arranged radially and/or longitudinally along the length of the catheter. In many instances, the device measuring pressure in the anal canal also has a balloon at its tip which can be placed in the rectum, inflated and the effect on the anal sphincters assessed.

The performance of many of the different systems have been compared [561, 562] and different measurements can be obtained with the different devices. Size and stiffness of catheter, rate of perfusion of water-perfused systems, orientation of sensors within the anal canal can all affect the measurement of pressure. [563] Some comparison between air-charged balloons, solid state systems and water-perfused catheters have shown minimal differences in pressure measurements. [564]

A study in 1998 showed that a water-perfused catheter
and a rectosphincteric balloon gave equivalent values of pressure (in 10 patients). [565]

A ‘historical’ state-of-the-art perspective of anal manometry was carried out in 1993 by Meunier and Gallavardin. [566] They discussed the methods of recording anorectal pressures with perfused catheters, sleeve catheters, water- or air-filled balloon catheters and microtransducers. They then discussed routine anorectal manometry and the parameters resulting from this investigation. The manometric findings in constipation in adults and children, in incontinence and in the descending perineum syndrome were presented and the usefulness of anorectal manometry in surgical and various conditions was discussed.

a) Units of pressure in anal manometry

There is no universal standard for units of pressure in anal manometry. These can be cm H2O, mm Hg or kPa. Although it would be convenient to have a standard unit of measurement, conversion from one unit to another is trivial and it could be argued that a standard is not absolutely necessary. However, when authors quote values without units of measurement in even the abstract of their work [567], there is a strong argument for having a standard because without a standard, recognised unit, parameters quoted without units are meaningless.

In this chapter, pressure values will be cited in the units originally published by the authors.

b) Position for manometry

Traditionally, manometry is performed in the left lateral position. However, there are significant differences in the pressures of patients when placed in the erect position [568] and, because these measurements correlate better with symptom severity, the authors postulate that manometry may be more physiological than in any other position, particularly because most patients have their symptoms when ambulating.

Nevertheless, currently most manometry continues to be performed with the patient lying in the left-lateral position

2. RESTING PRESSURE

Pressures are recorded along the length of the anal canal with the patient at rest. As mentioned previously, the resting pressure within the anal canal arises from both internal and external anal sphincter activity; with the former thought to contribute the majority of the tone (between 50%-85% of the total). Therefore, measurement of the maximum resting pressure in the anal canal is thought to be indicative of internal sphincter function. It can be measured relative to atmospheric pressure or relative to rectal pressure (as is also encountered when measuring maximum pressure in the urethra) and, amongst others, it can be termed as ‘maximal resting pressure’, ‘basal anal pressure’, ‘maximum resting anal pressure’. The term ‘rectoanal pressure gradient’ is also used but it is most frequently used to describe the pressure difference between the rectum and anal canal on defaecatory manoeuvres.

a) Reproducibility of resting pressure

In 1989, Rogers et al studied 16 subjects (mean (s.d.) age 50.7 (12.8) years, three men) on two separate occasions by two experienced investigators in random order. No significant differences were found between the results obtained by the two investigators in the measurements of anal canal length, and canal resting pressure and squeeze pressure. [569]

In a study of 10 healthy individuals in 1998, measurement of resting pressure was shown to be reproducible on occasions four hours apart and four days apart. [570] A small study of 6 women suggested that resting pressure was not affected by the menstrual cycle. [571] Goke et al demonstrated in 12 healthy volunteers that the day to day intraindividual variability of resting pressure was 13.5 % (which was considered to be relatively low). [572]

In 1991, Ekhardt and Elmer looked at the reproducibility of sphincter pressure and length on three different days in 10 male and 10 female healthy subjects with the use of a pneumohydraulic capillary perfusion system. There was complete agreement between both observers in the analysis of anal resting pressure. The pressure profiles from different days correlated significantly (p < 0.01) with each other regardless of whether the studies were performed in the prepared or unprepared bowel. [573]

In 2004, Bharucha et al assessed the intra-individual day-to-day reproducibility of resting pressures in 19 healthy subjects and judged that they were highly reproducible on the basis of a value of r ≥0.7. [574]

In 1997, Ryhammer et al showed in 58 healthy females that the mean difference for maximum anal resting pressure was 2.2 (95% confidence interval: -3.5 - 7.8) cm H2O. They concluded that there was no systematic variation in the repeated measurements however, the nonsystematic variation was generally large. [575]

b) Normal values of resting pressure

Although there are some publications containing normal values for anal manometry, these are only specific for the type of manometer being used and how the manometric parameters were recorded. Therefore they cannot be universally applied.

Often they just include a small number of subjects (e.g. a recent determination of the normal ranges for manometry and balloon expulsion and rectal sensation determined in Thai men and women comprised 17 men and 13 women). [576] The mean resting pressure in this group of healthy Thai adults was 55.4 mm Hg
(1SD, 15.3 mm Hg). The measurements of resting pressure were similar in both men and women.

In 1987 McHugh and Diamant, using a multilumen continuously perfused catheter and a mechanized rapid pull-through technique, studied anal pressures in 143 incontinent patients and a control population of 157 healthy subjects. [577] In 10 male volunteers, pressures were determined using catheters that varied from 3 mm to 18 mm in diameter. In the control population, the resting anal pressure was significantly lower in females 40 years of age and over as compared to males. In women, parity did not correlate with resting anal pressure but aging was associated with a consistent reduction in resting anal pressure. In males, there was a similar but less impressive age-related reduction for resting anal pressure. A linear increase in resting anal pressures was recorded as catheter diameter increased from 3 to 12 mm. Normative data for the resting anal pressures are shown in Table 10.

In 1992, Cali measured resting pressures in normal volunteers; 20 males, 21 nulliparous females and 18 multiparous females. The resting pressures were similar between males and nulliparous females; the nulliparous females had higher resting pressures than the multiparous females. [578]

In 2007, Chaliha et al reported that 95% of resting pressures in 286 healthy women in the third trimester of their first pregnancy were between 29-90 mm Hg. 12 weeks after delivery 161 of these women returned for re-evaluation and 95% of these resting pressures were between 27–98 mm Hg (with similar values between those who had bowel problems and those who did not). [579]

In 1998, Wong et al produced normal values of resting pressure from 11 normal subjects. [550] In 1994 Sultan et al reported the normal values of resting pressure for 93 nulliparous women and 21 healthy men. [580]

In 1994 Benninga et al carried out some studies of resting pressure in 13 healthy children. [581]

In 1991, Felt-Bersma et al produced normal values of resting pressure for 40 men and 40 women aged 20-87 with a perfused catheter system. The mean maximum basal pressure for the men was 68 mm Hg (1SD 21 mm Hg) and for the women was 63 mm Hg (1SD 19 mm Hg). There was no significant difference between the two however, the maximum basal pressure decreased significantly with age. [582]

In 1986 Gibbons et al studied resting pressure in 14 normal males and 11 normal females using probes of between 0.4 and 3 cm in diameter. The larger the probe, the higher the pressure. [583]

Normal values of resting pressure were tabulated in a 1999 review of anorectal testing techniques. [584] These are reproduced in Table 10 along with a set of more recent data.

c) Sensitivity and specificity of resting pressure

The previous consultation noted that although resting pressure was lower in faecally incontinent patients, there was poor sensitivity to distinguish between continent and incontinent individuals [577, 591].

In 1987, McHugh and Diamant showed that although resting anal pressure was lower in 143 incontinent patients compared to a control population of 157 healthy subjects, 39% of incontinent females and

The values are expressed as means in units of mm Hg with either the SEM or the range in parantheses.
44% of incontinent males fell within the 'normal' range. [577]

In 1995, Penninckx et al compared 'conventional' anal manometry in 27 control subjects (M:8, F:19; mean age: 47 yr) and in 40 incontinent patients (M:5, F:35; mean age: 49 yr). Discriminatory values of > 40 mmHg for maximum basal pressure could identify continent patients with 96%, and incontinent patients with 88% accuracy. [592]

In 1999, Osterberg et al compared maximum resting pressure in 156 patients with faecal incontinence (mean age 63 yr; 139 women, 17 men) and 25 healthy controls (mean age 54 yr; 20 women, five men) using a perfused catheter with a station pull-through technique. Although maximum resting pressure was higher in the continent group, there was not sufficient sensitivity and specificity to consider it as a diagnostic test. [593]

There has been no further evidence to dispute this although it has been suggested, in a reasonably sized study of 80 continent patients and 47 patients with idiopathic faecal incontinence that resting pressure gradient may be a more sensitive and specific discriminator than resting pressure itself. [594] However a study, 3 years earlier, in 22 individuals with normal faecal control and 36 patients with faecal incontinence suggests that resting pressure gradient is no better a discriminator than maximum resting pressure. [595]

Interestingly, Lejeune et al found that basal anal pressure had as good a sensitivity (77.2%) and specificity (82%) as cardiac criteria in assessing diabetic autonomic neuropathy [596]

**d) Resting pressure's sensitivity to change**

In 1986, Holmstrom et al showed that in 11 patients who had a Ripstein operation for procidentia, the mean maximum anal resting pressure increased from 39 to 55 mm Hg (p = 0.01). [597]

In 1991, Sainio et al studied 28 patients who underwent transabdominal repair of rectal prolapse. In the 22 patients who were incontinent prior to the procedure, they demonstrated an increase in resting anal pressure in those who achieved continence after the procedure. [598]

In 1993, Kushwaha et al showed that resting anal pressure decreased 6 months after radiotherapy of the prostate and bladder [599]

Also in 1993, Church et al showed measurable changes in resting pressure following ileal pouch-anal anastomoses in 134 patients and coloanal anastomoses in 16 patients. [600]

In 2003, Norton et al showed in a randomised study to assess the effect of biofeedback, that resting pressure improved in 171 patients with faecal incontinence; irregardless of what conservative therapy they received. These improvements were largely maintained 1 year after finishing treatment. [601]

In 2004, Torrabedella et al showed that Sildenafil reduced the resting pressure of patients with chronic anal fissure. [602]

Also in 2004, Yeoh et al showed that in 38 patients who had radiation therapy for localized carcinoma of the prostate showed progressive reductions of basal anal pressures up to 2 years following the treatment and this was associated with an increase in bowel frequency, urgency and faecal incontinence. [603]

Again in 2004, Martinez-Puente Mdel et al evaluated biofeedback for treating faecal incontinence in 53 patients. Maximum anal resting pressures significantly increased after therapy. [604]

In 2005, Ram et al found that there were changes in basal resting pressure up to a year after lateral sphincterotomy for anal fissure. 50 patients with anal fissure were included in this study and underwent sphincterotomy; 12 healthy patients served as controls. All patients were examined 1 month before surgery and 1, 3, 6, and 12 months following surgery. The control group had 3 manometric evaluations 6 months apart. They showed that the mean basal resting pressure before surgery was 138 ± 28 mm Hg. One month after surgery, the pressure dropped to 86 ±15 mm Hg (p < 0.0001) and gradually rose to a plateau at 12 months (110 ± 18 mm Hg, p < 0.0001). At 12 months, the manometric pressure was significantly lower than the baseline (p < 0.0001). However, manometric measurements in the fissure group were still significantly higher than in the control group (110 ± 18 versus 73 ± 4.8 mm Hg, p < 0.0001). All patients were free of symptoms at the 12-month follow-up. They concluded that lateral internal sphincterotomy caused a significant decline in the resting anal pressure. During the first year following surgery, the tone of the internal anal sphincter gradually increased, indicating recovery, but still remained significantly lower than before surgery. However, postoperative resting pressures were higher than those in the control group, and no patient suffered any permanent problems with incontinence, so this decrease may not be clinically significant. [605]

In 2005, Alper et al extended the above report to include resting pressures in 38 patients with third-degree or fourth-degree symptomatic haemorrhoids who underwent haemorrhoidectomy in addition to the 50 patients with anal fissure who underwent sphincterotomy, and 12 healthy patients who served as controls. Before surgery, the resting pressure in the fissure group was significantly higher than in the haemorrhoid group, which was significantly higher than in the control group (138 ± 28.4 mm Hg vs. 108.4 ± 23 mm Hg vs. 73 ± 5.9 mm Hg, p< 0.0001). Twelve
months after surgery, anal resting pressure was significantly lower than the baseline measurements in both the fissure (110 ± 18.2 vs. 138 ± 28.4, p< 0.0001) and haemorrhoid groups (103.6 ± 21.5 vs. 108 ± 23, p< 0.0001), but both remained higher than the control group (103.6 ± 21.5 mm Hg vs. 73 ± 5.9 mm Hg, p< 0.0001). [606]

In 2006, Lovegrove et al conducted a meta-analysis of stapled versus ileal pouch anal anastomosis (IPAA) following restorative proctocolectomy published between 1988 and 2003. This comprised 4183 patients (2699 hand-sewn and 1484 stapled IPAA). Anorectal physiological measurements demonstrated a significant reduction in the resting pressure in the hand-sewn IPAA group by 13.4 mm Hg, with the stapled IPAA group having improved nocturnal continence, which was reflected in a higher anal pressure. [607]

In 2007, Toyonaga et al showed that maximum resting pressure significantly decreased following fistulotomy for intersphincteric fistula-in-ano in a prospective study of 148 patients. [608]

In 2008, Brisinda et al treated 80 patients with botulinum toxin for recurrent anal fissure following lateral internal sphincterotomy. Anorectal manometry at 1 month demonstrated a significant reduction in resting pressure. [609]

e) Does resting anal pressure predict outcome of intervention?

In 1993, Church et al, showed that pre-operative resting pressure was not predictive of continence following IPAA in 134 patients and coloanal anastomoses in 16. [600]

In a retrospective study in 1999, Hool et al found that preoperative resting pressure did not predict faecal continence following sphincter repair in 51 patients.

In 2000, Stadelmaier et al determined the clinical and physiologic parameters enabling the prognosis of continence after protective ileostomy closure secondary to rectal resection for rectal cancer. 65 patients who had undergone rectal resection (of whom 24 had had radiochemotherapy) were evaluated by clinical examination, anorectal manometry and orthograde contrast enema before ileostomy closure (baseline). Continence was evaluated by clinical findings 91 ± 52 weeks after stoma closure with the help of standardised questionnaires and classified according to the Wexner continence score. Correlations were found to be significant between the continence score and the level of anastomosis (r = -0.58, p < 0.001), median baseline resting pressure (r = -0.52, p < 0.001), and baseline rectal compliance (r = -0.43, p < 0.001). Additionally, radiochemotherapy impairs continence (p = 0.0001). Correlations were not significant between continence and baseline functional sphincter length, squeeze pressure, threshold for perception, urge and maximal tolerable volume, and continence for semiliquid contrast medium. Based on these findings, the continence score can be calculated before closure of a diverting ileostomy by applying multivariate analysis with the help of the following formula: Continence score = 18.23 - 0.94 x level of anastomosis - 0.18 x resting pressure + 3.72 x radiochemotherapy. [610]

In 2001, Mylonakis carried out a prospective study in 100 patients who had different types of surgery for various types of anal fistulae. The type of fistula and the preoperative anal pressures determined the operative procedure that was used. Six patients had some soiling postoperatively and 3 patients had impaired control of flatus. On the basis of this, the authors concluded that preoperative anal manometry is important in deciding the operative procedure for fistula surgery [611]

Also in 2001, Herman studied 33 patients with small, mobile rectal tumors (adenoma and carcinoma) undergoing transanal endoscopic microsurgery. They underwent anorectal motility studies (using pull-through anorectal manometry and rectal barostat) and endoanal ultrasound prior to surgery and 3 weeks and 6 months after TEM; controls were 20 healthy volunteers. The main risk factors of anorectal dysfunctions following TEM included: postoperative internal anal sphincter defects, low preoperative resting anal pressure, disturbed rectoanal coordination, extent (>50% of wall circumference) and the depth (full thickness) of tumor excision. They concluded that preoperative anorectal motility studies and anal ultrasound allow the identification of patients with the risk of postoperative anorectal dysfunctions. [612]

In 2002, Halverson et al prospectively measured perioperative resting pressures in 1439 patients undergoing ileal pouch-anal anastomosis. Postoperative functional status was assessed at various time intervals from 6 months to 8 years after the procedure. They found that perioperative resting anal sphincter pressures greater than 40 mm Hg were associated with significantly better function and quality of life after the procedure. However, a low perioperative resting pressure (< 40 mm Hg) did not preclude a successful outcome. [613]

In 2004, Pescatori found that preoperative resting pressure did not predict continence following fistulotomy in 38 males. [614]

Prather, in a review in 2004 concluded that few physiological parameters have been consistently identified as important in predicting response to either biofeedback or surgery. He states that the process of isolating these factors has been hampered by heterogeneity in the definition of fecal incontinence, lack of consensus on what constitutes a successful
outcome, lack of follow-up data, variations in the way ‘standard’ treatments are implemented, and lack of properly powered randomized controlled trials. Factors that have not been found to be important in predicting outcome following biofeedback retraining include pudendal nerve damage and pretreatment anal canal pressures. The presence of some degree of anorectal sensation is the only preoperative assessment that has been found to be predictive of response to surgical therapy. [615]

In 2005, Gearhart et al studied 20 women, 29 to 84 years of age (mean age 50 years), with severe fecal incontinence and large (>or=50%) sphincter defects on ultrasound. All underwent an overlapping sphincter repair following anal manometry (mean resting pressure, mean squeeze pressure, anal canal length, compliance) and pudendal nerve terminal motor latency (PNTML) testing but none of these parameters was able to predict outcome following sphincteroplasty. [616]

In 2006, Glasgow et al showed that mean resting pressure measured preoperatively in 45 patients undergoing perineal proctectomy for rectal prolapse was not predictive of continence postoperatively. [617]

In 2007, Toyonaga et al showed that maximum resting pressure was not predictive of developing postoperative incontinence following fistulotomy for intersphincteric fistula-in-ano in a prospective study of 148 patients. [608]

In 2007, Pascual et al found that resting anal pressure was unable to predict success of pharmacological treatment of anal fissure in 124 patients. [618]

f) Comparison of measurement of resting pressure with digital examination

In 1989, Hallan et al compared digital examination and manometric evaluation in 66 patients and controls. There was good correlation between digital basal score and maximum basal pressure. The sensitivities and specificities of each assessment were similar in separating incontinent from continent individuals and they concluded that digital estimation was equally as good as assessment of anal sphincter function as anal canal manometry. [619]

In 1993, Siproudhis et al evaluated 50 patients (38 females and 12 males; mean age, 44.7 +/- 15 years) who complained of defaecatory difficulties to determine the accuracy of the clinical examination in diagnosing and quantifying pelvicrectal abnormalities. Each parameter was then compared with the features of anorectal manometry and evacuation proctography performed by two independent observers. When compared with anal manometry, digital assessment was able to quantify resting and squeeze pressures and length of the anal canal with excellent correlation and good global agreement as well as predicting a short or hypotonic anal canal. [620]

In 1994, Herbst and Teleky showed that digital rectal examination preceding measurement of maximum resting pressure in 84 incontinent individuals and 14 controls caused unpredictable results, especially in patients with lower maximum resting pressures, and concluded that this practice should strictly be avoided. [621]

In 1998, Buch et al compared digital and manometric assessment of anal sphincter function in 191 patients who were divided into three groups: control, obstructive defaecation and faecal incontinence. A significant correlation was established between the digital and manometric tone assessments, both at rest and at squeeze. Digital assessment was found to be more sensitive but less specific than manometry in differentiating between faecal continence and incontinence. They concluded that digital examination is not an adequate substitute for anorectal manometry, but is a reasonable option where manometry is unavailable [622]

In 2005, Jones et al studied 40 consecutive patients (21 male) with chronic anal fissure. Twenty-two had normal maximum resting pressure on anal manometry and a further 3 had low pressures on anal manometry. On digital assessment, only five patients were evaluated as having no anal hypertonia. Digital assessment of anal tone correctly identified 14 of 15 patients with high manometric maximum resting pressure (STV, 93%), yet detected only 4 of 25 patients with normal or low pressures (SPT, 16%). The PPV of clinical assessment of anal tone was 40% and the NPV, 80%. Therefore, digital examination poorly correlated with manometric findings. [623]

In 2007, Dobben et al prospectively compared digital rectal examination with anal manometry and endoanal ultrasonography in 312 patients with faecal incontinence; 90% were females. Regarding resting pressure, they found that absent, decreased and normal resting pressures at rectal examination correlated to some extent with mean (+SD) resting pressures of 41.3 (+20), 43.8 (+20) and 61.6 (+23) mm Hg (p<0.001) respectively. They concluded that digital rectal examination can give accurate information about internal anal sphincter function. [624]

Conclusions (evidence level 3)

• Measurement of resting pressure in the anal canal is a parameter produced by devices of different type and size. There is no standardisation regarding how the measurement is made nor is there any universal agreement as to what unit of pressure should be used.

• In many hands the measurement is reproducible and sensitive to change following intervention.

• However, it is not of sufficient sensitivity and specificity to distinguish individuals with normal anal continence from those with anal incontinence.
There is little evidence that it has any prognostic power regarding the outcome of intervention.

It gives a more sensitive indication of anal tone than digital examination

**Recommendation (grade C)**

- That this parameter continues to be used clinically in those situations where an objective measure of resting tone will help in the management of a patient with faecal incontinence.
- That consideration is given to some degree of standardisation in the measurement of this parameter.

### 3. HIGH PRESSURE ZONE AND ANAL CANAL LENGTH

The lower GI tract analogue of the “functional urethral length” is the “functional anal canal length” or “length of the high pressure zone (HPZ)”. Rink et al defined this as the length of the anal canal which exerts at least 50% of the maximum resting pressure. [625] However, there is not universal agreement regarding this definition.

In 2006, Liu et al measured the HPZ in 17 asymptomatic nulliparous women and found it to be 39 (±1) mm in length. [626]. In 1989, Pedersen et al measured the physiological variation in this parameter in 78 healthy volunteers and found the maximum variation to be 10 mm with a 95% confidence interval of 4 mm. [589] Although they found higher resting and squeeze pressures in males, there was no gender difference in the length of the high pressure zone.

Although some workers have measured this parameter, it has not generally proved to be of any more value than the resting pressure.

However, in 1999, Yamana et al did show that, amongst other parameters, a longer preoperative HPZ was associated with better defaecatory function six months after low anterior resection for rectal cancer in 32 patients. [627]

Also in 1999, Hool et al carried out a retrospective review of the manometric data of 51 patients having a sphincter repair. Following data entry into a logistic regression model, postoperative anal canal length was highly significant in predicting postoperative continence. [628]

Again in 1999, Osterberg et al compared the length of the high pressure zone in 156 patients with faecal incontinence (mean age 63 yr; 139 women, 17 men) and 25 healthy controls (mean age 54 yr; 20 women, five men) using a perfused catheter with a station pull-through technique. Although the high pressure zone was longer in the continent group, there was not sufficient sensitivity and specificity to consider it as a diagnostic test. [593]

In 1991, Ekhardt and Elmer looked at the reproducibility of sphincter pressure and length on three different days in 10 male and 10 female healthy subjects with the use of a pneumohydraulic capillary perfusion system. There was complete agreement between both observers in the analysis of sphincter length but anal sphincter length varied greatly on different days. [573]

In 2007, Toyonaga et al showed that the length of the high pressure zone significantly decreased following fistulotomy for intersphincteric fistula-in-ano in a prospective study of 148 patients but it was not predictive of developing postoperative incontinence. [608]

In 2008, Rink et al showed in 61 patients having restorative proctocolectomy for ulcerative colitis that the HPZ at rest using vector manometry (see later) only had a sensitivity of 63.6% and a sensitivity of 59.1% for predicting incontinence after the procedure. [625]

**Conclusions (evidence level 3/4)**

- Measurement of manometric sphincter length in the anal canal is an unstandardised measurement which has been considered by relatively few investigators.
- It is not of sufficient sensitivity and specificity to distinguish individuals with normal anal continence from those with anal incontinence.
- There is little evidence that it has any prognostic power regarding the outcome of intervention.

**Recommendation (grade C)**

- That the manometric length of the anal sphincter is not a clinically useful parameter.

### 4. PRESSURE ON VOLUNTARY CONTRACTION

Measurement of the maximum pressure in the anal canal on voluntary contraction is taken to be a measure of external anal sphincter function. Careful observation of the patient during this manoeuvre is essential to ensure that the patient has understood what is required and is using the appropriate muscle group (which is seen as an upward and inward movement of the anal region). Many patients will inappropriately use their gluteal muscles during this manoeuvre; others will tend to “bear down” instead of “squeezing”. Achieving the correct manoeuvre, whilst remaining fairly still, is essential for a valid measurement. Nevertheless, it is also important to appreciate that even when the patient carries out the correct manoeuvre, there can be movement of the catheter; resulting in an erroneous
Pressure reading. In essence, whilst the measurement of resting pressure within the anal canal is a fairly robust measure, the accurate measurement of pressure during voluntary contraction is beset by practical difficulties.

Pressure during voluntary contraction can be measured relative to atmospheric pressure and relative to rectal pressure. It can also be measured relative to the resting pressure at the corresponding location along the anal canal. Different terms have been used to describe pressure on voluntary contraction such as ‘maximal squeeze pressure’, ‘incremental squeeze pressure’, ‘maximal voluntary squeeze’, ‘maximum squeeze pressure’ and ‘maximum voluntary contraction pressure’. It can be measured in units of cm H$_2$O, mm Hg or kPa. There is no universal standard for these measurements.

**a) Reproducibility of squeeze pressure**

In 1989, Rogers et al studied 16 subjects (mean (s.d.) age 50.7 (12.8) years, three men) on two separate occasions by two experienced investigators in random order. No significant differences were found between the results obtained by the two investigators in the measurements of squeeze pressure. [569]

In 1991, Ekhardt and Elmer looked at the reproducibility of sphincter pressure and length on three different days in 10 male and 10 female healthy subjects with the use of a pneumohydraulic capillary perfusion system. There was complete agreement between both observers in the analysis of squeeze pressure. The squeeze pressures on different days correlated significantly (p<0.01) with each other regardless of whether the studies were performed in the prepared or unprepared bowel. [572]

In 1992, Goke et al demonstrated in 12 healthy volunteers that the intraindividual day-to-day variability of maximal squeeze pressure was 17.3% (which was considered to be relatively low). [573]

In a small study of 6 healthy women in 1994, Schnegg et al showed that pressure on contraction was not markedly affected by the menstrual cycle. [571]

In 1997, Ryhammer et al showed in 58 healthy females that the mean difference for maximum anal squeeze pressure was -1 (95% confidence interval: -6.5 - 4.5) cm H$_2$O. They concluded that there was no systematic variation in the repeated measurements however, the nonsystematic variation was generally large. [575]

In 1998, Freys et al showed that in 10 healthy volunteers, maximum squeeze pressure was not reproducible on occasions 4 hours apart and four days apart. [570]

In contrast, Bharucha assessed the intra-individual day-to-day reproducibility of squeeze anal pressures in 19 healthy subjects in 2004 and judged that they were highly reproducible on the basis of a value of r $\geq$0.7. [574]

**b) Normal values of pressure on voluntary contraction**

Although there are some publications containing normal values for anal manometry, these are only specific for the type of manometer being used and how the manometric parameters were recorded. Therefore they cannot be universally applied.

Often they just include a small number of subjects (e.g. a recent determination of the normal ranges for manometry and balloon expulsion and rectal sensation determined in Thai men and women comprised 17 men and 13 women). [576] The mean squeeze pressure in this group of healthy Thai adults was 170.3 mm Hg (1SD, 81.7 mm Hg). However, the measurements of squeeze pressure were greater in men than in women.

In 1987 McHugh and Diamant, using a multilumen continuously perfused catheter and a mechanized rapid pull-through technique described the resting and squeeze pressures in 143 incontinent patients and a control population of 157 healthy subjects. [577] In the control population, maximum squeeze pressures were significantly lower in females compared to men at virtually all ages. In women, parity did not correlate with maximum squeeze pressure but aging showed a consistent reduction in maximum squeeze pressure. In men there was no change in maximum squeeze pressure with age. The normal values for maximum squeeze pressure are summarised in table 11 and shows that maximum squeeze pressure decreases with age in females but not males. Parity does not affect the maximum squeeze pressure.

In 1992, Cali measured pressures in 20 males, 21 nulliparous females and 18 multiparous females. The squeeze pressures were greater in the males compared to both the female groups. [578]

In 2007, Chaliha et al reported that 95% of squeeze pressures in 286 healthy women in the third trimester of their first pregnancy were between 50-163 mm Hg. 12 weeks after delivery 161 of these women returned for re-evaluation and 95% of these resting pressures were between 43–156 mm Hg (with similar values between those who had bowel problems and those who did not). [579].

In 1994 Sultan et al reported the normal values of squeeze pressure for 93 nulliparous women and 21 healthy men. [580]

In 1994 Benninga et al carried out some studies of squeeze pressure in 13 healthy children. [581]

In 1991, Felt-Bersma et al produced normal values of squeeze pressure for 40 men and 40 women aged 20-87 with a perfused catheter system. The mean
maximum squeeze pressure for the men was 183 mm Hg (1SD 73 mm Hg) and for the women was 102 mm Hg (1SD 36 mm Hg). There was a significant difference between the sexes (p<0.001) and squeeze pressure decreased significantly with age (p<0.001) in both men and women. [582]

In 1986 Gibbons et al studied squeeze pressure in 14 normal males and 11 normal females using probes of between 0.4 and 3 cm in diameter. The larger the probe, the higher the squeeze pressure. [583]

Normal values of squeeze pressure were tabulated in a 1999 review of anorectal testing techniques. [584] These are reproduced in Table 11 along with a set of more recent data.

c) Sensitivity and specificity of squeeze pressure

The previous consultation noted that although squeeze pressure was lower in faecally incontinent patients, there was poor sensitivity to distinguish between continent and incontinent individuals [577, 591].

In 1987, McHugh and Diamant showed that although maximum squeeze pressure was lower in 143 incontinent patients compared to a control population of 157 healthy subjects, 39% of females and 44% of males fell within the "normal" range. [577]

In a study of anal manometry on 350 patients, 178 of whom had fecal incontinence and 80 control subjects, Felt-Bersma et al showed in 1990 that incontinent patients had lower anal sphincter pressures during squeeze compared to continent individuals. Although differentiation between incontinent and continent patients was not possible with a single test because there was complete overlap, they found that maximum squeeze pressure had a better sensitivity and specificity for identifying faecal incontinence than resting pressure. [629]

In 1995, Penninckx et al compared "conventional" anal manometry in 27 control subjects (M:8, F:19; mean age: 47 yr) and in 40 incontinent patients (M:5, F:35; mean age: 49 yr). Discriminatory values of ≥ 92 mmHg for squeeze pressure could identify continent patients with 96%, and incontinent patients with 88% accuracy. [592]

In 1999, Osterberg et al compared maximum squeeze pressure in 156 patients with faecal incontinence (mean age 63 yr; 139 women, 17 men) and 25 healthy controls (mean age 54 yr; 20 women, five men) using a perfused catheter with a station pull-through technique. Although maximum squeeze pressure was higher in the continent group, there was not sufficient sensitivity and specificity to consider it as a diagnostic test. [593]

d) Pressure on voluntary contraction’s sensitivity to change

In 1991, Sainio et al studied 28 patients who underwent transabdominal repair of rectal prolapse. In the 22 patients who were incontinent prior to the procedure, they demonstrated an increase in voluntary contraction pressure in those who achieved continence after the procedure. [588]

In 1993, Kushwaha et al showed that incremental squeeze pressure decreased 6 months after radiotherapy of the prostate and bladder [599].

In 2003, Norton et al showed in a randomised study to assess the effect of biofeedback, that squeeze pressures improved in 171 patients with faecal incontinence; irregardless of what conservative therapy they received. These improvements were largely maintained 1 year after finishing treatment. [601]

The values are expressed as means in units of mm Hg with either the SEM or the range in parantheses.
Similarly in 2004, Again in 2004, Martinez-Puente Mdel et al evaluated biofeedback for treating faecal incontinence in 53 patients. Maximum anal squeeze pressure significantly increased after therapy. [604]

In 2004, Yeoh et al showed that in 38 patients who had radiation therapy for localized carcinoma of the prostate showed progressive reductions of anal squeeze pressures up to 2 years following the treatment and this was associated with an increase in bowel frequency, urgency and faecal incontinence. [603]

In 2006, Leung et al showed in 12 children who completed a programme of electrical stimulation and biofeedback exercise of pelvic floor muscle for children with faecal incontinence after surgery for anorectal malformation that there was a significant improvement in faecal soiling 1 year after treatment and a significant increase in anal sphincter squeeze pressure of 29.9 mmHg (p = 0.007). [630]

Also in 2006, Lovegrove et al conducted a meta-analysis of stapled versus hand-sewn IPAA) following restorative proctocolectomy published between 1988 and 2003. This comprised 4183 patients (2699 hand-sewn and 1484 stapled IPAA). Anorectal physiological measurements demonstrated a significant reduction in the squeeze pressure in the hand-sewn IPAA group by 14.4 mm Hg, with the stapled IPAA group having improved nocturnal continence, which was reflected in the higher anal pressure. [607]

In 2005, Singh et al conducted a prospective randomized controlled trial for treatment of postoperative pain in 32 patients undergoing haemorrhoidectomy. Patients were given an inter-sphincteric injection of either placebo or botulinum toxin (150 units). Maximal squeeze pressure was significantly lower in the botulinum toxin group at weeks six and twelve (mean 87.1 mmHg; 95% CI 68.9 - 107.1) compared to the placebo group (mean 185.8 mmHg; 95% CI 134.2 - 237.4) at week twelve (p=0.0014). [631]

Also in 2008, Brisinda et al treated 80 patients with botulinum toxin for recurrent anal fissure following lateral internal sphincterotomy. Anorectal manometry at 1 month demonstrated a significant reduction in maximum voluntary squeeze pressure. [609]

Again in 2008, Munasinghe et al carried out on audit of biofeedback in 50 patients with faecal incontinence. They showed significant increases in maximal squeeze pressure. [632]

e) Does voluntary squeeze pressure predict outcome of intervention?

As detailed in section 2e, Stadelmaier et al determined the clinical and physiological parameters enabling the prognosis of continence after protective ileostomy closure secondary to rectal resection for rectal cancer. There were no significant correlations between continence and baseline squeeze pressure. [610]

As detailed in section 2e, Prather, in a review in 2004 concluded that pretreatment pressures in the anal canal are not important in predicting response to either biofeedback or surgery. [615]

As detailed in section 2e, Gearhart et al found that mean squeeze pressure was unable to predict outcome following sphincteroplasty in 20 women with severe faecal incontinence. [616]

In 2006, Glasgow et al found in 45 patients that squeeze pressures >60 mm Hg preoperatively were a good indicator of post-operative continence following perineal proctectomy for rectal prolapse. However, abnormalities of pudendal nerve function and mean resting pressures were not predictive of postoperative incontinence. [617]

In 2008, Dobben et al attempted to develop an efficient diagnostic strategy for patients with faecal incontinence to identify subgroups that may benefit from pelvic floor physiotherapy. They studied 281 consecutive patients with faecal incontinence (mean age 59 years), 252 were female. All patients were then offered standardised pelvic floor physiotherapy. A high maximal squeeze pressure by anorectal manometry was associated with a positive treatment outcome but was not a strong predictor. [633]

In the same year, the authors from this study, together with many others, reported on 250 consecutive patients (228 women) who underwent medical history and a standardized series of tests, including physical examination, anal manometry, pudendal nerve latency testing, anal sensitivity testing, rectal capacity measurement, defaecography, endoanal sonography, and endoanal magnetic resonance imaging. Subsequently, patients were referred for pelvic-floor rehabilitation. In addition to the baseline Vaizey score, three elements from medical history were significantly associated with a poor result (presence of passive incontinence, thin stool consistency, primary repair of a rupture after vaginal delivery at childbed). The predictive value was significantly but marginally improved by adding the following test results: perineal and/or perianal scar tissue (physical examination), and maximal squeeze pressure. They concluded that anorectal physiology studies have a limited role in predicting success of pelvic-floor rehabilitation in patients with fecal incontinence. [634]

f) Comparison of measurement of pressure on voluntary contraction with digital examination

In 1989, Hallan et al compared digital examination and manometric evaluation in 66 patients and controls. There were good correlations between digital squeeze score and maximum squeeze pressure. The sensitivities and specificities of each assessment were similar in separating incontinent from continent individuals and they concluded that digital estimation was equally as good as assessment of anal sphincter function as anal canal manometry. [619]
In 1991, Kaushal and Goldner carried out a digital and manometric determination of maximal anal squeeze pressure in 27 patients. Subjective digital assessment showed that three patients had absent squeeze pressure (grade 0); two patients had markedly reduced (grade +1); six patients had reduced (grade +2); and the remaining 16 patients had normal maximal squeeze pressure (grade +3). Simultaneous objective anal sphincter pressure measurements, when compared with these subjective values, revealed a correlation coefficient of 0.97 (p < 0.05). They concluded that the clinician can reliably use the digital rectal examination to voluntary anal sphincter contraction strength. [635]

However, Eckardt and Kanzler in 1993 showed considerable differences between the two methods of assessing voluntary anal contraction. [636]

In the same year Siproudhis et al evaluated 50 patients (38 females and 12 males; mean age, 44.7 ± 15 years) who complained of defecatory difficulties to determine the accuracy of the clinical examination in diagnosing and quantifying pelvic rectal abnormalities (as detailed in section 2f). They found that digital assessment was able to quantify squeeze pressures with excellent correlation and good global agreement. [620]

As detailed in section 2f, Buch et al compared digital and manometric assessment of anal sphincter function in 191 patients who were divided into three groups: control, obstructive defaecation and faecal incontinence. They concluded that digital examination is not an adequate substitute for anorectal manometry, but is a reasonable option where manometry is unavailable [622]

In 2007, Dobben et al prospectively compared digital rectal examination with anal manometry and endoanal ultrasonography in 312 patients with faecal incontinence; 90% were females. Regarding squeeze pressure, they found that absent, decreased and normal squeeze pressures at rectal examination correlated to some extent with mean (±SD) incremental squeeze pressures of 20.6 (±20), 38.4 (±31) and 62.4 (±34) mm Hg (p<0.001) respectively. They concluded that digital rectal examination can give accurate information about external anal sphincter function [624]

g) Endurance and fatigability

Apart from measuring pressure at the height of a maximal contraction, some workers have assessed the voluntary sphincter squeeze endurance with mixed results.

The consensus statement of 1999 defined ‘sphincter endurance’ as the length of time the patient can maintain a squeeze pressure above the resting pressure. [637]

In 1993, Chiarioni et al studied anorectal sensorimotor function in 16 patients with liquid stool incontinence and severe urgency (10 with diarrhoea) unresponsive to conventional medical treatment, and in 16 healthy volunteers. The only significant difference found between incontinent patients and controls was a reduction in squeeze duration. Fourteen patients were selected to receive biofeedback treatment. Treatment was associated with a substantial improvement in incontinence in 12 patients and with a significant decrease in urgency (p < 0.05). Bowel frequency was not significantly influenced. Most patients showed a persistent improvement in anal motor function. Functional parameters were not predictive of outcome of treatment. [638]

In 1996, Rao et al showed that biofeedback therapy improved duration of squeeze in 19 patients with faecal incontinence. [639]

In a retrospective study in 1998, Marcello et al examined the records of 26 healthy volunteers, 33 patients with anal seepage, 75 patients with gross incontinence and 49 patients with severe constipation. For these patients they had calculated both fatigue rate (which is the slope of a linear regression line fitted to the declining pressure when the patient is instructed to contract for 40 seconds) and also the fatigue rate index (which is the projected time in minutes, from this linear regression line, for pressure to reach resting pressure). They showed that fatigue rate index was much shorter in the faecally incontinent group compared to the patients with severe constipation. [640]

In 1998, Mitrani et al showed that squeeze duration on manometry was better in 7 men with idiopathic faecal incontinence compared to 24 women with faecal incontinence of a similar age. [641]

In 1999, Rao et al showed that squeeze duration on manometry was better in healthy men compared to healthy women. [642]

Telford et al in 2004 showed differences in fatigue rate index between 42 continent patients and 20 continent controls. Fatigue rate and maximum squeeze pressure were not different between the two groups. [643]

In the same year, Martinez-Puente Mdel et al showed that maximum duration of anal squeeze improved following biofeedback therapy in 53 patients with faecal incontinence and this was matched by an improvement in both incontinence scores as well as the patient’s subjective satisfaction. [604]

Work by Saad suggested that duration of squeeze might be a better distinguisher between normal and abnormal rather than resting or squeeze pressures. [644] However, Bilali and Pfeifer in 2005 [645] have more recently suggested that such measurements are not clinically useful in distinguishing normal from abnormal. However, they compared 96 faecal incon-
Conclusions (evidence level 3)

- Measurement of pressure in the anal canal on voluntary contraction is a parameter produced by devices of different type and size. There is no standardisation regarding how the measurement is made nor is there any universal agreement as to what unit of pressure should be used.
- There is no conclusive evidence to show that the measurement is reproducible.
- In many hands the measurement is sensitive to change following intervention.
- However, most workers agree that it does not have sufficient sensitivity and specificity to distinguish individuals with normal anal continence from those with anal incontinence.
- There is little evidence that it has any prognostic power regarding the outcome of intervention.
- It gives a more sensitive indication of anal pressure on voluntary contraction than digital examination.
- There have been a few studies which have investigated the endurance or fatigability of the external anal sphincter on voluntary contraction. There is no consensus as to its ability to distinguish individuals with normal anal continence from those with anal incontinence. There is some evidence that it is sensitive to change following intervention.

Recommendation (grade C)

- That measuring pressure changes on voluntary contraction of the external anal sphincter continues to be used clinically in those situations where such an objective measure will help in the management of a patient with faecal incontinence.
- That consideration is given to some degree of standardisation in the measurement of this parameter.
- That further investigation is made of the clinical value of measuring the endurance of the external anal sphincter and, if appropriate, the optimum way of measuring it.

5. VECTOR MANOMETRY

Pressures, both at rest and on contraction, can be measured radially within the anal canal and symmetry indices calculated to quantify the degree of asymmetry of pressures around the anal canal. Vector volumes can also be calculated from these pressures along the anal canal. These measurements do not have a sound scientific basis to them because they are not measuring true sphincter pressures (because pressure is a scalar quantity which cannot be different across the diameter of the anal canal). Rather, they are detecting directionally dependent forces which are artefactual and vary considerably with the stiffness and position of the catheter.

In 1992, Ho and Goh compared conventional anal manometry with computerised three-dimensional vector volume analysis in 25 people with normal faecal control and 22 patients with idiopathic faecal incontinence. The conventional parameters of mean resting and maximum voluntary contraction pressures did not differ significantly between normal and incontinent subjects. The computer calculated vector volumes and pressure symmetries (both at rest and during contraction) were not significantly different between the two groups. They concluded that the vector volume calculations gave little additional objective information to the conventional indices to discriminate milder degrees of idiopathic faecal incontinence. [647]

In 1993, Williams et al studied the effect of lateral sphincterotomy on internal anal sphincter function in patients with chronic anal fissure. They showed that lateral sphincterotomy produces a decrease in anal canal resting pressure and produces a significant increase in manometric asymmetry of the resting anal canal by creating a detectable segmental defect. [648]

In 1994, Yang and Wexner assessed anal pressure vectography (APV) in 50 consecutive patients with faecal incontinence and compared it with anal manometry, anal sphincter electromyography, and anal ultrasonography. Fifty consecutive patients with faecal incontinence were evaluated. APV showed significantly higher mean maximal resting and mean maximal squeeze pressures than conventional manometry. Thirty eight patients had isolated decreased EMG activity in a single quadrant. However, only five of the 38 patients (13.2%) had the same defect localised by APV. Twenty seven patients had anal sphincter defects on ultrasound examination but only 3 of the 27 patients (11.1%) had the same defects localised by APV. The authors concluded that APV has no apparent advantages, so its use cannot be supported because it had poor correlation with other anorectal physiological tests, including anal manometry, anal sphincter EMG, and anal ultrasonography. [649]
In 1997, Sentovich et al evaluated how well anorectal manometry and transanal ultrasonography diagnose anal sphincter injury. Computerised manometry analysis (mean maximum resting and squeeze pressures, sphincter length, and vector symmetry) and transanal ultrasonography were performed in 20 asymptomatic nulliparous women and 20 asymptomatic parous women, and the results were compared with those obtained in 31 incontinent women who subsequently underwent sphincteroplasty and, thus, had operatively verified anal sphincter injury. Decreased anal sphincter length and vector symmetry were found in only 42% of women with known anal sphincter injury. [650]

In 1999, Zbar et al compared conventional water-perfused and vector volume anal manometry in female patients with neurogenic fecal incontinence and chronic anal fissure and in healthy female volunteers. There was a statistically significant relationship between parameters measured by conventional manometry and those variables derived from vector volume manometry at rest and squeeze. [651]

In 2000, Fynes et al tried to determine the role of anal vector manometry in the assessment of postpartum anal sphincter injury and to establish the most suitable method of anal vector volume analysis for identifying significant external anal sphincter (EAS) injury in an at-risk parous population. They recruited 101 consecutive women with a history of instrumental or traumatic vaginal delivery and performed anal ultrasonography and anal vector manometry. Seventeen women had significant EAS disruption identified by anal ultrasonography. Anal vector symmetry index (VSI), determined by analysis of mean maximum squeeze pressure, yielded 100% sensitivity for significant EAS disruption, with a positive predictive value of 61%. They concluded that anal vector manometry complements endoanal ultrasonography and that VSI, determined by means of the squeeze pressure profile, correlates best with significant EAS disruption identified at anal ultrasonography. [652] However, it is difficult to see how vector manometry complements ultrasonography on the basis of this study; the figures suggest that 11 patients who had a defect on ultrasound would have been judged not to have a defect on VSI.

In 2002, Nazir et al used transanal ultrasonography and vector volume manometry to determine whether a correlation exists between anal incontinence, occult sphincter injuries, anal manometry values, and delivery variables in primiparous women after their first vaginal delivery. Nineteen of the 86 women studied experienced flatus incontinence postpartum. After 12 months, only one-third of the women were still incontinent. Fourteen women (19%) showed anal sphincter injuries on ultrasound but these were not associated with vector volume manometry values at 5 months. Vector volume manometry values were not associated with flatus incontinence at 5 months, but were reduced in women who had flatus incontinence at 12 months after labour. [653]

In 2002, Damon et al studied anal sphincter defects detected by ultrasonography, in a population of fecal incontinent parous females without previous anorectal surgery. From 100 consecutive incontinent patients, 61 females with at least one previous vaginal delivery and no past anorectal surgery were studied. Anal vector manometry was performed to measure anal pressures at rest and during voluntary squeeze, and the anal asymmetry index. Twenty-three had a normal sphincter (38 percent), and 38 (62 percent) had a defect detected by ultrasonography: 20 isolated defects of the external sphincter and 18 combined defects of the internal and external sphincters. Combined defects were significantly larger. The radial size of the defects was positively correlated with the severity of clinical symptoms. Anal pressure asymmetry index was significantly increased in the group with combined defects compared with the two other groups. An index of 25 percent or greater had a very high (100 percent) negative predictive value for the presence of a defect larger than 90 degrees. They concluded that anal vector manometry may be a useful tool to confirm the relation between echographic anal sphincter lesions and fecal incontinence. [654]

In 2003, Damon et al assessed the impact of rectal prolapse on anal pressure asymmetry in patients with anal incontinence. 44 patients, (42 women, mean age: 64 (11) years), complaining of anal incontinence, underwent anal vector manometry, endo-anal ultrasonography (to assess sphincter defects) and pelvic viscerogram (for the diagnosis of rectal prolapse). Resting and squeeze anal pressures, and anal asymmetry index at rest and during voluntary squeeze were determined by vector manometry. Patients with rectal prolapse had a significantly higher anal sphincter asymmetry index at rest, whether patients with anal sphincter defects were included in the analysis or not. Among patients without rectal prolapse, a higher anal sphincter asymmetry index during squeezing was found in patients with anal sphincter defects. They concluded that in anal incontinent patients, anal asymmetry index may be increased in case of anal sphincter defect and/or rectal prolapse. In the absence of anal sphincter defect at ultrasonography, an increased anal asymmetry index at rest may point to the presence of a rectal prolapse. [655]

In 2008, Rink et al studied in 61 patients at a median of 86 months after restorative proctocolectomy for ulcerative colitis using 3-dimensional vector manometry. The specificity and sensitivity of the vector volume at rest of the HPZ for the prediction of incontinence was 63.6% and 59.1%, respectively. The corresponding values were 67% and 68%, respectively, for radial asymmetry at rest. They
concluded that a strong anal sphincter at rest and a consistent radial distribution of the sphincter pressure are the most reliable indicators of continence after restorative proctocolectomy obtained by vector manometry but their clinical usefulness is limited. [625].

Conclusions (evidence level 3)

- Measurement of pressure in the anal canal by vector manometry is, at best, comparable to other methods of anal manometry.
- Measuring asymmetry by vector manometry is not as sensitive as endoanal ultrasound in detecting sphincter deficiencies.

Recommendation (grade C)

- Although vector manometry can be used to measure pressures in the anal canal for clinical purposes, it should not be used for diagnosing sphincter deficiencies where there is access to endoanal ultrasound.

6. RECTAL SENSITIVITY BY BALLOON DISTENSION

Some workers assess the response of the rectum to distension by a water-filled or air-filled balloon without manometry to assess the threshold volume for sensation (onset of sensation), sensation of desire to defaecate and maximum tolerated volume (urgency of defaecation). Whilst there are differences between different patient groups [656, 657] there is no validation or standardisation of the technique and no real literature on its sensitivity or specificity. Intuitively, values must depend on the size of the balloon, the rate of inflation and the substance with which it is inflated.

In 1978, Farthing and Lennard-Jones showed that the maximum volume of air tolerated within a rectal balloon was less in colitic patients than in normal subjects. Smaller volumes were tolerated by patients with a spontaneously bleeding mucosa than by those with less severe inflammation. Severe urgency of defaecation with incontinence was experienced by about half those with spontaneous mucosal haemorrhage but was infrequent among other colitics. [656]

In 1989, Fergusson et al compared the subjective response to rectal balloon sensation in 37 healthy subjects, 54 patients with idiopathic faecal incontinence, and 36 with complete rectal prolapse and incontinence. There was no significant difference for any parameter of rectal balloon sensation between patients with idiopathic faecal incontinence. Patients with complete rectal prolapse and incontinence differed only in onset of sensation. They concluded that the appreciation of rectal distension is maintained in idiopathic faecal incontinence. [658]

In 1990, Sun et al studied ramp distention of the rectum with water and air at randomised rates of 10, 20, 50, and 100 mL/min and during intermittent rapid distension with air in 12 normal male subjects. There were no significant differences between the results of ramp inflation with water or with air, and the repeated infusion of the same medium yielded reproducible results. However, they showed that the rectal sensory and anorectal motor responses to distension depend on the rate and pattern of distension. They concluded that results from different laboratories cannot be compared directly unless the pattern and rate of distension are the same. [659]

In 1991, Felt-Bersma et al showed, by rectal balloon distension in 80 mainly healthy volunteers (40 men and 40 women aged 20-87, mean 45 years) that the volume of rectal perception increased with age and should be taken into account when interpreting the measurement. [582]

In 1995, Hoffmann et al retrospectively evaluated anal manometric studies on 170 patients with varying degrees of faecal incontinence. They were divided into three groups based on presenting complaints: complete incontinence (incontinence of gas and liquid and solid stool), partial incontinence (incontinence of gas and liquid stool), and seepage and soiling (incontinence of small amounts of liquid and solid stool without immediate awareness). Amongst other parameters, the minimum rectal sensory volume, and minimum volume at which reflex relaxation first occurs, were compared with those of 35 control group subjects with normal faecal continence. The minimum rectal sensory volume was greater in all incontinent groups than in controls. Sensory volume of the seepage and soiling group was significantly greater than that of the complete incontinence and partial incontinence groups. The difference between sensory volume and the volume producing reflex relaxation was greatest in the seepage and soiling group and differed from that of the partial incontinence and control groups. They concluded that the findings suggest that the mechanism of incontinence is different in seepage and soiling patients and involves a ‘dyssynergy’ of rectal sensation and anal relaxation. [660]

In 1998, Rasmussen et al compared ‘standard’ anal manometry parameters with rectal compliance measurements in 36 patients with faecal incontinence and in 22 control subjects. Patients with faecal incontinence had lower rectal volumes than controls at constant defecation desire (median 138 mL and 181 mL, p < 0.05) and at maximal tolerable volume (median 185 mL and 217 mL, p < 0.05). They concluded that patients with faecal incontinence have a lower rectal volume tolerability than control subjects with normal anal function. [595]

In 2003, Chang et al in a randomised study treated 22 patients who had functional constipation with
impaired rectal sensation. Twelve were treated with electrical stimulation therapy and 10 with biofeedback therapy. Overall symptoms of patients significantly improved after each therapy in both groups but rectal sensory threshold volumes for desire and urge to defecate and maximal tolerated volume improved significantly only in the electrical stimulation therapy group. [661]

However, this test may have some relevance to faecal seepage because Rao et al in 2004 confirmed some of the conclusions of Hoffman et al [660] showed there was a link between impaired threshold for first rectal sensation and faecal seepage in a prospective study of 25 patients with faecal seepage, where their results were compared with 26 faecal incontinence patients and 43 healthy controls. [662]

Also in 2004 Chang et al, following the earlier work of 2003, reported the case of a 25-year-old female patient who complained of intractable constipation for ten years. She had impaired rectal sensation and was treated by electric stimulation therapy for the purpose of improving impaired rectal sensory function. After 14 sessions of electric stimulation therapy, her constipated symptoms improved dramatically. Furthermore, the desire and urge threshold volumes were decreased. [663]

In 2004, Shafik et al investigated the hypothesis that sympathetic skin response can be used as a tool for objective assessment of rectal sensation. The response was recorded in 24 healthy male volunteers using a surface electrode applied to the skin of the palmar surface of the subject’s hand and a reference electrode to the dorsum of the same hand. The EMG activity of the pelvic floor muscles was registered by a surface electrode fixed to the perineal skin and a rectal balloon was filled in increments of 10 mL of saline. Skin and pelvic floor responses occurred with every rectal sensation and corresponded with the volunteers’ subjective perception. The authors concluded that that they had identified a novel approach whereby skin response from the hand could act as a surrogate for measuring rectal sensation by balloon distension. However they acknowledged that further studies were required to investigate the role of this reflex in defaecation and sympathetic disorders. [664]

In 2005, Milone and DiBaise showed in 10 healthy volunteers that sildenafil increases rectal volumes to first sensation, desire to defecate and maximal tolerable volume. [665]

In 2007, De Ocampo et al examined sensory and motor responses of the anorectum during rectal distension in 23 healthy subjects by placing a six-sensor probe in the anorectum and utilising graded rectal balloon distensions. Studies were repeated in six subjects. In 4 subjects (17 percent) the senso-motor (anal contractile) response first occurred synchronously with a sensation of fullness (Group 1) and in 19 (83 percent) with a desire to defecate (Group 2). Mean balloon volume for inducing the sensorimotor response in Groups 1 and 2 were 80 ± 14 mL and 96 ± 26 mL and were not significantly different. Repeat studies showed good reproducibility (intraclass correlation coefficient = 0.9; p < 0.05). They concluded that a desire to defecate is associated with a unique, consistent, and reproducible anal contractile response: the sensorimotor response. This response could play an integral role in regulating anorectal sensation and function. [666]

Conclusions (evidence level 3)

- Measurement of rectal sensitivity to balloon distension is age and technique dependent.
- It is sensitive to change following intervention
- Faecally incontinent patients may have some degree of rectal hypersensitivity.
- There is a link between impaired first rectal sensation and faecal seepage.

Recommendation (grade C)

- The committee recommends that rectal sensitivity to balloon distension continues to be used in the assessment of the anorectum for clinical purposes.
- However, further investigation is required to explore the full potential of measuring this parameter in the patient with anal incontinence by standardising the technique.

7. ANAL AND RECTAL MUCOSAL SENSITIVITY TESTING BY ELECTRICAL STIMULATION

In 1986, Roe et al described a new technique for quantifying anal sensation utilising mucosal electrosensitivity and described the findings in 97 patients. Normal subjects (n = 20) have a sensory threshold varying from 2 to 7.3 mA; being most acute in the region of the anal valves. Sensory awareness also extends into the upper anal canal. Patients with faecal incontinence (n = 17) have a sensory deficit whilst patients with haemorrhoids have less sensitive mucosa displaced into the upper anal canal. Patients with acute fissure-in-ano (n = 10) have lower thresholds of sensation at the site of the fissure and slow transit constipation patients (n = 22) have normal anal sensation. They concluded that the technique is reproducible and should prove useful in the investigation of anorectal disorders. [667]

In 1988, Rogers et al utilised the same technique to compare, amongst other parameters, mucosal electrosensitivity in 11 patients with idiopathic faecal incontinence and nine normal controls. [668] Electrical
stimulation was by a constant current generator delivering square wave pulses of 0.1 ms and delivered at a rate of 5 pulses per second. Two platinum electrodes mounted on a probe delivered these pulses to the mucosa and the current was increased in steps of 0.1 mA until the patient experienced a tingling sensation. They showed that there was a sensory deficit in the anal canal in patients with faecal incontinence compared with controls. For example, the median threshold current was 10.1 mA in the mid anal canal of those with faecal incontinence compared to 3.7 mA for those with normal faecal control.

In 1995, Gee et al studied 16 subjects (mean (s.d.) age 50.7 (12.8) years, three men) on two separate occasions using two experienced investigators in random order. Amongst other tests, they carried out electrophysiological assessments of anorectal motor and sensory function. No significant differences were found between the results obtained by the two investigators in the measurements of the thresholds of mucosal electrosensitivity. They concluded that the standard tests of anorectal sensorimotor function are repeatable by different investigators. [569]

In 1990, Kamm and Lennard-Jones compared rectal sensation assessed by balloon distension and rectal mucosal electrosensitivity using a bipolar ring electrode. The methods were compared in 13 healthy control women and 26 women with severe idiopathic constipation. Balloon distension in the rectum revealed an elevated sensory threshold (16.9 ± 4.4 vs. 30.4 ± 3.1 mL air, controls vs. patients, p = 0.018) and the volume required to elicit a call to stool (61.1 ± 9.1 vs. 97.5 ± 6.4, p = 0.003) in subjects with severe constipation. The maximum tolerated volume was similar in the two groups. Rectal mucosal electrosensitivity testing demonstrated an elevated sensory threshold in the constipated subjects (16.3 ±3.0 vs. 27.4 ± 2.1 mA, p = 0.005). They concluded that electrical testing avoided the variables inherent in balloon distention and was well tolerated, accurately quantifiable, and reproducible. The raised threshold to electrosensory mucosal testing suggests the presence of a rectal sensory neuropathy in patients with severe idiopathic constipation. [669]

In 1995, Ho and Goh compared the accuracy and sensitivity of annular and unilateral electrodes in assessing patients with haemorrhoids, perineal descent, incontinence, constipation, or after low anterior resection (107 subjects). They found that in normal controls (n = 19), annular thresholds ranged from 0.5 to 2.7 mA and unilateral thresholds from 0.6 to 2.6 mA. In prolapsed hemorrhoids, unilateral was more sensitive than annular electrode in detecting deficits at the upper (p < 0.0001), mid (p < 0.005), and lower (p < 0.0005) anus. Patients with perineal descent had a sensory deficit in the upper anal canal, detected more consistently by unilateral electrode (p > 0.05). No significant abnormalities were found in neuropathic incontinence, after anterior resection and in patients with chronic constipation. Repeated measurements of the unilateral electroscopic technique were found to be consistent (r = 0.8878; p < 0.001). They concluded that by being more sensitive than the annular technique, the unilateral electrode method may become, with refinement, a useful test for quantifying anal sensation. [671]

In 1996, Meagher et al assessed the validity of tests of rectal mucosal electrosensitivity by studying 68 patients in three groups (group 1: 50 patients undergoing assessment in the anorectal physiology unit, group 2: 10 patients with coloanal or ileoanal anastomosis, group 3: 8 patients with a stoma). In addition the electrosensitivity was measured in groups 1 and 2 by placing the electrode, mounted on a catheter with a central wire, against the anterior, posterior, right and left rectal or neorectal walls. To assess the influence on this test of loss of mucosal contact due to faeces, a further 8 cases with a normal rectum had electrosensitivity evaluated with and without a layer of water soaked gauze around the electrode to stimulate faeces and prevent the electrode from making contact with the rectal mucosa. There was marked variance in the sensitivity of the different regions of rectal wall tested. In group 1 patients the mean sensitivities were: central 36.6 mA, anterior 27.4 mA, posterior 37.9 mA, right 22.3 mA and left 25.6 mA. This circumferential variation suggests that the pelvic floor rather than rectal mucosa was being stimulated. All patients in group 2 had recordable sensitivities, and the mean sensitivity threshold was significantly higher than group 1 patients in the central (p = 0.03), right (p = 0.03) and left (p = 0.007) positions. In group 3 the sensitivity was greater within the stoma at the level of the abdominal wall muscle than intra-abdominally or subcutaneously, again suggesting an extra-colonic origin of the sensation. The sensitivity threshold was significantly greater with the electrode wrapped in gauze (p < 0.01), and loss of mucosal contact was not detected by the EMG machine. They concluded that it is uncertain what is being measured during rectal mucosal electrosensitivity testing. It does not appear to measure mucosal sensitivity, and is probably influenced by the presence of faeces. [672]

In 1997, Felt-Bersma et al undertook a study to determine the anal sensitivity in controls and in different
patient groups and to establish which factors determine anal sensitivity. Anal sensitivity was assessed in 387 patients with different anorectal diseases and in 36 controls by means of a catheter with two electrodes placed in the anal canal. A constant current (square wave stimuli 100 microsec, pulses per second) was increased stepwise from 1 to 20 mA until the threshold sensation was reached. Controls had a threshold sensation of 3.4 ± 1.7 mA and this was significantly increased in patients with faecal incontinence, soiling, hemorrhoids, mucosal prolapse, constipation, anal scars, anal surgery, and sphincter defects; patients with faecal incontinence had the highest mucosal electrosensitivity (MES) of 6.7 ± 4.3 mA. They concluded that anal sensitivity is diminished in all patients with anorectal diseases except for anal fissures and proctitis but it has limited clinical value and should be used in conjunction with other tests in a research setting. [673]

In 1998, Poen et al investigated the long-term clinical and anorectal functional results 5 years after primary repair of a third-degree obstetrical perineal rupture. In 40 of the 117 women who responded to a postal questionnaire and attended for investigation, anal mucosal electrosensitivity was increased at 4.7(1.7) mA compared to the values in normal controls of 2.5(0.8) mA. However, the risk of incontinence was only related to the presence of a combined sphincter defect or subsequent vaginal delivery. [674]

In 1999, Yamana et al studied 32 patients who underwent low anterior resection for rectal cancer. Anorectal physiological studies were performed preoperatively and six months postoperatively. In univariate regression analyses, a longer preoperative high pressure zone and a more sensitive anal mucosa were associated with better postoperative defecatory function. Using multiple regression analysis, in which age, gender, the level of anastomosis, and preoperative physiologic parameters were examined as independent variables, a longer preoperative high pressure zone, a larger preoperative maximum tolerable volume, and lower sensory threshold of the anal canal were associated with better postoperative defecatory function. Postoperative function score was found to be predictable using the following formula: 1.47 + 0.496 x high pressure zone (cm) + 0.007 x maximum tolerable volume (ml) - 0.247 x sensory threshold (mA) of the anal canal.

Hence, they concluded that early postoperative defecatory function after low anterior resection is predictable from preoperative high pressure zone, maximum tolerable volume, and anal mucosal electrosensitivity. [627]

In 2005, Broens and Penninckx assessed the effect of age and sex on the rectal filling sensation and anal electrosensitivity and explored the relation between anal electrosensitivity and the parameters of the rectal filling sensation. Tests were carried out in 19 control subjects; 10 were younger than 60 years and 9 were older than that. Altogether, there were 11 men and 8 women. They showed that anal electrosensitivity did not differ between the two age groups but women had a significantly lower electrosensitivity 4 and 5 cm from the anal verge than men.

The rectal filling sensation did not differ between sexes. However, in the older age group, the rectal volumes required to induce filling sensations were smaller than those observed in the younger age. Anal electrosensitivity at different anal levels did not correlate with the rectal volume or pressure parameters of successive rectal filling sensations. They concluded that rectal sensation did not correlate with anal electrosensitivity, probably because the receptors are not stimulated by the type of anal stimulation used or because different receptors are involved. Hence, the rectal filling sensation test cannot be replaced by the simpler anal electro-sensitivity test. [675]

In 2007, Tomita and Igarashi examined the significance of the anal canal sensitivity contribution to soiling in 40 patients a mean of 103.6 months following ileostomy closure after ileal J pouch-anal anastomosis for ulcerative colitis. They studied 26 patients without soiling, 14 patients with soiling and compared them with a group of 28 healthy controls. They showed that there was significantly lower sensitivity in the proximal and middle anal canal in ileal J pouch-anal anastomosis patients with soiling. [676]

Conclusions (evidence level 3)

- Measurement of anal mucosal sensitivity testing by electrical stimulation is reproducible by different operators. There is no clear indication whether the measurement is affected by gender or age.

- Measurement of rectal mucosal sensitivity testing by electrical stimulation has been found to be reproducible by some workers but others have not found this and have demonstrated to some extent that the presence of faeces in the rectum affects the result.

- There are differences in the sensitivities between some patient groups and controls.

- Anal mucosal sensitivity is one of the factors that may help predict early postoperative defecatory function after low anterior resection.

Recommendation (grade C)

- Anal and rectal mucosal sensitivity testing by electrical stimulation has limited proven clinical value and it use should be currently restricted to research.
In 2001, Altomare et al studied the long term effects of stapled haemorrhoidectomy; particularly with regard to some concern about the risk of injury to the internal anal sphincter. Internal anal sphincter function and morphology, and anal canal sensitivity were studied prospectively in 20 patients (11 women) with stage III haemorrhoids. All underwent preoperative anorectal manometry, rectoanal inhibitory reflex testing and three-dimensional transanal ultrasonography. A test of anal sensation was administered to evaluate ability to discriminate between air and warm water. All the investigations were repeated 6 months after the operation. The maximal resting pressure, the maximal squeeze pressure, the rectoanal inhibitory reflex and the width of the internal anal sphincter did not change after operation. However, the ability of the anal mucosa to discriminate air from warm water improved in five patients. The authors concluded that stapled haemorrhoidectomy can improve anal sensation in patients with preoperative sensory impairment. [680]

Also in 2001, Salvioli et al quantified anal perception of temperature and light touch in 22 unselected patients with faecal incontinence (21 F, 33-75 yr). Control values were obtained from two groups of 11 (seven F, 32-53 yr), and 32 (18 F, 19-44 yr) volunteers. Most of the patients had low sphincteric pressures and ultrasonic abnormalities. Temperature perception was impaired in incontinent patients, to a greater extent in the proximal anal canal and in patients with passive, as opposed to urgency, incontinence. Intraluminal pressures for sensations of rectal distension were lower in incontinent patients (p = 0.02). Artificial stools elicited sensations of rectal filling at lower volumes than did a barostat bag, and in patients with urgency, as opposed to passive, incontinence. Therefore, they found that although temperature sensation is impaired, the perception of rectal distension is not always reduced in faecal incontinence. Artificial stool tended to induce sensations at lower volumes than did balloon inflation. They concluded that altered sensory mechanisms may contribute to the pathophysiology of faecal incontinence. [681]

In 2003, Chan et al used a thermal probe in the rectum to assess rectal sensation as an alternative to either balloon distension or electrical testing. This was carried out in 31 healthy subjects and compared with other anorectal physiological measurements. The median rectal heat threshold was similar in males (median, 47 C; range, 44-50 C) compared with females (median, 45 C; range, 43-50 C). There was a high degree of repeatability with rectal heat and balloon distension thresholds, but not electrostimulation thresholds. A strong correlation was found between rectal heat thresholds and defecatory desire and maximum tolerable volumes measured with balloon distension. The authors concluded that heat stimulation is a simple technique that has a high degree of repeatability and may be an objective assessment of sensory function in the rectum. [682]

In 1988, Miller et al used this technique to determine the thermal sensitivity in the anal canal in 20 continent patients with haemorrhoids and to compare the results with 40 control subjects and 22 patients with idiopathic faecal incontinence. Anal manometry was performed and sensation to mucosal electrostimulation and temperature change in the lower, middle, and upper zones of the anal canal assessed. Thermal sensation was impaired in the hemorrhoid group as compared with controls, but not to the same degree as in idiopathic faecal incontinence. There was some correlation between the two tests of sensation and the reproducibility of thermal sensory thresholds was reasonable (correlation coefficient of 0.82). They concluded that patients with hemorrhoids have a mild anal sensory deficit, but continence in this group is likely to be augmented by other factors. [678]

In 1996, Solana et al compared anorectal sensitivity to electrical and thermal stimuli in 21 healthy controls (11 females and 10 males; mean age 51.8 ±11 years, range 33-67) and 19 patients (18 females and 1 male; mean age 48 ±15 years, range 20-71) with obstructed defaecation. In the controls the electrical sensitivity threshold was minimal in the mid anal canal, where sensory receptor presence is greater. Sensitivity was significantly higher in the upper and lower anal canal regions and much higher in the rectum. A similar sensory profile was recorded in the patients with obstructed defaecation, though with significantly higher thresholds at all points with respect to the controls. The thermal stimulus thresholds in the lower and middle anal canal were significantly smaller than in the upper canal region and rectum, and the thresholds were again higher among the patients with obstructed defaecation than among the controls. In all cases the thresholds for heat were lower than for cold stimuli. They concluded that patients with obstructed defaecation had sensory deterioration at all points studied in the anal canal and rectum. Sensory pudendal neuropathy was found to be associated with the pudendal motor neuropathy. [679]
Conclusions (evidence level 3/4)

- Different patient groups have different responses to thermal testing of the anal canal and rectum.
- The reproducibility of the measurement is unknown regarding thermal testing of the anal canal but appears to be reproducible in the rectum (in the one study that looked at this)
- Intervention may alter the response of the anal canal to thermal testing.

Recommendation (grade C/D)

- Thermal testing of the anal canal and rectum has no proven clinical value and it use should be restricted to research.

9. SALINE RETENTION TESTS

The saline continence/retention test assesses the ability of the lower GI tract to retain fluid in the rectum. It is used as an outcome measure following treatment [683-686] but there is a paucity of data regarding what is normal.

The saline continence test measures the ability to retain 1500 ml of saline infused in the rectum, via a tube at a rapid rate of 60 ml/min whilst the patient is seated on a commode. The time and volume of first leak as well as the total volume leaked can be measured. [585]

In 1982, Leigh and Tumberg evaluated 76 patients with diarrhea due to a variety of causes. Using a saline retention test, they found that all but 7 of 42 continent subjects could retain more than 500 ml before leaking, whereas 19 of 22 frequently incontinent subjects leaked after infusion of less than 500 ml. They proposed that the saline-infusion test was a simple method of measuring this disturbance of anorectal function. [687]

In 1988, Allen et al compared the ability to retain rectally infused saline in three groups of subjects: 14 patients complaining of faecal incontinence, 14 age- and sex-matched continent patients, and 14 sex-matched younger normal controls. An additional group of unmatched normals and incontinent patients demonstrated significant differences in their ability to retain rectally infused saline. The patients leaked sooner and retained less; however, the performance of the normals was considerably reduced from that reported in previous studies. [688]

In 1989, Penninkcx et al described a balloon-retaining test which consists of progressive filling of a compliant intrarectal balloon in a patient in the sitting position. The pressure inside the balloon is monitored and the patient is asked to retain the balloon as long as possible and to report first, constant, and maximal tolerable sensation levels. They claimed that this test is a more realistic approach to the evaluation of faecal continence than the rectal saline infusion test and proposed that it permits objective evaluation of the effect of different treatments in incontinent patients. [689]

Also in 1989, Yoshioka et al performed posterior abdominal rectopexy in 12 patients with a full-thickness rectal prolapse of whom 9 had faecal incontinence. The prolapse was successfully controlled in all cases and six of nine patients were rendered continent. They found that delayed leakage during the saline infusion test preoperatively helped predict the return of continence. [690]

In 1990, Felt-Bersma et al carried out the saline-infusion test in 350 patients, 178 of whom had faecal incontinence and 172 of whom were continent. Compared with continent patients, incontinent patients leaked earlier and more with the saline infusion test. However, differentiation between incontinent and continent patients was not possible because there was considerable overlap. [629]

In 1995, Penninkcx et al carried out the rectal saline infusion test and the balloon-retaining test in 27 control subjects (M:8, F:19; mean age: 47 yr) and in 40 incontinent patients (M:5, F:35; mean age: 49 yr). The uncontrollable evacuation of a balloon, progressively filled with water at 60 ml/min, before the maximum tolerable sensation level was reached, was related to the degree of clinical incontinence. The balloon-retaining test proved to be superior to the rectal saline infusion test for the determination of the severity of incontinence. The saline infusion test, however, was found to be more adequate to identify minor defects of continence. [592]

Conclusions (evidence level 3/4)

- Different patient groups have different abilities to retain saline or a fluid-filled balloon in the rectum.
- Although continent individuals have better retention than incontinent patients there is considerable overlap between the two groups
- The reproducibility of the measurement is unknown
- It may help predict the return to continence of some patient groups post-operatively

Recommendation (grade C/D)

- Saline retention and balloon retention tests have limited clinical value and it use should be restricted to research.

10. RECTAL COMPLIANCE

Isometric and isobaric distension of the rectum to assess its compliance (the ratio of changes in volume to changes in pressure) are options available for
testing of the faecally incontinent (although more commonly used for those with constipation).

In isometric assessment, compliance of the rectum is assessed in a manner similar to cystometry whereby a rectal balloon is filled with water up to a specified volume and the pressure change inside the balloon from the start to the end point enable compliance to be calculated (after correcting for the compliance of the balloon).

In the isobaric assessment of compliance, a barostat (a device used to maintain constant pressure in a closed system) is connected to a thin, infinitely compliant bag which is inflated in the rectum in a variety of ways; often ‘stepwise’ and ‘ramp’ are used. The volumes at various pressures and levels of rectal sensation can be measured.

Measurement of rectal compliance has been used in both paediatric [691, 692] and adolescent [693] constipated subjects. It has also been used in adults with constipation. [694] It has also been used in the investigation of subjects with irritable bowel syndrome (IBS) [695], ulcerative colitis [696] and obstructed defaecation. [697]

There is little data to assess its sensitivity in detecting the faecal incontinent from healthy subjects.

In 1986, Varma and Smith showed that in 15 patients, the proctometrogram (a method of measuring rectal distensibility by continuous controlled fluid inflation with a balloon) was reproducible. [698]

In 1990, Rasmussen et al studied rectal compliance in 31 patients with faecal incontinence, 8 patients with constipation, and 16 control subjects. Patients with faecal incontinence experienced a constant defaecation desire at a lower rectal volume and also had a lower maximal tolerable volume and a lower rectal compliance than control subjects (median 126 vs 155 mL, 170 vs 220 mL, and 9 vs 15 mL/mm Hg, respectively; p < 0.05). Constipated patients had a higher constant defaecation desire volume and maximal tolerable volume than controls (median, 266 mL and 300 mL; p < 0.05). There were no differences in the parameters between patients with idiopathic faecal incontinence and patients with incontinence of traumatic origin, indicating that a poorly compliant rectum in patients with faecal incontinence may be secondary to anal incontinence due to the lack of normal reservoir function. [699]

In 1992, Sorensen et al measured the volume of air inflated in a latex balloon placed in the rectum and the corresponding pressures in 48 subjects (24 men and 24 women) at three points: (1) earliest defaecation desire; (2) constant defaecation desire; and (3) maximum tolerable volume. The rectal pressures in all three cases were higher in men than in women. Woman aged over 60 years had higher rectal compliance than men in the same age group, while no difference was found between men and women below the age of 60 years. Day-to-day variation of the measurements was tested in ten subjects. Reproducibility was good only for maximum tolerable volume. Reproducibility of rectal compliance decreased with increasing values for this parameter. They concluded that maximum tolerable volume is a reproducible parameter and suitable for clinical use in evaluation of patients with faecal incontinence or constipation. [700]

In 1997, Whitehead and Delvaux presented a standardisation of barostat procedures for testing muscle tone and sensory thresholds in the GI tract. [701]

In 1998, Hammer et al examined the reproducibility of repeated assessments of sensory perception, basal tone, and compliance and/or elastance of the rectum during distension. They studied 5 healthy volunteers and found that repeated distensions evoked reproducible responses of sensation and compliance and/or elastance on a single day, providing a conditioning distension preceded them. They also found that day-to-day variability was also sufficiently small to allow valid comparisons to be made on different days in healthy persons. [702]

In 1998, Rasmussen et al studied whether anorectal pressure gradients discriminated better than standard anal manometry between patients with faecal incontinence and subjects with normal anal function. Anorectal pressure gradients were measured during rectal compliance measurements in 36 patients with faecal incontinence and in 22 control subjects. With standard anal manometry, 75% of patients with faecal incontinence had maximal resting pressure within the normal range, and 39% had maximum squeeze pressure within the normal range. Anorectal pressure gradients did not discriminate better between faecal incontinence and normal anal function, since, depending on the parameters used, 61%-100% of the incontinent patients had anorectal pressure gradients within the normal range. They concluded that measurements of anorectal pressure gradients offer no advantage over standard anal manometry when comparing patients with faecal incontinence to controls. [595]

In 2000, Felt-Bersma et al measured the rectal compliance in 974 consecutive patients and compared them with 24 controls. Rectal compliance measurement was performed by filling a latex rectal balloon with water at a rate of 60 ml per minute. Volume and pressure at three sensitivity thresholds were recorded for analysis: first sensation, urge, and maximal toleration. At maximal toleration, the rectal compliance (volume/pressure) was calculated. They did not see any effect of age or gender in either controls or patients. They concluded that rectal compliance measurement
with a latex balloon is easily feasible and some patient groups showed an abnormal rectal visceral sensitivity and compliance. However, there was an overlap with controls. [703]

In 2001, Krogh et al noted that pressure-volume measurement during distention with a compliant balloon is the most commonly used method for computation of rectal compliance. However, they stated that intraindividual and interindividual variations are apparently large, restricting the usefulness of the method. Therefore, they compared the in vivo reproducibility of pressure-volume measurement during distention with a compliant balloon and pressure-volume measurement during rectal distention by a large, noncompliant bag, and rectal impedance planimetry. They also carried out an in vitro study of their reproducibility and validity. For the in vivo study, 10 healthy volunteers (6 men) aged 21-59 years were randomised to either rectal pressure-volume measurement with a compliant balloon or rectal impedance planimetry. After a one-hour rest, the other procedure was performed. After two weeks, both procedures were again performed in the same order. During rectal impedance planimetry the volume of the bag used (maximum volume 450 ml; secured at both ends to the probe) was continuously registered, measuring pressure-volume relations during rectal distention by a large, noncompliant bag. They found that in vivo reproducibility for pressure-volume measurement with a large, noncompliant bag and rectal impedance planimetry was significantly better than for pressure-volume measurement with a compliant balloon. No statistically significant difference was found between pressure-volume measurement with a large, noncompliant bag and rectal impedance planimetry. In vitro reproducibility was studied using polyvinyl chloride tubes with known cross-sectional areas. The reproducibility of pressure-volume measurement with a large, noncompliant bag and rectal impedance planimetry was good, but some elongation occurred, reducing the validity of pressure-volume measurement with a compliant balloon. Coiling and elongation of the balloon within the lumen were major sources of error for pressure-volume measurement with a compliant balloon. They concluded that in vivo and in vitro reproducibility of methods used for measurement of rectal compliance can be improved by restricting the effects of elongation within the lumen either by using a large-volume, noncompliant bag or by rectal impedance planimetry. However, pressure-volume measurement will to some degree depend on the properties of the balloons or bags. [704]

In 2001, Herman et al showed, using a rectal barostat that transanal endoscopic microsurgery in 33 patients with small, mobile rectal tumors, rectal compliance significantly changed 3 weeks after surgery and remained low at 6 months. There was a control group of 20 healthy volunteers. [612]

In 2005, Cremonini et al demonstrated that isobaric testing is fairly reproducible in healthy volunteers. The 34 participants had rectal barostat assessments carried out three times, at 2 centres. The results from the 2 centres differed minimally and the authors concluded that pressure threshold for pain and sensory ratings at 36-48 mmHg of distension are reproducible. [705]

In 2005, Siproudhis et al showed that rectal compliance was altered in some patients with faecal incontinence. They investigated 148 patients (12 men, 136 female) with incontinence to liquid and/or solid stools. Pain during isovolumic rectal distension at a level of 100 mL or less was experienced in 21 subjects. They showed that, as defined by isobaric distensions, incontinent patients with this low maximal tolerable volume more frequently had a poorly compliant rectum when compared with those with a higher maximal tolerable volume. Unsurprisingly, incontinent patients with low maximal tolerable volume more frequently had a hypersensitive rectum when compared with those with normal or high maximal tolerable volume. However, only four of 21 incontinent subjects with low maximal tolerable volume had an isolated hypersensitive rectum. They concluded that both sensitivity and compliance are altered in patients with low maximal tolerable volume but a more extensive study of the role of sensory and compliance aspects of subjects with incontinence is warranted. [706]

In 2006, Fox et al validated a barostat measurement of rectal capacity. Slow staircase (0-40 mm Hg) and rapid phasic (12-40 mm Hg) barostatic distentions were performed on two separate days in 41 healthy, continent subjects, filling sensations were assessed by visual analog score. Correction for rectal capacity measured at 40 mm Hg reduced the “normal range” of compliance measurements. Compared with unadjusted volume measurements, normalised rectal volume (percentage filling relative to rectal capacity) improved the description of rectal sensation visual analogue score. They concluded that barostat measurements of rectal capacity at 40 mm Hg are highly reproducible and not affected by distention protocol. Correction for rectal capacity provides an assessment of rectal wall stiffness independent of rectal geometry and improves the association of barostat volume measurements with rectal sensitivity and continence. [707]

In 2008, de Nardi et al studied 10 patients with third-degree and fourth-degree haemorrhoids who underwent stapled haemorrhoidopexy. One week before and six months after surgery, they underwent three different rectal distensions (pressure-controlled stepwise, volume-controlled stepwise, and ramp) controlled by an electronic barostat. They showed that rectal distensibility and volume thresholds for sensations decrease after stapled haemorrhoidopexy and persist for at least six months after surgery. [708]
The American Gastroenterological Association concluded in 1999 that measurement of rectal compliance, by whatever means, had no established clinical value. [584]. They stated that although the measurement appears to be reproducible in some patients and is sensitive to change in some patients, there is overlap of values between abnormal and controls and it has no role in the prediction of outcome. Therefore, its clinical value has still not been demonstrated. Papers published since 1999 do not appear to have substantially challenged this view.

A recent report from the German Societies of Neurogastroenterology (committee for proctology), Abdominal Surgery (coloproctology working group), and Coloproctology concluded that if compliance measurements have to be carried out, they are best done with a ‘static’ system measuring the pressure change on instilling 100 mL of fluid in the rectal balloon rather than using a barostat. [709]

Conclusions (evidence level 2)

- Measurement of rectal compliance is fairly reproducible to some extent; particularly at the maximum tolerable volume.
- There are differences in rectal compliance between some patient groups and controls. However there is a fair degree of overlap and there is no proven clinical benefit from carrying out this measurement.
- There is some evidence that rectal compliance is altered by intervention.

Recommendation (grade B)

- Measurement of rectal compliance has limited clinical value and its use should be restricted to research.

11. NEUROPHYSIOLOGICAL TESTING

There are some electrophysiological tests employed in faecal incontinence. The techniques and their limitations are described in the chapter relating to imaging, neurophysiology and other tests and there has been a recent review paper [710]. However, it is worth briefly mentioning a few points here.

a) Pudendal nerve motor latency

Pudendal nerve terminal motor latency (PNTML) testing has been applied in lower GI tract dysfunction since its development in 1984 [711]. An intrarectal device electrically stimulates the pudendal nerve where it angulates around the ischial spine in the pelvis and the latency is the measurement of the time taken for the electrical impulses to travel down the nerve and cause the external anal sphincter to contract. The initial work by Kiff and Swash showed that patients with faecal incontinence had a slowing of electrical conduction along the pudendal nerves compared to those with normal faecal control.

Whilst initially it was used to investigate the aetiology of faecal incontinence, it has since been used prognostically to predict likely success from various operative procedures such as post anal repair, procedures for rectal prolapse and sphincteroplasty. However there are different opinions regarding its use in this way. For example, Gilliland et al demonstrated that it has good prognostic value in predicting success following sphincteroplasty [712] whilst Chen et al in the same year demonstrated it has no prognostic ability in this respect [713].

These differences in conclusions probably reflect the fact that this is an inherently insensitive test (see chapter on imaging, Neurophysiology and other Tests) which is operator dependent and it is probably for limitations such as these that the American Gastroenterological Association in 1999 could not recommend its use in faecal incontinence [584]. Nevertheless some workers still regard it is a useful test and even spend time considering how best to teach the technique to trainees [714]. It continues to be widely used, particularly in a research setting [715, 716] when trying to understand the effects of therapeutic intervention.

Initial work showed some correlation between PNTML and external anal sphincter function as assessed by manometry. [717] However, several workers have more recently demonstrated that pudendal nerve terminal motor latency does not correlate with the function of the external anal sphincter [718-720], even when considering patients with intact sphincters on endoanal ultrasound.

Bilateral neuropathy has been shown to correlate with poor resting pressure in the anal canal but not with squeeze pressures [721]

Chemoradiation prior to restorative proctectomy for rectal cancer appears to have a significant risk of prolonging nerve latencies [722]

Fistula and haemorrhoid surgery do not appear to affect pudendal nerve latencies (although a mean of 2.4 ms in both groups tends to suggest that either these patients are already compromised or the technique of measurement is not ideal) [723]

Even recently its value in predicting success from sacral nerve stimulation has been assessed although it has not been found to have any predictive value [724]

Obtaining the same measurement by intravaginal stimulation appears to produce equivalent results to intrarectal stimulation [725]

Although most nerve latency assessments are carried out with a digital device, other workers have reported good results using an externally manipulated device which causes less discomfort to the patient. [726, 727]
Recently, the whole compound muscle action potential (CMAP) from the external anal sphincter (produced by stimulating the pudendal nerve) has been studied [728]. Initial results show some differences between nerve latency and the other parameters of the CMAP (the amplitude of the response, the duration of the response and the area under the curve). However, these differences may prove to be of no real clinical significance and the CMAP may have no real advantage over PNTML.

Pudendal nerve latency testing has also been used in studying perineal neuralgia although the measurements have not been of much use in detecting the problem, clinical evaluation has been shown to be superior [729].

- **NORMAL VALUES OF PNTML**

Normal values of PNTML have been published but vary widely. Pradal-Prat et al describe average values of 5.52 ± 1.9 ms on the right and 5.74 ± 1.6 ms on the left in male subjects and 6.16 ± 1.8 on the right and 6.42 ± 1.96 on the left in female subjects. [730]

Lefaucheur reported values of between 1.8 to 5.6 ms (mean ± SD 2.94 ± 0.8 ms) using a St Mark's electrode and a range of 2.2 to 5.4 ms (3.7 ± 0.9 ms) using an externally manipulated device [727].

Many workers use the threshold values of between 2.2 ms and 2.4 ms, reported by Ricciardi [721] with 2.2ms being reported by Hill et al [719]; derived from the previous work of Smith et al [731] and Allen et al [726].

Tetzschner reported normal values for mean PNTML of 1.91 ms (2 SD, 0.52 ms) in women and 1.74 ms (2 SD, 0.33 ms) in men [732]. Allen et al reported a mean value of 1.9 ms (1 SD, 0.2ms) in the immediate post-partum period and 8 weeks post-natally in over 50 women having their first child. [726]

Smith et al reported a mean value of 1.6 ms (1 SD, 0.2 ms) in 28 nulliparous women and 1.7 ms (1 SD, 0.2 ms) in 14 parous women with normal urinary control. Women with USI had a mean value of 1.9 ms (1 SD, 0.2 ms); 42 women with both USI and genito-urinary prolapse had a mean value of 1.9 ms (1 SD, 0.3 ms), whilst continent women with genito-urinary prolapse had a mean value of 2.1 (1SD, 0.3 ms). [731]

- **REPEATABILITY OF PNTML**

There is some evidence to suggest that PNTML has both good intraobserver and interobserver reproducibility [732].

**Conclusions (evidence level 2/3)**

- The substantially different published ‘cut-off’ values discriminating normal from abnormal demonstrate that the measurement is operator dependent and may often not be carried out in an optimal fashion.
- There is no conclusive evidence that it is predictive of success following intervention.
- Patients with incontinence have may have longer latencies than continent individuals but there is considerable overlap between the groups.

**Recommendation (grade B/C)**

- Measurement of pudendal nerve motor latency has no proven clinical value.
- There may be merit in continuing to use it as a research tool provided that it is carried out in a well-controlled, optimal manner. Although it is an inherently insensitive measure of neuropathy, patients with genuinely markedly prolonged values of latency could have a different response to therapy compared to those who do not.

**b) Needle electromyography**

Needle EMG of the external anal sphincter has been used for many years to help understand the aetiology of faecal incontinence. Both single fibre [733] and concentric needle techniques [734] have been used and continue to be used in a research setting[735, 736]. In a clinical setting, concentric needle EMG has been used to map the integrity of the external anal sphincter but the advent of endoanal ultrasound, which is a more comfortable procedure, has largely made this application of EMG obsolete [737]. The current sole clinical application for concentric needle EMG is in the investigation of possible anismus (see later) where it is considered to be more sensitive than defaecography.

**c) Strength-duration tests**

The strength-duration test is an electrophysiological test of superficial muscle which predates EMG. It can determine muscle denervation directly by putting a surface electrode over the muscle, applying square waves of diminishing pulse width and determining at each pulse width the current required to elicit a twitch from the muscle. Normally innervated muscle and denervated muscle have different shaped curves when the current required to elicit a twitch is plotted against the pulse width. Denervated muscle is less excitable and requires more current to elicit a response. This technique has recently been applied to the external anal sphincter and distinguishes people with normal faecal control from those with faecal incontinence, especially when combined with manometry [738]. Work has confirmed that this technique is measuring properties of the sphincter [739] and the optimum position for stimulating the muscle has been
d) Endoanal ultrasound

Perhaps one of the universal investigations relating to faecal incontinence, along with manometry, is that of endoanal ultrasound to image the sphincters. The usefulness of this is discussed in the chapter on Imaging, Neurophysiology and other Tests.

V. TESTS RELATING TO SECONDARY INCONTINENCE

1. RECTOANAL INHIBITORY REFLEX

In the normal, healthy individual, the internal sphincter relaxes in response to rectal distension. [547, 742] In some individuals, there can be a lack of the nervous connections between the upper GI tract and the internal sphincter (e.g. Hirschsprung’s Disease) [743-745]. Usually this is congenital and occurs in infants but there are rare occasions when it can manifest itself in the adult. [746]

The relaxation of the internal sphincter in response to rectal distension can be simply be assessed by inflating a balloon in the rectum and measuring pressure in the anal canal – a decrease in pressure indicating the presence of the rectoanal inhibitory reflex (RAIR).

Technically, the reflex can be difficult to elicit if the anal canal has poor resting pressure.

Whilst biopsy is the gold standard investigation for Hirschsprung’s Disease, there is evidence that looking for the RAIR is just as sensitive [747] and is an effective screening test before biopsy is considered to provide the definitive diagnosis. [857]

In 2007, Kawahara et al described a micromanometry sleeve technique for assessing the RAIR in newborn infants. They claim that the technique has very good sensitivity. [748]

A systematic review in 2006, compiled from the results of the testing of 933 infants, confirms that manometry and rectal suction biopsy are the most accurate tests in the diagnostic workup of Hirschsprung disease. [749]

Assessment of the RAIR has not been confined to infants. In 1998, Deen et al used it to assess 30 patients with diabetes and compare it with the data from 22 age- and sex-matched healthy controls. Twelve of the diabetics had impaired continence for gas (n = 12) and liquid faeces (n = 3). None of the controls had incontinence. They classified the RAIR into three categories: normal, present, abnormal (requiring more distension than normal to elicit a response). They found that the RAIR was present in eight, abnormal in five (one incontinent) and absent in 17 (11 incontinent) diabetics, while it was present in 18 and abnormal in four controls (p = 0.031). They concluded that the RAIR was impaired in significantly more patients with diabetes than controls and that it was either impaired or absent in all diabetic patients with incontinence. [750]

In 2007, Shafik et al [751] noted that the RAIR was elicited with a lower volume of rectal distension in a large proportion of women who suffer from the inadvertent passage of flatus during intercourse compared to women without this problem.

There is also evidence that the RAIR can be altered by therapy:

In 2002, Sunic-Omejc et al treated 49 children with chronic idiopathic constipation; 24 were allocated to conventional and 25 to biofeedback therapy. Amongst other factors, the volume to elicit the RAIR became significantly higher in the group who had had biofeedback therapy (and this group had a better symptomatic response to therapy compared to the group treated with conventional therapy). [752]

In 2003, Saigusa et al retrospectively reviewed the records of 100 patients who had ARPS before and after restorative proctocolectomy with ileal pouch-anal anastomosis for mucosal ulcerative colitis. The rectoanal inhibitory reflex was noted in 96 patients before surgery, but it was found in only 53 (53 percent) after ileostomy closure. Incontinence status data was available in only 62 of the 100 patients (32 RAIR-positive; 30 RAIR-negative). There were significant differences relative to the incidence of nocturnal soiling (12/30 (40%) 23/32 (72%), p = 0.0012) favouring the presence of the rectoanal inhibitory reflex. They concluded that preservation of the rectoanal inhibitory reflex correlated with a decrease in the incidence of nocturnal soiling after double-stapled ileoanal reservoir construction. [753]

In 2004, Sangkhathat et al showed that the RAIR was present in 94% of cases without constipation and 12.5% of cases with constipation following anoplasty in 24 infants aged less than 3 years. They concluded that RAIR plays an important role in emptying function and, as far as possible, this function should be preserved during reconstruction. [754]

Conclusion (evidence level 1/2)

- Assessment of the rectoanal inhibitory reflex in infants is a valuable tool in screening for Hirschsprung’s Disease.

Conclusions (level 3)

- The rectoanal inhibitory reflex may be different in different patient groups and can be modified by intervention.
Recommendation (grade A/B)

- Assessment of the rectoanal inhibitory reflex by manometry is clinically valuable in screening for Hirschsprung’s Disease.

Recommendation (grade C)

- Assessment of the rectoanal inhibitory reflex in any other patient group is of no proven clinical value.

2. ANISMUS

When a patient attempts to defaecate by initiating a Valsalva manoeuvre, puborectalis and the external sphincter should relax. In some patients, the muscles tighten up and this is termed anismus.

Its presence can be detected by EMG of the muscles using surface electrodes or needle electrodes. Evacuation proctography is also used to detect anismus but the results do not always correlate with EMG and evacuation proctography may be a less sensitive indicator of anismus. [755, 756]

Difficulty evacuating a rectal balloon (see next section) is also used as a marker for anismus but again, this does not always correlate with EMG. [755, 756]

A further option to detect anismus is by measuring pressure in the anal canal when the patient performs a Valsalva manoeuvre. [757] If a water-perfused system is used, this may stimulate abnormal muscle activity and overdiagnose anismus. [758] Movement of the pressure sensor during straining is another confounding factor in this assessment and it is not particularly sensitive.

In 2007, Murad-Regadas et al used a different imaging approach to determine anismus. They showed that on anal endosonography, changes in the ano-rectal angle on straining correlated with the presence or absence of anismus as determined by anal manometry [759]

Therefore, it can be seen that there several different methods to test for the presence or absence of a paradoxical contraction of puborectalis and the external anal sphincter on straining. However, measurements by the different techniques are not always in agreement and, whilst it is tempting to consider that needle EMG may be the most sensitive indicator of anismus, there is no real evidence to substantiate such a claim. Perhaps the presence of anismus, detected by one of the methods above, is best confirmed with a positive finding on one of the other tests. This sensible approach was suggested by Park et al in 1996. [760]

The other consideration relating to this topic is that it is difficult to know what the clinical significance of the finding of anismus is. Although there are individuals with defaecatory difficulty who have the finding of anismus, there appear to be many patients who have no difficulty with evacuation who also show evidence of anismus. [756, 761, 762]

Nevertheless, if anismus is treated by biofeedback or botulinum toxin, some patients will show relief of their symptoms and a measurable normalisation of muscle function on straining. [763, 764]

Conclusions (evidence level 3)

- Anismus, the paradoxical contraction of puborectalis and the external anal sphincter on straining, can be detected by various techniques. The techniques all have different sensitivities to detect this phenomenon but there is no evidence to demonstrate which is the best.
- Although anismus can be found in patients with difficult defaecation, it is present in many who do not have such problems. Therefore its clinical significance is uncertain.
- Treatment of anismus can result in normalisation of muscle function and defaecation difficulty in some patients

Recommendation (grade C)

- Techniques to detect anismus may have some validity and lead to the effective treatment of some patients with difficult defaecation.
- The clinical significance of anismus needs more verification and the optimum technique to detect it needs to be determined

3. RECTAL COOLING TEST

In 2007, Shafik et al carried out measurement of rectal pressure with saline at 30°C and then at 4°C. They found that the iced fluid increased rectal tone in healthy controls and constipated patients with anismus while it had no effect in the other patients with consipation. They postulated that the lack of increase of rectal tone may be secondary to rectal inertia. They concluded from this preliminary study that this test might be useful in subdividing constipated patients into those who have rectal inertia and those who have anismus. [765] There have been no further reports on this measurement.
4. BALLOON EXPULSION TESTS

The test determines the ease with which a balloon in the rectum can be expelled. It is alleged to help determine the cause and management of difficult defaecation [766] and study the effects of treatment [767, 768]. However the lack of standardisation coupled with the often unphysiological position a patient has to adopt for defaecation is a current limitation of tests of this sort.

5. AXIAL FORCES

In 2006, Bharucha et al studied the dynamics of defaecation. They measured axial rectoanal forces with an intrarectal sphere or a latex balloon fixed at 8, 6, or 4 cm from the anal verge and connected to axial force and displacement transducers. [769] Rectoanal forces and rectal pressures within the latex balloon were measured at rest and during squeeze, simulated evacuation, and a Valsalva manoeuvre.

The measurements were carried out in 12 asymptomatic women and 12 women with symptoms of difficult defaecation. Anal resting and squeeze pressures were also assessed by manometry and were similar in control patients and symptomatic patients.

At rest, axial rectoanal forces were directed inward and increased as the device approached the anal verge. Control patients augmented this inward force when they squeezed and exerted an outward force during simulated expulsion and a Valsalva maneuver.

The force change during these manoeuvres was also affected by device location and was highest at 4 cm from the verge. In the patients with difficult defaecation, the force at rest and the change in force during all manoeuvres was lower than in control patients.

The rectal pressure during a Valsalva maneuver was also lower in those with difficult defaecation compared to control patients, suggestive of impaired propulsion. They concluded that the women with defecatory symptoms had weaker axial forces not only during expulsion but also during a Valsalva manoeuvre and when they contracted their pelvic floor muscles, suggestive of generalized pelvic floor weakness.

This is an interesting development but the sample size is much too small to determine whether this test has any clinical or research potential. There have been no further publications relating to this measurement.

VI. PUBLISHED RECOMMENDATIONS/GUIDELINES REGARDING PRACTICE OF ANORECTAL PHYSIOLOGY STUDIES

To date, there has been no universal standardisation of the tests, the terminology or the units of pressure employed in anorectal physiology studies. In 2007, there were some recommendations regarding manometry (including sensory testing and compliance measurement) published in German [709]. 8 years prior to that, there were recommendations published by the American Gastroenterological Association [584] and even earlier in 1989, a British working party made some recommendations relating to these measures [770]. None have been universally adopted.

In 2002, Azpiroz et al stated that tests for which there is consensus regarding their clinical utility include 1) resting anal canal pressure, 2) anal canal squeeze pressure (peak pressure and duration), 3) the rectoanal inhibitory reflex elicited by balloon distension of the rectum, 4) anal canal pressure in response to a cough, 5) anal canal pressure in response to defaecatory manoeuvres, 6) simulated defecation by means of balloon or radiopaque contrast, 7) compliance of the rectum in response to balloon distension, and 8) sensory thresholds in response to balloon distension. However, they acknowledged that the clinical utility of all anorectal manometric tests is limited by the relative absence of 1) standardisation of test protocols and 2) normative data from a large number of healthy individuals. They also stated that the interpretation of these diagnostic tests is also complicated by the fact that patients are able to compensate for deficits in specific physiological mechanisms maintaining continence and defaecation by utilising other biological and behavioral mechanisms. [771]

In 2004, Kouraklis and Andromanakos discussed evaluating patients with anorectal incontinence. They discussed the investigations used to evaluate anorectal physiology including anorectal manometry, anal endosonography, nerve stimulation techniques, electromyography, defaecography, endoluminal magnetic resonance imaging, the saline continence test, and the balloon-retaining test. They concluded that, although all of these tests are important, the most useful for patients with incontinence are anal manometry, anal endosonography, and the pudendal nerve terminal motor latency test, because they can identify anatomical or physiological abnormalities for which there may be effective treatments. [772]

In 2004, Bharucha discussed outcome measures for faecal incontinence. Whilst acknowledging that there is no standardisation for anal manometry, he expressed the opinion that, providing careful attention was paid to techniques, that there was sufficient
reproducibility for anal pressures, rectal compliance and sensation to enable them to be used as outcome measures. He outlined problems with surface EMG and pudendal nerve terminal motor latency assessment which prevents them from being considered as an outcome measures. He thought that needle EMG was a more reliable measure than surface EMG but did not pass an opinion as to whether there was evidence for it being a good outcome measure; he expressed the view that it may help identify people who would respond to therapy such as sphincter repair or sacral nerve stimulation. [773]

In 2005, Prott et al acknowledged that there were conflicting recommendations from consensus groups with regard to the assessment of resting anal sphincter pressure. In 54 patients suffering with constipation or faecal incontinence, they evaluated and compared the performance of stationary, stationary pull-through and slow pull-through techniques for evaluating resting anal sphincter pressures. Although the measurements from each technique highly correlated with each other, they concluded that resting anal sphincter pressure varies according to the specific technique employed and made a plea that standardised anal sphincter testing should be established to enable inter-laboratory comparisons. [774]

In 2005, Ortolani et al stated that anorectal manometry is the basic investigation for the study of anorectal function. However, they stated that lack of a standard execution technique and of any common definition of the manometric parameters constitutes a major limitation. They proposed a standard technique for performing manometry which would enable manometry to be performed in less than 30 minutes and yield approximately 10 parameters which are easily identified and interpreted. [775] However, there does not appear to be any subsequent publications using this proposal.

In 2007, Deutekom et al studied a consecutive series of 162 patients with faecal incontinence. They found that the hypothesised associations between urgency and passive incontinence and functional and anatomical impairment of the anorectum were less clear-cut than previously assumed. They concluded that patients presenting with faecal incontinence should undergo physiological investigation. [551]

In 2007 a consensus conference on faecal incontinence formed part of the programme at the International Conference on Faecal Incontinence (Bari, Italy). [776] The expert participants discussed the place of endoanal ultrasound, PNTML assessment, anal manometry, EMG and rectal sensitivity testing by balloon distension in the assessment of a patient with faecal incontinence. Most thought that endoanal ultrasound was the most useful investigation in helping to determine treatment and some carry it out on every patient they see with faecal incontinence. There was also a strong opinion that assessment of rectal sensation was important. At best, the other tests were carried out on an individual basis, some carrying out PNTML assessment in order to counsel patients regarding the outcome of a sphincter repair. Interestingly, one expert carried out anal manometry and PNTML assessment not because he needed it but because “there’s no journal that will accept a paper from me when I haven’t done it!”

In 2008, Thekkinkattil et al again acknowledged that that there is no standardisation of investigations, and treatment outcomes are variable for patients with faecal incontinence. They also pointed out the lack of a pretreatment classification of incontinence. They proposed that patients could be divided into four groups: traumatic incontinence, neuropathic faecal incontinence, combined faecal incontinence and idiopathic faecal incontinence (according to manometric variables and demographics). Their hope is that such a classification system will enable comparison and interpretation of the outcomes of different studies and also help in the selection of patients for appropriate treatments. [777]
There have been old [778] and more recent reviews of these tests[779]

1. The only test under the umbrella of anorectal physiology studies that appears to have proven clinical value is determining the presence or absence of the RAIR in newborn infants.

2. There have not been any major studies setting out normal ranges for the parameters measured in ARPS. Therefore, the sensitivity of the measures to distinguish normal from abnormal is largely unknown.

3. This situation is compounded by the great variety in techniques of testing, size and types of catheter for manometry, the lack of standardisation of other techniques of testing the lower GI tract, the lack of standardisation of terminology and even simple issues such as to whether particular tests require an empty or full rectum.

4. A minor point but there is no universal unit of pressure adopted for anal manometry which does not help comparisons of the results from different centres.

5. Many studies have shown changes in the measured parameters as a result of treatment but, without there often being a control arm, the significance and relevance is unknown.

6. There is some evidence to suggest that some of the tests under the umbrella of ARPS can help in determining patient management.

### Recommendations

The committee recognises that anorectal physiology studies are helpful in objectifying the function of the anorectum and aiding the diagnosis of the cause of faecal incontinence. There is some evidence that some of the tests can help determine patient management.

However, the committee recommends that urgent consideration needs to be given to standardising the tests and terminology. This will then help to better determine the reproducibility, reliability and prognostic value of the tests. It should then also be possible to generate a universally useful set of normative data.

### H. ACKNOWLEDGEMENTS

The authors of this chapter wish to acknowledge the following other contributors to “urodynamics” and “dynamic testing” in the three previous consultations: JE Batista, SB Bauer, M Craggs, N Diamant, DJ Griffiths, P Hilton, Y Homma, G Kramer, S Kulseng-Hanson, LLiao, G Lose, HPalmotag, W Schäfer, MWF Stöhrer, N Yoshimura. We have built on the solid foundation that they have helped to establish.

Thanks are also expressed to Bärbel Junginger who translated and summarised the guidelines of the
German Societies of Neurogastroenterology (committee for proctology), Abdominal Surgery (coloproctology working group), and Coloproctology.

Finally, thanks to the members of the committees for Conservative and Surgical treatment of Faecal Incontinence, especially Prof Chris Norton, for their comments on an early draft of the section on anorectal physiology studies.

Neurophysiological investigations of muscles and nerves in the perineum and pelvis originated over 60 years ago, and have evolved with the developments in general clinical neurophysiology. The data from these investigations can assist clinicians in diagnosing neurological disease or injury, and are applicable in research. Compared to neurophysiological testing of the limbs and trunk, pelvic neurophysiological testing is relatively limited because of the restrictions imposed by pelvic neuroanatomy.

This text details the investigations, their applications and limitations, enabling investigators and clinicians to make a well informed decision about using these tests. The present text is based on the previous chapter on clinical neurophysiology prepared for the International Consultations on Incontinence [1], which has been updated by a literature search in Medline using key words incontinence, clinical neurophysiology, electro-myography, reflex, evoked potentials.

1. CLASSIFICATION OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Although different types of tests may be included under the term “neurophysiological”, it is particularly the electrophysiological tests that shall be discussed in the present text.

Electrophysiological tests are an extension of the clinical examination, and a functional anatomic approach to classification makes most sense. For the purpose of this categorisation, the nervous system is divided into the somatic and the autonomic nervous systems. The somatic nervous system provides motor innervation to the skeletal muscles, and sensory innervation from skin and muscle spindles. The autonomic nervous system provides motor innervation to the viscera and other end-organs not under voluntary control (e.g., sweat glands). Its sensory fibres are referred to as visceral afferents. Both systems have central pathways (neurons participating in spinal cord and supraspinal control) and peripheral nerves (those going to and from end-organs).

Thus, electrophysiological tests can be divided into:

a) somatic motor system tests (EMG, terminal motor latency measurements/ motor nerve conduction studies, and motor evoked potentials (MEP));
b) somatosensory system tests (sensory neurography, somatosensory evoked potentials (SEP));
c) reflexes;
d) the autonomic nervous system tests (for sympathetic or parasympathetic fibres).

Electrophysiological tests may also be categorized “technically” into those which “just” record some bioelectrical activity (for instance: electromyography), and those which record some biological response to stimulation (these may be subsumed under the term “conduction tests”).

2. BIOLOGICAL CORRELATES OF ELECTROPHYSIOLOGICAL TESTS

a) Conduction Tests: Nerve Conduction, Evoked Potential and Reflex Studies

The electrophysiological responses obtained on stimulation are compound action potentials and relate to populations of biological units (neurons, axons, motor units, muscle fibres, etc.). Latency and amplitude are commonly measured parameters of responses during neurophysiological testing. If the onset of the potential is measured, the latency of a compound potential represents the fastest conduction through a particular neural channel. As a general rule, latency measurements are not markedly affected by technical factors, but provide little information about the loss of biological units (e.g., motor neurons or axons).

The amplitude of the compound potential correlates with the number of activated biological units. In theory, the amplitudes are the more relevant physiological parameter, as they reflect the functional or structural loss of biological units. Unfortunately, amplitudes are also strongly influenced by many poorly controllable technical factors. Measurements of latencies and amplitudes of evoked potentials and reflex responses, including sympathetic skin responses, relate not only to conduction in peripheral and central neural pathways, but also to trans-synaptic transmission.
b) Electromyography (EMG)

Knowledge of the structure and function of the motor unit (Figure 1) is fundamental to understanding the application of EMG. Motor neurons, which innervate striated muscle, lie in the anterior horn of the spinal cord and are called “lower motor neurons”. (Neurons that innervate the sphincters lie in Onuf’s nucleus in the sacral spinal cord; they are somewhat smaller than those innervating skeletal limb and trunk muscles).

Within the muscle, the motor axon branches to innervate a certain number of muscle fibres, which are scattered throughout the muscle. All muscle fibres innervated by one lower motor neuron are activated simultaneously; all these constituents together are called “motor unit”. The innervation of muscle fibres is such that it is unlikely that muscle fibres that are part of the same motor unit will be adjacent to one another.

It is difficult to estimate the number of muscle fibres innervated by a single axon (i.e., the "innervation ratio") or the number of motor units supplying a muscle, by clinically available neurophysiological techniques.

3. GENERAL METHODOLOGICAL CONSIDERATIONS

To date, there are no universally accepted standards for conducting individual uro-genital-anal neurophysiological tests, but the variations of testing in different laboratories are minor.

There are technical standards on equipment safety; standardisation of concentric needle EMG and penilo/clitoro-cavernosal testing has been proposed.

a) Equipment

Clinical neurophysiological tests are conducted with complex electronic instruments and various devices that come into contact with the patient. Though this equipment is mostly standard, some specially constructed electrodes or stimulating devices have been devised to conform to uro-genital-anal anatomy.

As long as the standards of electrical safety are adhered to, the risk to patients is negligible.

The common form of neurophysiological testing is electrophysiological. Surface electrodes, which are applied to skin or mucosal surfaces, or needle electrodes are used for electrical stimulation and to record bioelectrical activity. The important neurophysiological difference between surface and needle electrodes is their selectivity, and the practical difference is their invasiveness. The choice and application of electrodes is guided by the need for selective recording or stimulation. Less commonly, special devices are used for magnetic and mechanical stimulation.

Stimulation Parameters. The electrical stimulus should be specified and characterised both in technical (e.g., rectangular pulse, 0.2 ms, 15 mA) and physiological terms (e.g., 3-times sensory threshold). A stimulus with defined technical parameters may have variable biological effects because of the variable influences of electrode condition, contact, tissue conductivity etc. Supramaximal stimulation is preferred to elicit a compound muscle action potential (CMAP) or sensory nerve action potential. Supramaximal stimuli yield responses with the largest amplitude and shortest latency, and are the least variable and most reproducible. The sites at which stimulation electrodes are applied should be described using anatomical terms.

b) Recording

1. APPARATUS SETTINGS

For recording, the apparatus settings (gain, sweep speed) have to be adapted to the known range of amplitudes, latencies, and duration of the response and it has to be appropriately displayed for analysis. Particularly important is the frequency setting of filters: for surface electrode recordings it is typically 2 Hz – 1 kHz; for concentric needle EMG recordings, it is 5 Hz – 10 kHz.

Placement of electrodes on the scalp for evoked potential recordings is defined according to the 10-20 International EEG System.

2. REPRODUCIBILITY AND RELIABILITY

Any potential elicited by stimulation should be reproducible; therefore, as a rule, at least two consecutive recording procedures need to be performed. To improve the signal-to-noise ratio some small amplitude responses need to be averaged. Therefore, many repetitions of stimulation/recording need to be done (typically 100-200). Even such an averaged recording needs to be repeated at least twice. CMAPs (i.e., M-waves), MEP, sacral reflexes and sympathetic skin responses (SSR) are recognisable after single stimuli. However, as a rule, several responses are recorded to demonstrate reproducibility. In contrast, other responses (e.g., SSR) show marked fatigability with stimulus repetition.

526
3. **Waveform Analysis**

For a particular stimulation procedure, the shape, latency, and amplitude of the recorded potentials are analysed. Morphologically, a particular response (or part of it) needs to be recognised as present or absent. The shape of potentials is important to accurately determine the latency and amplitude of the response. The onset of the response (for M-waves, MEP and sacral reflex testing) or the individual peaks of the potentials (for SEP) are used to determine the latency. The amplitudes are analysed relative to the baseline or “peak to peak”.

**II. CLINICAL NEUROPHYSIOLOGICAL TESTS**

1. **SOMATIC MOTOR SYSTEM TESTS**

   a) **Electromyography (EMG)**

   The term "EMG" is often used for several different procedures, the common denominator of which is the recording of bioelectrical activity from muscle. The term applies particularly to recordings from striated muscles.

   EMG is used a) “just” to record muscle activity (as for instance in combined sphincter EMG and pressure-flow study) and b) to differentiate between normal, denervated, reinervated, and myopathic muscle. For a) see below - “Kinesiological EMG”.

   Although EMG abnormalities are detected as a result of a host of different lesions and diseases, there are in principle only two standard manifestations which can occur: a) disease of the muscle fibres themselves (“myogenic” changes), and b) changes in their innervation (“neuropathic” changes). "Myogenic changes may result from muscle disease, probably also from direct trauma (e.g., the anal sphincter tear during vaginal delivery). Neurogenic changes may be attributable to injury at any level along the lower motor neuron supplying the external anal sphincter, extending from the motor neuron body, sacral nerve roots to the small branches within the external sphincter. In the pelvic floor muscles, only neurogenic changes are well recognised and routinely evaluated.

   The EMG signal may be further used to indicate that muscle has been activated through its motor nerve, either by stimulation applied to motor pathways (M-wave, MEP) or to sensory pathways (reflex response).

   b) **Concentric needle EMG (CNEMG)**

   The examination is conducted with a single use, disposable electrode. The commonly used amplifier filter settings for CNEMG are 5 Hz – 10 kHz, and need to be defined if MUP parameters are to be measured, as are filter settings employed during data acquisition.

   The concentric needle electrode consists of a central insulated platinum wire inserted through a steel cannula and the tip ground to give an elliptical area which can record spike or near activity from about 20 muscle fibres [2]. The number of motor units recorded therefore depends both upon the local arrangement of motor units within the muscle fascicle and the level of contraction of the muscle.

   CNEMG can provide information on a) insertion activity, b) abnormal spontaneous activity (Figure 2), c) MUPs, and d) interference pattern (IP).

   In normal muscle, needle movement elicits a short burst of “insertion activity,” which is due to mechanical stimulation of excitable muscle cell membranes. This is recorded at a gain setting of 50 µV per division (sweep speed 5 – 10 ms/division), which is also used to record spontaneous activity. Absence of insertion activity with appropriately placed needle electrode usually means a complete denervation atrophy of the examined muscle.
The amount of recruitable motor units during voluntary and reflex activation can also be estimated. Normally, MUPs should intermingle to produce an “interference” pattern on the oscilloscope during muscle contraction, and during a strong cough. In addition, the number of continuously active MUPs during relaxation [3], MUP variability as well as MUP recruitment on reflex and voluntary activation can be observed [4].

MUPs (and occasionally encountered end-plate activity) are recordable in normal resting sphincter muscles in a relaxed subject. This is in contrast to limb muscles where relaxation is associated with “electrical silence” by EMG. In addition to continuously firing motor units, new MUPs are recruited voluntarily and reflexly in the sphincters. It has been shown that the two MUP populations differ in their characteristics: reflexly or voluntarily activated “high-threshold MUPs” being larger than continuously active “low-threshold MUPs”. As a consequence, standardised level of activity at which a template based multi-MUP analysis obtains 3-5 MUPs on a single muscle site was suggested [5]. In partially denervated sphincter muscle there is – by definition – a loss of motor units (MUs). This can be estimated during relaxation by counting the number of continuously firing low-threshold MUPs. In patients with cauda equina or conus medullaris lesions, fewer MUPs fire continuously during relaxation [6], probably due to partial axonal loss. The main obstacle to qualified assessment of reduced number of activated MUs and activation of MUs at increased firing rates (as occurs in limb muscles) is a lack of concomitant measurement of level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

There are two approaches to analysing the bioelectrical activity of motor units: either analysis of individual motor unit potentials (MUPs), or analysis of the overall activity of intermingled MUPs. (This is the so called “interference pattern” – IP. Exploring different sites of the activated muscle with a needle electrode provides “samples” of intermingled motor unit potentials (IP epochs), which can be analysed).

Generally three different techniques of MUP analysis (manual-MUP, single-MUP and multi-MUP) and 1 technique of IP analysis (turn/amplitude – T/A) are available on advanced EMG systems [6].

It is easy to grasp the “motor unit potential analysis”, as it is simply a measurement (by different methods) of the “parameters” of single individual MUPs (ie. its amplitude, duration, number of phases...). The changes in MUP parameters furthermore are “direct” results of understandable physiological changes, and are thus “meaningful” to the interpreter.

The changes in IP parameters are, however, less readily grasped. These are: numbers of turns per second (any peak or trough of the signal where the activity changes by more than 100 µV); amplitude/turn (change in volts between two turns); number of short segments (parts of signal that has “sharp” activity) percent activity (percent of epoch with sharp activity); envelope (peak to trough amplitude exceeded by 1% of peaks/troughs). These parameters relate both to MUP parameters and to the activation level of the muscle. Recorded data are log transformed and linear regression lines are created. Amplitude/turn, and number of turns/second data from normal subjects can be used to create upper and lower boundaries (95 % confidence intervals) for assembly of future data from individual patients. Individual data create a scatter plot (“cloud”) which compares to the normative boundaries (Figure 3). It has been asserted that this approach does not require a standardized muscle contraction, but the shape of the “cloud” is dependent on the strength of muscle contraction. Therefore it has been suggested to standardize the method by measuring pressure exerted by the contracting sphincter [7].

Both the template based multi-MUP analysis of MUP and T/A analysis of IP are fast (5-10 and 2-3 minutes per muscle, respectively), easy to apply, and, technically, represent clinically useful techniques.

i) CNEMG Findings due to denervation and reinervation

After complete denervation, all motor unit activity ceases. In a denervated muscle, complete "electrical silence" is noted in the first days after such an event. The diagnosis of complete denervation is confirmed by the absence of muscle response during electrical stimulation. Because motor axons take days to degenerate after injury, this proof is not available for up to 5-7 days after a denervation injury. However, it is rarely necessary to demonstrate complete denervation in the acute stage because the clinical condition is usually obvious. Denervated muscle fibres become hyperexcitable and start to fire spontaneously giving rise to abnormal spontaneous activity, but these may take up to three weeks to appear. The "insertion activity" becomes prolonged and short biphasic spikes (fibrillation potentials) and biphasic potentials with prominent positive deflections (positive sharp waves) appear (Figure 2). Thus, concentric needle EMG (CNEMG) correlates of denervation are pathologically prolonged insertion activity and pathological spontaneous activity. Completely denervated muscle may be reinnervated by axonal regrowth from the proximal nerve stump with few muscle fibres constituting "nascent" motor units. These are short, bi- and triphasic, soon becoming polyphasic, serrated and with prolonged duration. In partially denervated muscle, collateral reinnervation takes place. Surviving motor axons will sprout and grow out to reinnervate those muscle fibres that have lost their nerve supply. This results in a change in the arrangement of muscle fibres within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibres to be part...
of the same motor unit, following reinnervation, several muscle fibres belonging to the same motor unit come to be adjacent to one another. CNEMG correlates are changes in MUPs (duration, amplitude, number of phases, turns, etc). Early in the process of reinnervation, the newly outgrown motor sprouts are thin. Therefore, they conduct slowly such that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. Moreover, the neuromuscular transmission is unstable due to immaturity of the motor end-plates. The CNEMG correlate is instability of long-duration complex potentials.

In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. Changes due to collateral reinnervation are reflected by: prolongation of the wave form of the MUP (Figure 3) which may have small, late components ("satellite potentials"). MUPs show "instability" due to insecure transmission in newly formed axon sprouts and end-plates. This "instability of potentials" (meaning both "jitter" and "blocking" of individual components in a complex potential) is not routinely assessed during sphincter EMG. Nonetheless, it can be a helpful parameter, and may be evaluated not only by SFEMG, as originally described [8], but also by CNEMG, if a low frequency cut-off filter of 0.5 (up to 2) kHz is used along with a trigger – delay unit. In skeletal muscle, the diameter of reinnervating axonal sprouts and conduction velocity increase with time, thereby improving synchrony of activation in the reinnervated motor unit. Thus MUP amplitude increases while MUP duration reverts towards normal. However, in degenerative neurological diseases (such as multiple system atrophy), long duration motor units are a prominent feature of anal sphincter reinnervation [9]. It is important to note that in patients with more severe neurogenic lesions, reinnervation may be inefficient resulting in MUP with parameters below confidence limits describing size (area, duration) [10].

The changes in MUP parameters (along with changed number of MUPs and changes in activation frequency of MUPs) will be reflected also in IP parameters.

Abnormalities of parameters evaluated by needle EMG are in principle non-specific, i.e. most abnormalities can occur both in neuropathic or myopathic conditions. It is the overall clinical picture that dictates interpretation of results.

**ii) CNEMG of the External Anal Sphincter**

The external anal sphincter (EAS) is the most practical indicator muscle for sacral myotomes because it is easy to access, has enough muscle bulk for exact EMG analysis, and its examination is not too uncomfortable.

The needle electrode is inserted into the subcutaneous EAS muscle about 1 cm from the anal orifice, to a depth of a 3-6 mm under the non-keratinised epithelium. For the deeper part of the EAS muscle 1-3 cm deep insertions are made at the anal orifice, at an angle of about 30° to the anal canal axis [5]. In most patients only examination of the subcutaneous EAS muscle is necessary. Separate examinations of the left and right EAS muscles are recommended. The needle is inserted into the middle of the anterior and posterior halves of each side ("quadrants") of the EAS muscle. After insertion in two positions on each side the electrode is turned backwards and forwards in a systematic manner. At least 4 sites in each of the subcutaneous and/or the deeper EAS muscle are thus analysed [5, 11].

Use of quantitative MUP and IP analyses of the EAS is further facilitated by the availability of normative values [11] that can be introduced into the EMG systems' software. It has been shown that normative data are not significantly affected by age, gender [11], number of uncomplicated vaginal deliveries [12], mild chronic constipation [12], and the part of EAS muscle (i.e. subcutaneous or deeper) examined [12].

Intramuscular electrode insertion into other perineal muscles and pelvic floor muscles is not standardized and is described in textbooks and primary literature.

**3. Single fibre EMG (SFEMG)**

The SFEMG electrode has similar external proportions to a concentric needle electrode, but with a smaller recording surface. It will pick up activity from within a hemispherical muscle volume 300 µm in diameter, much smaller than the volume of 2-3 mm diameter from which a concentric needle electrode records [2]. Because of the arrangement of muscle fibres in a normal motor unit, a SFEMG needle will record only 1-3 single muscle fibres from the same motor unit.

The SFEMG parameter that reflects motor unit morphology is fibre density, which is defined as the mean number of muscle fibres belonging to an individual motor unit per detection site. To assemble this data, recordings from 20 different intramuscular detection sites are necessary [8].

SFEMG recording needles are very expensive, and disposable needles are not available.

**4. Kinesiological EMG**

Kinesiological EMG is used to assess patterns of individual muscle activity/inactivity during defined manoeuvres (Figure 4), typically during urodynamics.
Figure 3: Consecutive firings of motor unit potential (MUP) and its average (left and right, respectively) as obtained from the external anal sphincter (EAS) muscle of 59-year-old woman by multi-MUP analysis. Note that multi-MUP analysis does not preclude inclusion of late components into MUP duration measurement; this is possible by manual correction of duration cursor (see arrow).
As such, the specific interpretation of electrical activity within a muscle is based on its presence or absence, rather than the type of activity. Technical issues will be dealt here; the relevance for diagnostics will be discussed in the Chapter on dynamic testing.

**Figure 4 :** Kinesiological EMG recording from the urethral sphincter muscle of a healthy 53 years old continent female. Recruitment of motor units on reflex manoeuvres and on a command to contract is shown; regular continuous activity of motor units represents "tonic activity". (Recorded with concentric needle electrode).

When using surface electrodes there are problems related to validity of signal (e.g., artefacts, contamination from other muscles). With intramuscular electrodes, the procedure is more invasive, and there are questions as to whether the whole muscle in large pelvic floor muscles is properly represented by the sampled muscle portions. Intramuscular electrodes should ideally be fine wire electrodes, as they do not dislodge, and no pain is induced with muscle contraction.

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. pubococcygeal) can be voluntarily activated typically for less than 1 minute [13]. Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough reflex [14].

Sphincter activity during voiding is characterised by the cessation of all EMG activity prior to detrusor contraction. Pathologic incoordination of the detrusor and sphincter is called detrusor sphincter dyssynergia.

5. **CLINICAL APPLICATION OF EMG**

**i) Neurogenic Conditions**

Trauma, surgery, and neurological disease have all been implicated in denervation of pelvic floor and perineal muscles and pelvic organs.

Following a cauda equina or a conus medullaris lesion, the MUP of pelvic floor and perineal muscles are prolonged and polyphasic, of increased amplitude, area, number of turns [6]. Surgical dissections can also affect the innervation of the sphincter and lead to loss of motor units and reinnervation of those surviving [15]. After pelvic trauma, gross changes of denervation and reinnervation may be detected in pelvic floor muscles. The bulbocavernous muscle is particularly useful in suspected recent minor partial denervation as it lacks on-going activity of low-threshold MU during relaxation. (In women the muscle is thin).

Neuropathic changes can also be recorded in sphincter muscles of patients with multiple system atrophy (MSA) [16]. MSA is a progressive neurodegenerative disease, which can be mistaken for Parkinson’s disease (PD). Urinary incontinence and erectile dysfunction occur, often some years before the onset of obvious neurological features [17]. Sphincter EMG has been used to distinguish MSA from Parkinson’s disease. EMG is probably not helpful to distinguish MSA from the later stages of Parkinson’s disease and from progressive supranuclear palsy. Extensive discussion on the subject can be found elsewhere [18].

In patients with acute idiopathic autonomic neuropathy and lower urinary tract (LUT) dysfunction the EMG of external sphincter muscles was reported as normal [19].

**ii) “Changes in Primary Muscle Disease**

In skeletal muscle, the “typical” features of a myopathy are small, low amplitude polyphasic units recruited at mild effort. There are few reports of pelvic floor muscle EMG in generalised myopathy. In a nulliparous woman with limb-girdle muscular dystrophy, histology revealed involvement of pelvic floor muscles, but concentric needle EMG of the urethral sphincter was normal [20]. Myopathic EMG changes were observed in the puborectalis and the EAS in patients with myotonic dystrophy (21), but not in another group of patients with myopathy [22].

**iii) Stress Incontinence**

Pelvic floor muscle denervation has been implicated in the pathophysiology of USI [23]. EMG techniques have been used to identify sphincter injury after childbirth and to evaluate women with USI. Stress incontinence and genitourinary prolapse were associated with partial denervation of the pelvic floor [24]. The changes were most marked in women who were incontinent after delivery, who had a prolonged second stage of labour, and had given birth to heavier babies.

Myogenic histological changes in pelvic floor muscles after vaginal delivery were also reported [25], with some EMG support by another group [26]. Myopathic EMG changes (i.e. short, small MUPs) may, however, be a consequence of deficient reinnervation [27]. There were claims urethral sphincter EMG can assist in selecting the type of surgery for patients with intrinsic sphincter deficiency [25].
Although CNEMG of the urethral sphincter seems the logical choice in patients with urinary incontinence of possibly neurogenic origin, only a small amount of pathological muscle tissue remains in many incontinent parous women which makes EMG of the muscle impractical [15]. CNEMG findings generally will not affect therapeutic considerations [28].

iv) "Idiopathic" Faecal Incontinence

"Idiopathic" faecal incontinence refers to patients in whom this symptom is not attributable to an underlying disorder, but has been often implied that it is a neurogenic condition. Vaginal delivery is proven to cause structural sphincter defects; it may cause outright sphincter denervation in rare cases, but its more widespread implication in causing "idiopathic" incontinence is controversial.

CNEMG may be helpful in selected patients with faecal incontinence if a specific neurogenic condition (e.g., trauma or disease affecting the conus, sacral roots, sacral plexus or pudendal nerves) is suspected on clinical grounds.

v) Idiopathic Urinary Retention in Women

In young women with urinary retention (or obstructed voiding) complex repetitive discharges in profuse amounts in the external urethral sphincter against a background of firing motor units have been described, suggesting that these findings are of pathogenic and diagnostic significance. The external urethral sphincter was reported to be hypertrophic. A percentage of these women were hirsute and had polycystic ovaries [29, 30].

Repetitive discharges are, however, prone to develop in chronically partially denervated sphincters, and are present even in a proportion of asymptomatic women [31]. The distinguishing feature of the spontaneous EMG activity defining the particular pathology in women with retention seems to be its abundance, but the issue remains in dispute.

vi) EMG in Urodynamic and Functional Anorectal Studies

In health, voiding is characterised by cessation of motor unit firing in the urethral sphincter prior to detrusor contraction, as can be demonstrated by recording of “kinesiological EMG”. Bladder-sphincter coordination is impaired with lesions between the lower sacral segments and the upper pons. Consequently, sphincter activity is not inhibited, and often increases before detrusor contraction (i.e., 'detrusor-sphincter dyssynergia'). On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described [32].

There are other clinical situations that mimic detrusor sphincter dyssynergia. Sphincter contraction or at least failure of relaxation during involuntary detrusor contractions can be seen in patients with Parkinson's disease. The pelvic floor muscle contractions of the so-called non-neurogenic voiding dyssynergia may be a learned abnormal behaviour [33], and are a feature of dysfunctional voiding [30].

The pubococcygeus in the healthy female reveals similar activity patterns to the urethral and anal sphincters at most detection sites: continuous activity at rest, often some increase of activity during bladder filling, and reflex increases in activity during any activation manoeuvre performed by the subject such as talking, deep breathing, coughing. The pubococcygeus relaxes during voiding; the muscles on either side act in unison [13]. In stress-incontinent patients, the patterns of activation and the co-ordination between the two sides can be lost [34]. A delay in muscle activation on coughing has also been demonstrated, as compared to continent women [14]. Little is known about the complex activity patterns of different pelvic floor muscles (the urethral sphincter, urethrovaginal sphincter, anal sphincter muscle, different parts of the levator ani) during different manoeuvres. It is generally assumed that they all act in a co-ordinated fashion functionally as one muscle. However there are demonstrable differences between the intra- and peri-urethral sphincter in healthy females [35] and in activation of the levator ani and the urethral sphincter [36]. Co-ordinated behaviour is frequently lost in abnormal conditions.

Kinesiological needle EMG analysis of the urethra with the patient at rest and coughing may predict the outcome after certain types of incontinence surgery [37].

Current concepts suggest that defecation requires increased rectal pressure co-ordinated with relaxation of the anal sphincters and pelvic floor muscles. Pelvic floor relaxation allows opening of the anorectal angle and perineal descent, facilitating faecal expulsion. During defecation puborectalis activity is as a rule inhibited, but was unchanged in 9 % and increased in 25% of healthy subjects [38]. Thus, while "paradoxical" puborectalis contraction during defecation is used to diagnose pelvic floor dyssynergia in patients with typical symptoms, this finding may be a variation of the normal.

d) Pudendal nerve conduction tests

Measurement of motor conduction velocity is routinely used to evaluate limb motor nerves, distinguishing between a demyelinating and axonal neuropathy. To make the measurement requires access to the nerve at two well-separated points and measurement of the distance between them, a requirement that cannot be met in the pelvis. Another way to evaluate peripheral motor nerve function is the measurement of the) motor latency of a muscle response, requiring only a single
stimulation site. The muscle response is the compound muscle action potential (CMAP) or M-wave. Because in limb nerves the site of stimulation to obtain only the motor latency (without measuring the actual conduction velocity) is as a rule placed distally on the nerve, it is also called the (distal or terminal) latency. For the pudendal nerve the site of stimulation may be more or less “distally”, but the term distal or terminal has – in accordance to general clinical neurophysiology – become generally used. Distal motor latency can be measured by recording with a concentric needle electrode from the bulbocavernosus, the EAS and the urethral sphincter muscles in response to bipolar surface stimulation placed in the perianal/perineal region, or with selective needle stimulation of the pudendal nerve (branches) in the perineum. The most widely employed technique to obtain pudendal nerve terminal motor latency (PNTML) relies on stimulation with a special surface electrode assembly fixed on a gloved index finger, known as the St Mark’s stimulator [39]. It consists of a bipolar stimulating electrode on the tip of the gloved finger with the recording electrode pair placed proximally on the base of the finger. The finger is inserted into the rectum or vagina and stimulation is applied close to the ischial spine. If a catheter-mounted electrode is used for recording, EMG responses from the striated muscle of the urethral sphincter can be obtained. Experts differ in their estimation of validity of this test. A prospective evaluation of anorectal physiologic tests in 90 patients with faecal incontinence did not find that PNTML results changed treatment decisions [40]. Indeed, the American Gastroenterological Association statement indicated that “PNTML cannot be recommended for evaluation of patients with faecal incontinence” [41].

c) Anterior sacral root (cauda equina) stimulation

Anterior root stimulation has been used to study conduction of the sacral nerve roots. Electrical stimulation with needle electrodes at vertebral laminae Th12-L1 elicit M-waves in the bulbocavernousus and EAS muscle [42].

Transcutaneous stimulation of deeply situated nervous tissue became possible with development of special electrical and magnetic stimulators. When applied over the spine, these stimulators activate the roots as they exit the vertebral canal. Needle EMG rather than non-selective surface electrodes should be used to record pelvic floor and particularly sphincter responses to electrical or magnetic stimulation of the cauda equina. These stimuli non-selectively depolarise underlying neural structures, thereby activating several muscles innervated by lumbosacral segments [43].

Invasive percutaneous stimulation of individual roots in sacral foramina is used to identify patients with lower urinary and anorectal dysfunction who are likely to benefit from long-term stimulation, e.g. with the Interstim (Medtronic, Inc., Minneapolis, USA). Electrical stimulation of nerve roots at the level of the appropriate sacral foramina results in observable muscle contraction in the foot and perineum. These responses can be identified as MEP or reflex responses on the basis of their latency.

In conclusion, demonstrating the presence of a perineal MEP on stimulation over lumbosacral spine may occasionally be helpful in patients without voluntarily activated muscles. It also identifies the particular nerve root before introducing therapeutic electrical stimulation. However, the clinical value of the test has yet to be established and there are no sensitivity and specificity data on test results in individual patients.

d) Motor evoked potentials

Using magnetic or electric stimulation, it is possible to depolarise the motor cortex and record a response from the pelvic floor. Magnetic cortical stimulation is better tolerated than electrical stimulation, which has been abandoned in awake subjects, but may be useful for intraoperative monitoring.

By performing the stimulation at two different sites (brain and spinal roots), it is possible to record three different conduction times: a total conduction time, a peripheral conduction time, and a central conduction time (Figure 5). The total conduction time corresponds to the transit time from brain to target muscle. The peripheral conduction time is the transit time from sacral roots to the muscle. The central conduction time is obtained by subtracting the peripheral conduction time from the total conduction time. The total conduction time can be measured both at rest and during a facilitation procedure. MEPs from the EAS, the urethral sphincter, the bulbocavernosus muscle, and the levator ani muscle have been reported, but normative values have only been obtained (for transcranial magnetic stimulation) for the urethral sphincter and the puborectal muscle in adult women [44]. The necessity to use concentric needle EMG for recording has been reconfirmed [45]. Substantially longer central conduction times have been found in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls [46]. However all patients in this study had clinically recognisable cord disease.

Conceptually, MEP may help to differentiate between involvement of motor and sensory pathways. However, the clinical utility of these measurements is not established. MEP have opened an avenue of research on excitability of motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles the anal sphincter motor cortex has less intracortical inhibition [47].

2. SENSORY SYSTEM TESTS

There are several methods of sensory testing for the perineum, the genitourinary and anorectal tract. Clinical
testing includes perineal and external genital skin sensation for light touch and pinprick, and sensation of bladder filling during cystometry. Anorectal sensory testing can be clinically assessed through rating of applied stimuli. More objective sensory testing can be performed with quantitative sensory testing (QST), which assesses sensory perception. For evaluation of the integrity of sensory pathways sensory neurography, and somatosensory evoked potentials (SEP) can be used.

**a) Sensory Measurements During Cystometry**

During routine cystometry bladder sensation is assessed by recording first sensation of bladder filling, first desire to void and strong desire to void.

Bladder and urethral sensory thresholds have also been measured using electrical stimulation [48], and mechanical traction on the bladder trigone [49]. There is no established clinical use for any of these tests other than simple reporting of sensation during cystometry.

**b) Assessment of Anorectal Sensation**

Rectal sensation is assessed by progressively distending a balloon manually or by a barostat while measuring thresholds for first perception, desire to defecate, and severe discomfort. The intensity of perception during rectal distension can be recorded by a visual analogue scale during phasic distensions of graded intensity [50]. The rate and pattern of distension affect rectal perception and internal sphincter relaxation [51].

Anal sensation can be assessed by determining the perception threshold to an electrical stimulus or temperature change in the anal canal. Electrical testing does not activate mucosal receptors. Anal sensitivity to temperature change has been reported reduced in faecal incontinence [52].

**c) Quantitative Sensory Testing**

Quantitative sensory testing (QST) of the urogenital system should provide more objective and reproducible data than routine clinical testing. QST sensory modalities applied to the evaluation of urogenital function include vibration [53], temperature [54], and electrical current [55]. There is no commonly accepted, detailed, standardised test, and the specificity and sensitivity of the tests are not known. The relationship of cutaneous quantitative sensory tests to bladder and urethral sensation and function is unknown. The physiological, psychophysiological and methodological issues and controversies will not be addressed in this chapter.

**d) Sensory Neurography**

Nerve conduction velocities of the dorsal nerve of the penis can be calculated by placing a pair of stimulating electrodes across the glans and a pair of recording electrodes across the base of penis. A nerve action potential can be recorded with amplitude of about 10 \( \mu V \). It can also be recorded by stimulating trans-rectally or transperineally. There is no known association between penile sensory neuropathy and bladder/sphincter dysfunction.

A few studies have recorded activity in sacral roots during electrical stimulation. Intraoperatively, when the sacral roots are exposed, compound sensory action potentials on stimulation of dorsal penile and clitoral nerve may be recorded directly [56]. This helps to preserve roots mediating perineal sensation in spastic children undergoing dorsal rhizotomy, and reduce the incidence of postoperative voiding dysfunction. These tests are limited to their very specific intraoperative indications.

**e) Somatosensory Evoked Potentials (SEP)**

Somatosensory evoked potentials are electric waveforms of biologic origin elicited by stimulation of a sensory nerve (or a sensory innervated skin area
– dermatome). The most commonly performed tests in the urogenitoanal region are pudendal somatosensory evoked potentials (SEP), which assesses conduction in large fibre pathways between the site of nerve stimulation and the parietal sensory cortex. Potentials can also be measured at the spinal level (spinal SEP). Visceral (thin) fibre pathways are assessed by recording SEPs while stimulating the proximal urethra and bladder, although this is technically not depolarization of nerves, but a mesh of afferents.

1. Pudendal Somatosensory Evoked Potentials
   i) Cerebral Pudendal SEP

On electrical stimulation of the dorsal penile/clitoral or perineal nerve, a cerebral SEP can be recorded. (Figure 6) This SEP is as a rule of highest amplitude at the central recording site (Cz - 2 cm : Fz of the International 10-20 EEG System) and is highly reproducible. The first positive peak at about 40 ms (called P40) is usually clearly defined in healthy subjects using a stimulus 2-4 times stronger than the sensory threshold [57]. The presence and amplitude of subsequent negative and positive waves are quite variable between subjects. Classically described pudendal SEP techniques stimulate both dorsal penile/clitoral nerves, thus reducing the sensitivity of the test. However, techniques of pudendal SEP that isolate each dorsal penile/clitoral nerve may be more sensitive for identifying pathology [58].

Pudendal SEPs have been advocated in patients with neurogenic bladder dysfunction, e.g. in multiple sclerosis [59]. However, even in patients with multiple sclerosis and bladder symptoms, the tibial cerebral SEP was more often abnormal than the pudendal SEP. The combination of an abnormal pudendal SEP with a normal tibial SEP suggests isolated conus involvement [60]. The pudendal SEP was less useful than neurological examination for identifying neurological disease in patients with urogenital symptoms [61]. Following spinal cord injury, tibial and pudendal SEPs may be of some value for predicting recovery in bladder control [62]. Cerebral SEP during penile/clitoral stimulation may be useful for intraoperative monitoring. Pudendal SEP were used to study the mechanism of sacral neuromodulation [63].

3. Sacral Reflexes
   a) Sacral Reflex on Electrical Stimulation

Electrical stimulation of the dorsal penile or clitoral nerve elicits (somato-somatic) sacral reflexes in perineal muscles with a typical latency approx. 33 ms, traditionally called the bulbocavernosus reflex (Figure 6). Stimulation of the perianal skin, bladder neck or proximal urethra elicits sacral reflexes with latencies above 50 ms. This latency is longer compared to responses conveyed by the pudendal nerve, suggesting that the afferent limb for these responses involves visceral afferent fibres accompanying the pelvic nerves, which are thinly myelinated and have a slower conduction velocity than the thicker pudendal afferents. With visceral denervation (e.g. following radical hysterectomy) the viscerosomatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernosus (penilo-clitorocavernosus) reflex is preserved. Loss of bladder-urethral reflex with preservation of bladder-anal reflex has been described with urethral afferent injury after recurrent urethral surgeries [64].

Figure 6: SEPs (traces on the left) and sacral reflexes (traces on the right) in a healthy woman. Cerebral SEPs are recorded from Cz - 2 cm; sacral reflexes from the anal sphincter. The dorsal clitoral nerve is being stimulated with rectangular electrical pulses at 2 Hz. Stimulation and recording is performed with surface electrodes. The cerebral SEP and sacral reflex are recorded simultaneously. In the upper row the stimulation is just above sensory threshold, in the middle row the stimulation is 1.5, and in the lower row at 2-times sensory threshold (pulse duration 0.2 ms; two consecutive averages of 128 responses are superimposed).
The longer latency anal reflex (the contraction of the EAS on stimulation of the perianal region) is quite variable thus limiting its usefulness as a diagnostic tool.

On perianal stimulation, a short latency response can also be recorded, as a result of depolarisation of motor branches to the EAS, possibly involving antidromic travelling of the depolarisation, with "returning" of the depolarisation orthodromically to the sphincter at a branching point of the motor axon.

EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g. observing and palpating the contraction) in males and particularly in females [65]. In men with cauda equina lesions penilo-cavernous reflex could not be elicited in 64%, 47% and 47% of patients on single electrical, double electrical, and mechanical stimulation, respectively. Measurement of the reflex latency increased the sensitivity to record abnormalities for 17%, 36%, and 34%, respectively. Furthermore, it has been shown that sacral reflex measurement increase sensitivity of quantitative EMG of the EAS muscles from 73% to 81-83% using the different stimulation techniques mentioned [66].

Sacral reflex testing has been studied extensively and is used in many laboratories in everyday practice to demonstrate objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernosus or penilo-clitoro-cavernosus reflex) was shown to be a complex response, often forming two components. The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernous reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response [67]. The second component has latency similar to the sacral reflexes evoked by stimulation perianally or from the proximal urethra, and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred absence of a response if only single pulse is used for stimulation.

During voiding sacral reflexes are un-elicitable but in presence of spinal cord lesions such as myelodysplasia this normal suppression is lost.

Sacral reflex responses recorded with needle or wire electrodes can be analysed separately for each side from the EAS or bulbocavernous muscle. Using unilateral dorsal penile nerve blocks, the existence of two unilateral BCR arcs has been demonstrated. Thus by detection from the left and right bulbocavernosus (and also the EAS) muscles separate testing of right and left reflex arcs can be performed. Some authors reported that the sensitivity of the test can be increased by use of the inter-side latency difference (normative limits: < 3 ms), but this finding could not be confirmed by others (normative limits: < 7.2 ms) [68]. In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one on clinical elicitation, but not on neurophysiologic measurements of the sacral reflexes.

As described above, penilo-cavernosus reflexes were absent in 47-64%, and delayed in additional 17-19% of patients with conus/cauda lesions. Of these patients 47% were incontinent for urine and 47% for faeces. However, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc, as demonstrated by pathologic quantitative EMG of the EAS in 79-86% of patients with conus/cauda lesions [66]. Furthermore, much delayed sacral reflex responses are compatible with normal bladder and sexual function as found in patients with hereditary motor and sensory demyelinating neuropathy.

Sacral reflex recording is suggested as a complementary test to CNEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions [4]. In addition to latency, a number of other parameters can also be measured using electrical, but not mechanical stimulation.

These are the sensory threshold (i.e., the stimulus strength (mA) at which subjects feels stimulation), reflex threshold (i.e., the stimulus strength (mA) at which the reproducible penilo/clitoro-cavernosus reflex appears on the screen), and stimulation strength (i.e., the stimulation intensity (mA) at which the response latency does not shorten and amplitude does not increase in spite of increasing the stimulus strength). Although for men normative data for these parameters is available (68), their utility in clinical situation remains unclear.

Continuous intraoperative recording of sacral reflex responses on penis/clitoris stimulation is feasible if double pulses or a train of stimuli are used [69].

b) Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicite BCR in both sexes and found to be a robust technique. Either a standard reflex hammer or a customised electromechanical hammer can be used. Such stimulation is painless and can be used in children. The latency of the BCR elicited mechanically is comparable to the electrically elicited reflex in the same patients, but depends on the electromechanical device used.

4. AUTONOMIC FUNCTION TESTS

Most uro-neurophysiological methods discussed so far assess myelinated fibres, but not the autonomic nervous system, especially the parasympathetic component, which is most relevant for pelvic organ functions. Methods for evaluating the autonomic nerves
innervating the pelvic viscera are not available. Cystometry indirectly evaluates the parasympathetic innervation to the bladder. However, from a clinical neurophysiological point of view direct electrophysiological testing would be desirable.

a) Tests in Generalised Autonomic Neuropathy

Cardiovascular autonomic function tests are useful for identifying generalised autonomic dysfunction in patients with bladder or gastrointestinal motility disturbances.

In cases when a general involvement of thin fibres is expected, an indirect way to examine autonomic fibres is to assess thin sensory fibre function. Thin visceral sensory fibres are tested by stimulating the proximal urethra or bladder, and by recording sacral reflex responses or cerebral SEP.

b) Smooth Muscle Electromyography

Technical problems have so far limited smooth muscle electromyography of the detrusor muscle, and of genital smooth muscle. There is no evidence to prove the clinical utility of these tests in the evaluation of urinary tract function.

c) Sympathetic Skin Response (SSR)

The sympathetic nervous system mediates sweat gland activity in the skin. Changes in sweat gland activity lead to changes in skin resistance. On noxious stimulation (such as a sudden noise, electrical pulse, etc.) a potential shift can be recorded with surface electrodes from the skin of the palms and the soles, and has been reported to be a useful parameter in assessment of neuropathy involving non-myelinated nerve fibres. The response, known as the SSR, can also be recorded from perineal skin and the penis.

The SSR is a reflex, which consists of myelinated sensory fibres, a complex central integrative mechanism and a sympathetic efferent limb with postganglionic nonmyelinated C fibres. SSR is the only electrophysiological method directly testing sympathetic fibres. Limited literature exists regarding the relationship between SSR results and bladder dysfunction. A correlation has been shown between the absence of the SSR response in the foot and bladder neck dyssynergia following spinal cord injury [62]. Recording from the perineal assesses sympathetic nerve function within the thoracolumbar cord [70].

Only complete absence of response can be regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not established.

Evidence-based medicine is founded on the assessment of evidence for and against the efficacy of particular types of therapeutic intervention. Clinical neurophysiology testing should thus demonstrate evidence that testing improves outcome (through treatment choice and patient selection), which would provide a strong basis for its use. However, testing and therapeutic intervention are different concepts, and neurophysiological testing has another important objective, which is not applicable to interventions and lies outside the scope of evidence-based medicine. It is to generate knowledge about the situation to be treated in a given patient, so that the practitioner can formulate rational treatment options based on knowledge rather than do so blindfold; that is, he or she can practice "knowledge-based medicine".

To judge the importance of this second objective different criteria are needed. Particularly in the referral setting, the physician is confronted with complicated cases in whom the underlying pathophysiology is quite uncertain, and what is required is to identify all the factors that may be contributing. Neurophysiology is helpful in assessment of neurogenic dysfunction because it contributes to "knowledge-based medicine", whether or not there is narrowly-defined "evidence" that it improves outcomes.

Of course, it remains true that we should seek evidence of the conventional kind for and against testing. Any test should be subjected to three questions:

1. Does the test have good technical performance?
2. Does the test have good diagnostic performance, ideally against a "gold standard" measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

Clinical diagnosis requires that measures obtained in individual patients be compared to population norms with the intent of determining whether they are "normal" or "abnormal". Data can be classified as "abnormal" only with the understanding that they are compared to a sample from the normal population. Predictive statements are made possible by the use of tolerance limits. For most clinical neurophysiological tests, one-tailed tolerance limits are recommended. For any given limit of normality, there is a certain probability
of falsely interpreting values (obtaining false-positives or false-negatives). Further confounding these issues is the practice of applying multiple criteria of abnormality. But ultimately, the adequacy of any given normal limit in discriminating between normal and abnormal must be supported by appropriate clinical or clinico-pathological correlations; for uroneurophysiological techniques, such data are scarce.

1. USEFULNESS OF CLINICAL NEUROPHYSIOLOGICAL TESTS IN EVALUATION OF INDIVIDUAL PATIENTS

Whenever pathophysiology is uncertain or unpredictable, and especially if irreversible treatment is necessary or contemplated, it seems logical to gather quantitative knowledge of the dysfunction in order to make a rational treatment choice. In most patient groups with neurogenic incontinence, the pathophysiology is unpredictable and comprehensive urodynamic evaluation is essential in order to practice knowledge-based medicine. In selected patients from these groups, clinical neurophysiological testing will clarify issues related to the neural control of lower urinary tract, relevant for understanding pathophysiology. Most patients, however, will not require a precise definition of the neurological lesion.

As is generally true for electrophysiological tests, uroneurophysiological examinations are particularly useful for substantiating the clinical diagnosis of a peripheral nerve lesion. The potential usefulness of testing in an individual patient needs to be analysed in the overall clinical setting. The indications for testing are guided primarily by expert opinion, not on definitely established criteria derived from controlled studies.

In the incontinent patient without other signs or symptoms of a neurological condition, neurophysiological testing is generally unnecessary. In patients with stress/urge, or mixed urinary incontinence electrophysiological testing is as a rule non-contributory [28].

2. USEFULNESS OF CLINICAL NEUROPHYSIOLOGICAL TESTS IN RESEARCH

Uro-neurophysiological techniques have been most often applied in research, for instance to elucidate the innervation of pelvic floor muscles; to study the physiology of contraction of sphincter muscle, to describe activation patterns of pelvic floor muscles. Suggestions of increased efficacy of sacral neurostimulation with the use of neurophysiologic tests have been made [71]. As understanding pathophysiology and neural control is essential in the application of more sophisticated therapeutic methods, such as electrical stimulation techniques, there seems to be a continuing place for clinical neurophysiology in research on neurogenic urinary and anorectal dysfunction and their therapy.

IV. RECOMMENDATIONS

1. RECOMMENDATION FOR CLINICAL NEUROPHYSIOLOGICAL TESTING

The information gained by clinical examination and urodynamic testing may be enhanced by uroneurophysiological tests in selected patient groups with suspected neurogenic urinary incontinence with lesions within the nervous reflex arcs of sacral segments 2 - 5. Concentric needle EMG to diagnose denervation and reinervation of pelvic floor and perineal muscles, and sacral reflex testing to assess the continuity of the sacral reflex arc, are the recommended tests.

Level of evidence: 2b
Level of recommendation: B

2. RECOMMENDATION FOR TECHNICAL STANDARDS

3. RESEARCH RECOMMENDATIONS

Clinical neurophysiological methods should be further used to better define the neural control in lower urinary tract function, demonstrating both the nervous system's "hardware" (integrity of anatomy) as well as "software" (level of activity, excitation thresholds) for co-ordinated urinary storage and voiding, in physiological and in pathological conditions. In particular, there is the opportunity to better define neurophysiological changes induced by therapeutic electrostimulation.

There is the challenge to develop tests to assess directly the sacral parasympathetic system.

A. INTRODUCTION

The Committee reviewed the evidence provided in the 2005 edition and updated the chapter with data from the peer-review literature published in the last 4 years. The chapter covers different issues including: imaging, neurophysiological testing, and other investigations (laboratory tests, tissue analysis and Pad test) with reference to paediatric and adult population, male and female subjects, neurogenic and non-neurogenic patients.

Imaging: the Medline database was searched using the following keywords: imaging, urinary incontinence, continence, anal incontinence and faecal incontinence; the search has been limited to period from 2004 to 2008. Neurophysiology: clinical neurophysiology, conventional urodynamics, neuourology, urinary dysfunction. Other investigations: keywords including urinary incontinence, continence, pad test, urinalysis, urine culture, tissue analysis were used. Members of the committee were allocated the different topics of the chapter based on their specific expertise in the field. All committee members reviewed the chapter draft, recommendations were collegially discussed on at the occasion of the ICI meeting in Paris (July 2008), the final draft was then edited first by the Committee Chair and then by the book Editors. As far as imaging is concerned, the chapter is structure based on anatomical issues: upper, lower urinary tract, bowel, central nervous system, and imaging technique: X-rays, ultrasonography, Magnetic Resonance Imaging. Imaging techniques were analysed taking into considerations the technique and its standardisation, intraobserver and interobserver variability, diagnostic accuracy, cost/benefit ratio and clinical benefit.

Levels of evidence and grades of recommendations were provided according to the guidelines of the ICUD summarised elsewhere in this book. Areas of future research were identified. The application of the ICUD guidelines to diagnostic issues such as those dealt with in this chapter is not without problems as they were developed for the evaluation of formal clinical trials.

Proper design, implementation and reporting of studies on diagnostic accuracy are essential to improve their quality and make evaluation of research easier. Most of the issues discussed in the present chapter fall within the remits of diagnostic tests and the evaluation of diagnostic accuracy as regulated by the Standards for Reporting of Diagnostic Accuracy (STARD) initiative provides a checklist and flow diagram that are essential to achieve transparent reporting [1]. The highly dynamic world of diagnostic tests requires a rigorous evaluation process to prevent premature dissemination of tests of unproven clinical value. Studies in this particular area provide additional information on patient health status that are important for managing the underlying condition or disorder such as pelvic organ prolapse, urinary or faecal incontinence. Evaluation of diagnostic accuracy can not be separated from analysis of the clinical benefit, in the absence of which diagnostic tests (laboratory and imaging tests, history, physical examination or pathology) can not be recommended.

Imaging studies should follow the suggestions of the STARD initiative and they differ substantially from clinical trials. The aim of clinical studies of diagnostic tests should in fact aim to provide information regarding the diagnostic accuracy of the proposed test. Imaging studies represent per se a unique category because of the known issues involving interrater variability in the interpretation of radiological pictures and the variability in imaging techniques (although this mainly applies to ultrasonography and endoscopy only). Consequently, the criteria proposed by the Agency for Health Care Policy and Research endorsed by the Oxford Centre for Evidence Based Medicine for evaluating levels of evidence and for deriving grades of recommendation do not apply as, for example, randomization is not a issue and consequently, levels of evidence 1 and 2 can not be found in the peer-review literature and grades of recommendation A and B rarely occur. Furthermore recommendation for imaging studies is not just related to the quality of the published manuscripts but on the presence or absence of clinical benefit for the patient category of interest. Imaging is currently used in the field of urinary and anal incontinence or pelvic organ prolapse to evaluate
parameters with proven positive or negative predictive value for patient management or to investigate the prognostic value of novel parameters. Imaging can be used to reduce the diagnostic burden providing information on parameters with known safety or prognostic value (eg: ultrasound imaging of post void residual) or to investigate new parameters that can not be investigated in any other way (eg: bladder wall thickness).

A few considerations on the levels of evidence in imaging studies may be instrumental in reading this chapter and are summarized herewith.

Imaging of parameters with known prognostic value (e.g. PVR)

• The first issue is to prove that imaging studies image what they are supposed to image. Although the issue may be trivial in case of PVR imaging or anal sphincter imaging, the issue is relevant in other areas (eg: enterocele imaging) and should be solved using imaging in cadavers or other approaches such as intraoperative confirmation of the observed condition.

• When the imaging is quantitative, accuracy versus the gold standard technique should be provided. When the imaging is qualitative (e.g. presence or absence of vaginal vault prolapse) the diagnostic value should be provided (sensibility sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability).

• Once validity has been proven, one can assume that the predictive value of the imaging study is equal to that observed for the parameter measured with the gold standard. The same applies to its value for patient management.

Imaging of parameters with unknown prognostic value (e.g. MRI of the pelvic floor)

• When the imaging in qualitative (eg: intact versus damaged levator ani), once validity is proven, the diagnostic value should be investigated providing sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability in cadavers or patients undergoing surgery.

• Once validity is proved, the prognostic value for patient management should be investigated.

• Extramural confirmation of the proposed imaging study is required ideally for both validity and prognostic value or at least for the latter parameter (we can assume that confirmation of the prognostic value is obtained, validity of the imaging technique can be inferred).

A proposal for new levels of evidence and grades of recommendations for imaging studies is provided elsewhere in this book.

B. IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION

B1. IMAGING OF THE UPPER URINARY TRACT

Urinary incontinence is defined as the complaint of any involuntary leakage of urine, it can be urethral or extrourethral. This latter condition either results from congenital anomalies such as ectopic ureters (inserting in the female distal urethra or vagina), iatrogenic or traumatic conditions such as fistula. In some patients, lower urinary tract dysfunction causing urinary incontinence, might compromise the transport of urine from the kidneys to the bladder resulting in hydronephrosis and renal failure. The relationship between high bladder storage pressure and renal deterioration was first identified in myelodysplastic children and then considered to apply in all neurogenic patients [1]. In male patients, chronic retention of urine can be associated with urinary incontinence and lead to chronic renal failure. In females, severe urogenital prolapse may cause angulation of the pelvic ureter by the uterine arteries leading to hydronephrosis in up to 30-40% of patients [2] (Figure 1 a,b).

I. INDICATIONS

Generally speaking, there is no need for upper tract imaging in cases of urinary incontinence unless any of the previously described conditions is suspected or diagnosed. Patients with extraurethral incontinence may also benefit from upper urinary tract imaging.

The objectives for upper tract imaging in the incontinent patient are as follows:

1. Evaluation of the upper urinary tract when the presence of an ectopic ureter or ureterovaginal fistula are suspected.

2. Evaluation of the kidneys whenever urinary incontinence is related to bladder dysfunction with high storage pressures (e.g. in neurogenic voiding dysfunction, chronic retention with overflow or low compliance bladders).

3. Exclusion of hydronephrosis in cases of urinary incontinence associated with severe uterine prolapse (Figure 2 a,b,c,d).

II. TECHNIQUES

Upper tract imaging modalities include intravenous ultrasonography (USS), intra-venous urography (IVU), computer-terized tomography (CT scan), MRI, and isotope scanning. No data as to specificity, sensitivity, predictive value or reproducibility in connection with the diagnosis and management of urinary incontinence are available. The use of the different imaging modalities also depend on availability, expertise, and local management policies. Generally speaking, low cost and low risk techniques such as USS should be preferred. Unless otherwise described, the following considerations regarding the different imaging modalities are based on expert opinion.

1. ULTRASONOGRAPHY

Ultrasonography is the gold standard technique for primary imaging of the upper urinary tract because of the relatively low cost of the equipment and therefore of the examination, its large wide availability, the lack of any exposure to ionising radiation. Renal USS is independent on kidney function, provides a good evaluation of renal anatomy including malformations, kidney size, cortex/medulla index, hydronephrosis. Concurrent kidney disorders such as urinary lithiasis and neoplasms can also be diagnosed. In patients with lower urinary tract dysfunction (LUTD), the detection of hydronephrosis is of importance and it can be related to either vesico-ureteral reflux or obstruction. Although, no correlation exists between the degree of dilatation and the severity of obstruction, the grade of hydronephrosis is correlated with the extent of cortical damage [3]. Measurement of the resistive index in the interlobar and arciform arteries of the kidney has been proposed for the diagnosis of urinary obstruction but this is rarely used in the evaluation of the incontinent patient [4]. Whenever hydronephrosis is diagnosed on USS, other imaging modalities are often used to evaluate renal function, the degree of obstruction or vesico-ureteral reflux. USS is an ideal technique to follow the degree of hydronephrosis over time or the response to treatment.

2. INTRAVENOUS UROGRAPHY

Intravenous urography or intravenous pyelography (IVU) is the original radiographic examination of the upper urinary tract which allows evaluation of upper urinary tract anatomy and function. Successful examination is dependent upon adequate renal capacity to concentrate urine and the examination is currently contraindicated when creatinine levels exceed 2.0 mg/dL [5]. A number of different conditions such as renal dysfunction, obstruction, congenital anomalies, fistula, stones and tumors may be detected. IVU is the appropriate first study in cases of extraurethral incontinence. When ectopic ureter is suspected (although this condition can also be responsible of for urethral incontinence), delayed films and tomography are important because the renal unit or moiety associated with an ectopic ureter is often poorly functioning. In fact, IVU is sometimes unable to detect a small, malfunctioning moiety associated with a duplication and ectopic ureter or a poorly functioning or abnormally located kidney with a single ectopic system [6-8]. In such cases where the diagnosis of ectopia is still suspected after IVU, another imaging modality such as CT, MRI (Figure 3 a,b) or isotope scanning should be considered [9-11]. IVU is the appropriate first imaging study when ureterovaginal fistula is suspected, usually after pelvic surgery. Typically, one sees ureteropelvicocaliectasis proximal to the level of the fistula. This finding has been reported in 84-92% of cases [12, 13]. Sometimes extravasation can be seen. Confirmation of the presence of the fistula, its size and exact location is often obtained with retrograde ureteropyelography.

3. COMPUTERIZED TOMOGRAPHY

High quality information of the upper urinary tract anatomy can be obtained using multislice CT and 3D reconstruction software. Differently from IVU which only acquires images in the antero-posterior straight or oblique CT acquires images in the transverse plane. Pictures can then be reconstructed in 2D along any plane or in 3D whenever required. CT scan can be used irrespective of renal function when no iodinated contrast media are used. Whenever hydronephrosis is found, urine can be used to delineate the collecting system avoiding the use of contrast medium.

Intravenous contrast medium can be required to highlight specific anatomic characteristics. CT scan is often used after a first line evaluation is performed using USS and constitutes a valid test if no better alternative to IVU and it is usually no more expensive. Several authors have reported the use of CT scan to detect ectopic ureter, in cases where the diagnosis is suspected, despite a normal IVU and ultrasound (14). In these cases the small size and poor function of the ectopic moiety make diagnosis difficult by IVU.

4. MAGNETIC RESONANCE IMAGING

MRI shares some of the advantages of CT over IVU in the evaluation of the upper urinary tracts. Furthermore acquisition can be performed along any plane and pictures can then be presented in a 2D or 3D fashion. The paramagnetic contrast medium is free of allergic reaction risk although its use in the upper urinary tract remains dependent upon renal function and concerns about its nephrotoxicity have been recently raised [15]. The development of the uro-MRI technique has gained an increasing role for the technology in the evaluation of hydronephrosis and urinary tract anomalies in as an alternative to IVU. MRI usefulness in the diagnosis of ectopic ureter has recently been described [16-18].
5. ISOTOPES

Isotopes are used primarily to examine morphological and functional characteristics of the upper urinary tract. Isotope scanning can be used to identify the location of a small kidney which is otherwise difficult to image with radiological techniques.

Renography is used to examine the differential function of the two kidneys, to identify disorders of urine transit and to quantify obstruction of the upper urinary tract. There are many physiological factors and technical pitfalls that can influence the outcome including the choice of radionucleotide, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function and compliance of the collecting system [19, 20]. Diuresis renography with bladder drainage is recommended when obstructive uropathy is suspected [21]. Renal scintigraphy may be useful in the evaluation of ectopic ureters associated with hypoplastic kidneys [22].

CONCLUSIONS AND RECOMMENDATIONS

Imaging of the upper urinary tract is NOT indicated in the evaluation of non-neurogenic stress, urge or mixed urinary incontinence. [Level of Evidence 3, Grade of Recommendation C]

Imaging of the upper urinary tract is indicated in cases of:

a) neurogenic urinary incontinence with high risk of renal damage (due to high detrusor pressure, e.g. myelodysplasia, spinal cord injury, and low compliance bladders) [Level of Evidence 3, Grade of Recommendation C]

b) chronic retention with incontinence [Level of Evidence 3, Grade of Recommendation C]

c) untreated severe urogenital prolapse [Level of Evidence 3, Grade of Recommendation C]

d) suspicion of extra-urethral urinary incontinence by upper tract anomaly [Level of Evidence 3, Grade of Recommendation C]

The choice of the imaging techniques and their sequence depend on the clinical question and their availability. The least invasive techniques should be preferred and should precede the more invasive, also taking into consideration cost effectiveness. [Level of Evidence 3, Grade of Recommendation C]

SUGGESTED RESEARCH AREAS

- Prevalence of upper tract deterioration in various urinary incontinence populations
- Natural history of upper tract damage
- Relation between upper tract dilation, renal damage and bladder function

B2. IMAGING OF THE LOWER URINARY TRACT

Imaging of the lower urinary tract (LUT) has a long tradition in the management of urinary incontinence, particularly in female patients. The techniques have changed, over the decades from static to dynamic imaging, from qualitative to quantitative information. Although some of the techniques are now more than 50 years old, their standardisation is insufficient and their clinical value often unclear. Most of the possible imaging modalities remain “investigational” as their impact on the management of urinary incontinence has not been established yet.

Voiding cystourethrogram (VUCG) was the mainstay of imaging studies in urinary incontinence until recently when US evaluation of the lower urinary tract through the pelvic window became prevalent because of its immediacy, low cost and availability.

While CT never gained acceptance because of the exposure of ionising radiations, MRI took the lead as the most promising imaging modality and a number of papers have been published over the years riding the wave of technological development.

In males the purpose of voiding cystourethography has been mainly to locate infravesical obstruction although it may play a role in the management of post-prostatectomy incontinence [1]. In children the diagnosis and classification of reflux and diagnosis of posterior urethral valves have been the primary goals [2]. The severity of the vesicoureteric reflux on one side determines the development of contralateral reflux and indicates a poorer resolution rate for the reflux [3].

Positive-pressure urethrography has been designed only for the diagnosis of female urethral diverticula, it was shown to be more sensitive than voiding cystourethrography [4-6] although MRI is the gold standard to diagnose diverticula and assess their anatomical relation to the surrounding structures [7, 8].
I. X-RAY IMAGING

The rationale for imaging studies of the lower urinary tract in this field derives from the supposed relation of morphology and function and particularly the causative role of urethral hypermobility in stress urinary incontinence. Investigation into cohorts of continent and incontinent patients failed to provide evidence to support the hypothesis and some imaging techniques have been abandoned. The same applies to outcome research in urinary incontinence where restoration of normal anatomy does not necessarily lead to cure of the condition. A renewed interest derived from the availability of USS which took imaging out of the radiology suite and moved it into the urological and gynaecological outpatient clinics opening new opportunities for clinical research in this field. The interest in MRI derives from the specific characteristics of this imaging modality which allowed both fast acquisition in the dynamic range and accurate evaluation of tissue characteristics together with the possibility to investigate the whole pelvis as one functional unit.

1. FEMALE CYSTOURETHROGRAPHY

X-ray imaging of the urinary bladder and urethra has been used to assess the female urinary tract in women suffering urinary incontinence to evaluate urethral/bladder neck hypermobility and to assess associated conditions such as urethral obstruction, vesico-urethral reflux, diverticula, fistula, stones and tumours. In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction [1, 9]. The diagnosis and classification of reflux and diagnosis of posterior urethral valves in children have been the primary goals [2]. In a study comparing cystourethrography with direct radionuclide voiding cystography and voiding urosonography with contrast medium were compared. Voiding sonography and direct radionuclide voiding cystography were shown to be the most sensitive [10].

2. BACKGROUND

History and methodology of cystourethrography in females had been reviewed by Olesen [6]. The technique is now over 70 years old. Voiding cystourethrography with lateral projection was first done by Mikulicz-Radecki in 1931 [11]. The use of a metallic bead to identify the urethra was introduced by Stevens and Smith in 1937, and in 1956 Ardran, Simmons and Stewart reported on a cinematographic technique with contrast media also in the vagina and rectum [12, 13]. In an attempt to combine qualitative and quantitative information as to the function of the lower urinary tract, the combined used of fluoroscopy and pressure-flow recordings was proposed during the sixties and seventies [14-18].

3. METHODOLOGY (PROJECTION, POSITIONING AND EXPOSURES)

Bladder neck displacement is best viewed and quantified in true lateral projection although image quality is sometimes poor because of the increased body mass and the overlap of bony structures with the bladder neck area. Consequently, oblique projections are sometimes used notwithstanding the lack of quantitative information. Achieving a quasi-physiological voiding in a radiology suite is difficult because of the inevitable impact of the environment. The use of a sitting position is recommended for micturition studies as voiding while standing or lying will increase the embarrassment and thereby the bias of the examination [11]. Especially in patients with large body mass index, imaging of female urethra in a true lateral projection is difficult, it necessitates high radiation doses as the central x-ray beam must penetrate the trocanteric regions and further because the urethrovesical junction is sometimes is overshadowed by the lateral parts of the bladder. A significant improvement in this area has been brought about by digital imaging which allows the subtraction of the bony structures (Figure 4). The position and mobility of the urethrovesical junction as well as urine leakage are supposed to be influenced by the filling volume as has been demonstrated on ultrasonography and leak point pressure measurements [19, 20]. However, in voiding cystourethrography the bladder is filled to capacity. Addition of a urethral bead chain or catheter and vaginal contrast to improve the visualisation of the urethra, bladder neck and trigone has been abandoned. Contrast in the rectum is not necessary for urinary incontinence purposes. Exposures at rest should be supplemented with provocative manoeuvres to test bladder neck mobility by contracting and relaxing the pelvic floor (e.g.: coughing, straining, and squeezing). Whenever possible, pictures while the patient is voiding the bladder should be obtained. It is important to consider that coughing and straining result in a different effect on the pelvic floor. Straining might be associated with relaxation or contraction of the pelvic floor, and the imaging can change accordingly.

During coughing there is a reflex contraction of the pelvic floor, but coughs are of short duration and difficult to catch on spot films. Bladder suspension defects were diagnosed at rest in 49% of 420 examinations, while coughing and micturition disclosed a further number of 20% and 4% respectively [11]. Squeezing can demonstrate pelvic floor awareness and contraction [21].

4. COMBINED IMAGING AND URODYNAMICS

Videourodynamics has been by some regarded as the “gold standard” in the evaluation of lower urinary tract dysfunction [21]. Reproducibility of the combined examination has not been assessed and further the
radiation dose has to be considered [13, 18, 22-24]. One study has attempted to compare videourodynamic with saline cystometry [21]. Independent observers carried out the two procedures with 75 women having the saline cystometry first and a further 75 women had videourodynamic first. The degree of bladder descent noted on screening was greater than on clinical examination. Nineteen women had trabeculation and a further 11 women had bladder or urethral diverticula, urethral stenosis and vesicoureteric reflux [1, 9, 12]. Only seven of the eleven women could have been predicted by a selective imaging policy based on history alone which would image 43% of the 150 women. This suggests that a selective policy of screening will unnecessarily expose patients to radiation while not using the optimal technique for investigation for all patients who need the test. Nevertheless simultaneous videomonitoring along with tracings of pressure and urine flow rate are important means to be sure that the exposures are made at appropriate moments so that the radiographs can be representative of the various functional states [11, 16, 25, 26].

Patients with Parkinson’s disease and multiple system atrophy are best evaluated by videourodynamic and sphincter motor unit potential analyses to identify characteristic features of these conditions including: external sphincter denervation, neurogenic sphincter motor unit potentials, open sphincter denervation bladder neck at rest and detrusor-external sphincter dyssnergia [27].

Neurogenic patients show severe bladder trabeculation with diverticula and pseudodiverticula, pelviureteric reflux, widening bladder neck and proximal urethra; narrowing at the level of the membranous urethra and the bladder neck can suggest the presence of neurogenic dysfunction of the lower urinary tract (occult spinal dysraphism, non-neurogenic neurogenic bladder) even in the absence of neurogenic symptoms and signs [28-30]. Urodynamic parameters in children do not discriminate between those with or without vesicoureteral reflux thus videourodynamic studies have been considered essential. Additionally children with non-neurogenic voiding dysfunction are found to have a number of abnormalities with videourodynamic [31, 32]. Indications for videourodynamic include previous continence and vaginal surgery, neurological disorders and suspicion of urethral diverticula.

5. NORMAL AND DEFECTIVE BLADDER SUPPORT

The whole issue about the clinical value of cystourethrogram is about the pathophysiology of defective bladder support in the pathophysiology of stress urinary incontinence in female patients and the relation between the surgical correction of such a defect and cure. The concept of urethral hypermobility was inherent to the classification of stress urinary incontinence and the concept that an impaired transmission of abdominal pressure to female urethra could be responsible for the observed leakage. Little remains about the concept of urethral hypermobility in a modern view of female stress urinary incontinence and this contributed to the gradual abandoning of cystourethrogram in the evaluation of a standard patient.

The normal resting bladder has a smooth surface although bladder trabeculation is often seen in elderly lady women and not necessarily related to any pathological condition. The internal urethral orifice is located just above a horizontal line through the lowermost part of the symphysis in a coronal projection. The urethra is straight and runs anteriorly and caudally toward the external meatus.

On coughing and straining, relaxation of the pelvic floor results in downward movement of the bladder...
neck, which can be associated with a backward movement of the bladder neck resulting in a change in urethral axis. Squeezing (and sometimes also straining) results in contraction of the pelvic floor muscle with a cranial movement of the bladder neck Figure 5a. During voiding (Figure 5b) the bladder base is usually lowered about 1 cm, the angle between the urethra and the trigone is straightened, making a funnelled appearance of the proximal urethra and the bladder base, the bladder contour is rounded and a fine sawtooth irregularity of the mucosa becomes visible above the trigone.

Angles and distances between the urethra, bladder base and symphysis pubis have been assessed radiologically. The following parameters have been assessed for reliability:

1. The posterior urethrovesical angle (PUV) is defined by lines along the posterior urethra and the trigone [33]. Cut off values were usually 115° or more [34, 35];

2. The urethral inclination is between the proximal urethral axis and the vertical plane, which is a plane outside the patient and, therefore, the angle also varies with pelvic inclination. In Green type I and type II descent the angle is less or more than 45° respectively [35];

3. The urethropelvic (UP) angle is measured during voiding as the anterior angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis through the lowermost part of the obturator foramen closest to the film. In normals the mean UP is about 95° and the cut off point for bladder descent are values below 70° [11];

4. Symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice. Normal values are 31 ± 6 mm (mean ± SD) and values less than 20 mm are the cut off points for descen t [11];

5. The urethral axis at rest (UAR) and during straining (UAS) (Figure 6)

Funnelling of the proximal urethra and flatness of the bladder base (both anterior and posterior to the internal urethral orifice) and the most dependent portion of the bladder base (the urethrovesical junction or a point posterior to that) are important qualitative parameters estimated on straining films [34].

Anterior bladder suspension defects or bladder base insufficiency (BBI) (Figure 7) is defined as SO < 20 mm with a normally positioned vagina at rest, during coughing or micturition and/or funneling of the bladder base at rest or with coughing. The insufficiency can be graded 1-3, which corresponds to Green's type I descent [11, 36]. The supportive defect is supposed to be in the fascial and ligamentous system and their abnormal detachments (eg., paravaginal defects).

Posterior bladder suspension defects (Figure 8) are defined as a posterior-inferior bladder displacement and a UP of less than 70° [11]. It corresponds to Green's type II [37]. Sometimes (Figure 9) only the trigone and posterior part of the bladder is involved. The supportive defect is supposed to be in the muscular pelvic floor, that is, the pubo-vesical part of the pubococcygeus muscle or in paravaginal detachment.

Interestingly, when UAR and UAS were examined in a group of 76 continent women and correlated with age, a perfect linear regression was noted between UAR and age (R^2= 0.28). Patients with stress urinary incontinence were found to have an average UAR value of 25° with a mean UAS of 43° leading to a threshold value of hypermobility of about 20°. When standing cystourethrograms were repeated 3 to 6 months after surgery for stress urinary incontinence, UAR and UAS values were found to be close to normal suggesting a relation between the correction of the defective bladder support and cure [37]. A more structured definition of cystocele (ranked by height in centimetres) was also obtained, adding to the

emerging data that the reliability of the pelvic organ prolapse quantification (POP-Q) system (POP-Q) increases when measurements are performed in a more upright position [37].

6. REPRODUCIBILITY

The observer variation has been evaluated in four university uro-gynecological units (Table 1) [21, 34, 38, 39]. The inter-observer agreement was 43-79% and the intra-observer agreement was 53-99%. These figures are in the same range as has been found for other diagnostic tests [40].

Accuracy for the diagnosis of stress incontinence and post-operative results

Evaluation of accuracy is the mainstay in the evaluation of a diagnostic technique. One has to consider that sensitivity and specificity depend on intrinsic factors such as reproducibility (as measured by intraobserver and interobserver variation) and extrinsic ones such as the characteristic of the patient cohort used for to assess accuracy.

The accuracy of the previously mentioned radiological criteria have been measured by comparing imaging data with the ‘so called’ index-test which in this case was a clinical diagnosis of urodynamic stress incontinence and expressed as specificity and sensitivity or as predictive values. Unfortunately the diagnosis of stress urinary incontinence is controversial and might be based on subjective criteria, urodynamic tests, or measurement of leakage. Even radiological criteria have been included in the diagnosis.

Reproducibility (e.g. test-re-test agreement) has not been measured, but intra- and inter-observer variation has been calculated and also adjusted for expected chance agreement (kappa coefficient). The predictive values and the kappa coefficient are supposed to depend on the prevalence, and therefore, comparison between different materials are difficult [40].

No consensus has been reached in the peer-review literature as to the lack of discriminant value of cystourethography between stress incontinence and continence, the majority of published papers are consistently negative although new promising data have been published [35, 37, 41-43]. The specificity of 5 radiological parameters on static bead chain cystourethography was 44-76% and the sensitivity 53-100% [43, 44]. Neither was the degree of stress incontinence correlated to the type or degree of suspension defects [21, 38, 45]. The positive and negative predictive values for a bladder suspension defect were 0.70 (95% C.I.: 0.62-0.78) and 0.52 (95% C.I. 0.41-0.63) respectively on voiding colposcystourethography [36, 46]. In a later publication on 159 women, positive and negative predictive values of 0.56 and 0.74 were obtained [43]. Evaluation of the urethral angle at rest and during stress in controls and in patients with stress urinary incontinence and various grades of anterior vaginal prolapse show a significant relation between UAR and aging (from 2.4° ± 14.9° in the third decade to 29° ± 9.2° in the 9th decade; \( r^2= 0.28 \)). In patients with SUI, UAR and UAS decreased from 25.7° ± 13.6° and 42.6° ± 15.9° to 16.6° ± 14.7° and 23.8° ± 17.5°, respectively; the observed change were found to be statistically
significant. A similarly significant difference was found in patients with moderate to grade 3 cystocele and urethral hypermobility (at least 5 cm descent of the bladder base below the inferior ramus of the pubic symphysis on the lateral view of a standing VUCG): UAR and UAS decreased from 48.1° ± 16.5° and 64.4° ± 16.8° to 22.3° ± 26.9° and 29.8° ± 22.8°, respectively.

Comparison of a randomly selected control cohort (aged-matched) with patients suffering SUI showed a significant difference of UAR and UAS at diagnosis while similar values were found after surgery (Figure 9). This was similar to patients with grade 3 cystocele in whom both UAR and UAS were significantly different from controls at baseline while showed similar values in the postoperative follow-up.

Measurement of the cystocele height (LATH), obtained as the distance between the inferior border of the pubic symphysis and the inferior edge of the cystocele in controls and patients with mild and severe cystocele showed a significant difference between the two cohorts (16.63 ± 10.9 mm versus 27.4 ± 12.3 mm versus 73.4 ± 15.6 mm, respectively). Following formal cystocele repair, a significant change of LATH values was found in patient with mild and severe cystocele (from 27.4 ± 12.3 mm to 13.9 ± 18.0 mm and from 73.4 ± 15.6 mm to 25.4 ± 24.6 mm, respectively [p<0.001]).

These are the first data supporting the used of standing VCUG as an outcome measured, previous peer-review

1: static bead-chain cystourethrography with straining [34]. The 5 landmarks were the posterior urethrovessical angle, urethral inclination, funnelling of the proximal urethra, flatness of the bladder base and most dependent position of the bladder base;

2: voiding colpo-cystourethrography (VCCU) at rest and with coughing, straining, micturition and squeezing; one observer against original diagnosis (that is, normal appearance or anterior, posterior or combined suspension defects) made by a few senior radiologists [20];

3: voiding colpo-cystourethrography at rest and with coughing, straining, squeezing and micturition. Possible diagnoses were: normal appearance or anterior, posterior or combined descent respectively [39].

4: voiding colpo-cystourethrography at rest, coughing, with holding and voiding. Possible diagnoses were: normal appearance and anterior or posterior descent respectively [38];

5: standing voiding cystourethrography, urethral angle was measured at rest (UAR) and during straining (UAS) [37].

Figure 9 : Mean 6 95% confidence interval for UAR (squares) and UAS (circles) before and after surgical correction compared with age-matched controls. Difference from “before” to “after” was significant for both surgical groups; difference between “after” and “control” was not significant.
papers suggested the inability of the technique to distinguish postoperative failures from success [11, 21, 40, 42, 44, 47-50].

7. COMPARISON OF CYSTOURETHROGRAPHY AND ULTRASONOGRAPHY

The development of USS techniques for the evaluation of the lower urinary tract raised the question of the relationship of X-ray versus USS imaging. Static bead chain cystourethrography has been compared with transrectal and perineal ultrasonography and voiding colpo-cystourethrography has been compared with perineal ultrasonography [44, 45, 51, 52]. The findings correlated well regarding bladder neck position and mobility, PUV, urethral inclination, SO distance and rotation angle.

Specificity, sensitivity and interobserver agreement were also comparable for the two methods. All the authors seem to prefer the sonographic modality because the imaging study can be performed at the same time as the physical examination. This has also been the case in men with neuromuscular dysfunction [9]. Simple and extensive funneling is more easily imaged in upright patients during cystourethrography than in the supine position frequently used for ultrasound studies [28].

8. COMPARISON OF CYSTOURETHROGRAPHY AND MRI

The introduction of MRI in the assessment of the LUT required an adequate comparison of this technique with standard X-ray imaging. The comparison of cystourethrography and colpo-cystourethrography with dynamic MRI showed comparable data on bladder neck position and cystocele extension [53, 54]. Although there is an obvious concern about the fact that dynamic MRI is usually performed with the patient lying in a dorsal lithotomy position, comparison of standing and lying colposcystourethrography did not show any significant difference [54].

CONCLUSIONS

The role of cystourethrography in the evaluation of female urinary incontinence remains to be established although preliminary evidence is now available that the measurement of urethral angle and cystocele height might have some clinical utility in the management of patients with urinary incontinence and genital prolapse who are scheduled for surgery. Defective bladder support can be diagnosed on voiding cystourethrography with a reliability comparable with other diagnostic tests.

Dependent on local facilities the method might be considered if the choice of a surgical procedure is based on type and degree of supporting tissue deficiencies and possibly if new procedures are evaluated for the ability to restore this deficiency. The method can not yet be recommended for the diagnosis or classification of urinary incontinence.

RECOMMENDATIONS

- Cystourethrography is NOT indicated in primary uncomplicated stress, urge or mixed female urinary incontinence [Level of Evidence 3, Grade of Recommendation C].
- Cystourethrography may be a reasonable option in the preoperative evaluation of complicated or recurrent female urinary incontinence [Level of Evidence 3, Grade of Recommendation C].

SUGGESTED RESEARCH AREAS

- Standardization of technique, parameters and interpretation of cystourethrography.
- Possible value of cystourethrography in the evaluation of pelvic floor dysfunction (correlation of imaging to pelvic floor physical examination and to clinical outcome following therapy)

1. BACKGROUND

X-ray imaging has been used for decades in the evaluation of the lower urinary tract; the contrast agents are used to visualize the bladder and a bead chain can help to outline female urethra. Dynamic cystograms, were used to classify female urinary incontinence, the technique was gradually abandoned for its poor accuracy in diagnosing the condition, its little impact on patient management and poor correlation with treatment outcome [1].

Ultrasonography has been used in the evaluation of urinary incontinence as early as 1980 [2]. In the late eighties and nineties of the previous millennium, the quality of ultrasonography greatly improved as well as its availability. Various new developments, such as the use of contrast medium, colour Doppler, 360 degree transducers and three-dimensional imaging have been introduced and have been instrumental to a more widespread use of ultrasonography in the evaluation of pelvic floor disorders.

A number of studies have reported good correlations between ultrasonography and x-ray in the evaluation of urinary incontinence [3-10]. In particular, the position of the bladder neck at rest and during Valsalva manoeuvre has frequently been compared, and all authors agree on a good correlation. Some authors even found a better accuracy for the ultrasonographic method [6], especially in obese women [3]. Ultrasonography is cheaper than X-ray imaging, it is often preferred by physicians because the imaging studies can be performed in their own office as part of the physical examination and it is also more acceptable to patients because of the lack of for radiation exposure.

2. TYPES OF ULTRASONOGRAPHY

Different imaging windows have been used, such as abdominal, transvaginal, transrectal, perineal and transurethral. Synonyms for perineal access are transperineal, introital, labial or translabial access. Abdominal ultrasonography is general not considered to be helpful in pelvic floor imaging because of the acoustic shadow caused by the pubic bones. All types of access have the potential risk of interference with the existing anatomy. With vaginal ultrasonography this risk is probably highest [11], although this has also been denied [12]. Most recent studies report on perineal ultrasonography that allows the visualization of all three compartments in one image.

The development of three-dimensional ultrasonographic systems has brought a new dimension to pelvic floor imaging. Three-dimensional ultrasonography was first described for the female urethra in 1999 [13]; the three-dimensional image can either be evaluated as a separate entity on the screen, or in combination with each of the two-dimensional planes from which it is derived (Figure 1). These three two-dimensional planes are the sagittal, coronal and axial. Three-dimensional images are built up as a rendered image of a self defined region of interest, major advantages over 2D imaging include the possibility to review the acquired images from any investigator and the ability to analyse the acquired volume through any plane (likewise CT scans or MRI) (Figure 2) so that, for example, the levator ani muscle can be easily visualised. Four-dimensional imaging, i.e. real-time three-dimensional imaging, incorporates the enormous improvement in speed of three-dimensional systems over the last few years and it makes three-dimensional assessment of the dynamic relation of the pelvic organs on Valsalva manoeuvre and pelvic floor contraction possible.

2. STANDARDISATION

No consensus has been reached as to the standardisation of image orientation. Some prefer orientation with cranial structures above (Figure 3a) [14] whereas others prefer presentation of the cranial parts below (Figure 3b) [15]. All authors agree that the symphysis pubis, and its inferior border in particular, is a well recognizable and fixed reference point. This point can be used in the evaluation of the various aspects of relevant structures at rest and during dynamic imaging. In general, ultrasonographic studies are performed in the supine position (Figure 4). Small differences between the supine and standing position of the patient have been documented, although these differences disappeared during a Valsalva manoeuvre [16]. Only a few studies have been performed in the standing position [17]. There is no clear consensus on the amount of bladder filling, some authors prefer significant bladder filling, others prefer a nearly empty bladder because an empty bladder seems to descend more on Valsalva manoeuvre compared with a full bladder [18, 19]. Attempts to standardize Valsalva manoeuvre, ideally with intra-abdominal pressure measurements, has not been widely accepted [20]. In a recent study [17], a peak flow meter has been used, where women were asked to “huff” maximally and to reach the same force during a number of “huffs”. It has been shown that the mobility of the bladder neck differs between coughing and Valsalva manoeuvre [21]. Co-activation of the pelvic floor muscles during Valsalva manoeuvre has been

documented and is one of the reasons for the lack of standardization [21].

4. THE URETHRA AND BLADDER NECK

When collagen fibres and muscle fibres are located parallel to the ultrasound beam, the structure becomes hypoechoic. These same structures will become hyperechoic, however, when the fibres are located perpendicular to the beam. On two-dimensional ultrasonography, this may result in variable images of the urethra, since the echogeneity of the structures depends on the position of the transducer in relation to the urethra. This may produce confusing images, especially in the dynamic process of pelvic floor contraction and Valsalva manoeuvre. In the midsagittal plane on perineal ultrasonography, and with normal anatomical position of the urethra at rest, the internal sphincter and inner mucosal layer of the urethra will appear hypoechoic (Figure 1), these structures cannot be distinguished from each other on ultrasonography. In the midsagittal plane and with normal anatomical position of the urethra at rest, the striated external sphincter or rhabdosphincter will appear hyperechoic, and can hardly be distinguished from the surrounding structures. It will, however, be easily visible as a hyperechoic circular structure in the axial plane as seen on three-dimensional ultrasonography. The rhabdosphincter has been found to be thinner dorsally [13], and both ventrally and dorsally [22] by various authors and more difficult to distinguish from the internal sphincter ventrally and dorsally compared with laterally [23].

With the use of ultrasonography, thickness and length of the urethral sphincter muscle can be measured and urethral volume calculated [15, 23, 24]. Some make use of intra-urethral ultrasonography for this purpose, [25] others use two- or three-dimensional ultrasonography of the urethra [13, 22, 26, 27]. Comparison of transvaginal and transrectal approach showed a lower degree of urethral compression with the latter approach [22, 28]. Ultrasound measurement of female urethra has been found to be reproducible [13, 27]. Sphincter volume may differ significantly when 2D or 3D imaging is used [27]. Urethral volumes, measured by 3D ultrasonography, were positively correlated with the actual volumes in cadavers [26]. A significant and positive correlation between rhabdosphincter volumes and symptoms and signs of urinary incontinence has been reported [13]; correlations with the urethral pressure profile (UPP) have been found [23, 24, 26, 29] but these data could not be reproduced [30]. Ultrasonography imaging during micturition has been explored with the aid of a remote control systems [31].

The use of intra-urethral ultrasonography with rotating probes (360°) has been proposed by various authors although no particular advantages over perineal US could be identified [25, 32-35].

The advantage of preoperative and intraoperative three-dimensional ultrasound scanning in women with urethral diverticula has been outlined by Yang et al. [36, 37].

5. BLADDER NECK

The bladder neck and proximal urethra are easily visible on all types of ultrasonography without the need for catherization (Figure 1). Measurements are usually taken at rest, during straining (Valsalva manoeuvre), and sometimes during a cough and squeeze. The position and movements are measured in relation to the lower margin of the symphysis pubis. The difference between rest and strain is referred to as the bladder neck descent (the distance between the bladder neck and a horizontal line through the lower end of the symphysis pubis) (Figure 5). On Valsalva manoeuvre the bladder neck rotates in a posterior and inferior direction under the symphysis pubis. The axis of the urethra in relation to a vertical or horizontal line can be measured in degrees and provide the degrees of urethral rotation ((hyper) mobility). Other parameters are the posterior urethrovesical angle and the anterior urethrovesical angle.

A number of studies have validated the use of ultrasonography in the assessment of the position and mobility of the bladder neck and proximal urethra. Good results for this validity testing have been reported although the clinical value of such measurements is still elusive [5, 12, 38-40]. Normal values of bladder neck mobility have not been defined, since there is a great range in mobility even in young nulliparous women. In one study amongst nulliparous continent women of approximately 20 years of age, the bladder neck descent varied between 1mm and 40mm [41]. Others [38] found an average descent of 15 mm on Valsalva manoeuvre and 8 mm on a cough. Brandt et al. have found an average bladder neck descent of...
only 5 mm in 16 year old girls [42]. Racial differences have been demonstrated, with white women having a greater bladder neck mobility compared with black women [43]. Genetic determination of bladder neck mobility has been suggested [44].

Numerous studies have found greater bladder neck mobility in parous compared with nulliparous women [12, 30, 45-47]. Bladder neck hypermobility, however defined, is considered to be related to stress urinary incontinence [15, 30]. A large number of studies have correlated ultrasonographic findings with urodynamic parameters [47-56]). Specificity and sensitivity of ultrasonography for the diagnosis of stress incontinence were 83 and 68% in one study [50] and 92 and 96% in another study [57].

One research group has specifically investigated simultaneous perineal ultrasonography and urethrometry. They were able to demonstrate that the variations in urethral pressure were caused by the activity of the urethral sphincter as well the pelvic floor muscles [58]. The contractions from the urethral sphincter are always fast contractions. Some studies have used ultrasonography in an attempt to optimize patient management, but despite the abundant literature on the use of ultrasonography in the work up in women with urinary incontinence, disappointedly, a clinical advantage in terms of patient outcome has not been studied up till now [59, 60].

Urethral funnelling can be observed on ultrasonography (Figure 6) particularly with the use of contrast agents. It is a typical finding in women with stress urinary incontinence but can be seen in asymptomatic women as well [61-63]. In a study on stress incontinent women, funnelling was found to be present in nearly all women [62, 64]. Urinary incontinence can be demonstrated by the use of colour Doppler of the urethra [65, 66]. Colour Doppler has, furthermore, been used to visualize the perirectal vasculature and differences have been described between continent and incontinent women [67, 68] and before and after estrogen supplementation in postmenopausal women. Doppler velocimetry has recently been used in a study on the vascularisation of the levator ani muscles and a correlation has been found between the absence of an end-diastolic shift and the presence of stress urinary incontinence [69].

6. DETERMINATION OF THE POST VOID RESIDUAL URINE AND BLADDER WALL THICKNESS

Ultrasonography is the gold standard technique for measuring bladder volume and post-void residual urine [70-74]. Ultrasonographic data have been compared with residual volumes obtained by in-and-out catheterization under ultrasound control and were found satisfactory. However, Khan et al. have challenged the methodology of these studies and have found deficiencies in all reports on the topic [75]. A simple formula often used is \[ \text{Volume (ml)} = \text{Height} \times \text{Width} \times \text{Depth} \times 0.7 \] in which the factor 0.7 is the correction for the non circular shape of the bladder.

Automated ultrasound systems for measuring bladder volume and post-void residual have been developed and found to be more accurate than standard ultrasound measurements, furthermore they can be safely used by health care providers with no training in ultrasound imaging and by the nursing staff [76]. These machines are widely used and are, in general, experienced as reliable enough for clinical use, however, in case of ascites [77] or an ovarian cyst [78] for example, the estimated urinary volumes can be
incorrect. Recently the normal values for the post void residual urinary volumes in asymptomatic women have been presented; in 60 year old women, the median residual volume was 19 ml, and 95% of women had a post void residual volume of less than 100 ml [71].

Ultrasound measurement of bladder wall thickness (BWT) and ultrasound estimated bladder weight (UEBW).

Ultrasound measurement of BWT was first proposed as a non-invasive method for diagnosing infravesical obstruction in children [79]. More recently, BWT has been used to predict the outcome of children with primary nocturnal enuresis [79-81]. BWT has also been proposed as a risk factor for upper urinary tract deterioration in children with myelodysplasia [82]. Measurement of BWT was also proposed to diagnose bladder dysfunction (DO and detrusor hypocontractility versus normal detrusor function) in children with urinary tract infection [83, 84]. Additional parameters such as the bladder wall thickness index (length x width x depth of the bladder at full bladder/average BWT) were proposed and a nomogram for the paediatric population provided [85].

In the adult population, higher BWT values have been measured in men than in women. Thickness may certainly differ depending the measurement technique; values of 3.3 ± 1.1 mm and 3.0 ± 1.0 mm, respectively were reported by Hackenberg and co-workers [86]. Oelke confirmed a significant difference between male and female detrusor thickness (1.4 versus 1.2 mm, respectively) [87]. A small increase of detrusor hypertrophy with age has been reported in both genders [86].

In men, measurement of bladder wall thickness proved to be the most sensitive parameter (outperforming uroflowmetry) to diagnose BOO in patients suffering LUTS [88, 89].

Transvaginal ultrasound was first proposed in 1994 for the measurement of BWT in women with bladder volume of less than 20 ml. A significant difference was shown in patients with DO and USI (6.7 ± 0.6 versus 3.5 ± 0.6 mm, respectively). Low intraobserver and interobserver variability were measured: 0.02 mm in both cases with a 95% confidence interval of -0.22 to 0.18 and -0.32 to 0.35 mm, respectively [90].

In 1996, Khullar and co-workers showed how ultrasound measurement of BWT is a sensitive method for diagnosing DO in symptomatic women without bladder outlet obstruction with 94% of women with BWT greater than 5 mm having involuntary detrusor contractions on videocystourethrogramy or ambulatory urodynamics [91]. In 2002, the same group showed no overlap in the 95% confidence intervals of BWT was shown in patients with DO and USI in women with storage symptoms, confirming the potential of this parameter for diagnosing DO [92]. In 2003, a study on ultrasound cystourethrography in women confirmed a significant association between age and intravesical pressure at maximum flow with BWT [93].

Methodological and technical issues in the ultrasound measurement of bladder wall thickness and weight remain open and constitute a major limitation for a more widespread use of these parameters. In 2005 Chalana and co-workers published an early report on automatic measurement of the ultrasound-estimated bladder weight from three-dimensional ultrasound. An average value of 42 ± 6 g was measured in healthy male subjects. A standard deviation of 4 g was seen among measurements performed in the same subject at different bladder
Further research in this area is certainly needed and further improvement in the accuracy of automated systems is eagerly awaited. Although data published in the peer review literature on this subject are quite consistent, two discordant papers were recently published from Australia. Blatt and co-worker showed uniform values of BWT among men and women with non-neurogenic voiding dysfunction suggesting this parameter cannot be used to diagnose storage or voiding dysfunction [95]. A retrospective study on women undergoing translabial ultrasonography suggests a significant association between BWT and DO although a low diagnostic accuracy was shown for the diagnosis of DO which could be due to the fact that translabial ultrasound is unreliable [96].

The association between detrusor hypertrophy and bladder dysfunction (DO and BOO) is a well established fact in Urology. Ultrasound measurement of BWT and UEBW is an interesting alternative approach that may avoid invasive urodynamics in some patients. The development of automated ultrasound systems for measuring UEBW is instrumental to foster further research in this area, particularly in the management of patients with LUTS and in the evaluation of bladder response to pharmacologic treatment.

7. PELVIC FLOOR MUSCLES

Ultrasoundography can be used to assess pelvic floor muscles and their function. Contraction of the pelvic floor results in displacement of pelvic structures that can easily be imaged on ultrasound (Figure 7) such as the cranial lift of the urethra in relation to the symphysis pubis during a maximal squeeze [16, 97] but also the dimensions of the genital hiatus or the posterior ano-rectal angle can serve this purpose [98]. Comparison with traditional measurements of pelvic floor muscle strength has been performed [97], and good correlations with palpation and perineometry have been found [99, 100]. Ultrasonography has been used to evaluate the effects of pelvic floor muscle training. A higher resting position of the bladder neck and a reduction in the rotational excursion of the urethra during Valsalva manoeuvre has been found with training [101]. Another research group has reported that the thickness of pelvic floor muscles increased after training [102]. A number of studies have assessed healthy female volunteers to establish normal values [41, 102], and one study has specifically compared elite athletes with normal volunteers [103]. Measurements of the levator ani muscle, with the use of two-dimensional imaging, has recently been described, and although direct comparisons to three-dimensional ultrasonography are lacking, the acquired data were comparable [104].

Almost half of women are unable to perform an optimal contraction of the pelvic floor muscles. Ultrasonography can be used in pelvic floor training to provide women a visual feedback of their exercise [16, 105]. In one study, 57% of the women who were not able to perform a proper pelvic floor contraction, were able to do so with the help of visual biofeedback of ultrasonography [16]. Whether this form of biofeedback results in better outcomes from pelvic floor physiotherapy is not known. The contraction of the pelvic floor muscle just before and during a cough, “the knack”, can also be visualized [106]. It has been demonstrated that the knack can significantly reduce urethral mobility during a cough.

Figure 7: Perineal midsagittal two-dimensional view at rest and on contraction. Levator contraction with ventro-cranial displacement of the urethra. Measurement of minimal dimension of genital hiatus (from symphysis pubis to levator ani muscle)
Direct measurement of the pelvic floor muscles is possible with the use of two and three-dimensional perineal ultrasonography. An alternative technique makes use of a 360 degree rectal probe intravaginally (Figure 8) [104]. Most studies, however, have used three-dimensional perineal ultrasonography for this purpose [17, 98, 103, 107, 108]. The thickness of the muscles as well as the hiatal area can be measured. Hiatal dimensions and pelvic floor muscle thickness have been extensively validated and have good test-retest and inter observer characteristics [17].

The pelvic floor muscles were found thinner in women with pelvic organ prolapse [15, 104, 109] and with urinary incontinence [110], whereas their genital hiatus was found larger [111]. Well trained women have thicker pelvic floor muscles compared with controls [103], and Chinese women had thinner muscles compared with Caucasian women [108]. In nulliparous Chinese women, the anterior/posterior hiatal diameter was significantly increased in women with a higher body mass index [108].

Pelvic floor biomechanics were investigated with ultrasound using the position of the bladder neck in combination with continuous vaginal pressure measurements [112, 113]. A novel biosensor was used to measure the force as well as the displacement of the pelvic floor during contraction [114]. Another research group has inserted a water filled plastic bag to study the shape of the vagina during contraction [115]. Others [116] have assessed elasticity by means of the correlation of the dynamic dimensions of the hiatal circumferences and direct palpation of the muscles.

8. LEVATOR TRAUMA

Avulsion of the levator ani muscle from the symphysis pubis is known to occur in up to 36% of parous women [59, 117]. The integrity of the attachment of the pelvic floor muscle to the symphysis pubis can be visualised (Figure 2 and 9a). This is best evaluated on a pelvic floor contraction, since detachments are better visualised when the muscle is retracted away from the symphysis, and the potential gap between muscle and bone increases. Another marker of the detachment of the muscle is the loss of the typical H shape of the vagina in the axial plane, with the upper arms of the H hanging aside after detachment (Figure 9a, 9b).

It has been shown that the detachment of the levator ani muscle from the symphysis pubis is associated with pelvic organ prolapse with an odds ratio of six [118] especially of the anterior and central compartment [119]. This is similar to results from MRI studies, where it has been shown that the risk of pelvic organ prolapse further increases when the levator injury goes together with vaginal architectural distortion [120, 121]. Although these defects have recently been identified during labour, it is not known whether there is any reasonable (preventive) treatment for these women [118, 122]. There is an increase of the occurrence of pelvic floor muscle trauma with maternal age at first delivery [123]. There was a strong correlation between the presence of levator muscle avulsion and poorer muscle strength [124]. It has, however, been shown that the correlation between the clinical assessment (palpation of the muscle) and three-dimensional ultrasonographic assessment of muscular defects was only poor [125], as well as the intero-bserver repeatability of the palpation of defects [126]. A quantification method for levator muscle defects on ultrasonography (tomographic ultrasound imaging) (Figure 9a and 9b) has been described [107].

Another parameter, which has been found to be related to the severity of pelvic organ prolapse, was the size of the inner circumference at minimal hiatal dimension of the levator ani muscle on Valsalva manoeuvre [104, 107, 118]. The area of the levator hiatus on Valsalva manoeuvre ranges from 6 to 36 cm² in nulliparous women, with an outlier of almost 50 cm² in a young nulliparous athlete [103, 111]. An area of more than 30 cm², 35 cm² and 40 cm² on Valsalva manoeuvre has been described as mild, moderate and severe ballooning of the genital hiatus respectively (Figure 10) [127]. The assessment of the levator hiatus has been shown to be a reproducible measurement [17, 117], whereas the reproducibility was less for muscle...
Figure 9a: Tomographic ultrasound imaging (TUI) in oblique axial plane. Normal attachment of the levator ani muscle.

Figure 9b: Tomographic ultrasound imaging (TUI) in oblique axial plane. Both-sided avulsion of the levator ani muscle from the symphysis pubis.
diameter measurements [17, 98, 111]. Comparisons of the hiatal diameters and hiatal area as measured by three-dimensional ultrasonography and MRI revealed good correlations, especially for the measurements at rest. The correlation for hiatal diameter at Valsalva manoeuvre was lower, which is most likely due to the difficulty to reach the correct plane of the levator ani muscle on MRI [128].

The presence and clinical relevance of paravaginal defects represent a controversial issue amongst urogynaecologists, and there is a lack of scientific proof for the concept. In a study by Reisinger et al., an echogenic layer in the lower anterior vagina, which was thought to be a part of the endopelvic fascia, could be identified reproducibly in nulliparous and parous women by transrectal three-dimensional ultrasonography [129]. According to more recent insights, however, previously described paravaginal defects with loss of the H-shape of the vagina in the axial plane on three-dimensional ultrasonography [124, 130, 131] are likely to represent the detachment of the levator ani muscle from the symphysis pubis [132].

9. PELVIC ORGAN PROLAPSE

In cases of mild and moderate pelvic organ prolapse, perineal ultrasonography can be used, for the investigation of the prolapse. Ultrasonography should, however, only be used in addition to the patients history and clinical examination. In cases of severe pelvic organ prolapse, ultrasonographic assessment is impracticable due to transducer dislocation by the prolapse.

The ultrasonographic imaging of the anterior compartment (i.e. bladder, bladder neck and urethra) is the easiest to perform, and the majority of scientific studies deal with this compartment (Figure 11). Correlations with clinical examination [133, 134] are also highest for this compartment. Reproducibility of ultrasonographic imaging of prolapse in the anterior compartment were shown to be good [133]. This reproducibility has not been studied for the other two compartments until now.

In studies amongst 83 and 117 women with the uterus in situ, the uterus could be visualized on perineal ultrasonography in 82% and 97% of cases, respectively (Figure 12) [134, 135].

A number of studies have focused on the posterior compartment [136-144]). The distinction between enterocele (Figure 13) and rectocele (Figure 14) is known to be difficult on clinical assessment. In these cases, two-dimensional ultrasonographic imaging in the midsagittal plane can be helpful. The ultrasonographic visualisation of an enterocele has been confirmed with defecography as well as intraoperative findings [136]. It has not been shown, until now, however, whether this extra ultrasonographic investigation indeed leads to superior clinical outcomes of prolapse surgery.

In a study on ultrasonography of the posterior compartment a differentiation between true rectocele, enterocele and perineal hypermobility has been made [139]. Intussusception can also be visualised on ultrasonography [145]. The true rectoceles were diagnosed in case of a sharp discontinuity of the rectovaginal septum, with herniation of the rectal wall through this discontinuity and with a depth of at least 10 mm (Figure 15). Perineal hypermobility and an enterocele was seen as a descent of the rectovaginal septum or abdominal content on Valsalva manoeuvre respectively, below a horizontal line through the inferior margin of the symphysis pubis (see below for more information on these measurements). Ultrasonographic staging was significantly correlated with clinical staging and the presence of symptoms of obstructed defecation [15, 140]. In one third of the patients with clinically diagnosed rectocele, however, no ultrasonographic abnormality could be found. As far as interrater reliability was concerned, two expert ultrasonographists have reached moderate to good interrater reliability for the detection of a rectovaginal septum defect, descent of rectal ampulla, and the depth and width of a rectocele [139].

In one study, rectocele and perineal hypermobility were present in nulliparous women in 12 and 13% respectively the significance of these findings has not yet been determined [141].

The posterior anorectal angle, which is the angle between the anal canal and the posterior rectal wall, can be measured at rest and under dynamic circumstances such as straining and squeezing. A number of studies have compared these findings with defecography and found in general a good correlation [143, 144, 146].

10. QUANTITATIVE ASSESSMENT OF PELVIC ORGAN PROLAPSE

In the quantitative assessment of prolapse in the various compartments, a reference line, such as the hymen in POPQ, is needed. For ultrasonography, a horizontal line drawn from the inferior margin of the symphysis pubis is the most widely used reference line for the purpose (Figure 3a). A disadvantage of this line is that only one fixed point through which the reference line is drawn is available, and the horizontal line may thus change with the rotation of a handheld transducer. The effect of rotation is obviously increasing with the distance from the fixed point, and consequently is greatest in the posterior compartment [134]. Although this problem has been overcome in research settings with the use of motion tracking systems, at the moment this is not a realistic option for routine use in clinical practice [147]. For quantitative assessment of rectoceles, the depths of the rectocele as measured

Figure 14: Perineal midsagittal two-dimensional view. Measurement of the depth of the rectocele, perpendicular to a straight line through the anterior border of the anal sphincter complex, i.e. 14 mm.
in relation to a line through the anterior anal canal, may be more useful as compared with the descent in relation to the horizontal reference line [148].

Since pelvic organ prolapse can be visualised well with the use of ultrasonography, it raises the question whether this assessment modality is superior to others, such as clinical examination. In a recent study on the relationship between prolapse symptoms and the most dependent point of the prolapse on POPQ and on ultrasonographic assessment, POPQ performed better in the prediction of prolapse symptoms with increasing stages of prolapse [148]. In a previous study, where only women with a single compartment prolapse were studied, the area under the receiver operating curve was, however, as good as 0.86 and 0.82 for the anterior and posterior compartment respectively [149]. In both studies the cut-off value for symptomatic prolapse averaged 15 mm below the horizontal reference line through the symphysis pubis.

As far as dynamic MRI and X-ray defecography are concerned, there are only a few studies available as yet, on comparisons with ultrasonography. For enterocele detection in women with obstructed defecation, perineal ultrasonography has been compared with X-ray defecography, but not with the clinical findings [143]. In the women in whom enterocele had been detected by either method, the enterocele was detected by both ultrasonography and X-ray in 71% of women. In this study, perineal ultrasonography showed more severe stages of enterocele compared with X-ray defecography. In another recent study from a different research group, X-ray defecography has been compared with perineal ultrasonography using a vaginal probe in women with impairment of the posterior pelvic floor. Good to excellent concordance has been found for the assessment of the anorectal angle, rectocele and intussusception. The authors claimed, however, that rectoceles with a depth less then 20 mm could not be detected on ultrasonography [138], which is discordant with most other publications on the topic and as well as the authors’ experience.

11. ULTRASONOGRAPHY IN RELATION TO PREGNANCY AND DELIVERY

Vaginal childbirth is commonly accepted as the major risk factor for the development of pelvic organ prolapse later in life. In nulligravid women, however, a wide variation in pelvic organ descent has been shown for all three compartments [114, 135, 150-152]. In a study on 169 women who underwent ultrasonography during and after pregnancy, a significant increase in pelvic organ mobility (downwards displacement) has been found in all three compartments [153]. The increase in mobility was significantly correlated with the length of second stage of labour and the mode of delivery. The highest mobility was found in women who underwent an operative vaginal delivery, but no association was found with the length of gestation at delivery, with the length of the first stage of labour, and with birth weight, although birth weight reached borderline significance. In a similar study, focussing on the posterior compartment in 52 nulliparous pregnant women, 8 women developed de novo true rectoceles, and the descent of the rectovaginal septum increased with 22 mm for the entire group, which was statistically significant [154]. On the other hand, in a study amongst 207 women, of whom half of the women had a clinically diagnosed rectocele, no relation has been found with (vaginal) parity, and only a weak correlation has been found with age for a posterior vaginal wall prolapse as assessed with ultrasonography [139]. This suggests that the effect of vaginal parity on pelvic organ descent, is most evident in the anterior and central compartment, and may have
another pathophysiology compared with the posterior compartment [153]. Concerning bladder neck descent, it has been shown that the first delivery caused the most marked changes compared with the subsequent deliveries, with the most marked changes with forceps delivery [155].

Another interesting point of view came from two different research groups, who have reported that an increased antenatal ultrasonographic bladder neck descent was associated with normal vaginal delivery [156, 157]. Furthermore, vaginal delivery was strongly associated with a larger, and more distensible antenatal levator hiatus [156]. The underlying reason remains hypothetical, but more antenatal laxity of the structures may allow for a smoother delivery. Women with increased bladder neck mobility, however, also have a increased risk of de novo urinary incontinence post partum [20].

Avulsion of the levator ani muscle from the symphysis pubis, as outline above, is typically found in vaginally parous women only (Figure 9b) [117, 119, 158]. It has, furthermore, been shown that a higher maternal age at first vaginal delivery is strongly related to an increased risk of these avulsions [117, 158]. These avulsions are again associated with an increased risk of urinary incontinence and more severe stages of prolapse later in life.

12. PELVIC FLOOR SURGERY

Ultrasonography has been used during anti-incontinence surgery with the aim of obtaining optimal results from surgery, for example during Burch colposuspension [159, 160]. On an individual basis, the bladder neck was lifted between 1 mm and 10 mm. The authors have obtained excellent results with a 94% continence rate after 1 year, but unfortunately no control group was incorporated in the study.

13. SLINGS AND MESHES

Monofilament meshes, for example polypropylene meshes, are easier to visualise on ultrasonography compared with multifilament meshes, such as IVS [161]. Ultrasonography has been widely used to localize the exact position of tension free midurethral tapes (Figure 15) [156, 162-165]. The tape is generally easily visible as an hyperechogenic structure under the urethra and is easy to recognize, which is in contrast with the poor visualisation on MRI [166]. Exact midurethral position of the tape is not essential for proper function [167]. Despite the fact that the tape was located in the midurethra in only two-third of cases, this had no relation to postoperative continence status [168]. During Valsalva manoeuvre, the tape moves in a semicircle movement around the inferior margin of the symphysis pubis [169]. This results in a position closer to the symphysis, which consequently leads to a certain degree of mechanical compression during Valsalva manoeuvre. Another mechanism of action is kinking of the urethra around the tape [170]. A number of studies have studied transobturator tape and compared these with retropubic tapes [161, 171-174]. Two studies could not detect any differences between the two types of tape [161, 174], whereas in the other two studies [171, 173], subtle differences with no apparent clinical consequences were found. No study has found a clear correlation between cure of stress incontinence or post-operative voiding troubles and the position of the tape.

Recently, ultrasonographic localization of polypropylene mesh as used in prolapse surgery has been described (Figure 16 and 17) [175]. These meshes are usually easily visible on ultrasonography. It appears that the ultrasonographic appearance of the mesh is significantly shorter than the size at implantation. It is unclear whether this is due to shrinkage of the mesh or represents difficulties in visualizing the full extent of the implanted mesh.

Perineal ultrasonography can, furthermore, be helpful in the assessment of recurrences after mesh implantation. The differentiation between recurrent herniation and the detachment of the mesh arms from the pelvic sidewall for example, will aid in the better understanding of the mode of action of these meshes [176].

14. BULKING AGENTS / INJECTABLES

Periurethral bulking agents/injectables, such as microparticulate silicone (Macroplastique), various gels (e.g. Durasphere, Zuidex) and collagen, can be visualized by imaging techniques. For MRI, an overview of appearances of periurethral bulking agents is already available [177]. On ultrasonography, the injectables appear hypoechogenic after injection, and become more hyperechogenic over time due to dehydrogenation. Good intra-observer variability of repeated measurements of periurethral collagen volumes have been found [178].

The location in relation to the bladder neck and a circumferential distribution of collagen injectables around the urethra, as well as the height and volumes of the injected periurethral collagen bumps, were associated with the treatment success of periurethral bulking agents [178-180]. Although the volume range was wide, a collagen volume of 2.8 cc on three-dimensional ultrasonography has been assessed as optimum volume from a continence point of view. Poon et al. have published a decision tree, in which a combination of the patients’ symptoms after collagen injection and the configuration and volume of the periurethral collagen on three-dimensional ultrasonography, assist in the decision for further treatment of women with intrinsic sphincter deficiency [178]. In this algorithm, women with asymmetric deposition and/or low collagen volumes were offered further treatment with injectables.
Ultrasonography has not only been used for follow-up, but also during placement of periurethral injections. Transurethral ultrasonography-guided injection of autologous stem cells has been used in women and men with stress urinary incontinence.

The technique allowed precise injection of the myoblasts directly into the rhabdosphincter, and was more effective in the resolution of incontinence compared with urethroscope guided collagen injectables in the submucosa in a randomized controlled trial [181, 182]. The use of stem cells in the management of urinary incontinence is of great interest although the subject remains controversial and confirmatory studies are eagerly awaited.

III. MRI

1. BACKGROUND

The role of MRI in evaluating pelvic floor disorders continues to evolve. This technique provides unparalleled images of pelvic floor muscles, connective tissue, and organs. In addition to the detailed static picture of the pelvic organ support system anatomy, MRI can also reveal the downward movement of each pelvic compartment during increases in abdominal pressure. Advances in MRI equipment and software have significantly improved image quality and provides ever more detailed pictures of anatomy and function. At present active investigation is ongoing to try to see if and how this imaging might result in a better understanding of these diseases.

One proposed rationale for the use of MRI in the evaluation pelvic floor disorders derives from the observation that although patients might present with symptoms isolated to one of the pelvic compartments, they may have concomitant defects in other compartments and that imaging can provide information to extend what can be determined on physical examination [1]. Furthermore, it has been suggested that surgical failures could result from lack of a thorough preoperative evaluation of the female pelvis and to inadequate diagnosis and staging of pelvic floor dysfunction [2]; accurate diagnosis of the coexisting abnormalities is essential in planning reconstructive and anti-incontinence procedures. Although most diagnoses of pelvic floor prolapse are made on detailed physical exam, some studies have alluded to the poor sensitivity and specificity of the pelvic exam in diagnosing various forms of pelvic floor prolapse [3-5]. Ultrasound and fluoroscopy have been used to improve diagnosis of certain aspects of pelvic floor dysfunction [6,7] and the role of MRI in pelvic floor dysfunction is rapidly changing and new developments may become clinical mainstays if they can demonstrate improved outcome.

MRI provides anatomical detail of the pelvic floor including assessment of bladder neck and urethral mobility, rectocele, cystocele, enterocoele and uterine prolapse, in a single non-invasive study that does not expose the patient to ionizing radiation [8-17]. MRI also provides a multiplanar thorough evaluation of the pelvic contents including the uterus, ovaries, ureters, kidneys, and levator muscles, as well as the urethra, that is unavailable by any other imaging modality [10,12-16,18,19]. MRI provides useful information regarding ureteral obstruction, hydronephrosis, and uterine and ovarian pathology, which is essential in the management of women with pelvic floor disorders. In addition, at this time, MRI is the study of choice for the evaluation of urethral diverticuli.

Proof that MRI has value will eventually need to come from increased operative success rates. It is possible that better documentation of preoperative and postoperative anatomy could allow us to seek reasons for operative failure. Because MRI provides a detailed picture of a woman’s pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure. This chapter provides a current view of where we are in evaluating the role of MRI in understanding the cause and treatment of pelvic organ prolapse.

2. METHODOLOGY

a) Conventional MRI

Standard MRI consists of two dimensional image acquisitions. Usually conventional T1 images and spin echo T2 weighted images are obtained and specifically proton density T2 weighted scans provide excellent soft-tissue definition (Figure 1). These static images provide good information on patient anatomy and pathological abnormalities but the long imaging time of conventional MRI hampers its ability to evaluate pelvic organ prolapse and pelvic relaxation. The muscular anatomy of the pelvic floor, as well as the anatomy of the pelvic organs can be visualized with the use of a body coil. The use of an endovaginal coil provides superior information regarding the zonal anatomy of the urethra but it can result in deformity of the normal anatomy [20-21]. Recent improvements in Magnet strength and instrument refinement produce remarkable images.

b) Ultra fast image acquisition and MRI sequences

It is possible to see pelvic organ movement during Valsalva using very fast single-shot MRI sequences allowing excellent visualization of the pelvic floor in women [14,15,22-23]. These sequences images allow a series of images to be obtained approximately once per second, either by acquiring a series of images covering the entire pelvis (static imaging) or repetitively in one plane while the patient is straining (dynamic imaging). The patients are placed in the supine position with legs slightly spread apart, and knees bent and supported by a pillow. There is no need for bowel preparation, premedication, instrumentation or contrast medium. The MRI torso coil is centred at the symphysis pubis. Images are acquired in the sagittal plane using single-shot fast spine echo (SSFSE) or half Fourier acquisition, single shot turbo spin echo (HASTE) sequences. Single, mid sagittal views are obtained during 3 seconds of apnea with the patient relaxed and during various degrees of progressive abdominal straining (Figure 2).

During a typical study two sets of images are obtained. The first set consists of static sagittal and para-sagittal...
images covering the pelvis from left to right sidewall. These images provide information on pelvic anatomy, pathological abnormalities, and are used to select the mid-sagittal plane for the dynamic second set of images. This static sequence also allows for anatomic delineation of the pelvic sidewalls and muscular and fascial components of the pelvic floor [14, 15, 22-23] (Figure 1). The perineal membrane and the levator ani musculature, as well as the anal sphincter anatomy, are also clearly demonstrated [24-25].

The static set consists of 17-20 sequential images independently acquired in a total of about 18 seconds. Static images can be acquired with a SSFSE pulse sequence using 128 x 256 matrix with repetition time (TR) of 4000 ms, echo time (TE) of 22.5 ms, 5 mm slice thickness and field of view (FOV) of 28 cm [15]. Other similar sequences have been described.

The second set of images consists of relaxed and straining mid-sagittal images used to assess the degree of pelvic floor relaxation and organ prolapse (Figure 2 a,b). One series [15, 23] describes the SSFSE parameters as 128 x 256 matrix, TR=3000ms, TE=90ms, FOV=28cm and 5 mm slice thickness. Variations in these parameters have been described and thus the image acquisition sequences have are not standardized yet. Images can then be looped for viewing on a digital station as a cine stack.

c) Three dimensional MRI

Three dimensional (3-D) MRI provides great detail of the bony and muscular pelvic structures (Figure 3). In this technique, static or dynamic images are reconstructed using consecutive planes in the axial, sagittal and coronal dimensions. Anatomic variations of the insertion and path of the pubococcygeus and iliococcygeus muscles can be easily seen. Fielding et al. studied nulliparous continent female volunteers and found that the muscle morphology, signal intensity and volume are relatively uniform [28]. They described an average volume of the levator ani of 46.6 cc, width of the levator hiatus of 41.7 mm and an average posterior urethrovesical angle of 143.5°.

3. NORMAL PELVIC ORGAN SUPPORT

Static, dynamic and three-dimensional MRI studies of normal subjects have improved our understanding of normal pelvic anatomy [24-26]. The use of MRI to image the pelvic floor musculature has also contributed greatly to our understanding of pelvic floor dysfunction [19, 21, 27]. MRI has been used to study the normal female pelvic anatomy, as well as the anatomy of the aging female and the symptomatic patient. It has been shown that in the supine position the female pelvic floor is dome shaped at rest [27, 28]. During voluntary pelvic floor contractions the levator musculature straightens and becomes more horizontal. With bearing down the muscle descends, the pelvic floor becomes basin-shaped, and the width of the genital hiatus widens. Studies are usually done with the patients supine and so the anatomy as it is seen in the standing position is not generally possible. Upright static and dynamic MRI are possible, but are used mostly as a research tool because they are not widely available. Recently, Bø et al [33] evaluated the changes seen with pelvic floor contraction in continent and incontinent women using MRI in an upright sitting position. Although there was no statistical difference between the two groups, the authors demonstrated an inward movement with pelvic floor contraction (average 10.8 mm) and an outward movement with straining (average 19.1 mm). This was also reflected in the bladder neck. Interestingly, the coccyx appeared to move in the cranial direction with contraction and caudally with straining.

4. PELVIC ORGAN PROPLASCE

MRI has proven to be a key assessment for understanding pelvic organ prolapse; a problem that arises from damage to connective tissue, muscles, and nerves that are invisible on standard radiography. With the advent of ultrasound and especially MRI the actual structures involved in the cause of prolapse can be seen and examined. This is possible not only in static scans that reveal morphological details of the pelvic structure, but also in dynamic scans where the movements of the various organs can be studied.

a) Normal Pelvic Floor Functional Anatomy

1. MRI OF THE NORMAL PELVIC ORGAN SUPPORT STRUCTURES

MRI in pelvic organ prolapse requires that the specific structures involved are identified and their normal
variations described (Figure 4). Tan [21] demonstrated that the anatomy of the female pelvic floor with endovaginal MRI. Ten healthy nulliparous volunteers (age, 22-26 years) underwent MRI with an endovaginal coil. Pelvic floor structures such as the pelvic diaphragm and the urogenital diaphragm were well depicted as were urethral supporting structures—the peri-urethral and paraurethral ligaments—were visualized. The zonal anatomy of the urethra was clearly visible. The endovaginal MRI findings in the volunteers correlated with the endovaginal MRI findings and gross anatomy in the cadavers. Chou [30] developed a systematic method for analyzing the normal MRI location and appearance of structural features involved in urethral support. Multiplanar proton density MRI of 50 nulliparous women were made at 0.5 cm intervals. This allowed the presence or absence of urethral support structures in each scan level relative to the arcuate pubic ligament to be evaluated and recorded as the percent likelihood that the structure is seen at that level. Support structures examined included the arcus tendineus fasciae pelvis, the perineal membrane, the pubococcygeal levator ani muscle and its vaginal and bony attachments, and the pubovesical muscle. This systematic magnetic resonance evaluation allows quantification of the normal anatomic location of urethral support structures.

Tunn et al [32] addressed the topic of anatomical variation in the normal pelvic floor. They developed a system to quantify inter-individual variation in the appearance of continence system structures in 20 healthy continent nulliparous women (mean age, 30.1 +/- 5.1 years) with normal pelvic organ support and urodynamics. The ratio of the maximum-to minimum measured values shows that 2- to 3-fold differences occur in distance, area, or volume measures of continence system morphologic features that are detailed in the paper. Umek et al [33] found that in 80 healthy women, the uterosacral ligaments exhibited greater anatomic variation than their name would imply.

It has long been recognized that the pelvic floor is greatly distorted in cadavers where loss of muscle tone and pressures caused during embalming distort pelvic floor topography. Otcenasek et al have recently used MRI of a normal nulliparous woman to establish geometry and then added details from dissection to produce an anatomically based topographically normal
Figure 4: Axial images in 22-year-old (A, D, G, and J), 24-year-old (B, E, H, and K), and 34-year-old (C, F, I, and L) nulliparous women without urogynecologic problems. A-C, Level of cervix (Cx) and ischial spine (IS); uterus (Ut) with bright endometrium is also seen. Paracolpium and parametrium suspend (open tips) vagina and cervix from lateral and posterior pelvic sidewall. Smooth muscle of uterosacral ligament (open tips) is best seen in C. GM, Gluteus maximus muscle. D-F, Level of bladder (B) base. Upper vagina between bladder and rectum (R) and its attachment to pelvic sidewall by vascular and connective tissue mesentery (small arrow) are seen. Levator ani muscle (iliococcygeal part, filled arrowhead) arises from arcus tendineus of levator ani muscle (filled arrow). OI, Obturator internus muscle. G-I, At level of proximal urethra, levator ani muscle (pubovisceralis part, filled arrowhead) arises from pubic bone (open arrow). Pubovesicalis muscle (open arrowhead) is clearly seen in H. Vessels (white gap) are visualized between smooth muscle layer of lateral vaginal wall and levator ani muscle at this level. J-L, At level of middle urethra, pubovesicalis muscle is seen as shown in J (open arrowhead). Vessel layer (white gap) between lateral vaginal wall and levator ani muscle (filled arrowhead) has disappeared; direct connection between vagina and levator ani muscle is seen at this level. Small white gap in levator ani suggests fascia between puborectalis and pubococcygeal muscles (especially in J and L). From Tunn et al. 2001. [31]
3-D model that displays the features of pelvic floor anatomy (Figure 5) [34].

2. LEVATOR ANI MUSCLE FUNCTIONAL ANATOMY

Recent work has extended our understanding of normal levator ani muscle anatomy. Guo and Li [35] studied MRI and CT images obtained at rest in 22 male and female volunteers and 10 cadavers. They described levator shape by dividing it into a transverse portion and a vertical portion. The anterior transverse portion was found to be basin-shaped; the middle transverse portion was funnel-shaped, while the posterior transverse portion was dome-shaped. The puborectalis was found to be a u-shaped muscle outside the vertical portion. Detailed information about the specific levator ani muscle subdivisions has also been studied. Margulies et al [36] have used detailed MRI images to visualize the specific origins and insertions of the five Terminologia Anatomica-listed levator ani components: pubovisceral (pubovaginal, puboperineal, and puboanal), puborectal and ilioococcygeal portions of the levator ani muscles in 80 nulliparous women with normal pelvic support.

In the axial plane, the puborectal muscle can be seen lateral to the pubovisceral muscle and decussating dorsal to the rectum. The course of the puboperineal muscle near the perineal body is seen best in the axial plane. The coronal view is perpendicular to the fibre direction of the puborectal and pubovisceral muscles and shows them as “clusters” of muscle on either side of the vagina. The sagittal plane consistently demonstrates the puborectal muscle passing dorsal to the rectum to form a sling that can consistently be seen as a “bump.” This plane is also parallel to the pubovisceral muscle fibre direction and shows the puboperineal muscle. Ultrasound has also been useful in evaluating levator ani muscle morphology. Similarities and differences between MRI and 3-D ultrasound have been studied recently [37] in a group of 27 nulliparous asymptomatic young women. Levator hiatal dimensions were measured and were data acquired at rest, on maximum Valsalva and maximum pelvic floor contraction. Interobserver repeatability was fair to excellent for all parameters measured with both methods. Moderate-to-substantial agreement between methods was shown for all tested parameters (intraclass correlation coefficients 0.587-0.783). There was a systematic but non-significant difference between methods, in that measurements on Valsalva tended to be larger for MRI, and the poorest agreement

Figure 5: Left lateral view from above the female pelvis. The vagina, endopelvic fascia, and levator ani muscle are cut in the sagittal plane. Urethra, urinary bladder, and rectum have been removed. OIM, obturator internus muscle; PCF, pubocervical fascia; ATLA, arcus tendineus levator ani; LA, levator ani muscle; ATFP, arcus tendineus fasciae pelvis; PS, pubic symphysis; VW, vaginal wall; RVF, rectovaginal fascia; ATFR, arcus tendineus fasciae rectovaginalis; PM, perineal membrane; PB, perineal body; EAS, external anal sphincter; SC, space of Courtney; ACR, anococcygeal raphe; ACL, anococcygeal ligament; PM, piriformis muscle; CL, cardinal ligament; USL, uterosacral ligament; C, cervix of the uterus; CM, coccygeus muscle; Co, coccyx; SP, sacral plexus. Illustration: Ivan Helekal. [34]
(intraclass correlation coefficient 0.587) was found for hialtal area on Valsalva. This demonstrates substantial similarity between the two methods for these assessments (Figures 6-7).

3. Functional MRI

Functional MRI of the brain has recently been used to better understand central control of pelvic floor muscles. Kuhntz-Buschbeck et al [38] used functional MRI to identify cortical and subcortical regions involved in voluntary pelvic floor muscle control. During pelvic muscle contraction they found a strong and consistent recruitment of the supplementary motor area (SMA), with foci of peak activity located in the posterior portion of the SMA, suggesting that this region is specifically involved in voluntary pelvic floor muscle control. Further significant activations were identified bilaterally in the frontal opercula, the right insular cortex and the right supramarginal gyrus.

These may reflect the attentive processing and evaluation of visceral sensations. Weaker signals were detected in the primary motor cortex (M1) and the dorsal pontine tegmentum. Similarly Seseke et al [39] in a study of 11 healthy women found that relaxation and contraction of pelvic floor muscles induced strong activation patterns including frontal cortex, sensory-motor cortex, cerebellum, and basal ganglia. Furthermore, well-localized activations were identified bilaterally in the pontine micturition centere and the periaqueductal gray were identified.

4. Pathophysiology

i) Levator ani muscle defects muscle bulk

Although it has long been known that birth is highly strongly associated with pelvic organ prolapse, proof of a specific injury that occurred at birth and was associated with prolapse later in life had not been found. Recent MRI studies have demonstrated that the type of LA injury seen after vaginal birth is highly strongly associated with pelvic organ prolapse. In [40] a case-control study with group matching for age, race, and hysterectomy status 151 women with prolapse (cases) were compared to 135 controls with normal support (controls). Magnetic resonance imaging was used to grade muscle defects on each side from 1 to 3 (with 0 designating normal muscle (Figure 8).

Defect severity for a woman was then classified by adding the scores for the two sides together to make a score from 0 to 6. These were then classified as “major” (4 to 6), “minor” (1 to 3), or no defects (0) in the levator ani muscles. Cases (n=151) were more likely to have major levator ani defects than controls (55% compared with 16%), but equally likely to have minor defects (16% compared with 22%) as seen in Figure 9. These defects had functional consequences. Women with defects generated less vaginal closure force during a pelvic muscle contraction than women without defects (2.0 Newtons compared with 3.1 Newtons) and women with prolapse also generated less vaginal closure force during pelvic muscle contraction than controls (2.0 Newtons compared with 3.2 Newtons), whereas the genital hiatus was 50% longer in cases than controls (4.7 +/- 1.4 cm compared with 3.1 +/- 1.0 cm). This confirmed earlier uncontrolled observations made with ultrasound [41] of urogynecologic patients with ultrasound. This added new information concerning specific muscle defects to previous studies of muscle bulk. It is important to distinguish between muscle thickness and muscle damage. A woman with a normally thin but intact muscle may have less muscle substance than a woman with naturally bulky muscles who has a defect that has involved 25% of her muscle bulk. The issue of muscle damage is relevant to seeing who is injured while that of muscle bulk, with the capability of the muscle to close the hiatus. Loss of muscle bulk in women with pelvic floor dysfunction was studied by Hoyte et al [42]. They studied two- and 3-dimensional MRI comparison of levator ani structure, volume, and integrity in women with prolapse and stress incontinence to identify imaging markers for urodynamic stress incontinence and pelvic organ prolapse by using MRI and reconstructed 3-dimensional models. Thirty women were examined; 10 with prolapse, 10 with urodynamic stress incontinence, and 10 asymptomatic volunteers. Manual segmentation and surface modelling was applied to build 3-dimensional models of the organs. Mean 3-dimensional parameters in the 3 groups showed levator volumes of 32.2, 23.3, and 18.4 cm (P <0.005); hiatus widths of 25.7, 34.7, and 40.3 mm (P <0.005); left levator sling muscle gaps of 15.6, 20.3, and 23.8 mm (P =0.03), right levator sling muscle gaps of 15.6, 22.5, and 30.8 mm, (P =0.003), and levator shape (90%, 40%, and 20% dome shaped; P <0.005). This studies show that MRI can be used to demonstrate both 2-dimensional magnetic resonance images and 3-dimensional models yield findings that differ among asymptomatic subjects compared with those with urodynamic stress incontinence and prolapse. Later in a similar design, they used a novel thickness mapping [43] to studied MRI datasets from 30 women who were studied: 10 asymptomatic, 10 with urodynamic stress incontinence, and 10 with pelvic organ prolapse. They found thicker, bulkier anterior portions of the levators in asymptomatic women, compared with women with prolapse or urodynamic stress incontinence while the more posterior portions of the muscle were not affected.

Hsu and colleagues quantified levator ani muscle cross-sectional area as a function of prolapse and muscle defect status [44]. They selected thirty women with prolapse and 30 women with normal pelvic support. For each of the two groups, 10 women were selected from three categories of levator defect
Figure 6: Three-dimensional model of levator ani subdivisions including the pubic bone and pelvic viscera. This model was created by using the magnetic resonance images shown in Figures 2, 3, and 4. The pubovaginal, puboperineal, and puboanal muscles are all combined into a single structure, the pubovisceral muscle. Inferior, left 3-quarter view. B. The same model without the pubic bone. PB, pubic bone; V, vagina; U, uterus; Ur, urethra; B, bladder; IC, iliococcygeus muscle; PR, puborectal muscle; PVi, pubovisceral muscle; EAS, external anal sphincter [36].

Figure 7: Axial scan of 25-year-old nullipara showing subdivisions of the levator. Level of scan in centimeters relative to the arcuate pubic ligament (A) is indicated in lower left corner with positive numbers cranial to the ligament and negative numbers caudal. Additional abbreviations: PP, puboperineal muscle; PVa, pubovaginal attachment; PA, puboanal muscle; OI, obturator internus muscle; STP, superficial transverse perineal muscle; R, rectum. White arrows indicate puborectal muscle progression [36].
severity: none, minor, and major identified on supine magnetic resonance scans. They calculated muscle cross-sections perpendicular to the muscle fibre direction of the pubic portion of the levator ani muscle based on 3-D reconstructions made from proton-density MRI. The ventral component of the levator muscle of women with major defects had a 36% smaller cross-sectional area, and women with minor defects had a 29% smaller cross-sectional area compared with the women with no defects (P < 0.001). In the dorsal component, there were significant differences in cross-sectional area according to defect status (P = 0.03); women with major levator defects had the largest cross-sectional area compared with the other defect groups. For each defect severity category (none, minor, major), there were no significant differences in cross-sectional area between women with and those without prolapse. This indicates that women with visible levator ani defects on magnetic resonance imaging have less muscle ventrally compared with women with intact muscles. Women with major levator ani defects had larger cross-sectional areas in the dorsal component than women with minor or no defects indicating that compensatory hypertrophy may occur in this area.

ii) Identifying the injury zone within the levator ani muscle most often involved by injury

The specific anatomical location of these injuries has been studied in several ways. Otcenasek and colleagues [45] created two 3D computer models of the female pelvic floor, one of a healthy nulliparous woman and the other of a woman with bilateral puborectal muscle avulsion after vaginal delivery based on magnet resonance imaging examinations. They found that the damage affected the pubic origin of the muscle and that this structurally altered the support to the whole endopelvic fascia and destabilized both the anterior and the posterior vaginal walls. Margulies [46] extended these findings by examining a unique set of 14 women who had significant muscle on one side that allows normal muscle and damaged muscle to be compared in the same individual. This allowed the anatomical connections affected by defects the pubovisceral portion of the muscle to be studied using 3-D reconstructions of the levator ani muscles the normal side in each woman could be compared with the side with muscle damage. It was shown that the injury involved the muscle’s origin from the posterior pubic bone. The insertion points of the missing muscle involved its connections with the vaginal wall, perineal body, and the space between the internal and external anal sphincter. It was accompanied by distortion of the surrounding connective tissue with lateral spilling of the vagina towards the obturator internus muscle in 50% of women. The defect was right sided in 71% of patients. In a separate study quantifying the amount of muscle lost in these types of injury, Chen [47] found that the average difference between the normal side and the defective side was up to 81% at locations...
nearest the pubic origin. Almost all of the volume difference (13.7%, P=0.0004) was attributable to a reduction in the pubic portion (24.6%), not the iliococcygeal portion of the muscle (Figure 10).

iii) Changes in the hiatus size and levator plate angle with prolapse

The levator ani muscles constant activity closes the genital hiatus. In addition to evaluating defect status and muscle bulk, MRI has revealed changes in the levator hiatus and angle of the levator plate (that midline portion of the muscle between the anus and the coccyx) whose angle is presumed to be influenced by muscle action. Hsu and colleagues [48] studied 68 women with pelvic organ prolapse and 74 normal controls. During Valsalva, controls had a mean levator plate angle of 44.3 degrees. Cases had 9.1 degrees (21%) more caudally directed levator plate angle compared to controls (53.4 degrees vs. 44.3 degrees), 15% larger levator hiatus length (7.8 cm vs 6.8 cm), and 24% more caudal perineal body location (6.8 cm vs 5.5 cm).

Increases in levator plate angle were correlated with increased levator hiatus length (r = 0.42) and perineal body location (r = .51). Ansquer and colleagues [49] sought to see if hiatus dimensions parameters varied with the degree of prolapse present in 40 patients referred for evaluation prior to genital prolapse surgery. They found that greater bladder neck descent at straining was correlated with the larger levator plate angle at rest, hiatus length at rest and at straining. Uterine cervix descent at straining was correlated with increased hiatus length and width at straining, and greater levator plate angle (p=0.007) at straining. Paradoxically anterior rectal bulging at straining was inversely correlated with the hiatus width at rest (p = 0.04).

Perineal descent and localized outward bulging of the during Valsalva was evaluated by Gearhart and colleagues [50]. In this study, dynamic magnetic resonance imaging of symptomatic patients with pelvic floor prolapse demonstrated unsuspected levator ani hernias. Eighty consecutive patients with pelvic organ prolapse, faecal and/or urinary incontinence, or chronic constipation were evaluated. Twelve patients (15 percent) were found to have unilateral (n = 8) or bilateral (n = 4) levator ani hernias on dynamic magnetic resonance imaging. No one specific symptom was directly associated with the presence of a levator ani hernia. Perineal descent on physical examination was associated with the finding of a levator ani hernia in nine patients. At present, the clinical implications of these hernias remain to be determined.

b) MRI of pelvic floor after vaginal delivery

Vaginal birth increases the likelihood that a woman will develop pelvic organ prolapse by 8 fold after 2 deliveries and 12 fold after 4 [51]. There are changes observed in the levator ani and pelvic floor musculature immediately after delivery that appear to change over time. Boreham [52] evaluated the normal visibility of the levator in postterm nulliparas using 3-dimensional (3-D) magnetic resonance. They studied 84 nulliparas and found that LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in the 92%. Mean LA volume was 13.5 (3.7) cm³. Interestingly there was a positive association between LA volume and higher fetal station increasing BMI. Tunn evaluated the changes that occur after delivery studying patients on postpartum day 1 and compared the MRI images to those obtained at 1, 2, and 6 weeks and 6 months after delivery [53]. They evaluated levator muscle signal intensity, muscle topography, muscle thickness and pelvic floor descent. There was increased muscle signal intensity on T2 weighted images at 1 day postpartum but the signal intensity approached normal by 6 months. The area of the urogenital and levator hiatus decreased significantly by 2 weeks postpartum. There was no statistically significant difference seen in muscle thickness over time. More recent studies have added further information to these investigations. Lienemann [54] studied 26 primiparous women after vaginal delivery and had a control group of 41 healthy asymptomatic nulliparous volunteers. They found thinning of the puborectal muscle in the study group (0.6 cm vs. 0.8 cm) and increased descent of the bladder, vaginal fornix, and anorectal junction in the study group during straining.

The relationship between delivery method and levator anatomy, has been studied. Baytur et al evaluated pelvic floor anatomy seen in MRI scans and muscle function after childbirth in young women who were recruited into 3 groups: 1. elective, prelabour caesarean delivery (n =12); 2. vaginal delivery (n = 15); and 3 age-matched nulliparas as controls (n = 13) [55]. Descent of the bladder and cervix on straining was greater in the subjects who delivered vaginally than in the caesarean delivery and nulliparous groups. There was a positive and significant correlation between the duration of labour and the area of the levator sling and also between birth weight and the descent of the cervix on straining.

In a study that evaluated changes in the levator ani muscles among primiparous women, DeLancey [56] studied 80 nulliparous asymptomatic women, 160 vaginally primiparous women half of whom had new stress incontinence after their first birth. A visible defect in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the pubovisceral portion of the levator and three were in the iliococcygeal portion. Both unilateral and bilateral defects were found. None of the nulliparous women showed these abnormalities. In a further study of this cohort they [57] evaluated obstetric factors associated
with development of levator ani injury after first vaginal birth. There were increased odds ratios for levator defect were found: forceps use 14.7, anal sphincter rupture 8.1 and episiotomy 3.1 but not vacuum delivery 0.9 or oxytocin use 0.8. Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labour. Differences in gestational age, birth weight, and head circumference were not statistically significant. The traumatic nature of these lesions has been supported by Dietz [58] who has reported the specific findings in a woman at vaginal delivery with a visible tear who had persistent evidence of muscle injury at 6 months on imaging. Excellent prospective information about damage is also available from 3-D ultrasound although this imaging modality is outside the topic covered by this chapter [59].

Danneker [60] studied women who experienced spontaneous vaginal delivery (n = 26) and compared them with women delivering by vacuum extraction (n = 49) and a control group that consisted of healthy nulliparous volunteers (n = 20). Significant differences for individual POPQ component measurements were noted for points Aa and Ba, TVL, and GH (spontaneous delivery versus control) and in addition for Ap, Bp, and D (vacuum extraction versus control). Significant differences for MRI measurements were observed for the position of bladder base, bladder neck, posterior fornix of the vagina, anorectal junction, hiatus perimeter and depth of rectocele.

Branham and colleagues [61] assessed postpartum changes in the levator ani muscle related these changes to obstetric events in 45 primiparous women and 25 nulliparous women comparing their status at 6 weeks to that at 6 months after delivery. The occurrence of muscle abnormality at any of the 4 sites (pubovisceral or iliococcygeal; left and right) was considered as abnormal. In those subjects recovering to normal magnetic resonance by 6 months an average of nearly 60% increase in right puborectalis muscle thickness compared with that seen at 6 weeks indicated the extent of the injury. Subjects with injury to both the “puborectalis” and iliococcygeus at 6 weeks did not recover to normal at 6 months, whereas those with injury only to the puborectalis tended to have normal magnetic resonance images at 6 months.
Younger white primiparous women had a better recovery at 6 months than older white women.

5. MRI AND BIOMECHANICAL INVESTIGATION OF THE PELVIC FLOOR

Dynamic MRI has allowed specific mechanistic hypotheses to be tested. Summers and colleagues [62] evaluated whether the degree of anterior compartment (bladder) and apical compartment (cervix) prolapse are correlated with maximal Valsalva. They studied 153 women with a complete spectrum of pelvic support loss from normal support to stage 4 prolapse using dynamic magnetic resonance scans taken during Valsalva. They found that there was a strong correlation ($r^2 = 0.53$) between prolapse of the how far the bladder base and of uterine cervix were below normal with was $r^2 = 0.53$ indicating that slightly over half of the observed variation was explained by apical support. Further analysis in the same patients to evaluate what other factors might be associated with cystocele size [63]. Anterior vaginal wall length, location of distal end of the vaginal wall and the curvature of the anterior wall were measured during maximal Valsalva. Vaginal length was the strongest secondary factor determining 30% of the variation after apical descent was taken into account. This finding that a longer vaginal wall was associated with increasing cystocele size was unexpected, but seems consistent with clinical observations.

MRI has also allowed anatomically based biomechanical models to be constructed. Simulations performed with these models have demonstrated important interactions between muscle and connective tissue in providing for anterior vaginal wall support [64]. MRI has also been used as a basis for biomechanical analysis by allowing construction of finite element analysis [65,66] and has allowed for capture of 3D shape variation of the levator ani during straining for studying dynamic shape changes of 3D structures where complete volumetric imaging is prohibited by the inherent temporal resolution of the scanning technique [67]. Research is just beginning on evaluating changes that can be seen in the vaginal wall and support tissues. Hsu et al. for example used axial magnetic resonance imaging to test the null hypothesis that no difference exists in apparent vaginal thickness between women with and those without prolapse [68]. They found that vaginal thickness is similar in women with and those without pelvic organ prolapse. However, the vaginal perimeter and cross-sectional areas are 11% and 20% larger in prolapse patients respectively. These techniques should provide objective evidence of changes in the tissues involved in pelvic organ support.

a) Racial differences in pelvic dimensions

There has been interest in racial differences in the occurrence of pelvic floor dysfunction. Several groups have evaluated differences in the bony pelvis and the levator ani muscles between women from different races [69-71]. In a study by Handa et al, 59 women with pelvic floor disorders were compared with 39 women without pelvic floor disorders. After controlling statistically for age, race, and parity, a wider transverse diameter (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.2) were found to be associated with pelvic floor dysfunction. Hoyte and colleagues compared pelvic morphology between asymptomatic African-American and white nulliparas in 3-D reconstructions from resting supine T2-weighted MRI images in 12 African-American (AA) and 10 white American (WA) women without pelvic floor dysfunction [70]. They found that levator ani volume was significantly greater in the AA compared to the WA group (mean = 26.8 vs. 19.8 cm$^3$, $P = .002$). The levator-symphysis gap was smaller in the AA (left-18.2, right-18.8 mm) versus the WA group (22.4, 22.6 mm, $P = .003$, .048) on the left and right. Significant differences were also seen in bladder neck position, urethral angle, and the pubic arch angle. In another study Downing et al compared levator and obturator thickness between asymptomatic black and white nulliparas using three-dimensional (3D) MRI colour mapping [71]. Using 3D color-mapped MRI of pelvic muscles in 22 similar nulliparas black (n=12) and white (n=10) women they found that levator thickness was significantly greater in blacks bilaterally yet obturator internus muscle thicknesses were similar. Hnda et al used static and dynamic MRI to compare dimensions of the bony pelvis and soft tissue structures in a sample of African-American and white women [72]. They included 104 primiparous women with an obstetric anal sphincter tear, 94 who delivered vaginally without a recognized anal sphincter tear and 36 who underwent caesarean delivery without labour. They found that the pelvic inlet was wider among 178 white women than 56 African-American women (10.7+/-.0.7 cm compared with 10.0+/-.0.7 cm, $P<0.001$). The outlet was also wider (mean intertuberosity diameter 12.3+/-.1.0 cm compared with 11.8+/-.0.9 cm, $P<0.001$). There were no significant differences between racial groups in interspinous diameter, angle of the subpubic arch, anteroposterior conjugate, levator thickness, or levator hiatus. A broader group of races was studied by Rizk et al who studied dynamic pelvic floor and bony pelvic morphologic condition with MRI in asymptomatic multiethnic nulliparous young volunteers from 5 ethnic groups (n=11 x 5 volunteers: Emirati, other Arab, Filipino, Indian/Pakistani, and European/white volunteers), with the white volunteers as the reference group [73]. The white volunteers were significantly taller ($P<0.0001$) than the other women. Their levator hiatus was significantly longer than the Emirati women ($P=0.03$) and wider than the Filipino women ($P=.04$). The bladder neck descent on straining was also
significantly greater than the other groups (P <0.00001). The white women also had the longest transverse diameter of the pelvic inlet (P=0.002). Their sagittal outlet diameter was significantly longer than the Emirati and Arab women (P=0.02), and their interspinous diameter was significantly longer than the Arab women (P=0.002).

1. MRI FOR CLINICAL EVALUATION OF PROLAPSE

There is growing experience with evaluating in the interpretation of MRI images of pelvic organ prolapse the type and size of prolapse visible in MRI. Several ways in which this might enhance patient care and treatment outcome are under investigation.

2. ENTEROCELE

Enterocoele can be seen during MRI [74,70]. In the past enterocoeles were usually only appreciated on radiographic examination after repeated straining after evacuation and usually required opacification of the vagina in order to demonstrate the insinuation of small bowel loops between the rectum and vagina [75]. MRI has proven to be a much simpler and less invasive technique for the evaluation of enterocoeles. Gousse et al. compared physical examination, intraoperative findings and MRI images in women with and without prolapse [15]. The investigators found that when compared to intraoperative findings, MRI had a sensitivity of 87%, specificity of 80%, and positive predictive value of 91%. MRI was significantly superior in detecting enterocoele when compared to physical examinations. The images are obtained with the patient supine in the relaxed and straining state (Figure 11). Neither instrumentation nor invasive procedures are required. Similarly, Lienemann et al., using MRI with opacification of organs with ultrasound gel, showed that MRI had a much higher sensitivity for detection of enterocoeles when compared to physical exam and dynamic cystoproctography [76]. Whether or not this technique alters clinical outcome remains to be seen.

b) CYSTOCELE

High-grade cystoceles, as other forms of prolapse, usually do not occur in isolation and represent a spectrum of pelvic floor dysfunction [1, 3, 14]. When a large vaginal mass is present differentiating between a high-grade cystocele, an enterocoele, vaginal vault prolapse or high rectocoele by physical examination alone can be challenging for those inexperienced with physical examination of prolapse [3-5]. Gousse et al. found that, repair of only the cystocele without attention to the rest of the pelvic floor predisposes patients not only to increased incidence of urinary incontinence, but also to an increased incidence of enterocoele, rectocoele, and/or uterine prolapse postoperatively [15]. In the same study, MRI had a sensitivity of 100%, specificity of 83%, and positive predictive value of 97% when evaluating for cystocele compared to intraoperative findings.

In addition, urethral hypermobility and post-void urine residual can be documented, as well as evaluation of ureteral obstruction and other pelvic abnormalities. Gousse et al. also found that MRI was able to diagnose other type of pelvic pathology besides prolapse in 55 of 100 patients studied, including 3 with bilateral hydrourereteronephrosis. Figures 12 a, b show an MRI of two patients with grade 2 and 3 cystocele, respectively.

Other uses of MRI can also be helpful in documenting the status of pelvic organ support as part of a program to assess operative efficacy [77,78] and differentiating such problems as Müllerian remnant cysts from cystocele [79].

c) RECTOCELE

Rectoceles have been considered to exist in up to 80% of asymptomatic patients with pelvic floor dysfunction [13]. The diagnosis is usually made by physical exam, the reported sensitivity of pelvic examination for diagnosis of rectocoele ranges from 31% to 80% [3-4, 6, 80,81]. This is usually secondary to organ competition for space in the vagina when accompanied by other significant prolapse [7]. In addition, it is often difficult to reliably distinguish an
enterocele from a high rectocele. Figure 13 shows a rectocele diagnosed by dynamic MRI. A rectocele is easily seen when filled with gas, fluid, or gel. Although highly specific, when no rectal or vaginal opacification is used, MRI can miss up to 24% or rectoceles [15].

When rectal opacification is used during MRI, a correct diagnosis of rectocele can be made in 100% of patients studied when compared to intraoperative findings [18]. It therefore appears that in order to increase MRI's ability to diagnose rectocele, rectal opacification is necessary. This is usually accomplished by introducing sonographic transmission gel or gadolinium into the rectum prior to MRI scanning. In complex situations such as rectal intussusception [82] by distinguishing mucosal from full-thickness descent MRI can provide important information. MRI defecography also shows movements of the whole pelvic floor.

In this study, 30% of the patients studied were found to have associated abnormal anterior and/or middle pelvic organ descent that would not necessarily be seen in traditional evacuation proctography (unless opacification of vaginal, bladder and intestine are carried out).

What remains unclear is the relationship between anatomical findings and functional problems. The diagnosis of an anatomical abnormality does not mandate surgery. Simply identifying a woman has having a rectocele on an imaging study based on the location of the intestinal lumen to a reference line does not mean that correction of the rectocele will cure defecation problems. Rectocele surgery is not without complications and the risk of dyspareunia after posterior colporrhaphy is real. Attention should be paid to make sure that symptoms are truly depending on stool trapping and the condition must be shown on imaging.

d) Uterine Prolapse

Although uterine prolapse is easily diagnosed on physical examination MRI is an excellent modality to permanently record the structural relationships with the bladder and rectum present in patients with uterine prolapse (Figure 14). In addition to depicting the position of the uterus and adjacent organs, it has the ancillary benefits that evaluates not only uterine size, position, orientation (retroversion) and pathology (fibroids, tumours, Nabothian cysts, etc.), but also ovarian pathology (cyst or mass) which is essential information in may sometimes prove useful if these problems have not been picked up on physical examination is helpful information in determining if a vaginal of abdominal hysterectomy is indicated. In addition, MRI provides information on the presence or absence of cystocele, rectocele, urethral hyper-mobility and urethral diverticula, and evaluates for ureteral obstruction [9-10, 13-15, 83]. Gousse et al. reported a sensitivity of 83%, a specificity of 100% and a positive predictive value of 100% when comparing dynamic MRI to intraoperative findings. These numbers were similar when compared to physical examination alone [15]. More importantly, MRI was able to clearly define the other compartments of the pelvic floor and diagnose uterine and/or ovarian disorders in 30 of 100 patients evaluated [15].

e) Grading of pelvic floor relaxation

A number of studies have described reference values for grading organ prolapse [14-15, 17]. In order to evaluate pelvic organ descent, certain anatomical landmarks are used. The pubococcygeal line (PCL) marks the distance from the pubis to the coccyx and serves as a fixed anatomical reference. In the nomenclature used by Comiter et al. [14], Gousse et al. [15], and Barbaric [23], the width of the levator hiatus is measured as the distance from the pubis to the pubococcygeus muscle (H-line). The hiatus is
formed by the puborectalis muscle and encompasses urethra, vagina, and rectum. The M-line depicts the relaxation of the muscular pelvic floor by measuring the descent of the levator plate from the pubococcygeal line. Using these three simple measurements, an MRI classification for degree of organ has been described [14, 23]. In the normal population, during straining, the hiatus (H-line) is less than 6 cm long and does not descend (M-line) more than 2 cm below the PCL line. The upper urethra, urethrovesical junction, bladder, upper vagina, uterus, small bowel, sigmoid colon, mesenteric fat and rectum are all above the H-line. As the pelvic floor descends, so do the organs above it. The grading system for prolapse of any pelvic organ is based on 2 cm increments below the H-line, the degree of rectocele, enterocele, cystocele, and uterine descent can be graded in a 0 to 3 scale as follows: 0=none, 1=minimal, 2=moderate, and 3=severe (Table 2). Other similar systems have been described [17] and therefore there is a need for standardization of nomenclature and grading of organ prolapse using MRI. Singh et al [84] assessed a new technique of grading pelvic organ prolapse by using dynamic MRI with the clinical staging proposed by the POP-Q system [85]. In a cross-sectional study, 20 patients with pelvic organ prolapse underwent dynamic MRI and clinical staging along with 10 women with normal support. A new reference line, the mid-pubic line, was drawn on the magnetic resonance image to correspond to the hymenal ring marker used in the clinical staging. The proposed staging by MRI showed good correlation with the clinical staging (kappa = 0.61). As this more closely approximates the location of the clinically used hymenal ring, the mid-pubic line was a useful reference line for grading prolapse on magnetic resonance imaging.

Torricelli [74] also used MRI to evaluate functional disorders of the female pelvic floor. Healthy volunteers and 30 patients with clinically suspected pelvic floor deficiency, with or without pelvic organ prolapse, were evaluated both at rest and during Valsalva’s manoeuvre. In the group of symptomatic women, MRI confirmed the pelvic examination findings in all cases; In 7 cases MRI detected additional alterations (4 cases of uterine prolapse and 3 of enterocele) that had been missed at clinical evaluation. Whether or not these would have been noted at the time of surgical repair or not remains to cannot be determined.

Figure 13: Resting (a) and straining (b) midline sagittal section showing a rectocele that traps intestinal contents.

Figure 14: Pelvic Floor MRI: Uterine Prolapse
Deval [85] compared dynamic MRI with physical examination as an alternative to dynamic cysto-proctography for the evaluation of pelvic floor prolapse. Pubococcygeal line and puborectalis muscle were the references points. The grading system is based on the degree of organ prolapse through the hiatus and the degree of puborectalis descent and hiatal enlargement. They also used the mid pubic line drawn on the magnetic resonance image to correspond to the hymeneal ring marker used in clinical staging. Intra-operative findings were considered the gold standard against which physical examination, dynamic colpocysto-defecography and MRI were compared. Using these criteria the sensitivity, specificity and positive predictive value of MRI were 70%, 100%, 100% for cystocele; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enterocele; 87%, 72% and 66% for rectocele.

More recently Etlik [86] studied 46 patients who were known to have pelvic prolapses from their vaginal examination and thirty women who underwent vaginal examination and shown not to have pelvic prolapse served as a control group. Physical examination and MRI findings were very concordant in the diagnosis of pelvic prolapse and statistical correlations in the stages of prolapse between both of the methods were significant for anterior and middle compartment (P<0.01), as well as for posterior compartment (P<0.05).

6. ASSESSING TREATMENT OUTCOME

a) Pelvic Organ Prolapse operations:

Various studies have looked at the anatomic changes seen after surgical procedures in order to better understand how surgical therapies affect pelvic support and structures. Lineman et al. [87] evaluated women after abdominal sacrocolpopexy. The authors found that functional cine MRI identified the exact sacral fixation points after the procedure and easily identified the axis of the vagina and the exact position of the synthetic material used for the repairs. Goodrich et al. used MRI to provide a dynamic analysis and evaluation of patients before and after surgical repair to evaluate structures involved in pelvic support [42]. Similar studies will be needed in order to better evaluate the structures important for pelvic support and, continence as well as the effects of surgical interventions. Sze [88] used MRI to study vaginal configuration on MRI after abdominal sacro-colpopexy and sacrospinous ligament suspension. This study was able to demonstrate the differences in the geometry of these two operations and should prove helpful in establishing outcome variables for different surgical procedures. Similarly Rane [89] used MRI to compare the vaginal configuration on MRI following transvaginal sacrospinous fixation (SSF), posterior intravaginal slingplasty (PIVS) (intracoccygeal sacropexy) and sacrocolpopexy (SCP) and was able to demonstrate significant improvements in the restoration of vaginal configuration were achieved in patients and differences between the procedures in final anatomy.

Boukerrou [90] used MRI scans to compare outcomes of 1) abdominal (Sacral cervicopexy), 2) vaginal hysterectomy with paravaginal repair, sacrospinous suspension and posterior colporrhaphy and 3) sacrospinous suspension and posterior repair without paravaginal suspension demonstrating objective effectiveness provided by these three techniques. The correction provided by the vaginal route resulted in a return of the bladder and the vaginal apex to their normal positions, which clearly demonstrates the short-term effectiveness of these surgical suspensions. In addition they confirmed that vaginal shortening and postoperative change in vaginal orientation were not present postoperatively.

Relationship between assessment of surgical correction studied with MRI and symptoms have been studied reported. Gufler [91] studied 15 patients with uterovaginal prolapse and 15 asymptomatic female volunteers comparing preoperative evaluations with those determined two to four months after surgery. Of the seven patients who had symptoms postoperatively, only two had abnormal findings on physical examination but MRI showed pathologic findings in five of the seven patients. Huebner et al. assessed symptomatic changes after anterior levatorplasty with morphologic changes visualized by magnetic resonance defecography [92]. They were able to demonstrate that anterior levatorplasty improved quality of life in patients with symptomatic rectocele and that correction of rectocele is accurately documented by magnetic resonance defecography, however only moderate correlation between morphologic and clinical improvements was observed.

b) Pelvic Floor Muscle Exercises

Studies have also been conducted concerning the effects of pelvic floor muscle training on the pelvic floor [93] demonstrating reduced levator ani surface area and volume encircled by the levator ani muscle at rest and during contraction. The fact that muscle morphology might be affected by training was investigated by comparing elite athletes to normal women, finding significant differences in the cross-sectional area and width of the pelvic floor muscles, measured in the line of the anal canal between athletic group and the controls [94]. These types of studies are being facilitated by improved techniques of aligning contracted and non-contracted muscle [95]. Assessment of techniques to evaluate structure and function has recently been reviewed [96].

7. COMPARISON OF MRI WITH OTHER EXAMINATIONS AND ASSESSMENT OF RELIABILITY

In the evaluation of incontinence and simple low-grade cystoceles, the studies of choice in the past have been the voiding cystourethrogram (VCUG) and urodynamics. VCUG is useful in determining the severity of cystocele, evaluating for urethral hypermobility, and SUI, and documenting PVR [6]. In addition to the above information, the evaluation of high-grade cystoceles should also provide information on concomitant pelvic floor prolapse and the presence or absence of urinary retention and ureteral obstruction [9-10, 13-15, 83]. Gufler et al. compared chain cystourethrography with dynamic MRI [83]. The authors found that with pelvic straining the measurements of bladder neck descent, angle of the urethra and the posterior urethrovaginal angle, were not significantly different. This was not the case with perineal contraction, where the difference between the measurements was more marked. In the diagnosis of cystocele, MRI had a high degree of correlation to lateral cystourethrography with a Spearman correlation coefficient of 0.95 [83].

Until recently, dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography were considered the best radiological studies for detecting organ prolapse. These studies rely on the opacification with contrast material of the bladder, vagina, small bowel, and rectum with all organs opacified together or in phases with each organ opacified individually prior to each straining phase [4, 89, 92,93]. These studies fail to detect up to 20 percent of all enteroceles [93, 97-99]. Therefore, MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In addition, MRI is able to differentiate the enteroceles according to their contents (small bowel, large bowel, rectosigmoidocele or mesenteric fat). MRI is also an excellent study to differentiate high rectoceles from enteroceles, thus allowing adequate surgical planning and safer planes of dissection [14, 15, 18, 76]. Although a recent study found that multiphasic MRI with opacification of organs and multiphasic fluoroscopic cystocolpoproctography had similar detection rates for enterocele [97], excellent images can be obtained from dynamic MRI without giving the patient oral contrast for opacification of the small bowel or giving rectal contrast. Thus the minimal added information obtained by contrast administration does not seem to warrant the invasiveness of organ opacification at this time [15, 75, 98].

In the evaluation of rectoceles, evacuation proctography has been used to diagnose enteroceles, rectoceles, perineal descent and rectal intussusception. Dynamic contrast roentography or fluoroscopic cystocolpoproctography have also been used [4. 80,81, 97,100] to diagnosed rectoceles. The disadvantages of these techniques are the inability to visualize the soft tissue planes comprising the pelvic floor, their invasiveness, and their use of significant levels of ionizing radiation. Without the use of rectal opacification, MRI appears to be a poor choice for the evaluation of rectoceles missing up to 25% of such defects. When rectal opacification is used during MRI, Tunn et al. showed that a correct diagnosis of rectocele can made in 100% of patients studied when compared to intraoperative findings [18]. Other investigators have also shown that triphasic dynamic MRI and triphasic fluoroscopic cystocolpoproctography have similar detection rates for rectocele [97]. Recently, upright dynamic MRI defecating proctography has been reported [101]. Although these studies might prove to be more sensitive in detecting anorectal anomalies, their utility seems to be more pronounced in patients with disorders of defecation include anismus, intussusception, and others, and may be too invasive to justify their routine use in the evaluation of rectocele.

Kaufman [102] evaluated dynamic pelvic magnetic resonance imaging and dynamic cystocolpoproctography in the surgical management of females with complex pelvic floor disorders. Twenty-two patients were identified from a Pelvic Floor Disorders Centre database who had symptoms of complex pelvic organ prolapse and underwent dynamic MRI, dynamic cystocolpoproctography, and subsequent multidisciplinary review and operative repair. Physical examination, dynamic MRI, and dynamic cystocolpoproctography were concordant for rectocele, enterocele, cystocele, and perineal descent in only 41 percent of patients. Dynamic imaging lead to changes in the initial operative plan for 41 percent of patients. Dynamic MRI was the only modality that identified levator ani hernias. Dynamic cystocol-poproctography identified sigmoidoceles and internal rectal prolapse more often than physical examination or dynamic MRI. Whether this type of imaging creates measurably better outcomes remains to be seen. Singh et al [103] showed was reasonably good correlation between
clinical staging and MRI staging (Kappa = 0.61) with the mid pubic line being used as a surrogate for the hymenal ring. In addition, specific features such as the levator-vaginal angle the area of the genital hiatus could be assessed quantitatively on magnetic resonance images. Torricelli [74] studied ten healthy volunteers and 30 patients with suspected pelvic floor deficiency with and without pelvic organ prolapse. They compared MRI findings with findings on pelvic examination. They found good concordance between physical examination and MRI with four cases of uterine prolapse and three cases of enterocele seen on MRI that had not been suspected on pelvic examination. Whether these would have been detected at the time of surgery was not discussed. In a study looking at the diagnostic characteristics of pelvic floor imaging, Deval [104] compared intraoperative findings as a gold standard for MRI based diagnosis. Using these criteria, they found that the sensitivity, specificity, and positive predictive value of MRI were 7%, 100%, 100% for cystoceles; 42%, 81%, 60% for vaginal vault and positive predictive value of MRI were 7%, 100%, 75% for enteroceles; 87%, 72%, 66% for rectocele. Although all of these measurements are somewhat subjective, these figures show that it is possible to quantify the individual elements of pelvic floor dysfunction. in reasonable parameters.

**RECOMMENDATIONS**

1. MRI is not yet indicated in the routine evaluation of patients with [uncomplicated primary] pelvic organ prolapse; however data concerning the causes of prolapse are rapidly accumulating and this may change soon. It can provide useful information concerning complex prolapses and can be used in difficult cases. [Level of evidence 3, Grade of Recommendation C]

**SUGGESTED RESEARCH AREAS**

1. Studies that identify specific defects in the connective tissue and the muscles of the pelvic floor that correlate these findings with the clinical presentation in prolapse are needed.
2. Additional studies comparing MRI of healthy volunteers and patients with pelvic organ prolapse are needed to better evaluated the anatomic changes involved in pelvic floor prolapse.
3. Quality control in MRI, including: what maneuversmanoeuvres are required to produce a maximal prolapse during MRI, standardisation of bowel conditions, degree of bladder filling, pushing instructions, etc.)

I. POST-VOID RESIDUAL

Post-void residual urine (PVR) is defined as "the volume of urine left in the bladder at the end of micturition [1]. Evaluation of PVR prevalence in women with symptomatic pelvic floor dysfunction suggests that 81% have a post-void residual of 30 ml or less [2]. This is not significantly different from asymptomatic perimenopausal and postmenopausal women in whom 15% of subjects had a PVR greater than 50 ml [3]. If symptoms can not predict elevated PVR, a urogenital prolapse beyond the hymen seems to be associated with incomplete bladder emptying [4]. Among patients with symptoms of overactive bladder, age older than 55 years, prior previous incontinence surgery, history of multiple sclerosis and vaginal prolapse stage 2 or greater, were found to be independent predictors of elevated PVR [5]. Similar data were obtained by Fitzgerald in patients with urgency incontinence, the presence of pelvic organ prolapse ≥stage 2, symptoms of voiding difficulty and absence of stress incontinence symptoms predicted 82% of patients with elevated PVR [6]. Higher prevalence of post-void residual was found in patients with stress urinary incontinence with 35.5% of women had a PVR >50 ml suggesting they have some degree of voiding dysfunction [7]. Although elevated PVR and bacteriuria are common among elderly residents in nursing homes, no association between the two was observed in a Swedish study [8]. Analysis of elderly patients with urinary incontinence failed to identify any significant association between PVR and any other clinical or urodynamic parameter [9]. Sanders and co-workers addressed the issue of the real need for measuring flow rates and post-void residual urine in women with urinary incontinence. Analysis of 408 women suggest a 4% incidence of PVR of 200 ml or greater and a 6% rate of PVR of 149 ml or greater. The authors calculated that only 1.5% of patients (6 of 408) had their management modified because of the results of free uroflowmetry and PVR measurement. In their opinion, these data do not justify the inclusion of these tests in the “minimal care” programme for assessing primary, uncomplicated, urinary incontinence in female patients [10].
PVR can be measured at the time of endoscopy, were reduced to 14% with a mean difference of 85 ml. However, education of the nurses, inaccurate assessments were found to be inaccurate [16]. After further residual volume of 76 ml in those measurements that a mean difference between the initial and the actual patients evaluated by full-time urological nurses with Millard showed inaccuracies in 26% of 515 male diverticula and vesicoureteric reflux [15]. Stoller and suprapubic pressure), especially in cases of bladder instructed as to the procedures and techniques to assure complete emptying (moving the catheter in and out slowly, twisting it, suctioning with syringe, suprapubic pressure), especially in cases of bladder diverticula and vesicoureteric reflex [15]. Stoller and Millard showed inaccuracies in 26% of 515 male patients evaluated by full-time urological nurses with a mean difference between the initial and the actual residual volume of 76 ml in those measurements that were found to be inaccurate [16]. After further education of the nurses, inaccurate assessments were reduced to 14% with a mean difference of 85 ml. PVR can be measured at the time of endoscopy, provided there is a blinded insertion of the instrument to avoid irrigation fluid inflow. Both invasive means are usually performed with some kind of local anaesthesia and carry a small the risk of urethral damage and urinary infection.

Before the era of ultrasonography, PVR was measured non-invasively by the phenolsulfonphthaleine excretion test or with isotopes [17, 18].

In 1967, Holmes described the use of ultrasonography in the evaluation of bladder volume and this technique rapidly gained widespread acceptance as a satisfactory level of accuracy was demonstrated [19, 20]. Using either three diameters (length, height, width) or the surface area in the transverse image and the length obtained in the longitudinal image, various volume formulae for a spherical or an ellipsoid body are utilised to estimate the bladder volume (Table 3). Twenty-one different formulae have been proposed over the years making assumptions about bladder shape which have often been questioned [21]. Comparison of values of bladder volumes obtained using different formulas did not result in any significant difference amongst the various calculations [22]. At present, no single formula can be indicated as the one best volume calculation formula. Several studies report a sufficient accuracy in the ultrasound estimation of PVR [20, 21, 23-26]. False negative results are rare with PVR less than 20 ml [27]. Recently portable scanners were introduced, with automatic measurement of bladder volume. In a prospective comparison of one hundred measurements of PVR by portable ultrasound with measurements by catheterisation, the mean absolute error of the scanner was 52 ml [28]. For volumes below 200 ml and 100 ml, the error was 36 ml and 24 ml respectively. More recent studies suggest a good level of accuracy in both female and paediatric populations [29, 30]. Residual urine is usually referred as an absolute value, but it can be measured also as a percentage of bladder capacity.

The intra-individual variability of PVR is high from day to day and even within a 24 hours period. This was reported in men with BPH by Birch et al. and by Bruskevitz et al. [31, 32]. Griffiths et al. examined the variability of PVR among 14 geriatric patients (mean age 77 years), measured by ultrasound at three times [32].

### 2. MEASURING PVR

The measurement of PVR can be performed by invasive and noninvasive means. Invasive methods include: in-and-out catheterisation and endoscopy. Noninvasive means are transabdominal ultrasonography with real-time ultrasound or fully automated systems, and radioisotope studies. In-and-out catheterization has been considered for some time, the gold standard for the measurement of PVR. Nevertheless the method is subject to inaccuracies, if the person performing the catheterization is not fully instructed as to the procedures and techniques to assure complete emptying (moving the catheter in and out slowly, twisting it, suctioning with syringe, suprapubic pressure), especially in cases of bladder diverticula and vesicoureteric reflex [15]. Stoller and Millard showed inaccuracies in 26% of 515 male patients evaluated by full-time urological nurses with a mean difference between the initial and the actual residual volume of 76 ml in those measurements that were found to be inaccurate [16]. After further education of the nurses, inaccurate assessments were reduced to 14% with a mean difference of 85 ml. PVR can be measured at the time of endoscopy, provided there is a blinded insertion of the instrument to avoid irrigation fluid inflow. Both invasive means are usually performed with some kind of local anaesthesia and carry a small the risk of urethral damage and urinary infection.

Before the era of ultrasonography, PVR was measured non-invasively by the phenolsulfonphthaleine excretion test or with isotopes [17, 18].

In 1967, Holmes described the use of ultrasonography in the evaluation of bladder volume and this technique rapidly gained widespread acceptance as a satisfactory level of accuracy was demonstrated [19, 20]. Using either three diameters (length, height, width) or the surface area in the transverse image and the length obtained in the longitudinal image, various volume formulae for a spherical or an ellipsoid body are utilised to estimate the bladder volume (Table 3). Twenty-one different formulae have been proposed over the years making assumptions about bladder shape which have often been questioned [21]. Comparison of values of bladder volumes obtained using different formulas did not result in any significant difference amongst the various calculations [22]. At present, no single formula can be indicated as the one best volume calculation formula. Several studies report a sufficient accuracy in the ultrasound estimation of PVR [20, 21, 23-26]. False negative results are rare with PVR less than 20 ml [27]. Recently portable scanners were introduced, with automatic measurement of bladder volume. In a prospective comparison of one hundred measurements of PVR by portable ultrasound with measurements by catheterisation, the mean absolute error of the scanner was 52 ml [28]. For volumes below 200 ml and 100 ml, the error was 36 ml and 24 ml respectively. More recent studies suggest a good level of accuracy in both female and paediatric populations [29, 30]. Residual urine is usually referred as an absolute value, but it can be measured also as a percentage of bladder capacity.

The intra-individual variability of PVR is high from day to day and even within a 24 hours period. This was reported in men with BPH by Birch et al. and by Bruskevitz et al. [31, 32]. Griffiths et al. examined the variability of PVR among 14 geriatric patients (mean age 77 years), measured by ultrasound at three times [32].

Modified from the Proceedings of the 4th International Consultation on Benign Prostatic Hyperplasia p. 205
different times of day on each of two visits separated by 2-4 weeks [33]. Within-patient variability was large (SD 128 ml) because of a large systematic variation with time of day, with greatest volumes in early morning. The inherent random variability of the measurement was much smaller (SD 44 ml). Several factors can influence PVR variability: voiding in unfamiliar surroundings, voiding on command with a partially filled or overfilled bladder, the interval between voiding and the estimation of residual (it should be as short as possible), the presence of vesicoureteric reflux or bladder diverticula. Several studies reported the questionable value of PVR as an important outcome prognosticator in male patients with benign prostatic enlargement and benign prostatic obstruction [34-39]. The cause of PVR is probably multifactorial, and no consensus exists on the relation of PVR, bladder outlet obstruction and detrusor contractility.

CONCLUSIONS

The knowledge as to the pathophysiology of PVR remains unclear. In patients with urinary incontinence, no consensus exists as to its value as a safety parameter and particularly its relation with upper tract dilatation, bacteriuria and urinary infection. The intra-individual variability of PVR has been investigated mainly in male patients with bladder outlet obstruction but little information is available as to its variability in patients with urinary incontinence.

Ultrasound is the recommended method for assessing PVR because it is the least invasive and it is sufficiently accurate for clinical purposes yet is the most expensive. In-and-out catheterization is invasive and can be inaccurate even if carefully performed.

The general opinion is that PVR measurement forms an integral part of the study of urinary incontinence, as a safety parameter to exclude a voiding dysfunction associated with incontinence.

RECOMMENDATIONS

1. Residual urine measurement is recommended in the initial assessment of urinary incontinence as a safety parameter and in the evaluation of treatment outcome (Level of evidence 3- Grade of recommendation C)

2. The determination should be performed utilising realtime sonography or portable scanner or in and-out catheterisation (Level of evidence 3- Grade of recommendation C).

3. Due to intra-individual variability, in cases where significant PVR is detected by the first measurement, several measurements should be performed (Level of evidence 3- Grade of recommendation C)

4. The modality of measurement should be indicated

SUGGESTED RESEARCH AREAS

1. Pathophysiology of PVR in male and female populations with UI;

2. Diurnal variation of residual urine in patients with UI;

3. Determination of the cut off value of significant residual urine in different patient populations with UI

4. Residual urine as a prognostic indicator of outcome in the treatment of incontinence

II. OPEN BLADDER NECK AND PROXIMAL URETHRA AT REST

An open bladder neck and proximal urethra at rest is usually an unexpected observation of voiding cystourethrograph or pelvic floor ultrasonography and its significance remains doubtful [1]. A 21% prevalence in nulliparous asymptomatic women has been reported [2]. In the non-neurogenic population there is no pathophysiological correlation between such this and urinary incontinence. Digges and co-workers reported a prevalence of 1:3 amongst females suffering LUTS. An open bladder neck at rest is not pathognomonic of sphincter incompetence although it is associated with USI [3]. In patients with stress incontinence, but also in asymptomatic women [4], funneling of the internal urethral meatus may be observed on Valsalva (Fig. 5) and sometimes even at rest; funneling is often associated with leakage. However, funneling may also be observed in urgency incontinence and cannot be used to prove USI. Marked funneling has been shown to be associated with poor urethral closure pressures [5, 6].

Reports in the peer reviewed literature suggest that the open bladder neck and proximal urethra at rest, during the storage phase, can be observed during cystography, videourodynamic or bladder ultrasound, both in patients with and without neurological disease and is interpreted as a sign of internal sphincter denervation as occurs in 53% of patients with MSA [7]. Distal spinal cord injury has been associated with an open smooth sphincter area, but whether this is due to sympathetic or parasympathetic decentralisation or defunctionalisation has never been settled [8]. Relative incompetence of the smooth sphincter area may also result from interruption of the peripheral reflex arc very similar to the dysfunction observed in the distal spinal cord injury. Twenty-one out of 54 patients with spinal stenosis were found to have an open bladder neck at rest [9]. In a review of 550 patients [10], 29 out of 33 patients with an open bladder neck had neurological disease. Although the association was more commonly seen in patients with thoracic, lumbar and sacral lesions, the difference when compared to cervical and supraspinal lesions was not significant. Damage of sympathetic innervation to the bladder was also frequently observed in patients undergoing major pelvic surgery, such as, abdominal perineal resection of the rectum. Patients with myelodysplasia had an inordinately high incidence of open bladder neck (10 out of 18 patients; versus 19 out of 290 having different neurological disorders).

Patients with sacral agenesis are included in the larger category of myelodysplastic patients and suffer from an open bladder neck with an underactive bladder. Shy-Drager syndrome is a Parkinson-like status with peripheral autonomic dysfunction. Neurogenic detrusor overactivity is usually found in association with an open bladder neck at rest and a denervated external sphincter [11]. Peripheral sympathetic injury results in an open bladder neck and proximal urethra from a compromised alpha-adrenergic innervation to the smooth muscle fibres of the bladder neck and proximal urethra [12]. Although it can occur as an isolated injury it is usually associated with partial detrusor denervation and preservation of sphincter EMG activity. The loss of bladder neck closure suggests an autonomic neural deficit. The site and nature of the requisite deficit is unclear. Most of the authors agree on the importance of the sympathetic system in maintaining the integrity of the bladder neck [13-16] although the possible role of parasympathetic innervation has been proposed by others [17, 18]. An open bladder neck at rest in children or in women without neurological disease can represent a different disorder, either related to a congenital anomaly or secondary to an anatomical pelvic floor defect. Stanton and Williams [19] described an abnormality in girls with both diurnal incontinence and bed-wetting, based primarily on micturating cystourethrogram, in which the bladder neck was wide open at rest. Murray et al [20] reported the “wide bladder neck anomaly” in 24.5% of the girls [35] and 9.3% of the boys [10] out of 251 children (143 girls and 108 boys) undergoing videourodynamic measurements. The assessment of non-neurogenic bladder dysfunction (mainly diurnal incontinence). The authors considered the anomaly congenital and made the hypothesis that wide bladder neck anomaly in girls may provide a basis for the development of USI in later life.

Open bladder neck is a key point in defining type III stress incontinence according to the classification of Blaivas and Olsson [21]. The classification is based on history, imaging, and urodynamics, and distinguishes five diagnostic categories of stress incontinence. Incontinence type III is diagnosed by the presence of an open bladder neck and proximal urethra at rest in the absence of any detrusor contraction suggesting an intrinsic sphincter deficiency. The proximal urethra no longer functions as a sphincter. There is obvious urinary leakage that may be gravitational in nature or associated with minimal increase in intravesical pressure. In pelvic fracture with membranous urethral distraction defects, when cystography (and/or cystoscopy) reveals an open bladder neck before urethroplasty, the probability of postoperative urinary incontinence may be significant, although the necessity of a simultaneous (or sequential) bladder neck reconstruction in controversial [22-24]. Skala and co-workers suggest that an open bladder neck at rest is associated with an increased risk of postoperative complications and failure after open colposuspension [25]. Further research in this area is required to confirm these data.

In conclusion, the diagnosis of open bladder neck at rest does not seem to be helpful to diagnose the underlying cause of urinary incontinence.
RECOMMENDATIONS

When observing an open bladder neck and proximal urethra at rest in male patients, during the storage phase, whatever imaging technique is used, it may be worthwhile to evaluate the possibility of an underlying autonomic neural deficit. (Level of Evidence 3, Grade of Recommendation C)

SUGGESTED RESEARCH AREAS

1. The relation of open bladder neck and proximal urethra at rest to the different neurogenic disorder
2. Longitudinal study of wide bladder neck and proximal urethra at rest in asymptomatic women
3. Evaluate the prognostic value of the open bladder neck and proximal urethra at rest

REFERENCES

The prevalence of urethral diverticula ranges between 1 and 6% with rates up to 10% in among symptomatic women from tertiary referral centres [1, 2]. The suspicion of a urethral diverticulum stems from LUTS or urethral masses on physical examination. Urethral masses include leiomyoma, vaginal cysts, malignancy, ectopic ureter, granuloma and urethral diverticula. The first case of female urethral diverticulum was reported in 1805 [3]. Since the report from Davis and Cian in 1956 [4] using positive-pressure urethrography (PPU), the diagnosis has become much more common even though, despite increased clinical awareness, this pathology continues to be frequently overlooked. Urinary incontinence is often associated with a urethral diverticulum. Incontinence may be a sequel to urine loss from the diverticulum itself with stress manoeuvres, USI or urgency incontinence [5]. Aldridge et al. [6] reported urethral diverticula in 1.4% of patients with stress urinary incontinence. The presenting symptoms of a urethral diverticulum have classically been described as the three Ds (Dysuria, postvoid dribbling, and Dyspareunia). Since most patients present with nonspecific lower urinary tract symptoms, and the pathognomonic presentation (postvoid dribbling, urethral pain, tender periurethral mass and expression of pus form the urethra) is very uncommon, these patients undergo extensive evaluation and treatment before a correct diagnosis is established [7, 8]. The diagnosis of a urethral diverticulum may be achieved by physical examination, voiding cystourethrography, positive-pressure (double-balloon) urethrography, urethroscopy, endovacitary (transurethral or transvaginal) or transperineal ultrasound sonography, urethral pressure profile or MRI. Positive pressure urethrography is usually accomplished using a double balloon catheter according to the method described by Davis and Cian [4]. Two different models exist: the Davis-TeLinde and the Tratner catheter. Positive-pressure urethro-graphy (and voiding urethrography) may result in a false negative study when the inflammation of the diverticulum neck prevents contrast medium to flow into the diverticulum cavity.

The accuracy of a diagnostic test may depend upon the characteristics of the study population and conflicting data are often reported in the peer-review literature. Blaivas et al report a diagnostic accuracy of VCUG of 97% in a series of 66 patients and similar results (95%) were obtained by Ganabathi et al. [7, 9]. Less favourable results were reported by others. Comparison of VCUG versus PPU in the diagnosis of urethral diverticula showed a clear superiority of the latter with good consistency among different studies [10, 11]. In some patients, VCUG only delineated the lower part of the diverticulum [12]. Ultrasound sonography and MRI should be theoretically free of such false negative imaging. Chancellor et al. [13] described the use of intraoperative intraluminal echographic evaluation which may be of help in dissecting the diverticulum and achieving complete excision without damaging the bladder neck and urethra. A number of studies have shown that MRI is a superior imaging modality to both voiding cystourethrography and positive-pressure urethrography and can be considered, if available, the imaging of choice when the diagnosis of urethral diverticulum is suspected [14-19] (Figure 28 a,b). MRI is superior to VCUG or double-balloon urethrography, particularly in diagnosing diverticula with narrow, noncommunicating necks [15, 16]. MRI proved to be superior to X-ray studies because diverticula can go undiagnosed on voiding cystourethrogram, furthermore size and complexity of the diverticulum is better defined on MRI [17]. Endoluminal MRI is considered to be of particular importance in the diagnosis of circumferential urethral diverticulum, a condition that is relatively rare but the diagnosis may increase with the increased use of this imaging technique. Proper evaluation of diverticular anatomy is essential in planning reconstructive surgery [1, 20]. MRI also proved to be useful in diagnosing inflammation and tumour of the diverticulum [21, 22]. Endoluminal MRI with either a vaginal or rectal coil, may provide even better image quality than simple MRI [18]. A comparison of MRI versus urethrography and urethroscopy, in a group of 20 women with urethral diverticulum, reported a 69 and 77 per cent accuracy of the two latter imaging studies versus MRI [14]. When surgical findings were compared to MRI, urethrography and urethroscopy, the diagnostic ability of the three methods was 70, 55 and 55 per cent, respectively. Diverticula ostia could not be identified by MRI study not withstanding the use of contrast material. Neitlich et al. [15] reported in a series of 19 patients that MRI (using a fast spin echo T2-weighted pulse sequence and a dedicated pelvic multicoil) had a higher sensitivity for detecting urethral diverticula and a higher negative predictive rate in comparison with double balloon urethrography. Blander et al. [17], comparing MRI and VGUG in 27 patients with urethral diverticula, found that endoluminal (endorectal or endovaginal) MRI was extremely accurate in determining the size and extent of urethral diverticula compared to VCUG; the related information can be critical when planning surgical approach, dissection and reconstruction. In conclusion, review of the peer reviewed literature suggests that positive pressure urethrography is still a valuable tool to diagnose female urethra diverticula not withstanding both ultrasound sonography and particularly MRI can represent valuable alternatives with a significantly higher diagnostic accuracy. In males, both VCUG and ultrasonography can be successfully used to diagnose syringocele (cystic dilatation of the Cowper’s gland), congenital and acquired diverticula [23].
RECOMMENDATIONS

In cases of female urinary incontinence if a urethral diverticulum is suspected, appropriate imaging (positive pressure urethrography, voiding cystourethrography, urethroscopy, ultrasound, MRI) is recommended. (The choice of the type of imaging depends on their availability. Data show a higher accuracy of MRI.) (Level of Evidence 3 – Grade of Recommendation C)

AREAS FOR RESEARCH

Properly conducted prospective studies are needed to compare the accuracy of ultrasonography and MRI in the diagnosis and staging of female and male diverticula

IV. IMAGING OF THE NERVOUS SYSTEM IN URINARY INCONTINENCE

1. LUMBOSACRAL SPINE X-RAYS

No significant update can be provided compared to the previous report of the 2005 [1]. In children with lower urinary tract dysfunction and urinary incontinence, the presence of a spinal dysraphism must be ruled out. Although in most of the cases abnormalities of the gluteosacral region and/or legs and foot are clearly visible, antero-posterior and lateral films of the lumbosacral spine have to be evaluated in order to identify vertebral anomalies. Sacral agenesis involves the congenital absence of part or all of two or more sacral vertebrae. In the absence of two or more sacral vertebrae a neurogenic bladder is the rule usually found. Spina bifida occulta has a variable significance. Simple failure to fuse the laminae of the fourth and fifth lumbar vertebrae is unlikely to be important, but if the spinal canal is noticeably widened, there may be cord involvement (diastematomyelia, tethered cord syndrome).

RECOMMENDATIONS

In patients with suspected congenital neurogenic incontinence, with or without abnormalities of neurologic physical examination, lumbo-sacral spine anteroposterior and lateral radiological evaluation (or MRI) is indicated. (Level Evidence 3, Grade of Recommendation C)

2. CT, MRI, SPECT and PET

Numerous papers refer to rare neurological conditions presenting with different symptoms including urinary incontinence in which CT scan, MRI, SPECT, and PET imaging were carried out to identifying the underlying CNS disease. These references have little impact on the daily practice although can be helpful in occasional difficult cases.

With regards to the clinical diagnostic use of CT or MRI, a few papers evaluated the role of fetal MRI imaging. Fetal MRI has higher contrast resolution than prenatal sonography and allows better identification of normal and abnormal tissue. Moreover, MRI can diagnose some abnormalities such as cerebral malformations and destructive lesions which can be occult on prenatal sonography, where the more anterior cerebral hemisphere cannot be properly evaluated due to reverberations by the overlying structures [2]. Common indications for fetal MRI include the evaluation of all the sonographically diagnosed abnormalities of ventriculi, corpus callosum, or posterior fossa, as well as all those fetuses at increased risk for brain abnormalities, such as in families with a history of a prior child or fetus with anomalies, genetic disorders, complications of monochorionic twinning, and maternal illness (such as maternal infection or major cardiac event). Moreover, with recent advances in fetal surgical techniques, fetal MRI is being increasingly used before surgical intervention [3]. The results of fetal MRI, whether verifying absence of abnormality, confirming sonographically detected abnormalities, or discovering additional abnormalities that were not apparent by sonography, have been shown to affect clinical decision-making during pregnancy, both by physicians and parents, resulting in changes in pregnancy management in nearly half of cases [2]. With regards to myelomeningocele, prenatal ultrasound can easily identify the absence of posterior elements of the vertebral bodies at affected levels and extension of the subarachnoid space posteriorly through the bony spina bifida, as well as the frequently associated presence of small posterior fossa alteration and haerniation of cerebellar tissue into the cervical subarachnoid, which define the Chiari II malformation. However, fetal MRI can be a helpful adjunct when sonography analysis is limited, such as in cases of large maternal body habitus, oligohy-dramnios, low position of the fetal head, or when the fetal spine is positioned posteriorly with respect to the mother. Moreover, fetal MRI can be very useful to detect additional associated anomalies, such as callosal agenesis or hypogenesis, periventricular nodular heterotopia, cerebellar dysplasia, syringo-hydromyelia, and diastematomyelia [3]. If fetal surgery will be shown to improve long-term outcome, fetal MRI will surely become a routine examination for affected fetuses.

MRI is also recommended in children with anorectal abnormalities as abnormalities of the spine and of the spinal cord are diagnosed in 42 to 46% of cases and in about 50% of cases the spinal cord is involved [1]. Wraige et Borzyskowski suggested that spinal cord imaging should be considered in children in whom day-time wetting is associated with impaired bladder sensation or poor bladder emptying even in the absence of clinical or radiological suspicion of lumbosacral spine abnormalities. Four out 10 children with these symptoms had a spinal cord defect diagnosed on MRI [4].

MRI imaging of the lumbar spine is now the gold standard for evaluating children with spina bifida and adults in which an occult form of spina bifida is suspected. A potential technical update might be the use of intrathecal contrast medium to perform cisternography and ventriculography contrast-enhanced MRI. Munoz et al., evaluated a series of 10 patients with complex cerebrospinal fluid diseases, where other imaging techniques had been unclear or inconclusive, performing MRI with intrathecal administration of gadopentate dimeglumine. In 8 out of the 10 patients, imaging findings influenced or changed the clinical decision-making program and the surgical planning [5].
Sharma et al. recently evaluated with MRI the surgical outcome in patients with spinal dysraphism. Specifically, MRI spectroscopy was used to evaluated the composition of cerebro-spinal fluid before and after surgery. Before surgery, high levels of lactate, alanine, acetate, glycerophosphate, and choline were observed in the cerebrospinal fluid of patients with spinal dysraphism, while these levels normalized postoperatively to those observed in control subjects. However, in those patients where cord re tethering occurred, increased concentrations of lactate and alanine were found, suggesting that MRI spectroscopy might be a promising tool in the assessment of surgical outcomes in patients with spinal dysraphism [6].

Several papers refer to the use of CNS imaging in clinical research of dysfunction and pathophysiology. Positron emission tomography (PET) and functional MRI studies provided information on specific brain structures involved in micturitions in humans. During micturitions an increase in regional blood flow was shown in the dorsomedial part of the pons close to the fourth ventricle, in the pontine micturitions centercentre (PMC), in the mesencephalic periaqueductal grey (PAG) area, as well as in the hypothalamus including the preoptical area [1].

A couple of significant original studies were have been published since the last International Consultation on Incontinence on the role of functional MRI in stress and urge urinary incontinence. Specifically, previous brain imaging studies showed that during pelvic floor muscle contraction there was activity in the superior medial precentral gyrus, anterior cingulate cortex (ACC), cerebellum, supplementary motor cortex (SMA) and the thalamus [7, 8]. Similarly, during anal sphincter contractions multifocal cerebral activity was shown in the primary and secondary sensory/motor cortices, the insula as well as the cingulate gyrus, prefrontal cortex, and the parietooccipital region [9]. Di Gangi Herms et al. evaluated the neuroplastic changes of cortical representation of pelvic floor motor functions induced with pelvic floor muscle training (PFMT) by biofeedback in patients with SUI [10]. Specifically, the authors used functional MRI to evaluate 10 patients with stress urinary incontinence SUI before and after a 12-week PFMT with EMG-biofeedback program. In the MRI performed before the beginning of PFMT, the authors identified significant brain activation in superior lateral and medial precentral gyrus and the superior lateral postcentral gyrus, in the SMA, the left premotor area, and in the left and middle cerebellum, as well as in the insula as well as in the ACC. In the MRI film after PFMT, less brain areas were activated, mainly the superior lateral and medial precentral gyrus, superior lateral post-central gyrus and the insula. In other words, after PFMT it was identified a more focused activation in the primary motor (superior lateral and superior medial precentral gyrus) and somatosensory areas, which is consistent with automatization automation of the relearned skillful behavior [10]. PFMT with biofeedback may improve muscular strength therefore enhancing support of the urethra and also optimize central muscular control of the pelvic floor, modulate bladder sensation, and reflect the emotional neutralization related to symptom reduction.

With regards to urge urinary incontinence, Tadic et al. reported a small study, which used functional MRI to investigate 11 patients with urge urinary incontinence and 10 healthy controls. Specifically, the connections of the right insula (RI) and anterior cingulate gyrus (ACG) to other cortical area were evaluated, based on the assumption that the two areas were among the most important regions of the supraspinal neuronal network controlling the bladder. In normal subjects, there were significant positive effective connections with many of the regions involved in supraspinal bladder control, including left insula and frontotemporal and parietal regions, thalamus, putamen and claustrum, posterior cortex, cerebellum, pontine micturition centre and mesencephalic periaqueductal grey. Vice versa, in the patients with urgency incontinence, significant negative connections to left parieto-temporal lobes, hippocampus, parahippocampal gyrus and cerebellum were found, with few positive connections [11].

In subjects with normal bladder function, RI and/or ACG have been reconfirmed to have effective connections with many of the brain regions involved in bladder control such as the frontotemporal and sensorimotor regions, thalamus, putamen, cerebellum and midbrain, as well as to the posterior cortex, a region which may have a role in the control of bladder function. Vice versa, in the patients with urgency incontinence, the connections were shifted to an alternative complex of brain regions, such as left parieto-temporal lobes, parahippocampal gyrus and parts of cerebellum, which might represent expression of the recruitment of accessory pathways in order to control urgency and the voiding reflex as well as the emotional charge due to the abnormal sensation of urgency [11]. On the whole the data of these recently published studies have improved our knowledge of nervous functional anatomy related to vesicourethral function and dysfunction but, to date, have no clear clinical relevance.

In conclusion, central nervous system imaging is rarely indicated in urinary incontinence. Spinal cord imaging is recommended in cases of children with anorectal malformation and whenever spina bifida occulta is suspected. In the case of clinical neurological signs and/or symptoms suggestive of central nervous lesions, imaging may be indicated along with more specific neurophysiological tests (e.g., signal latency, testing, evoked potential, etc.). Further improvements in the knowledge of the correlation between
morphologic and functional evaluation of the CNS is foreseeable using present CNS functional imaging technology.

**RECOMMENDATIONS**

Neuroimaging should be considered when a nervous system disorder is suspected on the basis of clinical and/or neurophysiologic test findings (Level of Evidence 3 - Grade of Recommendation C)

**REFERENCES**

5. Evaluation of the membranous and prostatic urethra in male patients with post-prostatectomy stress incontinence to appraise possible iatrogenic damage of the external sphincter region. Assessment of bladder outlet in males with urgency incontinence considered to be secondary to bladder outlet obstruction to appraise prostate morphology.

2. EVALUATION OF THE FEMALE BLADDER OUTLET

Robertson described the procedure of dynamic urethroscopy to evaluate the bladder neck [1]. In this procedure a gas urethroscope is used to observe the urethra, bladder neck, and portions of the bladder.
During visualisation manometric recording can be performed. Robertson described the appearance of SUI as a sluggish closure of the bladder neck and the appearance of the overactive bladder as a bladder neck that closes and then opens like the shutter of a camera. This procedure was reported to be extremely useful in patients with urinary incontinence as the bladder neck can then be observed at rest, with straining, and Valsalva manoeuvres. Unfortunately, in Robertson’s original description of this procedure, it was never compared to other standard methods of measuring outlet resistance. Others who advocate the technique of Robertson reported that only 43% of patients with SUI actually had loss of bladder neck support on urethroscopy [2]. Scotti, et al performed a retrospective review of 204 patients who underwent dynamic urethroscopy for the evaluation of USI [3]. Of the 204 patients, 99 had USI. Urethroscopy was found to be an imprecise predictor of USI with a 62% sensitivity, a 74.6% positive predictive value and a specificity of 79.1%. Moreover, there were many equivocal studies. The authors concluded that urodynamic evaluation rather than urethroscopy was a more accurate predictor of stress incontinence. Sand, and associates compared supine urethrocystographic cystometry (dynamic urethroscopy) to the gold standard of multichannel urethrocystometry [4]. They found a sensitivity of only 24.6% and a positive predictive value of only 65.2% in predicting detrusor overactivity.

Horbach and Ostergard tried to predict urethral sphincter insufficiency in women with SUI using urethroscopy [5]. They retrospectively reviewed the records of 263 women who had a diagnosis of USI. They defined ISD as a maximal urethra closure pressure of 20 cm H2O or less with the patient upright. They then divided patients into two groups, those with ISD and those with maximal urethral closure pressures of more than 20 cm H2O. Based on this classification, 132 women, or 50.2%, had evidence of ISD. However, when urethral function was assessed by endoscopy, only six of 132 patients with ISD were found to have an open or partially open proximal urethra and urethrovessical junction at rest during urethrocystoscopy. Clinically, these patients had very low urethral pressures and reported difficulty with continuous leakage of urine. Endoscopy appeared to have little predictive value for ISD as defined by urethral pressure profilometry. Govier et al compared cystoscopic appearance of the female urethral sphincteric mechanism to the videourodynamic studies in 100 consecutive women with complex types of urinary incontinence [6]. Sphincteric dysfunction was classified as minimal, moderate, and severe based on the radiographic appearance of the bladder neck with straining. Urethrocystoscopy underestimated the degree of sphincter deficiency 74% of the time in patients with moderate sphincteric dysfunction and 44% of the time in patients with severe sphincteric dysfunction. The authors concluded that cystoscopy is inadequate to judge the functional integrity of the bladder outlet. Furthermore, cystoscopy alone will underestimate intrinsic sphincter deficiency in a large number of patients.

3. EVALUATION OF THE BLADDER

Is cystoscopy necessary to rule out concomitant bladder pathology in patients with urinary incontinence? Langmade and Oliver reported on 253 patients who were operated on for SUI [7]. They used a simple evaluation that consisted of history, stress tests, and urinalysis alone. They did, however, recommend cystoscopic evaluation if the patient also complained of symptoms of urgency. Although this dogmatic approach was recommended, it was never clearly stated if it made a difference in the treatment or outcome in these patients. Fischer-Rasmussen, et al performed extensive evaluation of women with urinary incontinence [8]. This included cystoscopy in 190 patients. They found cystoscopy to be abnormal in only 12 patients, 8 who had stress incontinence and 4 who had other types of incontinence. Abnormal findings were trabeculated bladder mucosa in five patients, benign bladder papillomas in four, and metaplasia of the trigonal mucosa in two. None of these was considered to be a significant finding. The authors concluded that cystoscopic examination did not contribute to the classification of incontinence in any case. Cardozo and Stanton evaluated 200 patients with SUI and detrusor overactivity [9].

Cystoscopy revealed no abnormalities amongst the 100 patients with USI. Fourteen of the 100 patients with detrusor overactivity had cystoscopic abnormalities, eg trabeculation, injected mucosa, sacculation, a bladder capacity of less than 100 cc. However, in none of these patients was the treatment affected by the results of cystoscopy. In support of these findings, Mundy has stated that there is no direct diagnostic value of endoscopy in a patient with an overactive bladder. It may sometimes be helpful to look for and exclude a cause of hypersensitivity when this is in the differential diagnosis [10]. Dulidulao and colleagues found this necessary only in patients with haematuria [11]. They performed urinalysis, urine cytology, and cystoscopy on 128 women who presented with urgency incontinence and/or storage voiding symptoms. Of these, 68 patients had urgency incontinence, 35 of whom also had microscopic haematuria. One patient with urgency incontinence and haematuria was found to have a transitional cell carcinoma of the bladder. None of the patients with urgency incontinence (or storage symptoms only) and no haematuria were found to have significant cystoscopic findings. This would support the routine use of cystoscopy for patients with urgency incontinence only if haematuria is present.
4. EXTRA-URETHRAL URINARY INCONTINENCE

Endoscopy can be an invaluable tool in the diagnosis and treatment of extraurethral incontinence due to vesico-vaginal fistula and ectopic ureter. With respect to vesico-vaginal fistula, cystoscopy can precisely localize the fistula site in the bladder and help plan surgical correction. Occasionally, a small fistula that is not seen on physical examination or radiographic studies, can only be diagnosed by cystoscopy.

Incontinence due to ectopic ureter in the female is usually diagnosed by radiographic studies. However, the exact location of the ureteral orifice in the urethra or vagina can be identified by cystourethroscopy and/or vaginoscopy. This can be extremely helpful in the planning of corrective surgery.

5. INTRAOPERATIVE LOWER URINARY TRACT EVALUATION

Several authors have studied the value of routine cystoscopy during operative procedures for incontinence and prolapse. The approach may be transurethral [12] or transvesical [13]. The American College of OB/GYN has published a Bulletin on Operative Lower Urinary Tract Injuries [14] in which it is stated “at the conclusion of the procedure, when hemostasis has been ensured, both ureters and the bladder should be inspected to confirm their integrity.” Harris and co-workers [12] reported 9 unsuspected ureteral or bladder injuries during urogynaecological surgery, which included 6 ureteral ligsations, with four of these occurring after Burch cystourethropexy. Burch sutures were also found in the bladder as well as fascial lata from a sling procedure.

6. EVALUATION OF THE MALE BLADDER OUTLET

Urgency incontinence is one of the lower urinary tract symptoms associated with benign prostatic hyperplasia, bladder outlet obstruction, and aging in the male population. Based on the available evidence and world literature, The Fourth International Consultation on BPH made the following recommendation: “Diagnostic endoscopy of the lower urinary tract is an optional test in the standard patient with LUTS because: 1) the outcomes of intervention are unknown, 2) the benefits do not outweigh the harms of the invasive study, 3) the patients’ preferences are expected to be divided. However, endoscopy is recommended as a guideline at the time of surgical treatment to rule out other pathology and to assess the shape and size of the prostate, which may have an impact on the treatment modality chosen” [15]. Several contemporary series have described the value of urodynamics in the diagnosis of post-prostatectomy urinary incontinence [16-20]. However, only one describes the routine use of urethrocystoscopy. In that series 67% of patients had urethral fibrosis confirmed by endoscopy [17]. However, how this finding affected treatment was not discussed. In the study by Leach and Yun treatment of incontinence was based solely on urodynamic findings and was successful in 87% of patients [21]. Anastomotic strictures may be suspected based on uroflow and urodynamic (pressure-flow) studies and can be confirmed by voiding cystourethrogram or videourodynamics as well as by endoscopy. However, if intervention for the stricture is deemed necessary, endoscopy would be a more critical part of the evaluation. Furthermore if surgical treatment of incontinence, such as, an artificial urinary sphincter, is planned it would seem to make good clinical sense to evaluate the urethro-vesical anastomosis with endoscopy prior to surgery.

7. EVALUATION OF URETHRAL SPHINCTER IN POST-PROSTATECTOMY INCONTINENCE

Iatrogenic UI in males usually occurs after prostate surgery for benign and malignant conditions. The pathophysiology of UI following transurethral surgery for BPH includes sphincter damage from extending the resection too distal, particularly in the ventral aspect of the sphincter where muscle fibres are more abundant. Endoscopy in post-TURP incontinence reveals insufficient closure at rest with tissue loss in the ventral aspect of the sphincter area, voluntary muscle recruitment is often good. The pathophysiology of UI in post-radical prostatectomy patients is unclear. Numerous studies investigated the relation between parameters of urethral pressure profile, morphology of the prostate apex and length of the external sphincter area to post-prostatectomy incontinence. Although the results of these studies suggest a relation between sphincter competence and UI, no consensus has been reached yet as to the gold standard test to be performed prior to surgery to assess the individual patient risk of incontinence.

Recently, Gozzi and Rehder suggested that post-radical prostatectomy incontinence may be related to prolapse of the sphincter complex and that repositioning of it by a transobturator sling may be successful. Pre-operative selection of surgical candidates for such intervention include endoscopy of membranous urethra testing whether manual push-up of the centrus tendineus perinei results in recruitment of the sphincter fibres comparable to a voluntary contraction. Contraction of the sphincter muscle upon repositioning in a more cranial position is used as an indication for a transobturator sling with the Gozzi and Rehder technique [22-24]. Further research is required to confirm such an interesting pathophysiological explanation of post-radical prostatectomy incontinence and to support the role of endoscopy in the evaluation of these patients.
RECOMMENDATIONS

- Routine urethro-cystoscopy is NOT indicated in primary female urinary incontinence, when other pathologies are not suspected (Level of Evidence 3, Grade of Recommendation C).
- Endoscopy can be considered (Level of Evidence 3, Grade of Recommendation C):
  - a) in urgency incontinence to rule out other pathologies, especially in case of microscopic haematuria (e.g., bladder tumor, interstitial cystitis, etc)
  - b) in the evaluation of recurrent or iatrogenic cases when surgery is indicated and planned
- Endoscopy is indicated in the evaluation of vesico vaginal fistula and extra-urethral urinary incontinence (Level of Evidence 3, Grade of Recommendation C).
- Endoscopy is indicated intraoperatively in incontinence surgery to evaluate for ureteral or vesical injury (Level of Evidence 3, Grade of Recommendation C).

SUGGESTED RESEARCH AREAS

To relate endoscopic features to diagnosis and outcome of urinary incontinence (mainly urgency incontinence)

C. IMAGING IN ANAL INCONTINENCE

I. BACKGROUND

Anal incontinence may result from anal sphincter weakness and/or rectal sensory disturbance. Imaging provides highly detailed evidence of changes to sphincter morphology. This started with the development of endoanal ultrasound (EAUS) in 1989, which soon became the gold standard[1] for demonstrating internal and external sphincters tears. Important early findings were the unexpectedly high incidence of occult sphincter damage following vaginal delivery[2], and an association between a history of obstetric trauma with faecal incontinence developing later at menopause. Parks’ original work[3] had focussed on denervation and striated muscle atrophy as the main cause of faecal incontinence. One limitation of EAUS was in measuring the external sphincter thickness, and it was not until MRI with an endocoil for the anal canal was developed that highly detailed images of the striated sphincteric muscle to show thickness and fat replacement were possible, and external sphincter atrophy could be assessed by means other than EMG. Studies of rectal evacuation are performed mainly fluoroscopically, and give only a rough indication that the patient suffers from incontinence. They are used mainly to investigate difficult defaecation and rectal prolapse.

II. INDICATIONS

The role of imaging is largely to place patients into treatment defined groups, so the emphasis may change as new treatments evolve. Endosonography took over from EMG studies as the optimum method to select patients with sphincter disruption for surgical repair, and this remains its main indication. When to investigate for external sphincter atrophy is a more complex question. Endocoil MRI may be indicated prior to sphincter repair if there is any doubt as to the quality of the external sphincter. Biofeedback has become a popular first line treatment, and a recent study suggests that imaging has only a limited role in predicting success[4], which could have a negative impact on the utilization of imaging.

III. IMAGING MODALITIES

1. ENDOANAL ULTRASOUND (EAUS)

Several systems are available, and recently integrated 3D systems are available (B&K Medical, Sandofen 9, 2820 Gentofte, Denmark). US probes designed for transvaginal examination with endfire linear arrays may be used in women to image the sphincters from the perineum. Women should be examined prone with an endoanal system to minimise anatomical distortion.

The standard EAUS image of the anal canal is of 4 layers (Figure 1):

- The subepithelial layer is moderately reflective.
- The internal sphincter is the most obvious landmark and is a well defined low reflective ring. The internal sphincter varies in thickness with age, being <1mm in neonate, 1-2mm in young adults, 2-3 in middle age and >3mm in the elderly.
- The longitudinal layer is a complex structure with a large fibroelastic and muscle component, the latter formed from the puboanal as well as the longitudinal muscle of the rectum (Figure 2).
- The external sphincter is better defined in men than women, where it tends to be less hypechoic. It is distinguished mainly by interface reflections between muscle/fat planes either side (Fig 1). In women the external sphincter is shorter anteriorly than posteriorly, which must not be misinterpreted as a tear. The transverse perinei fuse anterior with the sphincter, whereas in men they remain separate.

With experience the examination can be performed in about 5 minutes and provides an ideal method for a rapid assessment of sphincter integrity and thickness.
2. MRI

Dedicated endoanal coils are no longer available, so that much of the research using these cannot now be transferred into routine practice. However, image quality has improved dramatically with standard external coils, and MRI is particularly useful to show atrophy and tears outside the sphincter, such as the puborectalis [5].

The advantages of MRI are multiplanar imaging and that the difference in signal between fat and striated muscle allows precise measurement of external sphincter (Figure 3) thickness and estimation of fat replacement.

3. EVACUATION PROCTOGRAPHY

The rectum is opacified with 120 mls of a barium paste and the small bowel with a dilute barium suspension given orally about 30mins before. The patient is seated sideways within the fluoroscopic unit on a radiolucent commode. Evacuation of the barium paste is recorded either on video or on cut film at 1 frame/sec using a low dose protocol. At rest the anorectal junction is at the level of the ischial tuberosities and the anal canal closed. Evacuation is rapid (<30sec) and the rectum below the main fold should be emptied completely. During evacuation the anorectal angle widens as the anorectal junction descends and the anal canal opens. At the end of evacuation pelvic floor tone returns and the puborectalis pulls the anorectal junction upwards and forwards back to the resting position. Intra-anal intussusception creates a thick double fold of rectum, which impacts into the anal canal on straining at the end of rectal evacuation. Rectal prolapse represents an extension of this process, with passage of the intussusception through the anal canal and inversion of the rectum (Figure 4a-c).

Dynamic examinations of rectal emptying may also be performed with MRI, though this is technically more difficult and perhaps not worthwhile unless a global view of pelvic floor prolapse is required, although it does eliminate any harmful radiation. A simpler method involves views during only rest and stress. This is useful to show bladder and uterovaginal prolapse as well as pelvic floor descent (Figure 5a-b), but gives limited information as to rectal function.

IV. SPHINCTERIC DISORDERS

1. THE INTERNAL ANAL SPHINCTER

Abnormalities of thickness have to be related to the patient's age. A sphincter less than 2mm thick in a patient more than 50 years of age is indicative of internal sphincter degeneration (Figure 6) and is associated with passive faecal incontinence.

Obstetric trauma to the internal sphincter parallels that of the external sphincter in extent, but should always be in the anterior half, so that any defect between 3 and 9 is due to some other cause.
Figure 4: Evacuation proctogram showing the development of rectal prolapse. Intussusception starts at the end of rectal emptying (a) and rapidly passes through the anal canal (b) to form the external prolapse (c).
Sphincterotomy may be more extensive than was planned, particularly in women, and 3D studies are especially helpful to assess the longitudinal extent of the defect. The length of the sphincter divided relates directly to the risk of incontinence[6]. Dilatation procedures are hazardous and may completely fragment (Fig 7) the internal sphincter.

2. THE EXTERNAL ANAL SPHINCTER

When striated muscle is stretched beyond the limits of its elasticity fibres rupture and heal with granulation tissue and eventually fibrosis. Most chronic tears are seen with scar formation, and present as a uniform area of low reflectivity distorting and obliterating normal anatomical planes (Figure 8). A key to the diagnosis is lack of symmetry with the anterior part of the external sphincter not fusing at 12 o’clock as the probe is moved slowly down the canal. This may also be seen on 3D studies in the coronal plane (Figure 9). Other perineal structures, such as the puboanalis and transverse perineii are frequently torn and distinguishing these tears from external sphincter trauma requires experience, and again may be helped by 3D multiplanar imaging. The distinction is important as tears of the puboanalis or transverse perineii are not associated with a significant fall in squeeze pressure[7], and it is only damage to the external sphincter that results in a significant change.

In healthy young adults a good correlation has been found between measurements of layers thicknesses on endosonography and endocoil MRI, with an Ri of 0.96 for the external sphincter[8].

The outer border of the external sphincter is easier to see on MRI, but fibrosis is not so markedly different in signal from normal muscle, so that the conspicuity of tears may not be as obvious as with endosonography.

Atrophy is a more difficult problem. Determining the thickness of the external sphincter on EAUS depends on visualising its borders from interface reflections between the longitudinal layer on the inside and subadventitial fat on the outer border. As atrophy involves a reduction of muscle fibres and an increase in fat, the outer interface reflection is lost and the thickness of the external sphincter cannot be measured. Such loss of definition of the outer border of the external sphincter on endosonography has a positive predictive value of 71% for atrophy[9]. Using 3D EAUS and a grading system based on definition (Figure 10) and echogenicity of the external sphincter showed a comparable accuracy to endocoil MRI in detecting atrophy [10].

Pelvic floor descent at rest with the patient seated and impaired movement during pelvic floor contraction[11] (measured either on MR or EP) are good indicators of generalised pelvic floor weakness, and if the anal canal is open (Figure 11) this indicates
Figure 7: Endosonography in the mid canal showing gross internal sphincter irregularity, typical of the "fragmented" appearance from trauma after an anal stretch procedure.

Figure 8: Tears of internal and external sphincters (arrows) between 10 and 1 o’clock following a traumatic vaginal delivery.

Figure 9: 3D EAUS of a small tear to the external sphincter (arrow).

Figure 10: EAUS showing a normal internal sphincter, but the external sphincter is not visible as it is echogenic and the interface reflections due to advanced atrophy.
significant sphincter weakness. Most other findings, such as rectal prolapse, are really either secondary or associated with faecal incontinence, and EP is used to investigate these rather than the incontinence.

**V. CONCLUSIONS AND RECOMMENDATIONS**

Claims for superiority of one or other modality for the detection of sphincter tears probably depend largely on individual experience, but the cheapness and speed of endosonography makes this an ideal screening procedure to assess sphincter integrity.

Fluoroscopic studies have little role in faecal incontinence, unless there is an underlying rectal abnormality such as prolapse. Dynamic MRI studies have the added value of demonstrating prolapse in the rest of the pelvis, but apart from the lack of ionising radiation, has no real advantage for studying rectal function.

A leading issue is the significance of occult sphincter tears (diagnosed on endosonography but not apparent clinically) following vaginal delivery. Although these may be detected by careful examination immediately post partum [12], retrospective detection will still require EAUS. A meta-analysis of 717 vaginal deliveries revealed a 26.9% incidence of anal sphincter tears in primiparous, with 8.5% new tears in multiparous women. Overall 29.7% of women with tears were symptomatic, compared to only 3.4% without tears. The probability of faecal incontinence being due to a sphincter tear was 76.8-82.8% [13]. Recent studies confirm the strong relationship between obstetric sphincter damage and faecal incontinence [14,14], and its late onset [15,16]. Subsequent deliveries increase the risk of incontinence particularly if there has been a tear at the first delivery [17]. Tears that involve the internal sphincter increases the severity of incontinence [18].

A sphincter tear at EAUS is therefore an important finding, but how is this used to decide management a little more controversial. Sphincter repair has fallen out of fashion a little following the finding that results deteriorate over a few years [19], although a more recent study [20] suggests a better response.

EAUS therefore remains the first line imaging investigation for faecal incontinence, giving accurate information as to external and/or internal sphincter tears and the likelihood of atrophy. Dynamic studies of rectal evacuation are required only if there is some other problem suspected, such as prolapse. The advantages of using MRI are the lack of ionising radiation and a global view of the pelvic floor. Although imaging gives hard evidence of sphincter damage, this is really only part of a much more complex functional problem, and colorectal abnormalities may be just as important [11] with tears accounting for perhaps only 45% of incontinence [21].

**RECOMMENDATIONS**

- EAUS is the first line imaging investigation for faecal incontinence providing accurate information as to external and/or internal sphincter tears and the likelihood of atrophy. **[Level of Evidence 3, Grade of Recommendation C]**.
- Dynamic imaging of rectal function is required when rectal abnormalities such as prolapse are suspected **[Level of Evidence 3, Grade of Recommendation C]**.
- MRI offers no advantage over other imaging modalities except for the lack of ionising radiation and a global view of the pelvis **[Level of Evidence 3, Grade of Recommendation C]**.

**SUGGESTED RESEARCH AREAS**

MRI has allowed a much clearer understanding of pelvic floor anatomy, and this in turn has enabled the sonographic anatomy to be worked out. However, conflicting views remain when sonographic abnormalities are compared to function. Are clinical symptoms related to the size of a tears [22] or not [23]?
Problems after sphincter repair include:

- understanding the significance of the image soon after surgery [24],
- the value of manometry and imaging in assessing the repair [25],
- confirming that the length of the repair affects outcome [20].

Perhaps the most valuable aspect of MRI imaging is that it gives a global view of the pelvis, capable of confirming that the length of the repair affects outcome [25], and should be the prime area future investigation.

REFERENCES

The use of a perineal electronic nappy using electrical conductivity to estimate the amount of urine leakage was first proposed by James et al.[1, 2]. Accuracy of this technique was, however, questioned by others and the technique was improved [3-8]. Walsh & Milis and Sutherst et al. introduced a more simple approach by estimating leakage by perineal pad weight gain [9, 10]. These tests were not standardised until Bates et al. described a "structured" one hour pad test which was endorsed by the International Continence Society in 1988 [11]. This test, however, was shown to have poor interdepartmental correlation and to be highly dependent on bladder volume [12, 13]. In an attempt to make pad tests more reliable 24 hour and 48 hour pad tests were developed. A more precise estimation of urine loss was shown, but they were more cumbersome. The Pyridium pad test was also proposed for diagnosing urinary incontinence [14].

**I. DEFINITION**

The pad test is a diagnostic method to detect and quantify urine loss based on weight gain of absorbent pads during a test period under standardized conditions.

**INDICATION AND METHODOLOGY**

A pad test allows the detection and quantification of urine loss, but it is not diagnostic of the cause of the incontinence. Several different standards have been developed. Tests can be divided in four groups according to the length of the test: <1h, 1h, 24h and 48 h. (Table 4)

**II. OFFICE-BASED PAD TESTING**

Pad tests up to 2 hours were developed to be performed in outpatient clinics or hospital wards under supervised conditions. Bladder volume is predefined to reduce variability and a structured set of exercise is usually implemented to elicit the occurrence of urine loss.

**1. SHORT PAD-TEST**

* a) Quantification

These tests are based on a fixed bladder volume and a standard set of activities to facilitate the occurrence of urine loss, if any, over a short period of time. Jakobseny et al. found that the 40 minute test with a bladder volume of 75% maximum cystometric capacity and similar activities as a 1-hour ward test produced consistently larger amounts of urine loss than a standard 1-hour ward test [17]. The difference was attributed to significantly larger bladder volumes during performance of physical activity in a 40 minute pad test.

Kinn & Larsson reported no correlation between a short 10 minute test with fixed bladder volume and the degree of incontinence as judged from the symptoms [18].

Hahn & Fall in a 20 minute test with half cystometric capacity showed no false negative results in 50 women with stress urinary incontinence although there was a discrepancy in 12% of patients between the perception of incontinence severity and pad test results [15].

These data suggest that short pad tests are more provocative than activities of daily living.

* b) Reproducibility

The correlation factor (Pitman’s nonparametric permutation test) between two separate 20 minute pad tests up to 2 hours was calculated by Hahn & Fall [15] and Jorgensen et al. [16]. The correlation was highly dependent on the bladder volume and the height of the physical activity.

*Maximum Cystometric Capacity
tests was 0.94 (p<0.001) [15]. Kinn and Kinn & Larsson showed that the 10 minute test with a fixed pre-test bladder volume of 75% of maximal capacity was moderately reproducible (r=0.74) [18]. Using a 1 minute pad test, a standardised bladder volume of 300ml and standardised physical activity mean differences of leakage was 8.5 ml and coefficient of repeatability was 33.6 ml [19].

2. ONE-HOUR TEST

The use of a one-hour pad test has been investigated thoroughly for validity, reproducibility and sensitivity to change.

a) Quantification

Jakobseny et al. reported that a one hour test detected less leakage at 3 g compared to a 40 minute (7 g) and a 48 hour pad test (37 g) [17]. In the elderly a one-hour ward test did not demonstrate incontinence in 66% of those complaining of incontinence compared to 90% with a 24 in-patient monitoring of urine leakage [20]. A one hour pad test was found to reflect everyday incontinence in only 48% of the patients in comparison to 81% in a 48 hour test and 77% in a 40 minute test. Jorgensen et al. noted that 90% completed the test and 69% had test results which correlated with daily leakage [16]. Lose et al. found a poor to moderate correlation of the modified one-hour test (200-300 ml in the bladder) with a history of stress urinary incontinence (n=31) [21]. Mouritsen et al. showed that a 1-hour ward pad test did not detect grade I stress incontinence in 46%, grade II in 27% and grade III in 66% [22]. Third & Gerstenberg compared a 1-hour ward pad test to a 24-hour home pad test and found that a 1-hour pad test had a 36% false-negative rate as compared to a 24-hour home pad test [23].

b) Reproducibility

Klarskov & Hald demonstrated in 3 consecutive 1-hour pad tests, a correlation coefficient of 0.75 and 0.97 depending on the activity regimen [24]. The test, however, was quite demanding and a lot of patients did not complete the full testing. Christensen et al. compared a one-hour pad test in two different urological and one Obstetrics & Gynecological departments (20 women) [13]. The test results in two urological departments did not differ with an average pad gain of 24g and 21 g (p>0.1). However, pad test results between the departments of urology and gynecology differed significantly, with average pad weight gain 9 g and 24 g respectively (p<0.05).

Lose and co-workers showed a significant variation between 1-hour ward test and retest in 18 patients (correlation coefficient 0.68) [12]. In 50% of patients the leakage volume was variable due to differing bladder volume. When the results of the 1-hour pad test were corrected for urine volume, the correlation coefficient value increased to 0.96. Simons et al found the reproducibility of the standard 1 hour pad test to be poor [25].

c) Validity

Walsh & Mills in the elderly and Holm-Bentzen et al. in patients with an AMS artificial sphincter showed that the one hour pad test did not correlate with subjective patient satisfaction but this may due to other lower urinary tract symptoms [9, 26].

c) Bladder volume

Jorgensen et al showed test-retest correlation was improved when the bladder volume was taken into account and the correlation value (r) raised from 0.68 to 0.93 [16]. Fantl et al used a one hour test with the bladder filled to capacity had a test-retest correlation of 0.97 which was improved if the fluid loss was expressed as a percentage of bladder volume [27]. Lose et al. using a 1-hour pad test with standardised bladder volume of 50% of maximal cystometric capacity (MCC) showed in 25 women a test retest correlation of 0.97 but the intertest variation was up to 24g [28]. Jakobsen et al. compared a 1-hour pad test with a bladder filled to 50% and 75% of maximal cystometric capacity and found that the final bladder volume was equal in both groups showing the importance of diuresis even with equal starting bladder capacities [29]. The amount of leakage in both groups was the same. Simons et al. found the volume in the bladder after a standard 1 hour pad test varies by ~44 to +66g in a test-retest situation [25]. The fluid volume in the bladder appears to be critical in making the pad test reproducible and increasing the sensitivity of the test for detecting leakage.

Aslan et al compared a 1 hour pad test loss with the symptom impact index (SII) and the symptom severity index (SSI) [30]. Only the SSI showed a relationship between the severity of the score and the pad test loss. The 1 hour pad test has also been used in assessing the validity of the Incontinence Impact Questionnaire and the Urogenital Distress Inventory unfortunately both had poor correlations with the pad test [31]. This is to be expected as the questionnaires assess other urinary symptoms than just leakage.

d) Diagnosis

Fluid loss was significantly greater in patients with detrusor overactivity in comparison to urodynamic stress incontinence [27, 32]. The reverse finding was reported by Matharu and co-workers [33]. There is high variability in patients with detrusor overactivity making the test impractical as a diagnostic tool.

e) Sensitivity to change

The 1 hour pad test has been shown to be useful in detecting significant improvements after pelvic floor exercises for men suffering urinary incontinence after radical prostatectomy [34]. Ward et al. found the
standard 1 hour pad test to show significant reductions in loss after tension free vaginal tape procedures from 18 g (IQR 6-37) and Burch colposuspension from 16 g (IQR 6-38) both decreasing to 0 g (IQR 0) [35]. The 1 hour pad test has also been tested for the reduction in loss after conservative and surgical therapy [36]. The changes were significant but there was moderate correlation (r = 0.53) with the changes in the St. George Urinary Incontinence Score.

3. 2-HOUR PAD TEST

A test period of 60-120 minutes after a 1 litre fluid load was proposed as the optimal duration for the pad test because of a consistently high bladder volume [37]. Han et al showed, however, that a 1-hour pad test is more practical [38]. In children a 2-hour ward pad test yielded 70% positive results for incontinence [39]. Griffiths et al found only a 10% false negative rate of good at detecting incontinence as a 48-h test [22]. This was better than the results of a 24-h home test. Lose et al. found that a 24h home test performed during daily activities is more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml [21]. High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% [42]. Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence [43].

b) Reproducibility

Lose et showed poor correlation in a test-retest study with a variation of more than 100% [21] although Groutz et al. using Lin’s CCC, found 24-h test very reliable instrument [44]. Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance.

The values for the pad test increase in asymptomatic men and women was reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women [45].

c) Diagnosis

Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities [33]. Pad test loss is unaffected by the degree of hypermobility however there is an increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH2O [46].

d) Validity

Karantanis et al found the 24-hour pad test was poorly correlated in women with USI with incontinence episodes on a 3 day urinary diary (Kendall’s corr coeff b = 0.4) and the ICIQ-SF (r = 0.4) [47]. Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up [48].

3. 48-HOUR PAD TEST

a) Quantification

Jakobsen et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients [17]. No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) [49] (Tables 5&6).

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exercise sessions of 3.19 ± 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients [53]. Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test [14]. In his study

III. HOME BASED PAD TESTING

These tests were developed to diagnose and measure urine loss in a situation as close as possible to standard daily life of the patient. The longer observation period usually requires a less structured procedure.

1. 12-HOUR PAD TEST

Quantification

Hellstrom et al. demonstrated in 30 children with incontinence a positive 12-hour home pad test in 68%. When a standard fluid load (13 ml/kg) was instituted in 20 children, the frequency of the positive test increased to 80% [39].

2. 24-HOUR PAD TEST

a) Quantification

Lose et al. found a 90% correlation of a 24-hour pad test with history of stress incontinence in 31 women [21]. This was better than the results of a 1-hour test. Thirteen of 31 patients were found to be continent after a 1-hour ward test in comparison to only 3 with a 24-hour home pad test. Mouriøtøen et al. showed that the 24-h home test is well tolerated and is as good at detecting incontinence as a 48-h test [22]. Griffiths et al. found only a 10% false negative rate of a 24-hour pad test in an elderly population [20]. Using non-parametric coefficient of correlation, they found a significant difference between the 1-hour test and the 24 hour test. Lose et al. found that a 24h home test performed during daily activities is more sensitive than a test performed during daily activities is more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml [21]. High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% [42]. Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence [43].

b) Reproducibility

Lose et showed poor correlation in a test-retest study with a variation of more than 100% [21] although Groutz et al. using Lin’s CCC, found 24-h test very reliable instrument [44]. Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance.

The values for the pad test increase in asymptomatic men and women was reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women [45].

c) Diagnosis

Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities [33]. Pad test loss is unaffected by the degree of hypermobility however there is an increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH2O [46].

d) Validity

Karantanis et al found the 24-hour pad test was poorly correlated in women with USI with incontinence episodes on a 3 day urinary diary (Kendall’s corr coeff b = 0.4) and the ICIQ-SF (r = 0.4) [47]. Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up [48].

3. 48-HOUR PAD TEST

a) Quantification

Jakobsen et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients [17]. No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) [49] (Tables 5&6).

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exercise sessions of 3.19 ± 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients [53]. Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test [14]. In his study

</table>
of the relation between the patient perception of UI and diagnosis of UI and entered the more interesting field of diagnostic accuracy of pad test versus a urodynamic test. Following this line of thought, research has moved away from the evaluation of diagnostic accuracy of pad test versus a urodynamic diagnosis of UI and entered the more interesting field of the relation between the patient perception of UI and pad test.

Franco and co-workers from the St. George Hospital in London, UK tested the correlation between different questionnaires for UI and 1-hour pad test showing that only the ICIQ-SF reached statistical significance with a Kendall’s tb of 0.177 and a P value of 0.037 while no significant correlation was found for a 0 to 10 VAS score, a patient-based 3-point symptom severity scale, Stamey grade, Urogenital Distress Inventory and the Incontinence Impact Questionnaire (IIQ-7) [56]. In another study from Wijma and co-workers, the diagnostic strength of pad test for self-reported symptoms of UI was evaluated during pregnancy and after childbirth and the authors conclude that the diagnostic value of pad testing has no clinical relevance in this setting [57]. A similar analysis, performed in a male population undergoing sling surgery for post-radical prostatectomy incontinence suggests a good correlation between ICIQ-SF and the Patient Global Perception of Improvement (PGPI) with a 24-hour pad test [58].

Studies from the Urinary Incontinence Treatment Network in US investigated the relation between different measures of incontinence severity and showed how pad weight from a 24-hour test had a good correlation with the incontinence episodes frequency derived from a 3-day bladder diary (Spearman correlation coefficient 0.61 but a much lower degree of correlation was found with questionnaires such as the Medical, Epidemiological, and Social Aspect of Aging (r=0.33), the Urogenital Distress Inventory (r=0.17) and the Incontinence Impact Questionnaire (r=0.34) [59].

In the same study, the use of pad testing as a prognostic parameter for treatment outcome was investigated but the 24-hours pad testing showed no prognostic value for treatment failure in a study of Burch colposuspension versus autologous rectus sling [60]. An interesting result was obtained in a predominantly female population of patients receiving neuromodulation for refractory urgency incontinence in which a 24-hour pad test performed after the initial test stimulation was able to predict long term satisfaction of this difficult patient population [61]. In this, as in other studies, the number of pads used per day proved to be an unreliable measure of urinary incontinence [62].

A couple of important methodological issues have been raised concerning the use of pad testing. Khan & Chien eloquently pointed out that test-retest comparison should include methods of blinding and use of an appropriate index of degree of agreement which is the intra-class correlation coefficient. In most of the literature this was not implemented [63]. Kromann-Andersen et al. argued that with considerable inter- and intra-individual variation of urine loss, the correlation of test/retest results may be overestimated and suggested different trials for small, modest and large leakage in large numbers of the patient [64]. This trial has not been carried out.

A recent Health Technology Assessment of pad testing concluded that although high sensitivity and specificity for the diagnosis of UI was reported in some studies, it was difficult to draw any conclusion about the diagnostic accuracy for SUI because of the differences existing in pad test methodology. The number of studies comparing the same pad tests with adequate reporting is insufficient and no formal pooling of published data could be performed [65].

c) Role of the investigation

The test has been standardised by ICS in 1988 for quantification of urine loss and suggested uses for assessment and comparison of treatment outcomes in different centres. Also, the AUA report on Surgical Management of Female Stress Urinary Incontinence includes a pad test (pretreatment evaluation) as a standard of efficiency for clinical trials [66]. The Urodynamic Society included a pad test in a Standards of Efficacy for Evaluation of Treatment Outcomes in Urinary Incontinence [67]. No suggestion was made in the last two reports of which test to use.
• The 1-hour pad test is not very accurate unless a fixed bladder volume is applied
• Set exercises during the test improve test-retest reliability
• The sequence of exercises has little effect on test results
• A pad weight gain $\geq 1$ g suggests a positive 1h test
• A 24 hour test correlates well with symptoms of incontinence
• A 24-hour test has good reproducibility but poorer compliance
• A pad weight gain $\geq 1.3$ g = positive 24 h test
• A test lasting longer than 24 h has little advantage
• A pad test cannot distinguish between urodynamic stress incontinence and detrusor overactivity

**RECOMMENDATIONS**

- The pad test is an optional investigative tool in routine evaluation of urinary incontinence (Level of Evidence 3, Grade of Recommendation C)
- Pad test is a useful outcome measure in clinical trials and research studies. (Level of Evidence 3, Grade of Recommendation C)

The following standards are suggested:

- 20 min-1 h ward test with fixed bladder volume (pad weight gain $\geq 1$ g = positive test) (Level of Evidence 3, Grade of Recommendation C)
- 24 h home pad test during daily activity (pad weight gain $\geq 1.3$ g/24h = positive test) (Level of Evidence 3, Grade of Recommendation C)

**SUGGESTED RESEARCH AREAS**

- Proper validation analysis using the coefficient of variability
- Evaluation of the ability to detect all the spectrum of urinary incontinence (from mild to severe)
- Sensitivity to change in time of incontinence status for 24 hour pad tests
- Validity of pad tests with other measures of incontinence such as urinary diaries and system questionnaires

### I. URINALYSIS

“Urinalysis is a fundamental test that should be performed in all urological patients” [1]. In patients with urinary incontinence, urinalysis is not a diagnostic test for the condition, but it is rather used to screen for haematuria, glucosuria, pyuria and bacteriuria. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved [2]. A positive urinalysis will prompt infection treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence in the female, urinalysis is recommended since 60% of women develop urge symptoms at the time of urinary tract infection (UTI). Pyuria was found to be common among incontinent but otherwise asymptomatic, female patients. Pyuria was not necessarily associated with UTI, the significance of sterile pyuria in the elderly population is still unclear [3].

A Norwegian survey of general practitioners' management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) [4]. Another survey suggested that urinalysis is one of the three-part assessment of UI together with patient history and physical examination [5]. The same applies, according to Stricker, for patient selection for collagen implant [6]. A minority of the reviewed papers suggested that urine culture should be carried out together with urinalysis [3, 7].

Urinalysis is also considered of importance in the evaluation of nursing home residents who are incontinent [8], in peri- and postmenopausal women [9], in older women reporting urinary incontinence [10]. Belmin et al., suggested than significant urine samples can even be obtained from disposable diapers in elderly incontinent women [11, 12].

It is recommended that geriatric incontinent patients undergo history, physical examination, tests of lower urinary tract function and urinalysis. The latter test is proposed to rule out the presence of UTI [12]. The clinical relevance of asymptomatic bacteriuria in the elderly is controversial. Although DuBeau and Resnick suggest the use of urinalysis in the diagnostic algorithm to identify asymptomatic bacteriuria in incontinent residents of nursing homes [13], others consider that the condition does not deserve any treatment [11].
The prevalence of renal damage or of biochemical abnormalities in the general population of patients with urinary incontinence is very low, but there are subgroups of patients where the prevalence can be higher (e.g., neurogenic incontinence, overflow incontinence). The routine use of a battery of common chemical and/or hematological tests in patients with urinary incontinence appears to be a prudent rule of good clinical practice in the following situations:

- a) chronic retention with incontinence
- b) neurogenic LUT dysfunction
- c) when surgery is contemplated
- d) when there is a clinical suspicion.

Special tests such as measurement of anti diuretic hormone (ADH) and atrial natriuretic polypeptide have proven useful in research of enuresis in childhood and nocturia in the elderly [1, 2]. Changes in the circadian rhythm of these, and probably also other hormones regulating the renal excretion of water, will in the future contribute to a better understanding of pathophysiology. Synthetic ADH analogues have already come into clinical use for the treatment of nocturnal enuresis. However, the clinical value of these specific tests remains to be established.

III. TISSUE ANALYSIS

Since the last report of the International Consultation on Incontinence in 2005, several papers have been published based on the analysis of sample of tissues coming from patients with stress urinary incontinence (SUI) and/or pelvic organ prolapse aiming at evaluating the molecular bases of these conditions. The main targets of both preclinical and clinical research have been the pelvic floor-supporting tissues and the role of steroid hormones, with some intriguing linkages between the two lines of research.

Pelvic floor-supporting tissues are composed mainly of connective tissue in which fibrous elements such as collagen and elastic fibres and visco-elastic matrix based on proteoglycans are the predominant components of the so called extracellular matrix. Extracellular matrix is a complex network of numerous macromolecules that fulfil a large number of mechanical, chemical and biological functions [1]. While collagens and elastin fibres confer strength and elasticity to tissues, respectively, structural proteoglycans allow tissue cohesiveness. Specifically, collagen is the most prevalent component, with type I fibres usually well organized and associated with ligamentous tissue, while type III collagen is more common in the loose areolar tissue, which makes up the vaginal wall adventitia and surrounds the pelvic organs [2]. According to the molecular weight, indeed, proteoglycans are distinguished into large molecules (aggrecan, versican and perlecan) and small molecules, such as decorin, fibromodulin, biglycan, lumican and chondroadherin [3].

The organized structure of the matrix is due to a clear balance between the production of the different constituents and their breakdown. There are many proteolytic enzymes capable of degrading the elements of the extracellular matrix, falling into three groups: the serine proteases, the cysteine proteases, and matrix metalloproteinases (MMPs) [4].

Several authors evaluated the expression of the different proteins as well as of their precursors and fragments of degradation. With regards to the metabolism of collagen, some studies seem to indicate that women with SUI have a reduced total collagen content in the skin and urogenital tissue [5-7], while other studies reported higher total collagen concentration and higher levels of mRNAs for type I and type III collagen in paraurethral connective tissue [8]. Chen et al., evaluating cultures of fibroblasts taken from endopelvic fascia and skin biopsies in 14 patients with stress urinary incontinence and 12 controls, showed that the overall collagen synthesis and the ratio of type III and type I fibres were not significantly different between fibroblasts obtained from women with or without SUI [4], indicating that alteration in the collagen synthesis might not be involved in SUI. On the other hand, a few studies reported change in the relative percentages of the different fibres, with decreasing in type I and increasing in type III ones [9, 10]. Skorpinski et al., evaluating in DNA obtained from peripheral blood leucocytes the transcription factor Sp1-binding site in the gene encoding a-1 chain of type I collagen, identified G-T polymorphism at the Sp1 binding site of the gene encoding a-1 chain of type I collagen as a possible risk factor for SUI [11], suggesting that alteration of the protein expression might be due to mutations in transcription factors. Again at molecular level, some studies evaluated the cycle regulatory proteins in patients with pelvic organ prolapsed, showing controversial results. Some papers reported reduced expression of proteins such as p53 and p21 which normally cause cycle G1 arrest suggesting an increase in proliferation capacities for fibroblasts derived from human cardinal ligaments of patients with prolapsed [2].

Other authors evaluated markers of collagen degradation. Specifically, Edwall et al. evaluated markers of collagen synthesis and breakdown such as the carboxy-terminal propeptide of type I procollagen (PICP), the carboxy-terminal telopeptide of type I collagen (ICTP), and the amino-terminal propeptide of procollagen III (PIIINP) in urogenital tissue homogenates and peripheral serum from 71 patients with SUI and 31 healthy control women [12].

After adjusting for age, BMI, parity, and hormonal status, the patients with SUI had significantly lower serum concentrations of PICP and significantly lower tissue concentrations of PIIINP and ICTP than the controls, suggesting reducing breakdown in the presence of unchanged synthesis of type I collagen and, regarding type III collagen, a potential reduction in either synthesis or breakdown, the second being considered more probable [12].

These data may lead to the hypothesis that SUI might be associated with impaired degradation of collagen, leading to reduced turnover and accumulation of aging collagen, negatively affecting the strength and elasticity of urogenital tissue. Further studies on transforming growth factor-β (TGF-β) identified the molecular basis of such mechanism, suggesting that overexpression of TGF-β might trigger the accumulation of aging collagen, inhibiting the expression of collagenases and increasing the production of the tissue inhibitor metalloproteinase [13-15]. Moreover, some genes, such as those of the Homebox A (HOXA) family, encoding transcription factors that regulate mammalian embryonic growth and development of the urogenital tract, have been shown to be underexpressed in patients with pelvic organ prolapsed, suggesting a further molecular basis for the alterations in collagens [16].
Other studies were focused on the expression of small proteoglycans. Wen et al. studied mRNA and protein levels of biglycan, decorin, and fibromodulin in vaginal wall tissue from women with SUI and menstrual-cycle matched continent women [1]. Specifically, the authors demonstrated that the mRNA expression of fibromodulin was significantly lower in patients in the proliferative phase compared to controls, while decorin mRNA expression was higher both in the proliferative and secretory phases in the patients with SUI, supporting the hypothesis that the expression of such small proteoglycans was hormonally modulated and may contribute to the altered pelvic floor connective tissues of the women with SUI [1].

Estrogens act interacting with specific receptors which, when activated by the ligand, have conformational change, dimerization and recruitment of co-factors, once translocated into the nucleus, these promote the expression of region of estrogen-responsive genes, called the estrogen response elements, leading to the synthesis of proteins [19]. More recently, selective modulators of estrogens receptors have been identified, that act modulating the activity of the receptors, working as agonists, partial agonists, or antagonists in a tissue-dependent manner [20]. Studies on these molecules supported a new role of estrogens in SUI and pelvic organ prolapsed. Specifically, in a randomized controlled trial testing one of these molecules (levormeloxifene) as osteoporosis treatment, a 3.4-fold increase in the reporting of pelvic organ prolapse and an almost 5-fold increase in the reporting of urinary incontinence have been observed [21]. To explain such effect, the expression of more than 500 proteins have been studied in the rat model, showing that estradiol induced the expression of metalloproteinase 7 and 14, reduced the expression of their inhibitors such as TIMP-3, while selective modulators of estrogens receptors such as raloxifene had minimal effects on metalloproteinase 7, and maintained or restored expression of the mRNA for tissue inhibitor of metalloproteinases-3 (TIMP-3) and other components of the extracellular matrix, such as glypican, and biglycan [19]. Although the role of selective estrogen-receptor modulators (SERMs) in the expression of the component of extracellular matrix has to be further clarified, these findings support the hypothesis that the increased occurrence of urinary incontinence and pelvic organ prolapse observed with estrogen therapy and SERMs such as levormeloxifene may be related to changes in expression of genes regulating collagen turnover that ultimately weaken the normal structural integrity and support for the genitourinary system [19].

To date, all these tissue analyses are not part of the everyday clinical practice but the data of these studies improved are improving our comprehension of the pathophysiology of urinary incontinence and pelvic organ prolapsed.

REFERENCES

Clinical research involving diagnostic accuracy and clinical benefit of imaging studies as other diagnostic tests is particularly difficult. Recommendation of a diagnostic test is based upon the evidence that the outcome of it provides valuable information for patient management and this often involves evaluating the outcome of surgery. Implementation of good clinical research in this area remains difficult and sometimes lack adequate founding. Research in this area is particularly daunting and often relies on academic founding only. We acknowledge that only a few of the imaging techniques and other investigations we reviewed in the current chapter have been properly evaluated with respect to reproducibility, specificity, sensitivity and predictive value in connection with the diagnosis and the management of urinary incontinence. Nevertheless, we acknowledge the great amount of work performed in the last four years and the continuous advancement in this field. The use of imaging and other investigations, described in this chapter, remains mostly based on expert opinion, common sense, availability and local expertise, rather than on evidence based clinical research. The diagnostic tests we considered can be subdivided into safety tests, tests with specific and selected indications, investigational tests.

**Safety tests** - Intended to protect patients’ health, they are indicated in all patients complaining of urinary incontinence. They include urinalysis and measurement of post-voiding residual urine. While a consensus is easily achieved for urinalysis, the clinical benefit and cost-effectiveness of PVR measurement in primary evaluation of urinary incontinence needs to be confirmed in prospective studies.

**Tests with specific and selected indications.** Upper urinary tract imaging (as well as renal function assessment) may be indicated in cases of neurogenic urinary incontinence with risk of renal damage, chronic retention with incontinence, incontinence associated with severe genitourinary prolapse and suspicion of extraurethral incontinence. No other imaging techniques is recommended in the primary evaluation of uncomplicated urinary incontinence and/or pelvic organ prolapse. Cystourethrogram remains a reasonable option only in the preoperative evaluation of complicated and/or recurrent cases. Videourodynamics, is the gold standard in the evaluation of neurogenic incontinence, particularly in the paediatric population, although the clinical benefit of it remains unclear. In female urinary incontinence videourodynamics is not recommended except under specific complex circumstances. MRI remains the gold standard for the diagnosis of urethral diverticula.
although ultrasonography is a good alternative option. Lumbosacral spine X-rays have specific indications in children with suspect neurogenic incontinence without gluteo-sacral stigmata. Imaging of the CNS should be considered when a neurological disorder is suspected on the basis of clinical, imaging and neurophysiological findings. Urethrocystoscopy is indicated in cases of incontinence with microscopic haematuria, in the evaluation of recurrent or iatrogenic cases, in the evaluation of vesico-vaginal fistula and extra-urethral urinary incontinence.

Endoanal ultrasound and endocoil MRI are the gold standard for the evaluation of anal sphincter disorders, dynamic X-ray imaging remain the standard for evaluating rectal prolapse.

**Investigational tests** Pelvic floor ultrasound is widely used as an adjunct to physical examination in patients with urinary incontinence and/or pelvic organ prolapse. Although the technique is rapidly evolving and much progress has been made in clinical research in this field, ultrasonography remains optional as evidence of its clinical benefit is not there yet.

MRI of the pelvic floor is rapidly gaining popularity in the evaluation of enteroceles and in the morphological analysis of pelvic floor muscles although evidence of its clinical benefit is still lacking. Both ultrasonography and MRI are the most rapidly evolving techniques and hold promises for potential future clinical applications.

Research in this area is also performed to improve our understanding of the pathophysiology of continence disorders and pelvic organ prolapse. Functional neuroimaging continues to provide new insight on functional anatomy of CNS related to vesicourethral function and dysfunction. The content of the draft reflects the composition of the Committee which is made of clinicians with a particular interest in a specific area of imaging and neurophysiology. The chapter certainly reveals the enthusiasm the authors poured in clinical research in this area but we believe that the methodology implemented by the Consultation is the best guarantee of a balanced opinion and trustful recommendations. We hope that this chapter will stimulate clinical research in this field and will inspire those involved in the management of continence disorders and pelvic organ prolapse.

Neurophysiological testing should be part of the armamentarium available in the management of neurogenic incontinence and the establishment of good collaboration with neurophysiologists is recommended.
Committee 8

Pharmacological Treatment of Urinary Incontinence

The function of the lower urinary tract (LUT) is to store and periodically release urine, and is dependent on the activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. The bladder and the urethra constitute a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors [Andersson, 1993; de Groat and Yoshimura, 2001; Andersson and Wein, 2004]. Malfunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in overflow incontinence. A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance [Wein, 2007].

Many drugs have been tried, but the results are often disappointing, partly due to poor treatment efficacy and/or side effects. The development of pharmacologic treatment of the different forms of urinary incontinence has been slow, but several promising targets and drug principles have been identified [Andersson et al., 2002; 2005; Andersson, 2007; Colli et al., 2007].

In this report, we update the recommendations from the 2004 International Consensus meeting [Andersson et al., 2005]. The most relevant information obtained since the last meeting is reviewed and summarised. Agents specifically used for treatment of urinary tract infections and interstitial cystitis, have not been included. Our clinical drug recommendations are based on evaluations made using a modification of the Oxford system (Table 1). The terminology used is that recommended by the International Continence Society (ICS) [Abrams et al., 2002].

I. PUBLICATION SEARCHES

The review undertook a comprehensive search of all major literature databases and the abstract books from several major conferences: American Urological Association, ICS, European Association of Urology, International Urogynaecological Association, International Consultation of Incontinence and Societe Internationale d’Urologie. There were no restrictions on the inclusion of publications by language; publications in languages other than English were translated into English.
II. CENTRAL NERVOUS CONTROL
